Uniqueness. It suffices to show that $e_1, \ldots, e_r$ are algebraically independent, since a difference of two representations of Φ is a power series R with $R(e_1, \ldots, e_r) = 0$, whose isobaric components of distinct weights land in distinct degrees in the a_j and so vanish separately. Let $Q = \sum_m \kappa_m y^m$ be a nonzero polynomial. The leading monomial of $e^m = e_1^{m_1} \cdots e_r^{m_r}$ is $a_1^{m_1+\cdots+m_r} a_2^{m_2+\cdots+m_r} \cdots a_r^{m_r}$, and the assignment $m \mapsto (m_1 + \cdots + m_r,\, m_2 + \cdots + m_r,\, \ldots,\, m_r)$ is injective, so distinct exponent vectors m produce distinct leading monomials. Among the finitely many m with $\kappa_m \neq 0$, take the one whose leading monomial is lexicographically largest. Every monomial of every other term is strictly smaller than it, so it survives in $Q(e_1, \ldots, e_r)$ with coefficient $\kappa_m \neq 0$, and $Q(e_1, \ldots, e_r) \neq 0$, as we sought to show.

One important result that was proven in the previous theorem is noted for future reference:

Lemma 20.2.9: S_n Extension

Let K be a field, $t_1, ..., t_n$ indeterminates, and let $s_1, ..., s_n$ be the elementary symmetric functions on $t_1, ..., t_n$. Then the extension:

$$K(s_1, ..., s_n) \subseteq K(t_1, ..., t_n)$$

is Galois, with Galois group S_n

From this, we can prove that every finite group is represented as a galois group:

Theorem 20.2.10: Finite Group Represented by Galois Group

Let G be a finite group. Then there exists a Galois extension F/k such that $\text{Aut}_k(F) \cong G$

***Proof*:**
exercsie

Note that it is not certain if every finite group G appears as an extension of F over $\mathbb{Q}$. This is called the *inverse Galois Problem.* more here! Can also checkout Aluffi p.473

Corollary 20.2.11

Let D be the discriminant of the field extension. Then:

$$K(s_1, ..., s_n)(\sqrt{D}) \subseteq K(t_1, ..., t_n)$$

is Galois, with Galois group A_n.

20.2.4 Solvability By Radicals

We are finally in a position to prove that an arbitrary degree 5 polynomial cannot be written in terms of it's coefficients using the operations $+, -, \times, \div, \sqrt{}$. Is is famously known, any quadratic polynomial over k ($\text{char}(k) \neq 2$) can be written in terms of:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

and similar equations exists for degree 3 and 4 polynomials, though they get horrendously messy.

20.2.12 Goal There exists irreducible polynomials of degree $n \geq 5$ that are unsolvable

To avoid complications, we will assume in this section that $\text{char}(k) = 0$.

Definition 20.2.13: Radical Extension

Let F/k be a field extension. Then if $F = k(\alpha_1, \alpha_2, ..., \alpha_n)$ where

$$k \subseteq k(\alpha_1) \subseteq k(\alpha_1, \alpha_2), \subseteq \cdots \subseteq k(\alpha_1, ..., \alpha_n)$$

where for each $i \in \{1, ..., n\}$, there exists an n_i such that $\alpha^{n_i} \in k(\alpha_1, ..., \alpha_{i-1})$, then F/k is called a *radical extension*

Elements of radical extensions are easy to picture: if $k = \mathbb{Q}$, then simply nest as many nth-roots as you please, for example:

$$\sqrt[7]{3 + \sqrt[2]{19}^5 \sqrt[11]{3+2}}$$

it is also clear by definition that a radical extension is the composition of cyclic exensions provided that the appropriate roots of 1 are in k. The next result insures us that any [separable] radical extension is contained in a radical extensions that is *Galois*:

Lemma 20.2.14: Separable And Galois Radical Extensions

Let F/k be a separable radical extension. Then F is conatiend in a Galois radical extension

***Proof*:**
Let F/K be a separable radical extension. Then F is a separable finite extension of K, and so by the primitive root theorem (theorem 19.6.20), there exists an $\alpha \in F$ such that $F = k(\alpha)$. Let L be the splitting field of $k(\alpha)$. Then L is equal to the composite of all the field $\sigma(F)$ for every σ that embeds F into $\overline{k}$:

$$L = \sigma_1(F) \cdots \sigma_n(F)$$

Then the composition of radical extensions is radical, showing that L is radical. Thus, L is the splitting field of a separable polynomial, and so it is Galois, completing the proof.

Lemma 20.2.15: Solvability In Char 0

Let k be a field such that $\text{char}(k) = 0$, and let $f(x) \in k[x]$ be an irreducible polynomial. Then the roots of $f(x)$ can be written in terms of field operations and radicals if and only if the splitting field fo $f(x)$ is contined in a Galois Radical extension

***Proof*:**

($\Leftarrow$) If the splitting field $f(x)$ is contained in a radical extension (not necessarily Galois), then *a fortiori* the roots can be written using field operations and radicals.

($\Rightarrow$) Conversely, assume the roots of the irreducible polynomial $f(x)$ can be written in terms of field operations and radicals . Then any formula for a root t_1 of $f(x)$ can be turned into a formula for t_i by applying an element σ_i of $\text{Aut}_k(\overline{k})$ sending t_1 to t_i (this automorphism exists since $f(x)$ is irreducible). Thus, if the formula exists for one root, a formula exists for all roots. Thus, $k(t_1), ..., k(t_n)$ are each radical extensions and

$$L = k(t_1)k(t_2) \cdots k(t_n)$$

is a radical extension that contains all the roots of $f(x)$. Thus, by minimality of the splitting field, it is contained in a radical extension of k. By lemma 20.2.14, it must also be contained in a galois radical extension, as we sought to show.

Thus, we can characterize when a polynomial is solvable by radicals by when it is contained in a Galois radical extension. Since the extension is Galois, we have a corresponding Galois group to analyze. We will soon see that the appropriate type of group that is needed for $f(x)$ to be solvable is one we have encountered a long time ago:

Definition 20.2.16: Solvable Extension

Let F/K be a Galois extension. Then F/K is a *solvable extension* if $\text{Aut}_K(F)$ is a solvable group

Recall that if G is a solvable group and finite, then G can be decomposed into a subnormal series with cyclic factors:

$$G = G_0 \trianglerighteq G_1 \trianglerighteq G_2 \trianglerighteq \cdots G_n = \{1\}$$

notice how this parrallels the fact that any radical extension is a sequence of cyclic extensions.

Lemma 20.2.17: Relating Radical And Solvable Extensions

Let F/K be a galois extension with $\text{char}(k) = 0$. If F/K has enough roots of 1, then F/K is radical if and only if it is solvable

What is meant by "enough roots of 1" is that K contains primitive mth roots of 1 for a common multiple m of the order of the corresponding cyclic factors.

***Proof*:**
This is a generalization of proposition 20.1.41.

Let F/K be a radical extension, so that:

$$K \subseteq k(\delta_1) \subseteq \cdots \subseteq K(\delta_1, ..., \delta_r) = F$$

where $\delta_i^{m_i} \in K(\delta_1, ..., \delta_{i-1})$. By assumption, K contains primitive m_ith roots of 1 for each i. Next, consider the corresponding subgroups of $G = \text{Aut}_k(F)$:

$$G = G_0 \supseteq G_1 \supseteq \cdots \supseteq G_r = \{e\}$$

where $G_i = \text{Aut}_{K(\delta_1,...,\delta_i)}(F)$. Next, note That F is Galois over each intermediate field (by proposition 19.5.16), and each extension:

$$K(\delta_1, ..., \delta_{i-1}) \subseteq K(\delta_1, ..., \delta_i)$$

satisfies proposition 20.1.41, and hence each G_i is cyclic. By theorem 20.1.23, each G_i is normal (since the automorphism group is abelian) in the previous G_{i-1} with a cyclic quotient, and hence G is solvable.

Conversely, the same argument works in reverse using the converse implication in proposition 20.1.41 to show that an extension with enough roots of 1 is radical.

We were dependent on each extension containing enough roots of unity. In the following, we show that we can drop them:

Proposition 20.2.18: Solvable In Char 0

Let K be a field where $\text{char}(K) = 0$, and let F/K be a Galois extension. Then F/K is solvable if and only if it is containd in a Galois Radical extension

Technically, we only need that $\text{char}(K)$ not divide the relevant degrees of the extensions, however for our purposes it is safe to assume $\text{char}(K) = 0$.

***Proof*:**

($\Rightarrow$) Assume $\text{Aut}_K(F)$ is solvable. Let M be the common multiple of the cyclic quotients and let ζ be a mth root of 1 in an algebraic closure $\overline{K}$ of K. The splitting field $K(\zeta)$ of $x^M - 1$ is Galois over K since $\text{char}(K) = 0$. By proposition 20.1.28, the extension $K(\zeta) \subseteq F(\zeta)$ is also Galois, with Galois group isomorphic to $\text{Aut}_{K(\zeta)\cap F}(F)$. Since $K(\zeta) \cap F$ is Galois over K (Aluffi says exercise 6.13), this subgroup is normal, and it follows (corollary IV.3.13) that $\text{Aut}_{K(\zeta)}(F(\zeta))$ is solvable.

Since $K(\zeta) \subseteq F(\zeta)$ has enough roots of 1, by lemma 20.2.17, it is radical. Thus, so is $K \subseteq F(\zeta)$ since $K \subseteq K(\zeta)$ is by trivially radical. Thus, F/K is contained in a radical extension.

($\Leftarrow$) Conversely, assume that F/K is Galois and contained in a radical Galois extension L/K. Let M be a common multiple of the order of the cyclic factors in this extensions,and let ζ be a primitive mth root of 1. The composite $L(\zeta)$ is Galois and radical over $K(\zeta)$ (show that if E/K is radical and T/K is any extension, then ET/K is a radical extension), and it has enough roots of 1.

By lemma 20.2.17, $L(\zeta)/K(\zeta)$ is solvable. Then we actually have that $L(\zeta)/K$ is solvable. Indeed, this extension is Galois since it's a composition of galois (exercise 6.13). Applying the fundamental theorem to:

$$K \subseteq K(\zeta) \subseteq L(\zeta)$$

to established that $\text{Aut}_K(K(\zeta))$ is isomorphic to the quotient of $\text{Aut}_K(L(\zeta))$ by its normal subgroup $\text{Aut}_{K(\zeta)}(L(\zeta))$. Both $\text{Aut}_{K\zeta)}(L(\zeta))$ and $\text{Aut}_K(K(\zeta))$ are solvable (being abelian), and it follows that $\text{Aut}_K(L(\zeta))$ is solvable.

Since F is an intermediate field and Galois over T, by the fundamental theorem, $\text{Aut}_K(F)$ is a homomorphic image of $\text{Aut}_K(L(\zeta))$. This shows that $\text{Aut}_K(F)$ is a homomorphic image of a solvable group, hence it is itself solvable, and so we're done.

Corollary 20.2.19: Galois Criterion

Let K be a field such that $\text{char}(K) = 0$ and let $f(x) \in K[x]$ be an irreducible polynomial. Then f(x) is solvable by radicals if and only if its galois group is solvable

***Proof*:**
This is an immediate consequence of lemma 20.2.15 and proposition 20.2.18.

Theorem 20.2.20: Abel's Theorem

Let $f(x)$ be a generic polynomial of degree 5 or higher. Then it admits no solutions by radicals

***Proof*:**
By lemma 20.2.9, the Galois group of the generic polynomial of degree n is S_n. The group S_n is not solvable for $n \geq 5$ (see ref:HERE), and hence the statement follows from the Galois Criterion.

Furthermore, we know that S_3 and S_4 *are* solvable, with subnormal series:

$$\{e\} \trianglelefteq \mathbb{Z}/2\mathbb{Z} \trianglelefteq D_6 = S_3$$

$$\{e\} \trianglelefteq V_4 \trianglelefteq A_4 \trianglelefteq S_4$$

hence all degree less than or equal to 4 polynomial have a root using radicals.

Exercise 20.2.1

1. Let $\alpha \in F$ for an algebraic extension $F/\mathbb{Q}$. In particular, we may think of F as being embedded in $\mathbb{C}$ so that $\alpha = a + bi$. Does there always exist an N such that $\alpha^N \in \mathbb{R}$?

20.3 Galois Groups of Polynomials

In this section, we shall focus on techniques to compute the galois group of polynomial. So far, much of the focus was on showing what properties can be deduced given properties of the galois group, there have not been many technics to find galois groups (for example, can you come up with a non-solvable degree 5 polynomial?). Hence, this section is a compilation of interesting facts and techniques useful for working with galois groups of poylnomials.

Lemma 20.3.1: Transitivity Of Galois Group

Let $f(x) \in k[x]$ be a separable irreucible polynomial of degree n. Then $\mathrm{Gal}_k(f(x))$ acts transitively on the set of roots of $f(x)$ in $\overline{k}$. In particular, $\mathrm{Gal}_k(f(x))$ may be identified with a *transitive* subgroup of the symmetric group S_n.

***Proof*:**
exercise

By corrollary 19.2.29, given α a root of $m_{\alpha,k}(x)$, then the elements of $\mathrm{Gal}_k(m_{\alpha,k}(x))$ are determined by where this root maps. This motivates the following definition:

(In general)

$$\mathrm{Gal}_k(fh) \leqslant \mathrm{Gal}_k(f) \times \mathrm{Gal}_k(h) \leqslant S_{n_1} \times S_{n_2} \leqslant S_n$$

(but more relations can be added: here)

This gives us the limits of the possible subgroups of galois groups:

1. The only possible group for degree 2 irreducible polynomials is: $\mathbb{Z}/2\mathbb{Z}$
2. The only possible groups for degree 3 irreducible polynomials is:
$$\mathbb{Z}/3\mathbb{Z} \cong A_3, S_3$$
3. The only possible groups for degree 4 irreducible polynomials is:
$$S_4, A_4, D_8, \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}, \mathbb{Z}/4\mathbb{Z}$$

Definition 20.3.2: Galois Conjugate

Let $\alpha \in L$ be an algebraic element of L over k. Then the set of roots of the minimal polynomial $m_{\alpha,k}(x)$ is called the *galois conjugates*, *algebraic conjugates*, or *conjugate elements* of α over k.

The motivation comes from the case of $\alpha \in \mathbb{C}$ which are algebraic over $\mathbb{R}$. In this case, the minimal polynomial is either $x - \alpha$ (in which case it has one root), or it is of degree 2 with galois conjugate $\overline{\alpha}$. We thus see that the galois conjugate is the generalization of the complex conjugate.

For the next result, we recall the following result of the discriminant;

Definition 20.3.3: Discriminant Reminder

Let $f(x) \in k[x]$ be a separable polynomial with roots $\alpha_1, ..., \alpha_n$ in its splitting field. Then the *discriminant* of $f(x)$ is the element $D = \Delta^2$ where
$$\Delta = \prod_{1 \leq i < j \leq n} (\alpha_i - \alpha_j)$$

Every permutation of the roots fixes D, so D is fixed by the whole Galois group, therefore $D \in k$. Odd permutations move Δ (if $\mathrm{ch}(k) \neq 2$) and even permutations fix it. Tus, Δ is fixed by the Galois group G (i.e. $\Delta \in k$) if and only if $G \subseteq A_n$

Lemma 20.3.4: Discriminant And Galois Group

Let k be a field where $\mathrm{ch}(k) \neq 2$ and let $f(x) \in k[x]$ be a separable polynomial with discriminant D. Then the Galois group o f $f(x)$ is contaiend in the alternating group A_n if and only if D is a quare in k

Example 20.3.5: Discriminant

1. Let $f(x) = x^3 + ax^2 + bx + c$ be a general monic cubic. By shifting by $a/3$, we get
$$f(x - a/3) = x^3 + px + q$$

for appropriate p, q. Then it can be computed that:

$$D = -4p^3 - 27q^2$$

Then by our above lemma, if D is a square then the galois group is S_3, and A_3 otherwise. For example, the galois group of $x^3 - 2$ is S_3 since $D = -108$ is not a square in $\mathbb{Q}$, while $x^3 - 3x + 1$ has galois group $A_3 \cong \mathbb{Z}/3\mathbb{Z}$ since $D = 81 = 9^2$.

2. Let $f(x) \in \mathbb{Q}[x]$ be of degree p for prime p with $p-2$ real roots and 2 non-real complex roots. Then $\mathrm{Gal}_{\mathbb{Q}}(f(x)) = S_p$. Prove this, then show that the galois group of $x^5 - 5x - 1$ over $\mathbb{Q}$ is S_5.

Other useful discriminants are:

$$\begin{aligned} \mathrm{D}(x^3 + ax + b) &= -4a^3 - 27b^2 \\ \mathrm{D}(x^4 + ax + b) &= -27a^4 + 256b^3 \\ \mathrm{D}(x^4 + ax^2 + b) &= 16b(a^2 - 4b)^2 \end{aligned}$$

(a word on the inverse galois problem? Sovled for every finite abelian group?)

Exercise 20.3.1

1. Let $K/\mathbb{Q}$ be Galois. Show that if $\mathrm{disc}(K)$ is square-free, then K has no intermediate fields

20.4 Kummer Theory and Artin-Schreier Extensions

As we saw an section 20.2.4, if a field extension F/K is a radical extension, then the Galois group is solvable. The converse is not necessarily true:

Example 20.4.1: Solvable, But Not Radical Extension

Consider $K = \mathbb{Q}(\sqrt{5})$ and $M = K(\zeta_3)$; recall the minimal polynomial of ζ_3 is $x^2 + x + 1$. Then $[M : K] = 2$, and it is easy to see then that if M/K were a radical extension then $M = K[\sqrt{\alpha}]$ for some $\alpha \in K$ but no such element can exist.

By doing multiple examples like these, the reader would notice that this seems to be more of a problem of there being a lack of roots of unity in K to insure there are enough solutions to $x^n - a$. In fact, there is no additional issues that arise when the characteristic of K is 0, and the issues in finite characteristic only happen for certain bad primes. We thus explore this converse: that under these mild extra conditions, if the galois group is solvable then the extension is a radical extension. As solvable groups are towers of cyclic groups, it shall suffice to show that if the galois groups in the tower of fields is cyclic, each corresponding field extension is given by a radical $\sqrt[n]{\alpha}$. An interesting consequence of this is that the galois groups of Kummer extensions shall be characterized by certain units of the base field. This shall in fact be true for all abelian extensions (not just Kummer extensions), but the proof of this result is a lot more complicated and was one of the crowning achievements 20th century number theory proved in 1930; the result is called the *Artin Reciprocity* and its proof can be found in [39].

Definition 20.4.2: Kummer Extensions and G-Extensions

Let L/K be a field extension. Then L/K is called a *Kummer Extension* if:

1. for some n, K contains μ_n (the roots of $x^n - 1$)
2. L/K is an Abelian extension with exponent n[a]

If in particular we want extensions with Galois groups G, we shall call such extensions G-extensions.

[a]The least common multiple of the orders of the elements

Example 20.4.3: Kummer Extensions

1. Any quadratic extension of $\mathbb{Q}$ is a Kummer extension of degree 2, since $\mathbb{Q}$ have $1, -1$ and has abelian extension. More generally, any multi-quadratic extension is a Kummer extension of degree 2
2. There is no Kummer extensions of degree 3 over $\mathbb{Q}$ since $\mathbb{Q}$ does not have a 3rd root of unity, since it's complex.
3. More generally if K contains μ_n (meaning the characteristic of K does not divide n), then adjoining any nth root of $a \in K$, $L = K(\sqrt[n]{a})$ is a Kummer extension (of degree m dividing n, since the minimal polynomial divides $x^n - a$)

So let's now say that L/K is a Kummer $\mathbb{Z}/n\mathbb{Z}$-extension where the characteristic of K does not divide n. In order to show $L = K(\sqrt[n]{a})$, we must find an appropriate $a \in K^*$. Let us find some necessary conditions. As $\text{Gal}_K(L) = \mathbb{Z}/n\mathbb{Z}$, there is a generator σ such that $\sigma^n = 1$. Then given $x^n = a$, we have the roots:

$$\sqrt[n]{a},\ \ \sqrt[n]{a}\zeta_n, ..., \ \sqrt[n]{a}\zeta_n^{n-1}$$

note all these roots of unity are distinct and in K by the characteristic condition. Thus, by field theory we know that σ must map $\sqrt[n]{a}$ to another one of these roots, and that this conditions characterizes σ; without loss of generality we can say $\sigma(\sqrt[n]{a}) = \zeta\sqrt[n]{a}$. Importantly, interpreting L as a K-vector space, $\sqrt[n]{a}$ becomes an *eigenvector* of σ. Note that as $\sigma^n = 1$, the possible eigenvalues must be $1, \zeta_n, ..., \zeta_n^{n-1}$. Thus if σ is diagonalizable, we can find such an a such that $a^n = \alpha \in K$. Exercise 20.4.1(20.4.1 (1)) gives a very intuitive computational approach to finding this. We present the following more abstract way of finding it that works more generally so that we can use it later in number theory and cohomology theory in this book:

Theorem 20.4.4: Hilbert's 90th Theorem

Let K be a field of characteristic 0 and L/K be an abelian extension such that

$$\mathrm{Gal}_K(L) \cong \mathbb{Z}/n\mathbb{Z}$$

If σ generate $\mathrm{Gal}_K(L)$, then:

1. For $\beta \in L^\times$ such that $\mathrm{Nm}_{L/K}(\beta) = 1$, there exists an $\alpha \in L^\times$ such that

$$\beta = \frac{\sigma(\alpha)}{\alpha}$$

2. Let $\beta \in L$ such that $\mathrm{tr}(\beta) = 0$. Then there exists an $\alpha \in L$ such that

$$\beta = \alpha - \sigma(\alpha)$$

***Proof*:**
Since L/K is a finite separable extension, pick t so that $L = K(t)$. Let

$$S = \beta + \beta\sigma(\beta) + \beta\sigma(\beta)\sigma^2(\beta) + \cdots = \sum_{i=1}^{n-1} \prod_{j}^{i} \sigma^j(\beta)$$

If $S \neq 0$, then:

$$\frac{\sigma(S)}{S} = \beta^{-1} \implies \frac{\sigma(S^{-1})}{S^{-1}} = \beta$$

Thus, we would need to guarantee such a nonzero S exists.

To see this, notice that solving $\beta = \frac{\alpha}{\sigma(\alpha)}$ is equivalent to $\beta\sigma(\alpha) = \alpha$. Notice that

$$\beta\sigma(-) : L \to L$$

mapping $\alpha \mapsto \beta\sigma(\alpha)$ is a K-linear map. If we show that it has an eigenvector with eigenvalue 1, then we solved our problem, for if α is such an eigenvector then (if we represent our function as f)

$$\alpha = f(\alpha) = \beta\sigma(\alpha)$$

We shall verify this by extending scalars from K to L. Recall by corollary 14.3.7 that extending scalars does not change the eigenvectors. We may thus extend our map to:

$$\begin{aligned} \mathrm{id} \otimes_K \beta\sigma(-) : L \otimes_K L &\to L \otimes_K L \\ \ell \otimes_K \ell' &\mapsto \ell \otimes_K \beta\sigma(\ell') \end{aligned}$$

Since L/K is finite and separable, there exists a γ such that $L = K(\gamma)$. Then γ has minimal polynomial $m_{\gamma,K}(x) \in K[x]$, and we have the isomorphisms:

$$(L \otimes_K L) \cong \left(L \otimes_K \frac{K[x]}{m_{\gamma,K}(x)}\right) \cong \frac{L[x]}{m_{\gamma,K}(x)} \cong L^n$$

Since any $\ell' \in L$ can be written as $\ell' = p(\gamma)$ for some polynomial $p(x) \in K[x]$, we have:

$$(\ell \otimes_K p(\gamma)) \mapsto \ell(p(\gamma), p(\sigma(\gamma)), ..., p(\sigma^{n-1}(\gamma)))$$

Thus, the map $\beta\sigma(-)$ becomes interpreted as $L^n \to L^n$ as:

$$\ell(p(\gamma), ..., p(\sigma^{n-1}(\gamma))) \mapsto \ell\left(\beta p(\sigma^{n-1}(\gamma)), \sigma(\beta p(\gamma)), ..., \sigma^{n-1}(\beta p(\sigma^{n-2}(\gamma)))\right)$$

or perhaps a bit more clearly:

$$(\ell_1, \ell_2, ..., \ell_n) \mapsto (\beta\ell_n, \sigma(\beta\ell_1), ..., \sigma^{n-1}(\beta\ell_{n-1}))$$

Since $\mathrm{Nm}_{L/k}(\beta) = 1$,

$$\left(1, \sigma(\beta), \sigma(\beta)\sigma^2(\beta), ..., \sigma(\beta)\sigma^2(\beta)\cdots\sigma^{n-1}(\beta)\right)$$

is an eigenvector with eigenvalue 1, hence our original transformation had an eigenvector of eigenvalue 1, as we sought to show.

For the trace argument, say $\beta \in L$ such that $\mathrm{tr}(\beta) = 0$. Take

$$S = \beta 2\sigma(\beta) + 3\sigma^2(\beta) + \cdots n\sigma^{n+1}(\beta)$$

Then:

$$\sigma(S) = \sigma(\beta) + 2\sigma^2(\beta) + \cdots + n\sigma^n(\beta)$$

since $\sigma^n = \mathrm{id}$, $\sigma^n(\beta) = \beta$, so we get:

$$S - \sigma(S) = -n\beta$$

Thus, set $\alpha = -\beta/n$, completing the proof.

20.4.5 Foreshadowing In part XI, we shall reformulate this theorem in purely Homological terms, namely it says that $H^1(G, L^*) = 0$

We now look at some properties of Kummer extensions. First, by some Galois theory, we see that if $\mathbb{Q}(\zeta_n) \subseteq K$, $L = K(\alpha)$ where $\alpha^n = \beta \in K$, then L/K is an abelian Galois extension, for:

$$\varphi : \mathrm{Gal}_K(L) \xrightarrow{\sim} \mu_n \qquad \tau \mapsto \frac{\tau(\alpha)}{\alpha}$$

which is well-defined, and any nth root of β gives the same isomorphism. Note how important $\mu_n \subseteq K$ is for this isomorphism to work! This is certainly not true in general (is $\mathbb{Q}(\sqrt[n]{2})/\mathbb{Q}$ galois for $n > 2$?). Using Hilbert's 90th problem, the converse of this statement is also true:

Theorem 20.4.6: Primitive Element For Cyclic Kummer Extension

Let $\mathrm{char}(K) = 0$, L/K be a Galois extension and $\mathrm{Gal}_K(L) \cong \mathbb{Z}/n\mathbb{Z}$. Assume K contains μ_n, the group of roots of unity generated by ζ_n. Then there exists an $\alpha \in L^\times$ such that

$$L = K(\alpha) \qquad \alpha^n \in K^\times$$

***Proof*:**
Let ζ_n be a primitive nth root of unity. Recall that $\mathrm{Nm}_{L/K}(\zeta_n) = \zeta_n^n = 1$. Thus, by Hilbert's 90th, there exists $\alpha \in L$ such that $\sigma(\alpha) = \zeta_n \alpha$. Since σ is a generator, we see that α is not fixed by any σ, hence:

$$L = K(\alpha)$$

Furthermore,

$$\sigma(\alpha^n) = \sigma(\alpha)^n = \zeta_n^n \alpha^n = \alpha^n$$

Hence, each σ fixes α^n, meaning $\alpha^n = \beta \in K$, hence

$$L = k(\sqrt[n]{\beta})$$

as we sought to show.

With the existence established, let us now established to what extent it is unique. Say $K(\sqrt[n]{a}) \cong K(\sqrt[n]{b})$. Then we know $\sqrt[n]{a}$ and $\sqrt[n]{b}$ are both eigenvectors, but they may have different eigenvalues. This is not an issue as we may raise one of them to the appropriate power, say $\sqrt[n]{b}$ so that the eigenvalue is the same root of unity as $\sqrt[n]{a}$ and it is still of order n (which we can do as $\gcd(n, n-1) = 1$). We may thus simply assume they have the same eigenvalue. But then:

$$\sigma\left(\frac{\sqrt[n]{a}}{\sqrt[n]{b}}\right) = \frac{\sqrt[n]{a}}{\sqrt[n]{b}}$$

and hence it is fixed for all σ^i, and hence is in K. We thus get the following correspondence:

Corollary 20.4.7: Cyclic Kummer Extension Correspondence

Let $\mu_n \subseteq K$. Then we have the following bijective correspondence

$$\left\{\begin{matrix} L/K \\ \mathrm{Gal}_K(L) \cong \mathbb{Z}/n\mathbb{Z}\end{matrix}\right\} \underset{\psi}{\overset{\varphi}{\rightleftarrows}} \left\{\begin{matrix} G \subseteq K^\times/(K^\times)^n \\ G \cong \mathbb{Z}/n\mathbb{Z}\end{matrix}\right\}$$

***Proof*:**
First finding ψ, pick $\overline{\beta} \in K^\times/(K^\times)^n$. Pick $\beta \in K^\times$ which represents $\overline{\beta}$. Then define

$$\psi(\langle \overline{\beta} \rangle) = K(\sqrt[n]{\beta}) = L$$

this is well-defined for if we have any other coset representative, $\beta' = \beta\gamma^n$, $K(\sqrt[n]{\beta}) = K(\sqrt[n]{\beta'})$. Certainly $\mathrm{Gal}_K(L) \cong \mathbb{Z}/m\mathbb{Z}$ and $m \big| n$. We need to show that $n = m$. For the sake of contradiction, suppose not. Then if σ generates $\mathrm{Gal}_K(L)$, then if we let $\alpha = \sqrt[n]{\beta}$, we have

$$\sigma(\alpha) = \zeta_m \alpha \implies \sigma(\alpha^m) = \zeta_m^m \alpha^m = \alpha^m$$

hence $\alpha^m \in K^\times$. Then $\beta = \alpha^n = (\alpha^m)^{\frac{n}{m}} \in (K^\times)^{n/m}$, a contradiction.

Conversely, to define φ, suppose we have an L where $\langle \sigma \rangle = \mathrm{Gal}_K(L)$. By theorem 20.4.6, pick $\alpha \in L^\times$ such that $\sigma(\alpha)/\alpha = \zeta_n$. Then α is well-defined up to being an element of $K^\times$. In particular, $[\alpha^n] \in K^\times/(K^\times)^n$ is well-defined. Thus, take the map:

$$\varphi(L) = \langle [\alpha^n] \rangle \subseteq K^\times/(K^\times)^n$$

It remains to show these maps are inverses of each other (important exercise!)

Corollary 20.4.8: Pontryagin Dual For Kummer Extensions

Let $\mathbb{Q}(\zeta_n) \subseteq K$, and $K_n \subseteq \overline{K}$ the maximal finite Kummer extension, that is the maximal finite abelian extension with $\text{ord}(\text{Gal}_K(K_n))\big|n$ (every element of the group has order that divides n). Then there exists a natural isomorphism:

$$\text{Gal}_K(K_n) \cong \text{Hom}(K^\times/(K^\times)^n, \mu_n)$$

$$\sigma \mapsto \left(\overline{\beta} \mapsto \frac{\sigma(\sqrt[n]{\beta})}{\sqrt[n]{\beta}}\right)$$

***Proof*:**
exercise

We can do all cyclic extensions at once by taking advantage of the infinite galois theory developed earlier

Theorem 20.4.9: Kummer Pairing

Let K contain all roots of unity, let M/K be the extension of K by all possible roots, and let μ_n be all nth roots of unity. Then there exists a map:

$$\varphi : \text{Gal}_K(M) \times (K^*/(K^*)^n) \to \mu_n \qquad \varphi(\sigma, a) = \frac{\sigma(a)}{a}$$

***Proof*:**
exercise.

Definition 20.4.10: Kummer Pairing

Let K contain all roots of unity, let M/K be the extension of K by all possible roots, and let μ_n be all nth roots of unity. Then the map

$$\varphi : \text{Gal}_K(M) \times (K^*/(K^*)^n) \to \mu_n \qquad \varphi(\sigma, a) = \frac{\sigma(a)}{a}$$

is called the *Kummer Pairing*.

This shows that the galois group and the units are almost dual to each other. A point was made to put μ_n instead of $\mathbb{Z}/n\mathbb{Z}$; these two groups are group isomorphic, however there as a different group-action on μ_n, namely the galois group acts on it non-trivially. The fact there is a non-trivial action is often called the *Tate Twist*.

Artin-Schreier Extensions

If $\text{char}(K)\big|n$, then $x^n - a$ has multiple roots and hence the extension is not Galois, and furthermore if L/k is cyclic, all eigenvalues of σ are 1, loosing the method to find the element α. Note that there do exist such galois extensions, for example $\mathbb{F}_{p^p}/\mathbb{F}_p$, and hence this is a valid problem.

The key is to use generalized eigenvalues.

I'll definitely type all of this up, I'll leave it blank for now but it is pretty neat to finish off the correspondence between solvable groups and field extensions

Definition 20.4.11: Artin-Schreier Extensions

Let L/K be a cyclic extension of order n where $\text{char}(K)\big|n$. Then L is an *Artin-Schreier* extension $L = K(\alpha)$ where $\sigma(\alpha) = \alpha + 1$ and $\alpha^p - \alpha \in K$ and α is the solution to $x^p - x - a$ (as compared to $x^n - a$ for Kummer extensions).

There is a similar Artin-Schreier pairing as well.

Exercise 20.4.1

1. Show that we can find α such that $L = K(\alpha)$ where L is a Kummer $\mathbb{Z}/n\mathbb{Z}$-extension showing all elements can be written as the sum of eigenvalues. (hint: `https://www.youtube.com/watch?v=UaeJNQ5x17g&list=PL8yHsr3EFj53Zxu3iRGMYL_89GDMvdkgt&index=15`)

21⋆

More Structures on Fields

⋆ *Optional. This chapter is an aside; nothing later in the book depends on it.*

The most common fields the reader will encounter are $\mathbb{Q}, \mathbb{R}$, and $\mathbb{C}$. Each of these fields are natural in some way; $\mathbb{Q}$ is initial in $\mathbf{Fld}_0$, $\mathbb{R}$ is the smallest complete ordered field[1], and $\mathbb{C}$ is the smallest complete and algebraically closed field. A key property all three of these fields share is that there is a notion of *size*. For $\mathbb{Q}$ and $\mathbb{R}$, there is even the stronger notion of *ordering* for all the elements. For $\mathbb{R}$ and $\mathbb{C}$, there is a notion of *differentiability*. In this chapter, we explore these properties

Recall that an order can be defined on a set (definition 0.1.14). In this section, we shall explore fields with orders, or fields for which these is a function that maps to an ordered field.

This chapter shall also incorporate some topology from chapter C as it is beneficial for a deeper understanding of the subjects presented in this chapter.

21.1 Ordered and Real Fields

Definition 21.1.1: Ordered Field

Let k be a field. Then k is a *totally ordered field* (or *ordered field* for short) if there exists a (total) order $\leq$ on k such that for all $x, y, z \in k$:

1. $x < y$, then $x + z < y + z$
2. If $z > 0$, then if $x < y$, $zx < zy$

If a field k admits a total ordering, then k is said to be a *formally real field*.

[1] More technically, it is the unique Dedekind-complete ordered field up to isomorphism

Famously, $\mathbb{Q}$ and $\mathbb{R}$ are ordered fields. The reader should prove that $\mathbb{C}$ is *not* an ordered field.

Proposition 21.1.2: Properties Of Ordered Fields

Let k be an ordered field and $x \in k$. Then

1. $x > 0$ if and only if $-x < 0$ (similarly, $x < 0$ if and only if $-x > 0$)
2. $x > y$ if and only if $x - y > 0$
3. $x < y$ if and only if $-x > -y$
4. $x > y > 0$, then $y^{-1} > x^{-1} > 0$
5. If $x < y$ and $z < 0$, then $xz = (-x)(-z) > (-y)(-z) = yz$
6. $x^2 > 0$ (hence $1 > 0$ always since $1 = 1^2 > 0$)

Furthermore, ordered fields have characteristic zero

***Proof*:**
All of these should be done as an exercise. For the last one, note that

$$0 < 1 < 1 + 1 < 1 + 1 + 1 < \cdots$$

Note how this proposition immediately shows that $\mathbb{C}$ is not ordered since $-1 = i^2 \not> 0$, and that it can be shown that all finite fields are not ordered. In fact, this is a characterizing property of non-ordered fields

Proposition 21.1.3: Artin-Schreier Conditions

Let k be a field. Then k can be an ordered field. Then the following are equivalent:

1. k is an ordered field
2. -1 is *not* the sum of squares
3. 0 is *not* a (non-zero) sum of square

***Proof*:**

($1 \Rightarrow 2$) see previous proposition.

($2 \Leftrightarrow 3$) If $-1 = \sum_i^n x_i^2$, then $0 = 1 + \sum_i^n x_i^2 = 1^2 + \sum_i^n x_i^2$. Conversely, if $0 = \sum_i^n x_i^2$ for nonzero x_i, then

$$-x_n^2 = \sum_i^{n-1} x_i^2 \quad \Leftrightarrow \quad -1 = \sum_i^{n-1} (\frac{x_i}{x_n})^2$$

Then by proposition 21.1.2, squares of elements cannot be negative, however $-1 < 0$.

(2 $\Leftrightarrow$ 1) Assume -1 is not a sum of squares. Let S be the set of all elements that are (non-zero) sums of squares. Notably, $0, -1 \notin S$, S is closed under addition, and since k is commutative S is also closed under multiplication. Furthermore, it is a multiplicative subgroup of $k \setminus \{0\})$ for if $s \in S$ then:

$$\frac{1}{s} = \frac{s}{s^2} = \frac{\sum_i x_i^2}{s^2} = \sum_i \frac{x_i^2}{s^2} = \sum_i \left(\frac{x_i}{s}\right)^2$$

Now take the collection of sets that include S and that are closed under addition, multiplication, and don't contain -1 and 0. These sets are closed under inclusion and are certainly closed under chains, hence by Zorn's lemma there exists a maximal set $M \subseteq k$ that is closed under addition is a multiplicative subgroup of $k \setminus \{0\}$, which also cannot contain $-1, 0 \in M$. Then $M, \{0\}$, and $-M$ must be disjoint. I claim that

$$k = -M \cup \{0\} \cup M$$

Given this is proven, k then must be ordered, where $x < y$ iff $y - x \in M$. Suppose $0 \neq a \in k$ such that $-a \notin M$. Define:

$$M' = \{x + ay \mid x, y \in M \cup \{0\}, (x \neq 0) \vee (x \neq y)\}$$

Certainly $M \subseteq M'$ and M' is closed under addition, and is closed under multiplication for if $x, y, z, t \in M \cup \{0\}$, Then:

$$(x + ay)(z + at) = (xz + a^2yt) + a(yz + xt)$$

where $(xz + a^2yt), yz + xt \in M \cup \{0\}$ (note that $a^2 \in S \subseteq M'$). Furthermore, it should be clear that $1 \in M'$ $1 \in S \subseteq M \subseteq M'$) and $0 \notin M'$ (or else $a \in -M$). Finally, if $t \in M'$, then:

$$t^{-1} = \frac{t}{t^2} = \frac{x}{t^2} + a\frac{y}{t^2} \in M'$$

since $t^2 \in M$. Thus, M' is a multiplicative subgroup of $k \setminus \{0\}$, and hence by maximality $M = M'$, giving $a \in M$.

Since any ordered field is characteristic zero, it must contain a subfield

$$Q = \left\{ \frac{m1}{n1} \;\middle|\; m, n \in \mathbb{Z} \right\}$$

field-isomorphic to $\mathbb{Q}$. In fact, Q is order-field isomorphic, for $n1 > 0$ in Q when $n > 0$ in $\mathbb{Z}$, and $m1/n1 > 0$ in Q when $m/n > 0$ in $\mathbb{Q}$, and so $a1/b1 > c1 > d$ in Q iff $a/b > c/d$ in $\mathbb{Q}$. Thus, we usually identify Q with $\mathbb{Q}$ as an ordered subfield. A property that we may take for granted that an ordered field may have is the following:

Definition 21.1.4: Archimedean Field

Let k be an ordered field. Then k is an *Archimedean field* if every positive element of k is less than a positive integer

Though it may seem like all fields have this property, there do exists field without it, most notably the *hyperreals numbers* which can be thought of as the "order completion" of the reals (think of adding an element ϵ st $0 < \epsilon < x$ for all $x > 0$ and a ω st $0 < x < \omega$ for all $x > 0$). Fortunately, all the ordered fields we shall work with will be Archimedean due to the following classification result:

Theorem 21.1.5: Classification Of Archimedean Fields

Let k be an Archimedean field. Then k is isomorphic to a field:

$$\mathbb{Q} \subseteq k' \subseteq \mathbb{R}$$

***Proof*:**
Grillet p.233

Let us focus on formally real fields. If k is formally real, then so is $k(x)$. For an algebraic extension

Proposition 21.1.6: Algebraic Extension Of Formally Real Field

Let k be a formally real field. Then if $\alpha^2 \in k$ such that $\alpha^2 > 0$, $k(\alpha)$ is a formally real field

***Proof*:**
exercise

If an algebraic extension of a formally real field is formally real, then it is called a *real extension*.

Proposition 21.1.7: Odd Extension Of Formally Real Field

Let k be a formally real field. Then every finite extension of odd degree is a formally real field.

***Proof*:**
Grillet p.234

Using this, we can find the real closure of a formally real field:

Definition 21.1.8: Closed Real Field

Let k be a formally real field. Then k is said to be *closed* if there is no real algebraic extension L/k.

Theorem 21.1.9: Detecting Real Closure

Let k be a formally real field. Then k is real closed if and only if:

1. every positive element of k is a square in k
2. every polynomial of odd degree has a root in k

From these condition, we get that $\overline{k} = k(i)$ where $i^2 = -1$.

***Proof*:**
Grillet p.235

Due to this, a real closed field can be made into an ordered field in a unique way, namely $x \leq y$ if and only if $y - x = a^2$ for some $a \in k$. It should also be clear that the field of all algebraic real numbers is certainly a real closed field.

Corollary 21.1.10: Irreducible Elements In Real Closed Field

Let k be a real closed field. Then $f \in k[x]$ is irreducible if and only if f has degree 1 or f has degree 2 with no roots

***Proof*:**
exercise

Finally, we have:

Theorem 21.1.11: Real Closure

Every formally real field has a real closure

***Proof*:**
Grillet p.236

The reader should verify that any two real closures of k are order-field isomorphic.

Finally, we state without proof the following characterization of real-closed fields that show a naturalness to the choice of $\mathbb{R}$

Theorem 21.1.12: Artin-Schreier Theorem

Let $k \neq \overline{k}$ be a field. Then the following are equivalent:

1. k is real closed
2. $[\overline{k} : k]$ is finite
3. there is an upper bound for the degrees of irreducible polynomials in $k[x]$

> ***Proof*:**
> Grillet p.236-7

A variant of the theorem is worth recording, also without proof. Let G_K denote the absolute Galois group of a field K, and let $\sigma \in G_K$ be an involution, so that $\sigma \neq \mathrm{id}$ and $\sigma \circ \sigma = \mathrm{id}$. Then the fixed field $\overline{K}^{\sigma}$ is real closed. The two statements carry the same content, since the fixed field of an involution sits at degree 2 below $\overline{K}$ and theorem 21.1.12 then applies to it.

21.1.1 The Fields That Carry a Geometry

A vector space over an arbitrary field has no length and no angle, and section 13.6 recorded what producing them takes: an ordering, so that $\langle v, v\rangle$ can be called nonnegative, and a conjugation, so that $\langle v, v\rangle$ can be forced into the ordered field underneath. Both were described there as structure that $\mathbb{R}$ and $\mathbb{C}$ happen to carry. The results of this section say where that structure comes from, and how little freedom there was in it.

Whether a field can support a notion of positivity at all is decided by the field itself. By proposition 21.1.3, k admits a total order exactly when -1 is not a sum of squares, a condition stated in the ring operations alone with no order mentioned.

One step further up, the order and the conjugation both stop being choices. Let k be real closed. Every positive element of k is a square by theorem 21.1.9, and every nonzero square is positive by proposition 21.1.2(6), so the positive elements are exactly the nonzero squares. Hence $x \leq y$ holds if and only if $y - x$ is a square, and the order is recovered from the field operations rather than imposed on them. The same theorem gives $\overline{k} = k(i)$. Since -1 is not a square in a formally real field this extension has degree 2; it is the splitting field of $x^2 + 1$ over k, hence normal, and separable because an ordered field has characteristic zero (proposition 21.1.2). So $k(i)/k$ is Galois, $\mathrm{Gal}(\overline{k}/k)$ has order 2, and its one nontrivial element is $a + bi \mapsto a - bi$. A real closed field therefore comes with a unique order and a unique conjugation, both determined by k.

Corollary 21.1.10 supplies the third property. Over a real closed k every irreducible polynomial has degree 1 or 2, so a characteristic polynomial factors into linear and quadratic pieces over k itself and not only over $\overline{k}$.

Theorem 21.1.12 says that no other configuration of this shape exists. If $k \neq \overline{k}$ and $[\overline{k} : k]$ is finite, then k is real closed and the degree is 2. In particular no field has an algebraic closure of degree 3: a field sits at finite distance below its algebraic closure in exactly one way, and that way is the real closed one.

What none of this pins down is $\mathbb{R}$. The field of real algebraic numbers is real closed as well and satisfies every condition above, so the separation between the two is order-completeness rather than an algebraic property. Theorem 21.1.5 gives the algebraic half of that separation by placing every Archimedean field between $\mathbb{Q}$ and $\mathbb{R}$. The geometry built on the order and the conjugation (inner products, orthogonality, adjoints, the spectral theorem) is carried out over $\mathbb{R}$ and $\mathbb{C}$ in *Linear Algebra* [17].

21.2 Absolute Values on General Fields

The reader [ought to have] showed that $\mathbb{C}$ is not an ordered field. The next best thing is some notion of "size". check this! Intuitively, size is a totally ordered concept, and hence the absolute value shall be a function that will capture the intuition of size with codomain $\mathbb{R}$:

Definition 21.2.1: Absolute Value

Let k be a field. Then an *absolute value real valuation* on k is a function $v : k \to \mathbb{R}$ whose image is denoted $|x|_v$ such that

1. (positivity) $|x|_v \geq 0$ for all $x \in k$ and $|x|_v = 0$ if and only if $x = 0$
2. (multiplicative) $|xy|_v = |x|_v|y|_v$
3. (triangle inequality) $|x + y|_v \leq |x|_v + |y|_v$

If the absolute value is unambiguous, $|x|_v$ will be denoted $|x|$. If the image of v is a finitely generated abelian group, then $| - |_v$ is called a *discrete absolute value*

21.2.2 Note The reader should be careful with the definition *real valuation* as there is a different concept called *valuation* that is not a generalization o specialization of the above (see definition 27.1.1).

If the reader is familiar with norms, then this can be thought of as the field-equivalent as norms are defined on vector-spaces. In fact, taking a field to be a vector-space over itself, the existence of a absolute value induces a norm. If the reader is familiar with some Lebesgue space theory, they may recall Hölder's inequality stating that:

$$\|fg\|_1 \leq \|f\|_p\|g\|_q \qquad \frac{1}{p} + \frac{1}{q} = 1$$

which contrasts with the strict equality result given above. Recall that equality happens if and only if $\alpha|f|^p = \beta|g|^q$ for $\alpha, \beta \neq 0$, that is they are "power multiples" of each other. This is certainly the case for fields. Furthermore, there is only one absolute value instead of the 3 norms present in Hölder's inequality. A norm that satisfies the 2nd condition (on an algebra!) is called a *multiplicative norm*, and implies certain geometric invariances in the space.

Example 21.2.3: Absolute Values

1. The usual absolute values on $\mathbb{Q}, \mathbb{R}, \mathbb{C}$ all satisfy the above definition
2. For any field k, there always exists the trivial valuation

$$|x|_t = 1 \qquad x \neq 0$$

   This real valuation shall be an example of a *nonarchimedean* real valuation.

3. Let k be any field and take $k(x)$, the simple transcendental extension of k. Then there are

two interesting valuations that may be defined. The first is called the infinity valuation:

$$|f/g|_\infty = \begin{cases} 2^{\deg f - \deg g} & f \neq 0 \\ 0 & f = 0 \end{cases}$$

and the 0 valuation:

$$|f/g|_0 = \begin{cases} 2^{\operatorname{ord} f - \operatorname{ord} g} & f \neq 0 \\ 0 & f = 0 \end{cases}$$

where $\operatorname{ord}(f)$ for a polynomial $f(x) = a_0 + a_1x_1 + \cdots + a_nx^n$ to be the smallest $k \geq 0$ such that $a_k \neq 0$. The choice of 2 was arbitrary in both and can be replaced with any positive constant.

From the 0-valuation, we may define:

$$\left|\frac{f(x)}{g(x)}\right|_a = \left|\frac{f(x-a)}{g(x-a)}\right|_0$$

These valuations when restricted to k are all trivial.

With positivity and the triangle inequality, the absolute value can define a metric (see chapter C) and hence a metric topology on a field:

$$d(x, y) = |x - y|_v$$

For the p-adic case, the idea behind this metric is that $|x - y|$ is small is $x \equiv y \mod p^n$ for a large n, that is a large power of p divides the difference.

Proposition 21.2.4: Equivalent Topoloies

Let v, w be two absolutes values on a field k. Then the following are equivalent:

($\Rightarrow$) v, w induce the same topology on k

($\Rightarrow$) Given $x \in k$, $|x|_v < 1$ if and only if $|x|_w < 1$

($\Rightarrow$) There exists a $n \in k$ such that $|x|_w = |x|_v^n$ for all $x \in k$

***Proof*:**
exercise

The following can be htougt of as the CRT for real valutions

Proposition 21.2.5: Approximation Theorem

Let $|-|_1, ..., |-|_n$ be pairwise inequivalent valuations for a field K, and let $a_1, ..., a_n \in K$ be some choice elements. Then for every $\epsilon > 0$,there exists a $x \in K$ such that

$$|x - a_i|_i < \epsilon \qquad \forall 1 \leq i \leq n$$

***Proof*:**
exercise, use the negation of the above proposition (or Neukrich p.118)

As mentioned earlier, the trivial valuation is non-Archimedean. The following show that non-Archimedean valuations can be thought of as absolute values induced by *ultra-metrics*

Definition 21.2.6: Archimedean Valuation

Let v be a real valuation on a field k. Then if for all $n \in \mathbb{N}$, there exists a $x \in k$ such that

$$|n|_v \leq |x|_v$$

the valuation is called an *Archimedean valuation.* On the other hand, if there exists an x such that for all $n \in \mathbb{N}$:

$$|n|_v \leq |x|_v \qquad \forall n \in \mathbb{N}$$

Then v is called a *non-Archimedean valuation.*

Proposition 21.2.7: Characterizing Non-Archimedean Valuation

Let v be a real valuation on a field k. Then the following are equivalent:

($\Rightarrow$) v is non-Archimedean

($\Rightarrow$) $|n|_v \leq 1$ for all $n \in \mathbb{N}$

($\Rightarrow$) $|n|_v \leq 1$ for all $n \in \mathbb{Z}$

($\Rightarrow$) for all $x, y \in k$,
$$|x+y|_v \leq \max(|x|_v, |y|_v)$$

The final inequality upgrading the triangle inequality is called the *strong triangle inequality* or *ultra-metric inequality.*

Note that if $|x| \neq |y|$ in an ultra-metric , then $|x+y| = \max(|x|, |y|)$!

***Proof*:**

(1) $\Rightarrow$ (2) Let v be a non-Archimedean valuation. For the sake of contradiction, suppose that for some $n \in \mathbb{N}$, $|n|_v > 1$. Then by multiplicity we may have an $|n|_v$ with an arbitrarily large valuation:

$$|n^k| = |n|_v^k \xrightarrow{k \to \infty} \infty$$

Which would imply there is no $x \in k$ such that $|n|_v \leq |x|_v$ for all $n \in \mathbb{N}$.

(2) $\Rightarrow$ (3) show that $|-1| = |1|$ and use this to conclude.

(3) $\Rightarrow$ (4) Take:

$$\begin{aligned} |x+y|^n &= \left|\sum_k^n \binom{n}{k} x^k y^{n-k}\right| \\ &\leq \sum_k^n \left|\binom{n}{k}\right| |x|^k |y|^{n-k} \\ &\leq \sum_k^n |x|^k |y|^{n-k} \\ &\leq (n+1)\max(|x|^n, |y|^n) \end{aligned}$$

Hence

$$|x+y| \leq (n+1)^{1/n} \max(|x|, |y|)$$

As this is true for all n, and $(n+1)^{1/n} \xrightarrow{n\to\infty} 1$, we get the desired result

(4) $\Rightarrow$ (1) by induction we get:

$$|n| = |1+1+\cdots+1| \leq |1| = 1$$

giving the desired result.

Corollary 21.2.8: Values On different characteristic

Let k be a finite with characteristic $p \neq 0$. Then there does not exist an Archimedean valuation on k.

If k is a finite field, the only valuation is the trivial valuation.

***Proof*:**
exercise.

In the case of characteristic 0, given $k = \mathbb{Q}$, all the absolute values may be classified. Define p-valuation to be:

$$v_p(m/n) = \begin{cases} p^{-k} & \frac{m}{n} = p^k \frac{m'}{n'} \neq 0,\ p \nmid m', n' \\ 0 & \frac{m}{n} = 0 \end{cases}$$

Then

Theorem 21.2.9: Classification Of Absolute Values On Rationals

Let $k = \mathbb{Q}$. Then every non-trivial valuation on k is either a p-valuation or the usual absolute value.

This result is due to Ostrowski.

***Proof*:**
Let v be a nonarchemidian valuation. Then $|n|_v \leq 1$ for all $n \in \mathbb{Z}$. If $|n|_v = 1$ for all $0 \neq n \in \mathbb{Z}$ then

$$|m/n|_v |n|_v = |m|_v = 1$$

which can be sued to show that $|x|_v = 1$ for all $x \in \mathbb{Q}$. Thus, the following set is non-empty:

$$P = \{x \in \mathbb{Z} \mid |n|_v < 1\}$$

This can be shown to be an prime ideal of $\mathbb{Z}$ (exercise), and since $\mathbb{Z}$ is a PID we have that $P = (p)$ for appropriate prime $p \in \mathbb{Z}$. Let

$$c = |p|_v < 1$$

Now, if

$$\frac{m}{n} = p^k \frac{m'}{n'} \neq 0$$

where $p \nmid m', n'$, then by definition of the prime ideal:

$$|m'|_v = |n'|_v = 1 \qquad \Rightarrow \qquad n \left| \frac{m}{n} \right| = c^k$$

This valuation is not equivalent to v_p. Note that v_p and v_q are not equivalent as that would imply $|p|_v = 1$ (exercise).

The Archimedean is left as a real-analysis exercise, or see Grillet p.242,

In *Commutative Algebra* [10] (valuation rings and DVRs), many of these concepts shall be generalized to more general valuations, namely we have been working with *real* valuations, however there are more generally G-valuations for totally ordered groups G.

In an analysis class, the absolute value is used to define the completion of a ring. If k is a field with an absolute value, then the completion $\widehat{k}$ of k is the collection of Cauchy-sequences under the appropriate quotient where k is dense in $\widehat{k}$, and the absolute value n extends naturally to $\widehat{v}$ in $\widehat{k}$.

21.2.2 Ostrowski Theorem

Show that if $(K, |-|)$ is a field with an Archimedean absolute value, then

$$\widehat{K} \underset{\sim}{\in} \{\mathbb{R}, \mathbb{C}\}$$

Neukirch p.124

21.3 Derivation on Field

Derivations are the algebraic form of differentiation, and the module of relative differential forms packages every derivation of a ring into a single universal one. The construction is pure commutative algebra and belongs here rather than in any geometry book: it is consumed by [27] for the canonical class of a curve, by [5] for the sheaf of differentials, and by [4] for invariant differentials on a group variety.

Definition 21.3.1: A-derivation

Let A be a commutative ring, B an A-algebra, and M a B-module. Then an A-derivation of B into M is a map $d : B \to M$ such that

1. $d(b+b') = d(b) + d(b')$
2. $d(bb') = d(b)b' + bd(b')$
3. $d(a) = 0$ for all $a \in A$

Definition 21.3.2: Module of Relative Differential Forms

Let A be a commutative ring, B an A-algebra. Then a module of relative differential form is a B-module $\Omega_{B/A}$ with an A-derivation $d : B \to \Omega_{B/A}$ which satisfies the universal property of relative differential forms: if M is another B-module and $d' : B \to M$ an A-derivation, then there is a unique B-module homomorphism $f : \Omega_{B/A} \to M$ such that the following diagram commutes:

$$\begin{tikzcd} B \arrow[r, "d"] \arrow[dr, "d'"'] & \Omega_{B/A} \arrow[d, "f"] \\ & M \end{tikzcd}$$

Certainly $\Omega_{B/A}$ exists via the usual construction: take the free B-module F generated by the primitives $d(b)$ for $b \in B$ and quotient by the submodule generated by the relationships:

$$d(b+b') - d(b) - d(b') \quad \text{and} \quad d(bb') - d(b)b' - bd(b') \quad \text{and} \quad d(a)$$

Then the map $d : B \to \Omega_{B/A}$ is given by $b \mapsto d(b)$. Then it is an exercise in algebra to see that this satisfies the universal property and $\left(\Omega_{B/A}, d\right)$ is unique up to unique isomorphism. The following gives an alternative insightful construction:

Proposition 21.3.3: Natural Differential Structure

Let B be an A-algebra, $\delta : B \otimes_A B \to B$ the diagonal map given by $f(b \otimes b') = bb'$, and let $I = \ker \delta$. Then I/I^2 has the structure of a left B-module, and we can define a map

$$d : B \to I/I^2 \qquad d(b) = 1 \otimes b - b \otimes 1 \bmod I^2$$

In which case $(I/I^2, d)$ is a module of relative differential for B/A.

***Proof*:**
Write $\delta \colon B \otimes_A B \to B$ for the multiplication map and $I = \ker \delta$. Give I/I^2 the B-module structure coming from the left factor, $b \cdot (x \otimes y) = (bx) \otimes y$; the two possible structures agree modulo I^2, since $b \otimes 1 - 1 \otimes b \in I$.

d is an A-derivation. Additivity is clear. For the Leibniz rule, compute in $B \otimes_A B$:

$$d(bb') - b\,d(b') - b'\,d(b) = \big(1 \otimes bb' - bb' \otimes 1\big) - b\big(1 \otimes b' - b' \otimes 1\big) - b'\big(1 \otimes b - b \otimes 1\big)$$

which expands to $-(1 \otimes b - b \otimes 1)(1 \otimes b' - b' \otimes 1)$, a product of two elements of I and so zero in I/I^2. And $d(a) = 1 \otimes a - a \otimes 1 = 0$ for $a \in A$, the tensor being over A.

Universality. Let $d' \colon B \to M$ be an A-derivation. Define $B \otimes_A B \to M$ by $x \otimes y \mapsto x\,d'(y)$, which is A-bilinear and hence well defined. It kills I^2: for $u = \sum x_i \otimes y_i$ and $v = \sum x'_j \otimes y'_j$ in I, meaning $\sum x_i y_i = 0$ and $\sum x'_j y'_j = 0$, expanding uv and applying the Leibniz rule for d' leaves $\big(\sum x_i y_i\big)\big(\sum x'_j d'(y'_j)\big) = 0$. So it descends to $f \colon I/I^2 \to M$, and $f(d(b)) = f(1 \otimes b - b \otimes 1) = d'(b) - b\,d'(1) = d'(b)$ since $d'(1) = 0$. Uniqueness holds because the $d(b)$ generate I/I^2: any $\sum x_i \otimes y_i \in I$ equals $\sum x_i(1 \otimes y_i - y_i \otimes 1)$ modulo nothing, using $\sum x_i y_i = 0$.

So $(I/I^2, d)$ has the universal property of definition 21.3.2, completing the proof.

Example 21.3.4: Relative Differential

1. Take $A = \mathbb{R}$ and $B = \mathbb{R}[x]$. Then $I = \ker \delta$. Then as $\mathbb{R}[x]$ is an integral domain, it can be shown that any element is a linear combination of elements of the form:

$$f(x) \otimes g(x) - f(x)g(x) \otimes 1 \in I$$

Then it should be verified any element in I can be written as:

$$f(x)(1 \otimes g(x) - g(x) \otimes 1)$$

The reader should then verify that I/I^2 is generated by $f'(x)(x \otimes 1 - 1 \otimes x)$[a]. Let dx represent this element. Notice that this is the image of $d(x)$. Now, let's consider:

$$d(f(x) = d\left(\sum_i a_i x^i\right) = \sum_i a_i d(x^i)$$

Hence, let's compute $d(x^i)$. For $i = 2$, we get:

$$d(x^2) = d(x \cdot x) = xd(x) - xd(x) = 2xdx$$

Repeating this pattern, we can see that:

$$d(x^n) = nx^{n-1}dx$$

2. For example, taking $B = \mathbb{R}[x_1, ..., x_n]$, Then $\Omega_{B/A}$ is a free B-module generated by $dx_1, ..., dx_n$.

3. In proposition 21.3.10, we shall see that if E/F is a finitely generated separable extension (of characteristic 0), then

$$\Omega_{B/A} = \bigoplus_{b \in T} B db$$

where T is a transcendental A-basis for B.

4. What if we take $B = A[\epsilon]/(\epsilon^2)$?

5. Let $A = \mathbb{R}$ and $B = C^\infty(M)$ for some smooth n-manifold M. Then $C^\infty(M)$. Then $\Omega_{C^\infty(M)/\mathbb{R}}$ is a locally free $C^\infty(M)$-module (based off of the patches of M), consisting of the space of sections of the cotangent bundle T^*M.

[a]Hint: what is $(1 \otimes x^2 - x^2 \otimes 1)$. Repeat for higher powers

Proposition 21.3.5: Base Change For Differentials

Let A', B be A-algebras and $B' = B \otimes_A A'$. Then:

$$\Omega_{B'/A'} \cong \Omega_{B/A} \otimes_B B'$$

Furthermore, if S is a multiplicative subset of of S, then:

$$\Omega_{S^{-1}B/A} \cong S^{-1}\Omega_{B/A}$$

***Proof*:**
Both statements are checked against the universal property of definition 21.3.2.

For the base change, a B'-module M receives an A'-derivation from B' exactly when it receives an A-derivation from B that is A'-linear on the second factor, since $B' = B \otimes_A A'$ is generated over A' by the image of B. So $\mathrm{Der}_{A'}(B', M) \cong \mathrm{Der}_A(B, M)$ naturally, and representing both sides gives $\Omega_{B'/A'} \cong \Omega_{B/A} \otimes_B B'$.

For the localization, an A-derivation $d\colon B \to M$ into an $S^{-1}B$-module extends uniquely to $S^{-1}B$ by the quotient rule $d(b/s) = \big(s\,d(b) - b\,d(s)\big)/s^2$, which is forced by the Leibniz rule applied to $b = (b/s) \cdot s$. So $\mathrm{Der}_A(S^{-1}B, M) \cong \mathrm{Der}_A(B, M)$ for such M, and representing gives $\Omega_{S^{-1}B/A} \cong S^{-1}\Omega_{B/A}$, completing the proof.

Proposition 21.3.6: Differentials and Exact Sequence I

Let $A \to B \to C$ be a (not necessarily exact nor a complex) sequence of rings. Then there is an exact sequence of C-modules:

$$\Omega_{B/A} \otimes_B C \to \Omega_{C/A} \to \Omega_{C/B} \to 0$$

***Proof*:**
The maps are the natural ones: $db \otimes c \mapsto c\,db$ and $dc \mapsto dc$, the latter making sense because an A-derivation of C is in particular one killing the image of A.

Exactness is checked by applying $\mathrm{Hom}_C(-, M)$ for an arbitrary C-module M and using definition 21.3.2, which turns the sequence into

$$0 \to \mathrm{Der}_B(C, M) \to \mathrm{Der}_A(C, M) \to \mathrm{Der}_A(B, M)$$

This is exact: a derivation of C over A kills the image of B exactly when it is a derivation over B, which is exactness at the middle term and injectivity on the left. Since $\mathrm{Hom}_C(-, M)$ is left exact and the resulting sequence is exact for every M, the original sequence is exact at $\Omega_{C/A}$ and at $\Omega_{C/B}$, completing the proof.

Proposition 21.3.7: Differentials and Exact Sequence II

Let B be an A-algebra, I be an ideal of B, and $C = B/I$. Then there is a natural exact sequence of C-modules

$$I/I^2 \xrightarrow{\delta} \Omega_{B/A} \otimes_B C \to \Omega_{C/A} \to 0,$$

where for any $b \in I$, if $\bar{b}$ is its image in I/I^2, then $\delta\bar{b} = db \otimes 1$. In particular, I/I^2 has a natural structure of a C-module, and δ is a C-linear map, even though it is defined via the derivation d.

***Proof*:**
First, δ is well defined and C-linear. For $b, b' \in I$ the Leibniz rule gives $d(bb') = b\,db' + b'\,db$, which lies in $I\,\Omega_{B/A}$ and so vanishes in $\Omega_{B/A} \otimes_B C$; hence δ kills I^2. C-linearity follows because multiplying b by an element of I again lands in I^2.

For exactness, apply $\mathrm{Hom}_C(-, M)$ as in proposition 21.3.6. The sequence becomes

$$0 \to \mathrm{Der}_A(C, M) \to \mathrm{Der}_A(B, M) \to \mathrm{Hom}_C(I/I^2, M)$$

An A-derivation of B into M, where M is a C-module and so killed by I, descends to $C = B/I$ exactly when it vanishes on I; and its restriction to I is precisely the composite with δ. That is exactness at the middle and injectivity on the left, and as before it holds for every M, giving the stated sequence, completing the proof.

Corollary 21.3.8: Finite Generation of Differential Forms

If B is a finitely generated A-module or a localization of a finitely generated A-module, then $\Omega_{B/A}$ is a finitely generated B-module

***Proof*:**
As B is a finitely generated A-module, it is the quotient of polynomial rings. Hence, it follows from our direct computations from example 21.3.4 and, proposition 21.3.7, and the localization result comes from proposition 21.3.5.

For finite extensions the module of differentials sees exactly one thing, namely separability, and it sees it sharply: a nonzero derivation exists precisely when some element of the extension fails to be separable. The mechanism is already visible on a simple extension $k(\alpha)$, where a k-derivation is pinned down by its value on α and that value is constrained only through the single scalar $f'(\alpha)$.

Lemma 21.3.9: Derivations Detect Separability

Let F/k be a finite field extension. Then the following are equivalent:

1. F/k is a separable extension
2. $\Omega_{F/k} = 0$
3. the only k-derivation of F into F is the zero map

***Proof*:**

($1 \Rightarrow 2$) Let M be any F-module and $D : F \to M$ a k-derivation. Since F/k is finite and separable, theorem 19.6.20 gives $F = k(\beta)$ for some $\beta \in F$, and β is separable over k by definition 19.6.3. Write $g(x) = m_{\beta,k}(x) = \sum_j c_j x^j$. Additivity and the Leibniz rule give $D(\beta^j) = j\beta^{j-1}D(\beta)$, and D kills each $c_j \in k$, so

$$0 = D\big(g(\beta)\big) = \sum_j c_j D(\beta^j) = g'(\beta)D(\beta)$$

Now β is a root of the separable polynomial g, hence not a multiple root, so $g'(\beta) \neq 0$ by proposition 19.6.6. As $g'(\beta)$ is a unit in the field F, this forces $D(\beta) = 0$. Every element of F is a polynomial in β with coefficients in k by proposition 19.2.24, so additivity and the Leibniz rule propagate $D(\beta) = 0$ to $D = 0$. Thus $\mathrm{Der}_k(F, M) = 0$ for every F-module M.
Apply this to $M = \Omega_{F/k}$: the universal derivation d of definition 21.3.2 is itself zero. Both the identity and the zero map $\Omega_{F/k} \to \Omega_{F/k}$ are F-module homomorphisms f with $f \circ d = d$, so the uniqueness clause of definition 21.3.2 forces them to agree, giving $\Omega_{F/k} = 0$.

($2 \Rightarrow 3$) By definition 21.3.2 the k-derivations of F into F are in bijection with the F-module homomorphisms $\Omega_{F/k} \to F$, and the zero module admits only the zero homomorphism.

(3 ⇒ 1) Take the contrapositive: assume F/k is inseparable and produce a nonzero k-derivation of F into F. Since F/k is finite, write $F = k(\alpha_1, ..., \alpha_n)$ and set $F_0 = k$ and $F_i = F_{i-1}(\alpha_i)$, so that $F_n = F$.

First, some α_i is inseparable over F_{i-1}. If instead every α_i were separable over F_{i-1}, then $[F_i : F_{i-1}]_s = [F_i : F_{i-1}]$ for each i by proposition 19.6.15, and multiplying these together using corollary 19.6.16 on the left and theorem 19.3.7 on the right would give $[F : k]_s = [F : k]$, whence F/k is separable by proposition 19.6.17, contrary to assumption. So let i be the *largest* index for which α_i is inseparable over F_{i-1}, and abbreviate

$$E = F_{i-1} \qquad \alpha = \alpha_i \qquad L = F_i = E(\alpha)$$

By maximality of i, each α_j with $j > i$ is separable over F_{j-1}; running the same product over the tower $L = F_i \subseteq \cdots \subseteq F_n = F$ gives $[F : L]_s = [F : L]$, so F/L is a finite separable extension, again by proposition 19.6.17.

A nonzero E-derivation of L. Let $f(x) = m_{\alpha,E}(x)$. It is irreducible, and it is inseparable because α is inseparable over E (definition 19.6.3), so proposition 19.6.7 gives $f'(x) = 0$. Reading off the leading term of f', this already forces $\mathrm{ch}(k) = p > 0$ and $f \in E[x^p]$, exactly as in the discussion preceding definition 19.6.9; in characteristic 0 there is nothing to prove, since corollary 19.6.8 rules out inseparable irreducibles outright. Regard L as an $E[x]$-module through the evaluation map $\mathrm{ev}_\alpha : E[x] \to L$ of theorem 19.2.8, whose kernel is (f), and consider

$$\partial : E[x] \to L \qquad \partial(h) = h'(\alpha)$$

with h' the formal derivative of definition 19.6.5. It is additive, it kills E, and the Leibniz rule for the formal derivative gives

$$\begin{aligned}\partial(h_1h_2) = (h_1h_2)'(\alpha) &= h_1'(\alpha)h_2(\alpha) + h_1(\alpha)h_2'(\alpha)\\ &= \partial(h_1)h_2(\alpha) + h_1(\alpha)\partial(h_2)\end{aligned}$$

so ∂ is an E-derivation in the sense of definition 21.3.1. It kills the ideal (f): for any $h \in E[x]$,

$$\partial(fh) = (fh)'(\alpha) = f'(\alpha)h(\alpha) + f(\alpha)h'(\alpha) = 0$$

because $f' = 0$ and $f(\alpha) = 0$. Hence ∂ factors through ev_α as an additive map $D : L \to L$, and the displayed Leibniz identity descends, since both sides depend only on the values $h_1(\alpha), h_2(\alpha)$. So D is an E-derivation of L into L with

$$D(\alpha) = \partial(x) = 1$$

and in particular $D \neq 0$.

Extending D across F/L. Since F/L is finite and separable, theorem 19.6.20 gives $F = L(\beta)$ with β separable over L. Put $g(x) = m_{\beta,L}(x)$; as in (1 ⇒ 2), $g'(\beta) \neq 0$ by proposition 19.6.6. For $h(x) = \sum_j c_j x^j \in L[x]$ write $h^D(x) = \sum_j D(c_j)x^j$; expanding a product coefficientwise and applying the Leibniz rule for D to each term gives

$$(h_1h_2)^D = h_1^D h_2 + h_1 h_2^D$$

Set
$$t = -\frac{g^D(\beta)}{g'(\beta)} \in F$$
and regard F as an $L[x]$-module through evaluation at β. Define
$$\Delta : L[x] \to F \qquad \Delta(h) = h^D(\beta) + h'(\beta)\, t$$
Then Δ is additive, and combining the two product rules just recorded,
$$\begin{aligned}\Delta(h_1 h_2) &= h_1^D(\beta)h_2(\beta) + h_1(\beta)h_2^D(\beta) + \big(h_1'(\beta)h_2(\beta) + h_1(\beta)h_2'(\beta)\big)t \\ &= \Delta(h_1)h_2(\beta) + h_1(\beta)\Delta(h_2)\end{aligned}$$
On a constant $c \in L$ we get $\Delta(c) = D(c)$, so Δ vanishes on E and a fortiori on k. By the choice of t,
$$\Delta(g) = g^D(\beta) + g'(\beta)t = 0$$
and therefore $\Delta(gh) = \Delta(g)h(\beta) + g(\beta)\Delta(h) = 0$ for every $h \in L[x]$, since $g(\beta) = 0$. So Δ kills the kernel (g) of evaluation at β and descends, by theorem 19.2.8, to an additive map $\widetilde{D} : F \to F$; as before the Leibniz identity descends with it. Thus $\widetilde{D}$ is a k-derivation of F into F restricting to D on L, and
$$\widetilde{D}(\alpha) = D(\alpha) = 1 \neq 0$$
So F carries a nonzero k-derivation into itself, which is the contrapositive of $(3 \Rightarrow 1)$, completing the proof.

Note that the primitive element theorem is used only where it is legitimate, on the separable extension F/L; it says nothing about F/k itself, which by example 19.6.22 need not be simple once separability fails. The whole content of $(3 \Rightarrow 1)$ is that an inseparable step in a tower is a step at which a derivation may be defined freely, and the remaining steps are separable and so carry the derivation along uniquely.

Proposition 21.3.10: Differentials and Field Extensions

Let K/k be a finitely generated field extension. Then:
$$\dim_K \Omega_{K/k} \geq \operatorname{trdeg} K/k$$
where equality holds iff K is separably generated over k.

Proof Key ideas:
This is the separability criterion for field extensions in differential form, and both implications reduce to the exact sequences above: for a separably generated extension a transcendence basis gives a basis of Ω, and conversely a nonzero differential of a purely inseparable generator is killed by the p-th-power relation. A full account is in [31, chapter II.8]; the statement is recorded here because [27] and [5] both use it to detect smoothness.

The finite algebraic case is the one this book uses most often, and it is not left to a citation:

lemma 21.3.9 proves that a finite extension K/k has $\Omega_{K/k} = 0$ exactly when it is separable. Note that the transcendence-degree statement above genuinely needs the finitely generated hypothesis, whereas the finite case does not.

Proposition 21.3.11: Local Ring and Relative Differential

Let B be a local ring containing a field k isomorphic to $B/\mathfrak{m}$. Then given the map δ from proposition 21.3.7:

$$\delta : \mathfrak{m}/\mathfrak{m}^2 \xrightarrow{\cong} \Omega_{B/k} \otimes_B k$$

***Proof*:**
By proposition 21.3.7 $\operatorname{coker}(\delta) = 0$, so δ is surjective. To show that δ is injective, we shall show the following dual vector space map is surjective:

$$\delta' : \operatorname{Hom}_k(\Omega_{B/k} \otimes k, k) \to \operatorname{Hom}_k(\mathfrak{m}/\mathfrak{m}^2, k)$$

The term on the left is isomorphic to $\operatorname{Hom}_B(\Omega_{B/k}, k)$, which by definition of the differentials, can be identified with the set $\operatorname{Der}_k(B, k)$ of k-derivations of B to k. If $d : B \to k$ is a derivation, then $\delta'(d)$ is obtained by restricting to $\mathfrak{m}$, and noting that $d(\mathfrak{m}^2) = 0$. Now, to show that δ' is surjective, let $h \in \operatorname{Hom}(\mathfrak{m}/\mathfrak{m}^2, k)$. For any $b \in B$, we can write $b = \lambda + c$, $\lambda \in k$, $c \in \mathfrak{m}$, in a unique way. Define $db = h(\bar{c})$, where $\bar{c} \in \mathfrak{m}/\mathfrak{m}^2$ is the image of c. Then one verifies immediately that d is a k-derivation of B to k, and that $\delta'(d) = h$. Thus δ' is surjective, as required.

We finish off this brief summary of the essential results about relative differentials by showing the relation between regular local rings and relative differentials. We require the following lemma:

Lemma 21.3.12: Characterizing Free Modules using Residue and Quotient Field

Let A be a Noetherian local integral domain, with residue field k and quotient field K. Then if M is a finitely generated A-module and $\dim_k M \otimes_A k = \dim_k M \otimes_A K = r$, then M is free of rank r.

***Proof*:**
Since $\dim_k M \otimes k = r$, by Nakayama's lemma M can be generated by r elements. Hence, there is a surjective map $\varphi : A^r \to M$. Let R be its kernel. Then we obtain an exact sequence

$$0 \to R \otimes K \to K^r \to M \otimes K \to 0,$$

As $\dim_K M \otimes K = r$, we have $R \otimes K = 0$. But R is torsion-free, so $R = 0$, and M is isomorphic to A^r, completing the proof.

22⋆

Bilinear, Quadratic and Alternating Forms over a Field

⋆ *Optional. This chapter is an aside; nothing later in the book depends on it.*

A bilinear form is a piece of data attached to a vector space, and section 13.3 said what that data is: a matrix, once a basis is fixed. It did not say when two such data are the same. Two forms should count as the same when some change of basis carries one to the other, and the matrix statement of that relation is $A \mapsto P^t AP$ rather than the $A \mapsto P^{-1}AP$ that governs linear operators. The two relations are genuinely different, and the invariants that survive the first are not the eigenvalues.

This chapter classifies bilinear forms over a field up to that relation, in the two cases that occur: the symmetric forms, where the answer is subtle and field-dependent, and the alternating ones, where it is not. The answer is controlled by a single group built from the field, the square classes $k^\times/(k^\times)^2$, and this is why the subject sits after Galois theory: for a field of characteristic other than 2 that group is exactly what Kummer theory at $n = 2$ (section 20.4) classifies. Over $\mathbb{C}$ the group is trivial and the classification collapses to the rank; over $\mathbb{R}$ it has two elements and one further invariant appears; over a general field it can be arbitrarily complicated, and the bookkeeping of what survives is the Witt group.

22.1 Quadratic Forms and Symmetric Bilinear Forms

The forms of interest are the symmetric ones, and over a field where 2 is invertible a symmetric bilinear form carries exactly the same information as the single-variable function $x \mapsto \varphi(x, x)$. That function is easier to write down and is what one meets in practice, so the correspondence between the two is recorded first. It fails in characteristic 2, and the failure is not a technicality to be waved past: it is why the whole theory below carries the hypothesis $\operatorname{char} k \neq 2$.

Definition 22.1.1: Quadratic Form over a Field

Let k be a field and V a finite-dimensional k-vector space. A *quadratic form* on V is a function $q\colon V \to k$ such that

1. $q(\lambda v) = \lambda^2 q(v)$ for all $\lambda \in k$ and $v \in V$;
2. the function $b_q\colon V \times V \to k$ defined by
$$b_q(x, y) := q(x + y) - q(x) - q(y)$$
is bilinear.

The form b_q is the *polar form* of q. It is symmetric, since the defining expression is unchanged by exchanging x and y.

Two consequences of the definition are used constantly and are worth extracting at once. Setting $y = x$ in the polar form and applying (1) gives
$$b_q(x, x) = q(2x) - 2q(x) = 4q(x) - 2q(x) = 2q(x)$$
so the polar form recovers q after division by 2, and only then. And if φ is any symmetric bilinear form, the function $q_\varphi(x) := \varphi(x, x)$ satisfies both conditions above, with $b_{q_\varphi} = 2\varphi$ by the same computation. The two constructions are therefore mutually inverse exactly when 2 is invertible.

Proposition 22.1.2: Quadratic Forms and Symmetric Bilinear Forms Correspond

Let k be a field with $\operatorname{char} k \neq 2$ and let V be a finite-dimensional k-vector space. The assignments
$$\varphi \longmapsto q_\varphi, \qquad q \longmapsto \tfrac{1}{2} b_q$$
are mutually inverse bijections between the set of symmetric bilinear forms on V and the set of quadratic forms on V.

***Proof*:**
Step 1: the assignments are well defined. Let φ be symmetric bilinear and put $q_\varphi(x) = \varphi(x, x)$. Then $q_\varphi(\lambda v) = \varphi(\lambda v, \lambda v) = \lambda^2 \varphi(v, v) = \lambda^2 q_\varphi(v)$, which is condition (1). For condition (2), expanding by bilinearity and using symmetry,
$$b_{q_\varphi}(x, y) = \varphi(x + y, x + y) - \varphi(x, x) - \varphi(y, y) = 2\varphi(x, y)$$
which is bilinear. So q_φ is a quadratic form and $b_{q_\varphi} = 2\varphi$. Conversely, if q is a quadratic form then b_q is symmetric bilinear by definition 22.1.1, hence so is $\frac{1}{2} b_q$, using $\operatorname{char} k \neq 2$ to divide.

Step 2: the composites are the identity. Starting from a symmetric φ, Step 1 gives $\frac{1}{2} b_{q_\varphi} = \frac{1}{2} \cdot 2\varphi = \varphi$. Starting from a quadratic form q and writing $\varphi = \frac{1}{2} b_q$, the computation recorded before the proposition gives $b_q(x, x) = 2q(x)$, so
$$q_\varphi(x) = \varphi(x, x) = \tfrac{1}{2} b_q(x, x) = \tfrac{1}{2} \cdot 2q(x) = q(x)$$
Both composites are the identity, so the assignments are mutually inverse bijections, as we sought to show.

Because of the proposition, the words *quadratic form* and *symmetric bilinear form* are used interchangeably below whenever $\operatorname{char} k \neq 2$, and disc, orthogonality and the matrix of a form are attached to either at will. The next example shows what is lost when the hypothesis is dropped, and it is the reason the hypothesis is carried explicitly rather than assumed silently.

Example 22.1.3: Polarization Fails in Characteristic Two

Let $k = \mathbb{F}_2$ and $V = k^2$ with coordinates (x, y).

The map $q \mapsto b_q$ is not injective. Take $q(x, y) = x^2$. Then $q(\lambda v) = \lambda^2 q(v)$ holds, and

$$b_q\big((x, y), (x', y')\big) = (x + x')^2 - x^2 - x'^2 = 2xx' = 0$$

since $2 = 0$ in k. So q and the zero form have the same polar form, yet $q(1, 0) = 1 \neq 0$. More generally $b_q(v, v) = 2q(v) = 0$ for every quadratic form in characteristic 2, so every polar form is alternating and the diagonal information in q is invisible to b_q. Throughout this example *alternating* means the vanishing condition of definition 16.1.3, that $\varphi(v, v) = 0$ for every v. In characteristic 2 that is strictly stronger than the sign rule appearing in definition 13.3.15, since there $-1 = 1$ makes the sign rule say nothing beyond symmetry.

The map $q \mapsto b_q$ is not surjective either. The form $\varphi\big((x, y), (x', y')\big) = xx'$ is symmetric bilinear, but $\varphi\big((1, 0), (1, 0)\big) = 1 \neq 0$, so φ does not vanish on the diagonal and is therefore not the polar form of anything.

Orthogonal bases can fail to exist. Let $\psi\big((x, y), (x', y')\big) = xy' + x'y$, with matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ in the standard basis. It is symmetric, nondegenerate, and nonzero, since $\psi(e_1, e_2) = 1$. But $\psi(v, v) = 2xy = 0$ for every v. Were w_1, w_2 an orthogonal basis, the matrix of ψ in it would be $\operatorname{diag}\big(\psi(w_1, w_1), \psi(w_2, w_2)\big) = \operatorname{diag}(0, 0)$, forcing $\psi = 0$ and contradicting $\psi(e_1, e_2) = 1$. So ψ admits no orthogonal basis at all. Contrast $\varphi(u, v) = xx'$ above, which is already diagonal in the standard basis: failing to be a polar form and failing to be diagonalizable are different failures, and ψ exhibits the second.

All three failures trace to the division by 2 in proposition 22.1.2. In characteristic 2 the quadratic and the bilinear theories separate, and the correct objects are quadratic forms together with their alternating polar forms, and that theory is not developed here.

The classification question can now be posed precisely. Fixing a basis turns a form into a matrix (definition 13.3.18), and changing the basis changes the matrix in a way that must be pinned down before any invariant can be extracted.

Theorem 22.1.4: Change of Basis for the Matrix of a Form

Let V be a finite-dimensional k-vector space with bases $\beta = (\beta_1, \ldots, \beta_n)$ and $\beta' = (\beta'_1, \ldots, \beta'_n)$, and let $\varphi\colon V \times V \to k$ be a bilinear form. Let P be the $n \times n$ matrix whose j-th column is $[\beta'_j]_\beta$, the coordinate vector of β'_j in the basis β (this is the change of basis matrix of definition 13.2.11). Then P is invertible, $[v]_\beta = P[v]_{\beta'}$ for every $v \in V$, and

$$[\varphi]_{\beta'} = P^t \, [\varphi]_\beta \, P$$

***Proof*:**
The columns of P are the coordinate vectors of a basis, hence linearly independent, so P is invertible. Writing $v = \sum_j c_j \beta'_j$, that is $[v]_{\beta'} = (c_j)_j$, linearity of the coordinate map gives

$$[v]_\beta = \Big[\sum_j c_j \beta'_j\Big]_\beta = \sum_j c_j [\beta'_j]_\beta = P[v]_{\beta'}$$

which is the second claim. For the third, write $A = [\varphi]_\beta$. By lemma 13.3.19, for all $v, w \in V$

$$\varphi(v,w) = [v]_\beta^t A [w]_\beta = \big(P[v]_{\beta'}\big)^t A \big(P[w]_{\beta'}\big) = [v]_{\beta'}^t \big(P^t A P\big)[w]_{\beta'}$$

Taking $v = \beta'_i$ and $w = \beta'_j$ makes the coordinate vectors the standard basis vectors e_i and e_j, so the displayed expression is the (i,j) entry of P^tAP. On the other hand that value is $\varphi(\beta'_i, \beta'_j)$, which is the (i,j) entry of $[\varphi]_{\beta'}$ by definition 13.3.18. The two matrices agree entrywise, completing the proof.

Definition 22.1.5: Congruent Matrices

Two matrices $A, B \in M_n(k)$ are *congruent* if $B = P^tAP$ for some invertible $P \in M_n(k)$. Congruence is an equivalence relation: it is reflexive by $P = I$, symmetric because $A = (P^{-1})^t B P^{-1}$, and transitive because $(PQ)^t A (PQ) = Q^t(P^tAP)Q$.

Theorem 22.1.4 says that the matrices of one form in the various bases of V form exactly one congruence class, so a property of matrices is a property of the form precisely when it is congruence-invariant. Similarity, the relation $A \mapsto P^{-1}AP$ appropriate to linear operators, is a different relation, and the invariants of a form are not those of an operator: the determinant, for instance, is not congruence-invariant, but the next definition extracts from it something that is.

Definition 22.1.6: The Square Classes of a Field

Let k be a field. The squares $(k^\times)^2 = \{c^2 \mid c \in k^\times\}$ form a subgroup of the abelian group $k^\times$, and the quotient

$$k^\times/(k^\times)^2$$

is the group of *square classes* of k. Every element has order dividing 2, so it is a vector space over $\mathbb{F}_2$. The class of $a \in k^\times$ is written $a\,(k^\times)^2$, and two elements lie in the same class exactly when their ratio is a square.

The square classes are where the classification lives, and their size measures how far the field is from having all square roots. For $k = \mathbb{C}$, or any algebraically closed field, every element is a square and the group is trivial. For $k = \mathbb{R}$ it has order 2, the classes being the positive and the negative reals. For $k = \mathbb{Q}$ it is infinite. The relevance to forms is immediate from theorem 22.1.4.

Definition 22.1.7: Discriminant of a Nondegenerate Form

Let φ be a nondegenerate symmetric bilinear form (definition 13.3.22) on a finite-dimensional k-vector space V, and let β be any basis. The *discriminant* of φ is the square class

$$\operatorname{disc}(\varphi) := \det\big([\varphi]_\beta\big)\,(k^\times)^2 \in k^\times/(k^\times)^2$$

Proposition 22.1.8: The Discriminant Is Well Defined and Is an Invariant

The class $\operatorname{disc}(\varphi)$ of definition 22.1.7 does not depend on the basis β, and congruent forms have equal discriminants.

***Proof*:**
Nondegeneracy makes $\det([\varphi]_\beta) \neq 0$ by lemma 13.3.23, so the class is taken in $k^\times$ and the definition makes sense. If β' is a second basis then $[\varphi]_{\beta'} = P^t[\varphi]_\beta P$ by theorem 22.1.4, and the multiplicativity of the determinant together with $\det(P^t) = \det(P)$ gives

$$\det\big([\varphi]_{\beta'}\big) = (\det P)^2 \det\big([\varphi]_\beta\big)$$

The two determinants differ by the square $(\det P)^2$ of the nonzero scalar $\det P$, hence lie in the same square class. The same computation, read as a statement about congruent matrices rather than about two bases, gives the second claim, as we sought to show.

22.1.9 Convention: the discriminant is unsigned, and the Witt group will twist it
Definition 22.1.7 takes the determinant with no sign attached. That is the right convention here and the wrong one for the Witt group, and the two sections genuinely differ, so the choice is recorded rather than left implicit.
At a fixed rank n the factor $(-1)^{n(n-1)/2}$ is a constant and carries no information, while multiplicativity over orthogonal sums, $\operatorname{disc}(\varphi \perp \psi) = \operatorname{disc}(\varphi)\operatorname{disc}(\psi)$, holds exactly as stated and is what the classification over a finite field uses.
The Witt group of section 22.6 identifies φ with $\varphi \perp \langle 1, -1\rangle$, and the unsigned discriminant does not survive that identification: adding $\langle 1, -1\rangle$ multiplies the determinant by -1. The *signed* discriminant $(-1)^{n(n-1)/2}\det$ does survive, since the rank rises by two and the sign changes to compensate; the price is that it is multiplicative only up to $(-1)^{mn}$. Each section therefore takes the convention its own problem needs, and section 22.6 states the twist when it introduces it.

The discriminant is the first invariant of the subject that is invisible over $\mathbb{R}$ and $\mathbb{C}$: there the square class group has at most two elements, so the discriminant carries at most one bit, whereas over a general field it is as large as $k^\times/(k^\times)^2$. The notion of sameness it is invariant under deserves its own name.

Definition 22.1.10: Isometry and the Orthogonal Group

Let (V, φ) and (V', φ') be finite-dimensional k-vector spaces equipped with symmetric bilinear forms. An *isometry* $f\colon (V,\varphi) \to (V',\varphi')$ is a linear isomorphism $f\colon V \to V'$ with

$$\varphi'\big(f(x), f(y)\big) = \varphi(x,y) \qquad \text{for all } x, y \in V$$

The two forms are *isometric*, written $\varphi \cong \varphi'$, if such an f exists. The isometries of (V, φ) to itself form a group under composition, the *orthogonal group* $O(\varphi)$ of the form.

Choosing bases turns an isometry into a congruence: if f is an isometry and β is a basis of V, then the matrix of φ' in the basis $f(\beta)$ is $[\varphi]_\beta$, so two forms on spaces of the same dimension are isometric exactly when their matrices are congruent. The classification of forms up to isometry and the classification of symmetric matrices up to congruence are therefore one problem in two languages. The chapter's opening example is a form the reader has already met.

Example 22.1.11: The Trace Form as a Quadratic Form

Let F/k be a finite separable extension with $\operatorname{char} k \neq 2$. The trace form $\langle x, y\rangle = \operatorname{tr}_{F/k}(xy)$ of definition 19.6.30 is a symmetric k-bilinear form on F, viewed as a k-vector space, and it is nondegenerate by proposition 19.6.31. Its associated quadratic form under proposition 22.1.2 is

$$q(x) = \operatorname{tr}_{F/k}(x^2)$$

so F carries a canonical quadratic form built from nothing but its field structure, and definition 22.1.7 attaches to it a square class in $k^\times/(k^\times)^2$.

Take $k = \mathbb{Q}$ and $F = \mathbb{Q}(\sqrt{d})$ with d a squarefree integer, $d \neq 1$. In the basis $\beta = (1, \sqrt{d})$ one computes $\operatorname{tr}(1) = 2$, since multiplication by 1 is the identity of a two-dimensional space. Next $\operatorname{tr}(\sqrt{d}) = 0$, since multiplication by $\sqrt{d}$ sends $1 \mapsto \sqrt{d}$ and $\sqrt{d} \mapsto d$, so its matrix in that basis has both diagonal entries zero. Finally $\operatorname{tr}(d) = 2d$. Hence

$$[\langle\,,\rangle]_\beta = \begin{pmatrix} 2 & 0 \\ 0 & 2d \end{pmatrix}, \qquad \det = 4d$$

and since 4 is a square,

$$\operatorname{disc} = 4d\,(\mathbb{Q}^\times)^2 = d\,(\mathbb{Q}^\times)^2$$

The discriminant of the trace form recovers the square class of d, which is precisely the datum distinguishing the fields $\mathbb{Q}(\sqrt{d})$ from one another. The invariant is doing real work already: over $\mathbb{Q}$ the square class group is infinite, so this single class separates infinitely many non-isometric forms, where over $\mathbb{R}$ or $\mathbb{C}$ it could not have separated more than two.

Exercise 22.1.1

1. Let q be a quadratic form with polar form b_q. Prove the parallelogram identity $q(x+y)+q(x-y) = 2q(x) + 2q(y)$ directly from definition 22.1.1, using no hypothesis on the characteristic. Then explain why the identity carries no information when $\operatorname{char} k = 2$, and say what that has to do with example 22.1.3.

2. Exhibit two matrices in $M_2(\mathbb{Q})$ that are congruent but not similar. Then show that when the

change of basis matrix P of theorem 22.1.4 satisfies $P^t = P^{-1}$ the two relations produce the same matrix, so congruence and similarity can differ only through changes of basis that are not of this kind.

3. Let φ and ψ be nondegenerate symmetric bilinear forms on V and W, and let $\varphi \perp \psi$ denote the form on $V \oplus W$ given by $(\varphi \perp \psi)\big((v,w),(v',w')\big) = \varphi(v,v') + \psi(w,w')$. Show that $\varphi \perp \psi$ is nondegenerate and that $\operatorname{disc}(\varphi \perp \psi) = \operatorname{disc}(\varphi)\operatorname{disc}(\psi)$.
4. Let $F = \mathbb{F}_{q^2}$ and $k = \mathbb{F}_q$ with q odd. Compute the trace form of F/k in a basis of your choosing and determine its discriminant as an element of $k^\times/(k^\times)^2$. Is it the trivial class?
5. Let φ be a symmetric bilinear form on V with radical $R = \operatorname{rad}(\varphi)$ (definition 13.3.22). Show that φ descends to a well-defined form $\bar{\varphi}$ on V/R, that $\bar{\varphi}$ is nondegenerate, and that $\operatorname{disc}(\bar{\varphi})$ is therefore defined even though $\operatorname{disc}(\varphi)$ is not.

22.2 Diagonalization and Orthogonal Bases

A symmetric matrix is congruent to a diagonal one, and the diagonal entries are visible invariants only up to squares. Both halves of that sentence are proved here, and together they reduce the classification problem to a question about the square class group of the field.

Theorem 22.2.1: Every Symmetric Form Has an Orthogonal Basis

Let k be a field with $\operatorname{char} k \neq 2$, let V be a k-vector space of finite dimension n, and let φ be a symmetric bilinear form on V. Then V has a basis $w_1, \ldots, w_n$ with $\varphi(w_i, w_j) = 0$ whenever $i \neq j$. Equivalently, every symmetric matrix over k is congruent to a diagonal matrix.

***Proof*:**
Induct on n. For $n = 0$ there is nothing to prove, and for $n = 1$ any basis is orthogonal because the condition $i \neq j$ is vacuous.

Step 1: either φ vanishes identically or some vector is non-isotropic. Suppose $\varphi(v,v) = 0$ for every $v \in V$. Then for all $x, y \in V$,

$$0 = \varphi(x+y, x+y) = \varphi(x,x) + 2\varphi(x,y) + \varphi(y,y) = 2\varphi(x,y)$$

and since $\operatorname{char} k \neq 2$ this forces $\varphi(x,y) = 0$, so φ is the zero form and every basis is orthogonal. This is the only place the characteristic hypothesis is used, and it cannot be dropped: the form ψ of example 22.1.3 is a nonzero symmetric form over $\mathbb{F}_2$ with $\psi(v,v) = 0$ for every v, so it falsifies the implication just proved, and that example shows it admits no orthogonal basis at all.

Otherwise choose $w_1 \in V$ with $a_1 := \varphi(w_1, w_1) \neq 0$.

Step 2: split off w_1. Let $W = \{w_1\}^\perp$, a subspace by lemma 13.3.21. Every $x \in V$ decomposes as

$$x = \frac{\varphi(w_1, x)}{a_1} w_1 + \left(x - \frac{\varphi(w_1, x)}{a_1} w_1 \right)$$

and the bracketed vector lies in W, since applying $\varphi(w_1, -)$ to it gives $\varphi(w_1, x) - \frac{\varphi(w_1,x)}{a_1} a_1 = 0$. So $V = kw_1 + W$. The sum is direct: if $\lambda w_1 \in W$ then $0 = \varphi(w_1, \lambda w_1) = \lambda a_1$, and $a_1 \neq 0$ forces $\lambda = 0$. Hence $V = kw_1 \oplus W$ and $\dim W = n - 1$.

Step 3: induct. The restriction $\varphi|_{W\times W}$ is a symmetric bilinear form on W, so by the inductive hypothesis W has an orthogonal basis $w_2, \ldots, w_n$. Then $w_1, w_2, \ldots, w_n$ is a basis of V by Step 2, and it is orthogonal: $\varphi(w_i, w_j) = 0$ for $2 \leq i \neq j \leq n$ by the choice of the w_i, and $\varphi(w_1, w_j) = 0$ for $j \geq 2$ because $w_j \in W = \{w_1\}^{\perp}$.

For the matrix formulation, a symmetric $A \in M_n(k)$ is the matrix of a symmetric form on k^n in the standard basis, and an orthogonal basis for that form has diagonal matrix, and by theorem 22.1.4 the two matrices are congruent, completing the proof.

In an orthogonal basis the form is determined by the n scalars $a_i = \varphi(w_i, w_i)$, and the standard notation records exactly that: write

$$\varphi \cong \langle a_1, a_2, \ldots, a_n \rangle$$

for a form admitting an orthogonal basis with those diagonal entries, so that the associated quadratic form is $q(x) = a_1 x_1^2 + \cdots + a_n x_n^2$ in the corresponding coordinates. The notation is an assertion about an isometry class, not about a chosen basis, and the next proposition says how far the entries themselves are from being invariants.

Proposition 22.2.2: Rescaling the Entries of a Diagonalization

Let $\operatorname{char} k \neq 2$. For any $c_1, \ldots, c_n \in k^{\times}$,

$$\langle a_1, \ldots, a_n \rangle \cong \langle a_1 c_1^2, \ldots, a_n c_n^2 \rangle$$

so each diagonal entry is well defined only up to multiplication by a nonzero square. A diagonal entry that is zero stays zero, and the number of zero entries is the dimension of the radical, hence is an invariant.

***Proof*:**
Let $w_1, \ldots, w_n$ be an orthogonal basis realizing $\langle a_1, \ldots, a_n \rangle$ and put $w_i' = c_i w_i$. Each c_i is nonzero, so $w_1', \ldots, w_n'$ is again a basis, and it is orthogonal because $\varphi(w_i', w_j') = c_i c_j \varphi(w_i, w_j) = 0$ for $i \neq j$. Its diagonal entries are $\varphi(w_i', w_i') = c_i^2 a_i$, which gives the displayed isometry. Since $c_i^2 \neq 0$, the entry $c_i^2 a_i$ vanishes exactly when a_i does.

For the last claim, in an orthogonal basis a vector $x = \sum_i x_i w_i$ lies in $\operatorname{rad}(\varphi)$ if and only if $\varphi(w_j, x) = a_j x_j = 0$ for every j, that is if and only if $x_j = 0$ for every j with $a_j \neq 0$. So the radical is spanned by those w_j with $a_j = 0$, and its dimension is the number of zero entries, which is independent of the diagonalization because the radical is, completing the proof.

Corollary 22.2.3: The Discriminant from a Diagonalization

Let $\varphi \cong \langle a_1, \ldots, a_n \rangle$ be nondegenerate, so every $a_i \neq 0$. Then

$$\operatorname{disc}(\varphi) = a_1 a_2 \cdots a_n \, (k^{\times})^2$$

***Proof*:**
In an orthogonal basis the matrix of φ is $\operatorname{diag}(a_1, \ldots, a_n)$, whose determinant is $a_1 \cdots a_n$. Apply definition 22.1.7, whose independence of the basis is proposition 22.1.8. Consistently with proposition 22.2.2, replacing each a_i by $a_i c_i^2$ multiplies the product by $(c_1 \cdots c_n)^2$ and so does not change the class, as we sought to show.

Two fields where the square class group is completely known illustrate how much of the classification the discriminant sees. The first is the degenerate case, in the sense that the group is trivial and nothing beyond the rank survives.

Example 22.2.4: Forms over an Algebraically Closed Field
Let k be algebraically closed with $\operatorname{char} k \neq 2$. Every $a \in k^\times$ has a square root, so $(k^\times)^2 = k^\times$ and the square class group of definition 22.1.6 is trivial. Given any symmetric form, diagonalize it by theorem 22.2.1 as $\langle a_1, \ldots, a_r, 0, \ldots, 0\rangle$ with the $a_i \neq 0$, and apply proposition 22.2.2 with $c_i = a_i^{-1/2}$ to obtain

$$\varphi \cong \langle \underbrace{1, \ldots, 1}_{r}, \underbrace{0, \ldots, 0}_{n-r} \rangle$$

So a form over an algebraically closed field is determined up to isometry by n and r, and r is the rank of any matrix of φ. The discriminant of a nondegenerate such form is the class of 1 and carries no information, as it must, the group having one element.

Example 22.2.5: Forms over a Finite Field
Let $k = \mathbb{F}_q$ with q odd. The group $\mathbb{F}_q^\times$ is cyclic by theorem 11.3.14, of even order $q - 1$, so the squaring map has kernel $\{\pm 1\}$ of order 2 and image of index 2. Hence

$$\mathbb{F}_q^\times / (\mathbb{F}_q^\times)^2 \cong \mathbb{Z}/2\mathbb{Z}$$

with the two classes the nonzero squares and the non-squares. Unlike the algebraically closed case, the discriminant now carries a genuine bit, and it obstructs isometries that the rank alone would permit.

Take $q = 5$, where the squares in $\mathbb{F}_5^\times = \{1, 2, 3, 4\}$ are $1 = 1^2$ and $4 = 2^2$, so the non-squares are 2 and 3. The forms $\langle 1, 1\rangle$ and $\langle 1, 2\rangle$ on $\mathbb{F}_5^2$ are both nondegenerate of rank 2, but by corollary 22.2.3 their discriminants are the classes of 1 and of 2 respectively, which are distinct in $\mathbb{F}_5^\times/(\mathbb{F}_5^\times)^2$. By proposition 22.1.8 an isometry would force those classes to agree, so

$$\langle 1, 1\rangle \ncong \langle 1, 2\rangle$$

Rank does not classify forms over $\mathbb{F}_5$. Whether rank together with the discriminant does classify them is a genuine question, and it is answered affirmatively in section 22.6 once enough is known about which values a form represents.

Exercise 22.2.1

1. Exhibit two different orthogonal bases for the same form on $\mathbb{Q}^2$ whose diagonal entries are not related by the rescaling of proposition 22.2.2 entry by entry, and reconcile this with that proposition.

2. Let $k = \mathbb{R}$. Determine the square class group, and show that every nondegenerate form is isometric to $\langle 1, \ldots, 1, -1, \ldots, -1\rangle$. Explain why the discriminant alone does not classify these, and identify the invariant that does. (This book does not prove that the counts are well defined; that is Sylvester's law of inertia, and it needs an order on the scalars.)

3. Over $k = \mathbb{Q}$, show that $\langle 1, 1\rangle$ and $\langle -1, -1\rangle$ have the same rank and the same discriminant and are nevertheless not isometric, by asking which nonzero rationals each represents. Conclude that rank and discriminant together do not classify forms over $\mathbb{Q}$, in contrast with example 22.2.4. Show also that $\langle 1, 1\rangle \cong \langle 2, 2\rangle$ over $\mathbb{Q}$, so a difference of diagonal entries is not by itself evidence of non-isometry.

4. Let $\varphi \cong \langle a_1, \ldots, a_n\rangle$ be nondegenerate over k and let $c \in k^\times$ be a value represented by φ, meaning $c = q(v)$ for some $v \in V$. Show that $\varphi \cong \langle c, b_2, \ldots, b_n\rangle$ for some b_i, and deduce that the set of represented values is a union of square classes.

22.3 Alternating Forms, the Linear Darboux Theorem, and Lagrangians

Section 22.1 and section 22.2 treated the symmetric forms, where the classification runs through the square classes of k and is not settled by the rank alone. The alternating forms are the second class of bilinear forms for which a classification is available, and there the answer does not depend on the field: a single integer, the codimension of the radical, determines the form up to isometry, and neither the statement nor its proof carries a hypothesis on the characteristic.

The classification is proved in the shape of a basis in which the matrix of the form is one fixed block matrix. That basis then makes visible the subspaces on which an alternating form vanishes identically. When the form is nondegenerate such a subspace has dimension at most half that of the ambient space, and the ones attaining the bound are the Lagrangian subspaces.

Definition 22.3.1: Alternating Bilinear Form

Let k be a field, with no hypothesis on its characteristic, and let V be a finite-dimensional k-vector space. A bilinear form $\varphi\colon V \times V \to k$ (definition 13.3.15) is *alternating* if

$$\varphi(v, v) = 0 \qquad \text{for every } v \in V$$

This is the vanishing condition of definition 16.1.3 read for a 2-multilinear map, and not the sign rule listed in definition 13.3.15. The two conditions differ in characteristic 2, and throughout this section *alternating* means the displayed vanishing condition.

Two alternating forms (V, φ) and (V', φ') are *isometric* if there is a linear isomorphism $f\colon V \to V'$ with $\varphi'\big(f(x), f(y)\big) = \varphi(x, y)$ for all $x, y \in V$. This is the condition of definition 22.1.10 with the hypothesis that the two forms be symmetric dropped, and it is used in that generality below.

One expansion carries the whole section. For $x, y \in V$ the vanishing condition applied to $x + y$ gives

$$0 = \varphi(x+y, x+y) = \varphi(x,x) + \varphi(x,y) + \varphi(y,x) + \varphi(y,y) = \varphi(x,y) + \varphi(y,x)$$

so every alternating form satisfies

$$\varphi(y,x) = -\varphi(x,y) \qquad \text{for all } x,y \in V \tag{22.1}$$

which is lemma 16.1.4(1) for the transposition in S_2, its hypotheses holding here because a field is a commutative ring and both V and k are k-modules. The converse needs 2 to be invertible, and that is lemma 16.1.4(2): over a field with $\operatorname{char} k \neq 2$ a bilinear form satisfying (22.1) is alternating, since setting $y = x$ there gives $2\varphi(x,x) = 0$. Over such a field, therefore, *alternating* and *skew-symmetric* name the same forms, and a form that is both symmetric and alternating is zero: symmetry and (22.1) together give $\varphi(x,y) = -\varphi(x,y)$, hence $2\varphi(x,y) = 0$, hence $\varphi(x,y) = 0$. The classification below and the one in section 22.2 therefore overlap only in the zero form. In characteristic 2 neither statement survives, and $-1 = 1$ makes (22.1) say only that φ is symmetric.

The condition is visible in the matrix of the form. Fix a basis $\beta = (\beta_1, \ldots, \beta_n)$ of V and let $A = (a_{ij}) = [\varphi]_\beta$ be the matrix of definition 13.3.18. If φ is alternating then $a_{ii} = \varphi(\beta_i, \beta_i) = 0$ and, by (22.1), $a_{ji} = -a_{ij}$. Conversely, suppose A has zero diagonal and satisfies $A^t = -A$. For $v = \sum_i x_i \beta_i$, lemma 13.3.19 gives

$$\varphi(v,v) = \sum_{i,j} x_i x_j a_{ij} = \sum_i x_i^2 a_{ii} + \sum_{i<j} x_i x_j \big(a_{ij} + a_{ji}\big) = 0$$

so φ is alternating. Both conditions on A are needed: in characteristic 2 the matrix $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ satisfies $A^t = -A$ and has a nonzero diagonal entry.

Example 22.3.2: The Determinant Form, and the Overlap in Characteristic Two

1. Let $V = k^2$ and
$$\varphi(x,y) = x_1 y_2 - x_2 y_1$$
which is the determinant of the matrix with columns x and y. It is bilinear in each column and $\varphi(x,x) = x_1x_2 - x_2x_1 = 0$, so it is alternating. Its matrix in the standard basis is $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$, of determinant 1, so φ is nondegenerate by lemma 13.3.23.

2. Over $k = \mathbb{F}_2$ the form in (1) reads $\varphi(x,y) = x_1y_2 + x_2y_1$, which is exactly the form ψ of example 22.1.3. That form is symmetric, nonzero and alternating at once, which is possible only because $\operatorname{char} k = 2$; the example also shows it admits no orthogonal basis, so the conclusion of theorem 22.2.1 genuinely fails for it.

3. Still over $\mathbb{F}_2$, the form $\varphi(x,y) = x_1y_1$ is symmetric, hence satisfies (22.1) because $-1 = 1$, but $\varphi(e_1, e_1) = 1 \neq 0$. So the sign rule does not imply the vanishing condition when 2 is not invertible, and the hypothesis in lemma 16.1.4(2) cannot be dropped.

The proof of theorem 22.2.1 split off one dimension at a time, and the entry it left behind was pinned down only up to a square (proposition 22.2.2). For an alternating form there is no such entry to leave behind, since $\varphi(v,v) = 0$ for every v, and the smallest piece that carries any information is two-dimensional. On such a piece the one scalar available can be scaled to 1 outright, which is why no square classes enter the answer. The resulting normal form deserves a name before it is proved to exist.

Definition 22.3.3: Symplectic Basis and Symplectic Space

Let k be a field, with no hypothesis on its characteristic, let V be a finite-dimensional k-vector space, and let φ be an alternating bilinear form on V (definition 22.3.1). A *symplectic basis* for φ is a basis

$$e_1, f_1, e_2, f_2, \dots, e_m, f_m$$

of V, necessarily of even cardinality $2m$, such that $\varphi(e_i, f_i) = 1$ for every i, while

$$\varphi(e_i, f_j) = 0 \quad (i \neq j), \qquad \varphi(e_i, e_j) = 0, \qquad \varphi(f_i, f_j) = 0$$

for all i and j. A pair (V, φ) with φ alternating and nondegenerate (definition 13.3.22) is called a *symplectic space*.

Example 22.3.4: The Standard Symplectic Space k^{2m}

Let k be any field and let $e_1, f_1, \dots, e_m, f_m$ be the standard basis of k^{2m}, listed in that order. Define

$$\varphi\Big(\sum_i (x_i e_i + y_i f_i),\ \sum_i (x_i' e_i + y_i' f_i)\Big) = \sum_{i=1}^m (x_i y_i' - y_i x_i')$$

Each summand is the form of example 22.3.2(1) in the coordinate pair (x_i, y_i), so φ is bilinear and vanishes when its two arguments agree, hence is alternating. Evaluating on basis vectors gives $\varphi(e_i, f_i) = 1$, while $\varphi(e_i, f_j) = 0$ for $i \neq j$ and $\varphi(e_i, e_j) = \varphi(f_i, f_j) = 0$ for all i and j, because the i-th summand involves only the i-th coordinate pair. So the standard basis is symplectic. The matrix of φ in this basis is block diagonal with m blocks $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$, so its determinant is 1 and φ is nondegenerate by lemma 13.3.23.

Listing the same basis as $e_1, \dots, e_m, f_1, \dots, f_m$ changes the matrix to $\left(\begin{smallmatrix} 0 & I_m \\ -I_m & 0 \end{smallmatrix}\right)$. The two orderings differ by a permutation matrix P, so by theorem 22.1.4 the matrices differ by $A \mapsto P^t A P$ and the determinant is unchanged, being multiplied by $(\det P)^2 = 1$. This second ordering identifies k^{2m} with $k^m \oplus k^m$ and writes the form as

$$\varphi\big((x, y), (x', y')\big) = x^t y' - y^t x' \tag{22.2}$$

for column vectors $x, y, x', y' \in k^m$, which is the shape used for computations below.

A degenerate example is obtained by padding. On k^{2m+r} with basis $e_1, f_1, \dots, e_m, f_m, z_1, \dots, z_r$, extend φ by declaring $\varphi(z_j, -) = \varphi(-, z_j) = 0$ for every j. The result is alternating, and its radical is $\operatorname{span}(z_1, \dots, z_r)$. To see this, write $v = \sum_i (x_i e_i + y_i f_i) + \sum_j c_j z_j$; then $\varphi(e_i, v) = y_i$ and $\varphi(f_i, v) = -x_i$ and $\varphi(z_j, v) = 0$, and since φ is linear in its first argument, v lies in the radical (definition 13.3.22) exactly when every x_i and every y_i vanishes.

Every alternating form is one of the forms just written down. This is the classification, and it holds over every field.

Theorem 22.3.5: Linear Darboux Theorem

Let k be a field, with no hypothesis on its characteristic, let V be a k-vector space of finite dimension n, and let φ be an alternating bilinear form on V (definition 22.3.1).

1. There are integers $m, r \geq 0$ with $n = 2m + r$ and a basis

$$e_1, f_1, \ldots, e_m, f_m, z_1, \ldots, z_r$$

of V such that $\varphi(e_i, f_i) = 1$ for every i, while every other value of φ on an ordered pair of basis vectors is 0 except $\varphi(f_i, e_i) = -1$.

2. For any such basis, $\mathrm{rad}(\varphi) = \mathrm{span}(z_1, \ldots, z_r)$. Hence $r = \dim \mathrm{rad}(\varphi)$ and $2m = n - \dim \mathrm{rad}(\varphi)$, so both integers are determined by φ and do not depend on the basis chosen in (1).

3. φ is nondegenerate if and only if $r = 0$, and in that case $n = 2m$ is even and the basis of (1) is a symplectic basis (definition 22.3.3). In particular a symplectic space has even dimension.

4. Let φ' be an alternating form on a k-vector space V' with $\dim V' = \dim V$. Then φ and φ' are isometric if and only if $\dim \mathrm{rad}(\varphi) = \dim \mathrm{rad}(\varphi')$. In particular, for each even n there is exactly one nondegenerate alternating form on an n-dimensional space up to isometry, and none at all when n is odd.

***Proof*:**

1. *Step 1: a pair e, f with $\varphi(e, f) = 1$.* Assume $\varphi \neq 0$ and choose $u, w \in V$ with $c := \varphi(u, w) \neq 0$. Put $e := u$ and $f := c^{-1}w$, so that $\varphi(e, f) = c^{-1}\varphi(u, w) = 1$, and $\varphi(f, e) = -1$ by (22.1). The two are linearly independent: if $\alpha e + \beta f = 0$ then applying $\varphi(e, -)$ gives $\alpha\varphi(e, e) + \beta\varphi(e, f) = \beta = 0$, and applying $\varphi(f, -)$ gives $\alpha\varphi(f, e) = -\alpha = 0$. Write $P = \mathrm{span}(e, f)$, a two-dimensional subspace.

   Step 2: $V = P \oplus P^\perp$. The set $P^\perp$ is a subspace and equals $\{e, f\}^\perp$, both by lemma 13.3.21 applied to the subset $\{e, f\}$, whose span is P. Given $v \in V$, set

$$v' := v - \varphi(e, v)\, f + \varphi(f, v)\, e$$

   Then, using $\varphi(e, e) = \varphi(f, f) = 0$, $\varphi(e, f) = 1$ and $\varphi(f, e) = -1$,

$$\varphi(e, v') = \varphi(e, v) - \varphi(e, v)\cdot 1 + \varphi(f, v)\cdot 0 = 0 \qquad \varphi(f, v') = \varphi(f, v) - \varphi(e, v)\cdot 0 + \varphi(f, v)\cdot(-1) = 0$$

   so $v' \in P^\perp$, and $v = \big(\varphi(e, v)f - \varphi(f, v)e\big) + v'$ exhibits v in $P + P^\perp$. The sum is direct: if $\alpha e + \beta f \in P^\perp$ then $\varphi(e, \alpha e + \beta f) = \beta = 0$ and $\varphi(f, \alpha e + \beta f) = -\alpha = 0$. Hence $V = P \oplus P^\perp$ and $\dim P^\perp = n - 2$.

   Step 3: induction on n. For $n = 0$ take the empty basis and $m = r = 0$. Let $n \geq 1$ and assume the statement for all spaces of smaller dimension. If $\varphi = 0$, any basis of V serves with $m = 0$ and $r = n$. Otherwise Steps 1 and 2 produce $V = P \oplus P^\perp$ with $\dim P^\perp = n - 2$.

The restriction of φ to $P^\perp \times P^\perp$ is bilinear and satisfies the vanishing condition, so it is alternating, and the inductive hypothesis gives a basis $e_2, f_2, \dots, e_m, f_m, z_1, \dots, z_r$ of $P^\perp$ with the stated table of values. Set $e_1 := e$ and $f_1 := f$. The concatenated list is a basis of V by Step 2. Its values are as claimed: within $P^\perp$ by the inductive hypothesis, on the pair (e_1, f_1) by Step 1, and for a pair with one entry in $\{e_1, f_1\}$ and the other in $P^\perp$ because $\varphi(e_1, v) = \varphi(f_1, v) = 0$ for $v \in P^\perp$ by the definition of $P^\perp$, whence also $\varphi(v, e_1) = \varphi(v, f_1) = 0$ by (22.1). Counting the list gives $n = 2m + r$.

2. Let $v = \sum_i a_i e_i + \sum_i b_i f_i + \sum_j c_j z_j$. Since φ is linear in its first argument, $v \in \operatorname{rad}(\varphi)$ holds if and only if $\varphi(x, v) = 0$ for x running over the basis. The table of values in (1) gives

$$\varphi(e_i, v) = b_i, \qquad \varphi(f_i, v) = -a_i, \qquad \varphi(z_j, v) = 0$$

for all i and j. So $v \in \operatorname{rad}(\varphi)$ if and only if every a_i and every b_i vanishes, that is if and only if $v \in \operatorname{span}(z_1, \dots, z_r)$. Those z_j are part of a basis, hence independent, so $\dim \operatorname{rad}(\varphi) = r$, and $2m = n - r$ follows from $n = 2m + r$. The radical was defined in definition 13.3.22 without reference to a basis, so r and m are the same for every basis as in (1).

3. By definition 13.3.22, φ is nondegenerate exactly when $\operatorname{rad}(\varphi) = 0$, which by (2) happens exactly when $r = 0$. Then $n = 2m$, and the list of (1) is a basis satisfying the conditions of definition 22.3.3.

4. Suppose first that $\dim \operatorname{rad}(\varphi) = \dim \operatorname{rad}(\varphi')$. By (2) the two forms have bases as in (1) with the same m and the same r, since $\dim V = \dim V'$. Let $f\colon V \to V'$ be the linear map carrying each basis vector of V to the correspondingly named basis vector of V'. It is an isomorphism, being a bijection on bases, and the two bilinear maps $(x, y) \mapsto \varphi'(f(x), f(y))$ and $(x, y) \mapsto \varphi(x, y)$ agree on every ordered pair of basis vectors by construction, hence agree everywhere by bilinearity. So f is an isometry in the sense of definition 22.3.1.

   Conversely let f be an isometry. Its inverse is one as well: putting $x = f^{-1}(x')$ and $y = f^{-1}(y')$ in the defining identity gives $\varphi\big(f^{-1}(x'), f^{-1}(y')\big) = \varphi'(x', y')$. Now let $v \in \operatorname{rad}(\varphi)$ and let $x' \in V'$. Since f is onto, $x' = f(x)$ for some x, and then $\varphi'(x', f(v)) = \varphi(x, v) = 0$. Hence $f\big(\operatorname{rad}(\varphi)\big) \subseteq \operatorname{rad}(\varphi')$, and the same argument for f^{-1} gives $f^{-1}\big(\operatorname{rad}(\varphi')\big) \subseteq \operatorname{rad}(\varphi)$, that is $\operatorname{rad}(\varphi') \subseteq f\big(\operatorname{rad}(\varphi)\big)$. So f restricts to an isomorphism between the two radicals, and their dimensions agree.

   For the last sentence, take φ and φ' nondegenerate of the same dimension n: both radicals are zero, so they are isometric, and the standard form of example 22.3.4 supplies one such φ when n is even. When n is odd, (3) forbids a nondegenerate alternating form outright, completing the proof.

The symmetric case behaves differently over the very same field. Example 22.2.5 exhibits two nondegenerate symmetric forms of rank 2 over $\mathbb{F}_5$ that are not isometric, the discriminant separating them, while part (4) makes any two nondegenerate alternating forms on a space of the same dimension isometric, over $\mathbb{F}_5$ or over any other field. No invariant of the discriminant's kind can exist for alternating forms. Indeed, if φ is nondegenerate alternating with symplectic basis β_0, then $[\varphi]_{\beta_0}$ is block diagonal with m blocks $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ by definition 22.3.3, so $\det[\varphi]_{\beta_0} = 1$. Any other basis β gives

$[\varphi]_\beta = P^t[\varphi]_{\beta_0}P$ by theorem 22.1.4, whence

$$\det[\varphi]_\beta = (\det P)^2$$

So the determinant of every matrix of φ is a nonzero square, and the square class that definition 22.1.7 extracts in the symmetric case is trivial here for every form and separates nothing.[1]

In odd dimension the theorem is a nonexistence statement: there is no nondegenerate alternating form at all, and every alternating form on a space of odd dimension n has a radical of odd dimension $n - 2m$. Symmetric forms are unconstrained in this respect, since $\langle 1, 1, 1\rangle$ has the identity as its matrix and is nondegenerate in dimension 3 by lemma 13.3.23.

The basis of theorem 22.3.5 exhibits two subspaces of dimension m on which φ vanishes identically, namely $\mathrm{span}(e_1, \ldots, e_m)$ and $\mathrm{span}(f_1, \ldots, f_m)$. Subspaces with that property have a name, and it is given for an arbitrary bilinear form since the symmetric case needs it too.

Definition 22.3.6: Totally Isotropic Subspace

Let k be a field, with no hypothesis on its characteristic, let V be a finite-dimensional k-vector space, and let φ be a bilinear form on V. A subspace $W \subseteq V$ is *totally isotropic* for φ if

$$\varphi(x, y) = 0 \qquad \text{for all } x, y \in W$$

equivalently if $W \subseteq W^\perp$ in the notation of definition 13.3.20. The shorter term *isotropic subspace* is used below for the same condition.

Example 22.3.7: Totally Isotropic Subspaces in Two Standard Forms

1. Let φ be alternating on V over any field. Every line $W = kv$ is totally isotropic, since $\varphi(\lambda v, \mu v) = \lambda\mu\, \varphi(v, v) = 0$. So an alternating form has isotropic subspaces in abundance, whatever the field.

2. In the standard symplectic space k^{2m} of example 22.3.4, the subspaces $E = \mathrm{span}(e_1, \ldots, e_m)$ and $F = \mathrm{span}(f_1, \ldots, f_m)$ are totally isotropic, since $\varphi(e_i, e_j) = 0$ and $\varphi(f_i, f_j) = 0$ for all i, j and the condition is bilinear in the two arguments. Each has dimension m, half of $\dim k^{2m}$.

3. Let $k = \mathbb{R}$ and let $\varphi = \langle 1, 1\rangle$ on $\mathbb{R}^2$, that is $\varphi(x, y) = x_1y_1 + x_2y_2$, with associated quadratic form $q(x) = x_1^2 + x_2^2$ under proposition 22.1.2. If W is totally isotropic and $v \in W$, then $q(v) = \varphi(v, v) = 0$, and a sum of two real squares vanishes only when both do, so $v = 0$. The only totally isotropic subspace is 0. So the abundance in (1) is a feature of the alternating case and not of bilinear forms in general.

The subspaces in item (2) have exactly half the dimension of the ambient space, and item (1) produces nothing larger there. Half is in fact the maximum whenever the form is nondegenerate, for symmetric and alternating forms alike, and the bound follows from a dimension count for orthogonal

[1] The name of the theorem is by analogy with Darboux's theorem in symplectic geometry, which states that a closed nondegenerate differential 2-form on a smooth manifold admits, around each point, coordinates in which it is the constant form displayed in example 22.3.4. That theorem is about manifolds and is not proved in this book; the statement here is its pointwise linear-algebra counterpart.

complements. Degeneracy destroys the bound at once: the zero form on any V is alternating, and V itself is then totally isotropic.

Proposition 22.3.8: The Dimension Bound for Isotropic Subspaces

Let k be a field, with no hypothesis on its characteristic, let V be a k-vector space of finite dimension n, and let φ a nondegenerate bilinear form on V (definition 13.3.22).

1. For every subspace $W \subseteq V$,

$$\dim W + \dim W^{\perp} = n$$

2. If W is totally isotropic (definition 22.3.6) then $\dim W \leq \frac{1}{2}n$, with equality if and only if $W = W^{\perp}$.
3. Assume in addition that φ is alternating, so that $n = 2m$ is even by theorem 22.3.5(3). Then every totally isotropic subspace of V is contained in a totally isotropic subspace of dimension m. Such subspaces exist, and the maximal totally isotropic subspaces of V are exactly those of dimension m.

***Proof*:**

1. Let $d = \dim W$ and define $\Psi\colon V \to W^*$ by $\Psi(y)(x) = \varphi(x, y)$ for $x \in W$. Each $\Psi(y)$ is linear on W and Ψ is linear in y, both by bilinearity of φ. By definition 13.3.20, $\Psi(y) = 0$ says exactly that $y \in W^{\perp}$, so $\ker \Psi = W^{\perp}$.

   Ψ is surjective. First, the map $\Theta\colon V \to V^*$ with $\Theta(y) = \varphi(-, y)$ has kernel $\mathrm{rad}(\varphi)$, which is 0 by definition 13.3.22 and the nondegeneracy hypothesis. The dual basis of proposition 13.3.5 is a basis of V^*, so $\dim V^* = \dim V$, while corollary 13.1.18 gives $\dim V = \dim \ker \Theta + \dim \Theta(V) = \dim \Theta(V)$. Hence the image $\Theta(V)$ is a subspace of V^* of the full dimension, so $\Theta(V) = V^*$. Second, every $g \in W^*$ extends to V: choose a basis $w_1, \ldots, w_d$ of W, extend it to a basis $w_1, \ldots, w_n$ of V, and let $\tilde{g} \in V^*$ be the linear map with $\tilde{g}(w_i) = g(w_i)$ for $i \leq d$ and $\tilde{g}(w_i) = 0$ for $i > d$; then $\tilde{g}$ and g are linear maps on W agreeing on a basis of W, so $\tilde{g}|_W = g$. Combining, given $g \in W^*$ pick y with $\Theta(y) = \tilde{g}$; then $\Psi(y) = \tilde{g}|_W = g$.

   Now corollary 13.1.18 applied to Ψ gives $n = \dim \ker \Psi + \dim \Psi(V) = \dim W^{\perp} + \dim W^*$, and $\dim W^* = \dim W$ again by proposition 13.3.5, this time for the space W.
2. If W is totally isotropic then $W \subseteq W^{\perp}$ by definition 22.3.6, so $\dim W \leq \dim W^{\perp} = n - \dim W$ by (1), which rearranges to $2 \dim W \leq n$. Equality holds exactly when $\dim W = \dim W^{\perp}$, and a subspace contained in another of the same finite dimension equals it, so equality is equivalent to $W = W^{\perp}$.
3. Let W be totally isotropic with $d = \dim W < m$. By (1), $\dim W^{\perp} = 2m - d > d = \dim W$, and $W \subseteq W^{\perp}$, so there is a vector $v \in W^{\perp}$ with $v \notin W$. Put $W' = W + kv$, of dimension $d + 1$. It is totally isotropic: for $w, w' \in W$ and $\lambda, \mu \in k$,

$$\varphi(w + \lambda v,\ w' + \mu v) = \varphi(w, w') + \mu\,\varphi(w, v) + \lambda\,\varphi(v, w') + \lambda\mu\,\varphi(v, v)$$

and the four terms vanish in turn because W is totally isotropic, because $v \in W^\perp$, because $\varphi(v, w') = -\varphi(w', v) = 0$ by (22.1) and $v \in W^\perp$, and because φ is alternating. Repeating the step $m - d$ times produces a totally isotropic subspace of dimension m containing W.

Existence follows by applying this to $W = 0$, or directly from theorem 22.3.5(3): the span of $e_1, \ldots, e_m$ in a symplectic basis is totally isotropic of dimension m. Finally, a totally isotropic subspace of dimension m is maximal among totally isotropic subspaces, since any subspace properly containing it has dimension exceeding the bound in (2); and one of dimension $d < m$ is not maximal, since the construction above properly enlarges it. So maximality is equivalent to having dimension m, as we sought to show.

Part (3) fails for symmetric forms: example 22.3.7(3) gives a nondegenerate symmetric form of rank 2 over $\mathbb{R}$ whose only totally isotropic subspace is 0, so there the maximal one has dimension 0 rather than 1. The alternating case is uniform because $\varphi(v, v) = 0$ holds for every v by definition: enlarging an isotropic W needs a vector of $W^\perp$ outside W on which the form vanishes, and the vanishing is automatic, so the dimension count in (1) supplies the vector by itself. The subspaces attaining the bound carry a name.

Definition 22.3.9: Lagrangian Subspace

Let k be a field, with no hypothesis on its characteristic, and let (V, φ) be a symplectic space of dimension $2m$, so φ is alternating and nondegenerate (definition 22.3.3). A *Lagrangian subspace* of (V, φ) is a totally isotropic subspace $L \subseteq V$ with $\dim L = m$.

By proposition 22.3.8(2) this is the same as requiring $L = L^\perp$, and by proposition 22.3.8(3) it is the same as requiring L to be maximal among the totally isotropic subspaces of V. That same part guarantees Lagrangian subspaces exist in every symplectic space.

Example 22.3.10: Lagrangian Subspaces of the Standard Symplectic Space

Work in $k^{2m} = k^m \oplus k^m$ with the form (22.2), $\varphi\big((x, y), (x', y')\big) = x^t y' - y^t x'$.

1. For $S \in M_m(k)$ let $L_S = \{(x, Sx) \mid x \in k^m\}$, the graph of S. It is a subspace of dimension m, the map $x \mapsto (x, Sx)$ being linear and injective. For $x, x' \in k^m$,
$$\varphi\big((x, Sx), (x', Sx')\big) = x^t Sx' - (Sx)^t x' = x^t Sx' - x^t S^t x' = x^t \big(S - S^t\big) x'$$
Taking x and x' to be the i-th and j-th standard basis vectors of k^m turns the right-hand side into the (i, j) entry of $S - S^t$, so the expression vanishes for all x, x' if and only if $S = S^t$. Hence L_S is Lagrangian exactly when S is symmetric. Taking $S = 0$ recovers $E = \operatorname{span}(e_1, \ldots, e_m)$.

2. Conversely, every Lagrangian L with $L \cap F = 0$, where $F = \{(0, y) \mid y \in k^m\}$, is of this form. The projection $\pi(x, y) = x$ restricts to a linear map $L \to k^m$ with kernel $L \cap F = 0$, hence injective, and $\dim L = m$ forces it to be bijective by corollary 13.1.18. Let σ be its inverse and write $\sigma(x) = (x, Sx)$, where S is linear because σ is. Then $L = L_S$, and S is symmetric by (1).

3. For $m = 1$ every line in k^2 is Lagrangian: a line is totally isotropic by example 22.3.7(1) and has dimension $1 = m$. Over $k = \mathbb{F}_q$ the lines of k^2 number $(q^2 - 1)/(q - 1) = q + 1$, so

there are $q+1$ Lagrangians. For $m \geq 2$ having dimension m is not sufficient: inside k^4 the subspace $\operatorname{span}(e_1, f_1)$ has dimension $2 = m$ and is not totally isotropic, since $\varphi(e_1, f_1) = 1$.

Items (1) and (2) together put the Lagrangians meeting F trivially in bijection with the symmetric $m \times m$ matrices, the assignment $S \mapsto L_S$ being injective because L_S determines Sx as the second component of its element with first component x. The symmetric matrices form a k-vector space of dimension $\binom{m+1}{2}$. The two counts agree where they overlap: for $m = 1$ every 1×1 matrix is symmetric, so over $\mathbb{F}_q$ that bijection accounts for q Lagrangians, and the one remaining line, F itself, brings the total to the $q+1$ of item (3).

Exercise 22.3.1

1. Over $k = \mathbb{F}_2$, show that every symmetric bilinear form on k^2 satisfies the sign rule $\varphi(x, y) = -\varphi(y, x)$. Then determine which of the eight symmetric bilinear forms on $\mathbb{F}_2^2$ are alternating in the sense of definition 22.3.1, and say how the count is consistent with lemma 16.1.4(2).

2. Let $\operatorname{char} k \neq 2$ and let φ be a nondegenerate alternating form on a k-vector space of dimension n, with matrix A in some basis. Using $\det(A^t) = \det(A)$ and $A^t = -A$, show directly that n is even. Then explain which step of your argument fails over $\mathbb{F}_2$, and why the conclusion nevertheless still holds there.

3. Let k be any field. Show that a bilinear form φ on k^n is alternating if and only if there are scalars a_{ij} for $1 \leq i < j \leq n$ with
$$\varphi(x, y) = \sum_{i<j} a_{ij}\big(x_i y_j - x_j y_i\big)$$
and that the a_{ij} are then determined by φ. Deduce that over $k = \mathbb{F}_q$ there are exactly $q^{n(n-1)/2}$ alternating forms on k^n.

4. Let $\operatorname{char} k \neq 2$. Show that every bilinear form φ on V is uniquely $\varphi = s + a$ with s symmetric and a alternating, and identify s and a in terms of φ and $(x, y) \mapsto \varphi(y, x)$. Then show the statement fails over $\mathbb{F}_2$ by exhibiting a bilinear form on $\mathbb{F}_2^2$ that is not such a sum.

5. Let (V, φ) be a symplectic space of dimension $2m$ and let L be a Lagrangian subspace with basis $e_1, \ldots, e_m$. Show that there exist $f_1, \ldots, f_m \in V$ making $e_1, f_1, \ldots, e_m, f_m$ a symplectic basis of (V, φ). (Suggestion: for each i apply proposition 22.3.8(1) to the span of the e_j with $j \neq i$ to produce u_i with $\varphi(e_j, u_i) = 1$ when $i = j$ and 0 otherwise, then replace u_i by $u_i + \sum_j c_{ij} e_j$ for a suitable choice of scalars, noting that this leaves the previous values unchanged.) Deduce that for any two Lagrangian subspaces L and L' of (V, φ) there is an isometry of (V, φ) carrying L onto L'.

6. Let φ be an alternating form on V with radical $R = \operatorname{rad}(\varphi)$. Show that $\bar{\varphi}(x+R, y+R) := \varphi(x, y)$ is a well-defined alternating form on V/R, that it is nondegenerate, and that $\dim V/R$ is even. Compare the resulting statement with theorem 22.3.5(2).

7. Let (V, φ) be a symplectic space of dimension $2m$. Show that there is a chain of subspaces $0 = W_0 \subset W_1 \subset \cdots \subset W_m$ with $\dim W_i = i$ and each W_i totally isotropic, and that W_m is then a Lagrangian subspace. Show also that no such chain can be continued to a totally isotropic W_{m+1}.

22.4 Isotropy, the Hyperbolic Plane, and Witt Decomposition

A diagonalization records the values a form takes on n chosen vectors and says nothing about the vectors the form kills. This section organizes a symmetric form around those vectors instead, the v with $\varphi(v, v) = 0$. Two cases are extreme. A form may have no such vector other than 0; or it may be spanned by two of them paired against each other, and then it is a single two-dimensional form which is the same over every field. The theorem of this section splits an arbitrary symmetric form into pieces of exactly those two kinds together with its radical, and so isolates the one summand in which the arithmetic of k is still visible.

The number of two-dimensional pieces and the isometry class of the remaining piece are determined by the form, but the argument for that is Witt cancellation and is deferred to section 22.5. What is available here without it is a statement about the subspaces on which the form vanishes identically: the largest dimension such a subspace can have is an invariant by construction, and it counts the two-dimensional pieces in a decomposition built from a subspace attaining it.

Every statement below breaks V into mutually orthogonal subspaces, and the notation for that is fixed first. It has already been used in box 22.1.9.

Definition 22.4.1: Orthogonal Sum of Forms

Let k be a field.

1. Let φ and ψ be bilinear forms on finite-dimensional k-vector spaces V and W. Their *orthogonal sum* is the bilinear form $\varphi \perp \psi$ on $V \oplus W$ given by

$$(\varphi \perp \psi)\big((v, w), (v', w')\big) := \varphi(v, v') + \psi(w, w')$$

   It is symmetric when φ and ψ are.

2. Let φ be a bilinear form on V and let $U_1, U_2 \subseteq V$ be subspaces with $V = U_1 \oplus U_2$ and $\varphi(u_1, u_2) = 0$ for all $u_1 \in U_1$ and $u_2 \in U_2$. Then V is the *internal orthogonal sum* of U_1 and U_2, written $V = U_1 \perp U_2$.

Both constructions iterate to finitely many summands.

The two halves of the definition describe one situation from outside and from inside. If $V = U_1 \perp U_2$ internally, then $(u_1, u_2) \mapsto u_1 + u_2$ is an isometry from $\varphi|_{U_1} \perp \varphi|_{U_2}$ to φ in the sense of definition 22.1.10, because expanding $\varphi(u_1 + u_2,\, u_1' + u_2')$ by bilinearity leaves only $\varphi(u_1, u_1')$ and $\varphi(u_2, u_2')$, the two cross terms being zero by hypothesis. Concatenating a basis β of U_1 with a basis γ of U_2 gives a basis of V in which every entry $\varphi(\beta_i, \gamma_j)$ vanishes, so by definition 13.3.18 the matrix of φ is block diagonal with blocks $[\varphi|_{U_1}]_\beta$ and $[\varphi|_{U_2}]_\gamma$. The determinant of an orthogonal sum is therefore the product of the determinants of its summands, and by lemma 13.3.23 the sum is nondegenerate exactly when both summands are. The diagonal notation of section 22.2 is an orthogonal sum of lines,

$$\langle a_1, \ldots, a_n\rangle = \langle a_1\rangle \perp \cdots \perp \langle a_n\rangle$$

so theorem 22.2.1 says exactly that every symmetric form is an orthogonal sum of one-dimensional forms.

Definition 22.4.2: Isotropic and Anisotropic Vectors

Let k be a field, let V be a finite-dimensional k-vector space, let φ be a symmetric bilinear form on V, and write $q(v) := \varphi(v, v)$ for the associated quadratic form. A nonzero vector $v \in V$ is *isotropic* if $q(v) = 0$, and *anisotropic* if $q(v) \neq 0$. The form φ is *isotropic* if V contains an isotropic vector, and *anisotropic* otherwise, that is if

$$q(v) = 0 \implies v = 0$$

The zero vector is excluded deliberately: $q(0) = 0$ for every form, so admitting it would make every form isotropic. An anisotropic form is automatically nondegenerate, since a nonzero $v \in \operatorname{rad}(\varphi)$ (definition 13.3.22) satisfies $\varphi(v, x) = 0$ for every x and in particular $q(v) = 0$, which is an isotropic vector. Restricting an anisotropic form to a subspace leaves it anisotropic, since the defining implication is inherited by subsets, and hence leaves it nondegenerate.

A subspace on which φ vanishes identically, $\varphi(w, w') = 0$ for all $w, w' \in W$, is *totally isotropic* (definition 22.3.6). When $\operatorname{char} k \neq 2$ it suffices to check the quadratic form on W: if $q(w) = 0$ for every $w \in W$, then for $w, w' \in W$,

$$0 = q(w + w') = q(w) + 2\varphi(w, w') + q(w') = 2\varphi(w, w')$$

and dividing by 2 gives $\varphi(w, w') = 0$. A totally isotropic subspace is thus one all of whose nonzero vectors are isotropic.

Example 22.4.3: Isotropy of Diagonal Forms

Whether a form is isotropic depends on the field and not only on the diagonal entries.

1. $\langle 1, 1\rangle$ over $\mathbb{R}$ is anisotropic: $x^2 + y^2 = 0$ forces $x^2 = -y^2$, and a sum of two nonnegative reals vanishes only when both do.

2. $\langle 1, 1\rangle$ over $\mathbb{F}_5$ is isotropic. The vector $(2, 1)$ is nonzero and $2^2 + 1^2 = 5 = 0$ in $\mathbb{F}_5$. Over $\mathbb{F}_3$ the squares are 0 and 1, so $x^2 + y^2$ takes only the values $0, 1, 2$ and vanishes only at $x = y = 0$: the same diagonal entries give an anisotropic form.

3. $\langle 1, -1\rangle$ is isotropic over every field, since $q(1, 1) = 1 - 1 = 0$ and $(1, 1) \neq 0$.

4. Let d be a squarefree integer with $d \neq 1$ and let $F = \mathbb{Q}(\sqrt{d})$. By example 22.1.11 the trace form of $F/\mathbb{Q}$ is $\langle 2, 2d\rangle$ in the basis $(1, \sqrt{d})$, with quadratic form $q(x, y) = 2x^2 + 2dy^2$. A zero with $y = 0$ forces $x = 0$, so an isotropic vector has $y \neq 0$, and dividing $x^2 = -dy^2$ by y^2 gives $-d = (x/y)^2$. The trace form is therefore isotropic exactly when $-d$ is a square in $\mathbb{Q}$. A positive squarefree integer is a rational square only when it equals 1, so this happens for $d = -1$ alone: of all the quadratic fields, only $\mathbb{Q}(i)$ has isotropic trace form, and $q(1, 1) = 2 - 2 = 0$ exhibits the vector.

Item (3) is the smallest isotropic form, and it is worth presenting in coordinates that make its two isotropic directions visible at once. In place of one distinguished isotropic vector it carries two, paired against each other, and that pairing is what keeps the form nondegenerate.

Definition 22.4.4: The Hyperbolic Plane

Let k be a field and let φ be a symmetric bilinear form on a k-vector space U. A *hyperbolic pair* in U is a pair of vectors $e, f \in U$ with

$$\varphi(e,e) = \varphi(f,f) = 0, \qquad \varphi(e,f) = 1$$

The form φ is a *hyperbolic plane* if $\dim U = 2$ and U has a basis which is a hyperbolic pair, so that the matrix of φ in that basis is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. A hyperbolic plane is written H. A subspace of (V, φ) is *a hyperbolic plane in* V when the restriction of φ to it is one, and the orthogonal sum of m copies,

$$mH := \underbrace{H \perp \cdots \perp H}_{m}$$

is the *hyperbolic space* of rank $2m$, with $0H := 0$.

Writing H for *the* hyperbolic plane is legitimate because any two are isometric: if (e, f) and (e', f') are hyperbolic pairs spanning U and U', then the linear isomorphism carrying $e \mapsto e'$ and $f \mapsto f'$ gives the two forms the same matrix in the corresponding bases, and by lemma 13.3.19 a form is recovered from its matrix in a basis, so the isomorphism is an isometry. That matrix has determinant $-1 \neq 0$, so a hyperbolic plane is nondegenerate by lemma 13.3.23, and its discriminant (definition 22.1.7) is the square class of -1.

Example 22.4.5: The Hyperbolic Plane as a Diagonal Form

Let $\operatorname{char} k \neq 2$ and let H have hyperbolic pair (e, f). Put

$$x := e + \tfrac{1}{2} f, \qquad y := e - \tfrac{1}{2} f$$

Then $x + y = 2e$ and $x - y = f$, and since $2 \neq 0$ these recover e and f, so (x, y) is again a basis of H. Expanding by bilinearity and using $\varphi(e,e) = \varphi(f,f) = 0$ together with $\varphi(e,f) = 1$,

$$q(x) = 2 \cdot \tfrac{1}{2} \varphi(e,f) = 1, \qquad q(y) = -2 \cdot \tfrac{1}{2} \varphi(e,f) = -1$$

$$\varphi(x,y) = -\tfrac{1}{2}\varphi(e,f) + \tfrac{1}{2}\varphi(f,e) = 0$$

so (x, y) is an orthogonal basis and

$$H \cong \langle 1, -1 \rangle$$

The product of the diagonal entries is -1, which agrees through corollary 22.2.3 with the determinant computed above. Over $\mathbb{R}$ this is the indefinite plane $x^2 - y^2$. Over a field containing an i with $i^2 = -1$, proposition 22.2.2 applied with $c_1 = 1$ and $c_2 = i$ gives $\langle 1, -1 \rangle \cong \langle 1, 1 \rangle$; combined with example 22.2.4, every nondegenerate binary form over an algebraically closed field of characteristic other than 2 is a hyperbolic plane.

The hyperbolic plane was assembled from a pair of isotropic vectors. The next result runs the construction in reverse: a single isotropic vector of a nondegenerate form always has a partner, and the plane the two span splits off as an orthogonal summand. The splitting is what makes the construction iterable, and iterating it is the proof of the decomposition theorem.

Proposition 22.4.6: Every Isotropic Vector Lies in a Hyperbolic Plane

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space, and let φ be a nondegenerate symmetric bilinear form on V. Let $v \in V$ be isotropic. Then there is an $f \in V$ such that (v, f) is a hyperbolic pair, and, writing $H_v := \operatorname{span}(v, f)$,

$$V = H_v \perp H_v^{\perp}$$

where H_v is a hyperbolic plane in V and $\varphi|_{H_v^{\perp}}$ is nondegenerate. In particular a nondegenerate symmetric form is anisotropic if and only if V contains no hyperbolic plane.

***Proof*:**
Step 1: producing the partner. An isotropic vector is nonzero, so $v \notin \operatorname{rad}(\varphi) = 0$ and there is a $w_0 \in V$ with $\varphi(v, w_0) \neq 0$. Replacing w_0 by $w := \varphi(v, w_0)^{-1} w_0$ gives $\varphi(v, w) = 1$. Set

$$f := w - \frac{q(w)}{2}\, v$$

which uses $\operatorname{char} k \neq 2$ to divide. Using $q(v) = \varphi(v, v) = 0$,

$$\varphi(v, f) = \varphi(v, w) - \frac{q(w)}{2}\varphi(v, v) = 1$$

and, expanding by bilinearity and symmetry,

$$\varphi(f, f) = \varphi(w, w) - 2 \cdot \frac{q(w)}{2}\varphi(w, v) + \frac{q(w)^2}{4}\varphi(v, v) = q(w) - q(w) = 0$$

so (v, f) is a hyperbolic pair. The two vectors are linearly independent: a relation $f = \lambda v$ would give $1 = \varphi(v, f) = \lambda\varphi(v, v) = 0$, and $v \neq 0$. Hence $\dim H_v = 2$, the matrix of $\varphi|_{H_v}$ in the basis (v, f) is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and H_v is a hyperbolic plane in V, nondegenerate by lemma 13.3.23.

Step 2: the splitting. Let $x \in V$ and put

$$x' := x - \varphi(x, f)\, v - \varphi(x, v)\, f$$

Using the values of φ on the pair (v, f),

$$\varphi(x', v) = \varphi(x, v) - \varphi(x, f)\varphi(v, v) - \varphi(x, v)\varphi(f, v) = \varphi(x, v) - \varphi(x, v) = 0$$

$$\varphi(x', f) = \varphi(x, f) - \varphi(x, f)\varphi(v, f) - \varphi(x, v)\varphi(f, f) = \varphi(x, f) - \varphi(x, f) = 0$$

so x' is orthogonal to v and to f, hence to their span by lemma 13.3.21, that is $x' \in H_v^{\perp}$. Since $x - x' \in H_v$, this gives $V = H_v + H_v^{\perp}$. The sum is direct: an element $u \in H_v \cap H_v^{\perp}$ lies in H_v and is orthogonal to every element of H_v, hence lies in $\operatorname{rad}(\varphi|_{H_v})$, which is zero by Step 1. The two summands are orthogonal by the definition of $H_v^{\perp}$ (definition 13.3.20), so $V = H_v \perp H_v^{\perp}$ in the sense of definition 22.4.1.

Step 3: the complement is nondegenerate. Let $x \in \operatorname{rad}\big(\varphi|_{H_v^{\perp}}\big)$, so $\varphi(x, y) = 0$ for every $y \in H_v^{\perp}$. Since $x \in H_v^{\perp}$ and φ is symmetric, $\varphi(x, y) = 0$ for every $y \in H_v$ as well. By Step 2 each element of V is a sum of one vector of each kind, so $\varphi(x, -)$ vanishes on V and $x \in \operatorname{rad}(\varphi) = 0$.

Step 4: the equivalence. If φ is isotropic, Steps 1 to 3 produce a hyperbolic plane in V. Conversely, a hyperbolic plane in V contains a vector e with $\varphi(e,e) = 0$ and $e \neq 0$, the latter because $\varphi(e,f) = 1$ forbids $e = 0$, so φ is isotropic. Hence V contains a hyperbolic plane precisely when φ is isotropic, completing the proof.

The proposition converts one-dimensional information, the existence of a single vector with $q(v) = 0$, into a two-dimensional summand of known isometry type. What is left of φ is the restriction $\varphi|_{H_v^\perp}$, again nondegenerate and of dimension two smaller, so the exchange can be repeated until no isotropic vector remains. In dimension two there is nothing left to repeat, and the statement becomes a criterion.

Example 22.4.7: Binary Forms and Hyperbolic Planes

Let $\operatorname{char} k \neq 2$ and let $\varphi \cong \langle a, b\rangle$ be a nondegenerate form of rank 2, so that $a, b \in k^\times$ by proposition 22.2.2. If φ is isotropic then proposition 22.4.6 puts a hyperbolic plane H_v inside V, and $\dim H_v = 2 = \dim V$ forces $H_v = V$, so $\varphi \cong H$. A nondegenerate binary form is therefore either anisotropic or a hyperbolic plane.

The entries determine which of the two occurs. An isotropic vector for $q(x,y) = ax^2 + by^2$ has both coordinates nonzero, since $y = 0$ forces $ax^2 = 0$ and hence $x = 0$, and symmetrically $x = 0$ forces $y = 0$. Multiplying $ax^2 = -by^2$ by b and dividing by x^2 gives

$$-ab = \left(\frac{by}{x}\right)^2$$

Conversely, if $-ab = c^2$ then $c \neq 0$ because $ab \neq 0$, and the nonzero vector (b, c) satisfies $ab^2 + bc^2 = ab^2 - ab \cdot b = 0$. So $\langle a, b\rangle$ is a hyperbolic plane exactly when $-ab$ is a square, which by corollary 22.2.3 says exactly that $\operatorname{disc}(\varphi)$ is the class of -1. For instance $\langle 1, 1\rangle$ over $\mathbb{F}_5$ has $-ab = -1 = 4 = 2^2$, so it is the hyperbolic plane, whereas over $\mathbb{F}_3$ the element $-1 = 2$ is not a square and the form is anisotropic, matching example 22.4.3.

Iterating proposition 22.4.6 splits a hyperbolic plane off a nondegenerate form as long as one isotropic vector can be found, and the process stops only when none can. A degenerate form has to be handled first: the nonzero vectors of its radical are isotropic and orthogonal to all of V, so no partner exists for them and proposition 22.4.6 does not apply. Splitting the radical off and then iterating gives the decomposition.

Theorem 22.4.8: Witt Decomposition

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space and let φ be a symmetric bilinear form on V. Then there are an integer $m \geq 0$, subspaces $H_1, \dots, H_m \subseteq V$ each of which is a hyperbolic plane in V, and a subspace $V_{\mathrm{an}} \subseteq V$ on which φ is anisotropic, such that

$$V = \operatorname{rad}(\varphi) \perp H_1 \perp \cdots \perp H_m \perp V_{\mathrm{an}}$$

Writing $r = \dim \operatorname{rad}(\varphi)$, this reads

$$\varphi \cong \underbrace{\langle 0, \dots, 0\rangle}_{r} \perp mH \perp \varphi|_{V_{\mathrm{an}}}$$

***Proof*:**
Step 1: splitting off the radical. Write $R := \mathrm{rad}(\varphi)$ and choose a basis of R. By theorem 13.1.8 it extends to a basis of V; let V' be the span of the added vectors, so that $V = R \oplus V'$. Every element of R is orthogonal to every element of V, in particular to every element of V', so $V = R \perp V'$ in the sense of definition 22.4.1, and $\varphi|_R = 0$.

The restricted form $\varphi|_{V'}$ is nondegenerate. Let $x \in V'$ satisfy $\varphi(x, y) = 0$ for all $y \in V'$. Since also $\varphi(x, y) = 0$ for all $y \in R$, and $V = R+V'$, the map $\varphi(x, -)$ vanishes on V, so $x \in R \cap V' = 0$.

Step 2: splitting hyperbolic planes off a nondegenerate form. It suffices to prove that a nondegenerate symmetric form ψ on a space U decomposes as $U = H_1 \perp \cdots \perp H_m \perp U_{\mathrm{an}}$ with each H_i a hyperbolic plane in U and $\psi|_{U_{\mathrm{an}}}$ anisotropic; applying this to $\varphi|_{V'}$ and appending Step 1 gives the theorem, because every summand of V' is orthogonal to R.

Induct on $\dim U$. If ψ is anisotropic, take $m = 0$ and $U_{\mathrm{an}} = U$. This covers $\dim U = 0$, where there is nothing to decompose, and $\dim U = 1$: an isotropic vector v would span U, and then $\psi(v, \lambda v) = \lambda\psi(v, v) = 0$ for every λ would put v in $\mathrm{rad}(\psi)$, contradicting nondegeneracy. Otherwise ψ has an isotropic vector, and proposition 22.4.6 supplies a hyperbolic plane $H_1 \subseteq U$ with

$$U = H_1 \perp H_1^{\perp}$$

and $\psi|_{H_1^{\perp}}$ nondegenerate. Since $\dim H_1^{\perp} = \dim U - 2$, the inductive hypothesis applies to $H_1^{\perp}$ and gives $H_1^{\perp} = H_2 \perp \cdots \perp H_m \perp U_{\mathrm{an}}$ with each H_i a hyperbolic plane and $\psi|_{U_{\mathrm{an}}}$ anisotropic. Every one of these subspaces lies in $H_1^{\perp}$ and is therefore orthogonal to H_1, so the displayed decomposition of U refines to $U = H_1 \perp H_2 \perp \cdots \perp H_m \perp U_{\mathrm{an}}$.

Step 3: the diagonal reading. Take the chosen basis of R, a hyperbolic pair in each H_i, and an orthogonal basis of V_{an}, which exists by theorem 22.2.1. Their concatenation is a basis of V, and by the block-diagonal description following definition 22.4.1 the matrix of φ in it is the block sum of the zero matrix of size r, m copies of $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and a diagonal matrix. That is the asserted isometry, completing the proof.

The three summands answer three different questions about φ. The radical is where the form carries no information at all, and its dimension is already known to be an invariant by proposition 22.2.2. The hyperbolic part carries no information beyond its rank, since any two hyperbolic planes over k are isometric, whatever k is. Everything that distinguishes φ from other forms of the same rank is therefore concentrated in $\varphi|_{V_{\mathrm{an}}}$, and how large that summand can be is a property of the field. Over an algebraically closed field it has dimension at most 1: a two-dimensional subspace of an anisotropic space is nondegenerate, hence a hyperbolic plane by example 22.4.5, hence isotropic, which contradicts anisotropy. This recovers example 22.2.4, where the classification collapsed to the rank. Over a finite field the bound is one step weaker, and a counting argument gives it.

Example 22.4.9: Isotropy over a Finite Field
Let $k = \mathbb{F}_q$ with q odd.

Every equation $ax^2+by^2 = c$ with $a, b \in k^{\times}$ and $c \in k$ has a solution. As recorded in example 22.2.5, the squaring map on $\mathbb{F}_q^{\times}$ has kernel $\{\pm 1\}$, which has two elements because q is odd, so there are $(q-1)/2$ nonzero squares and the set $\left\{x^2 \;\middle|\; x \in k\right\}$ has $(q+1)/2$ elements. Multiplication by a is a bijection of k, so

$$S := \{ax^2 \mid x \in k\}, \qquad T := \{c - by^2 \mid y \in k\}$$

each have $(q+1)/2$ elements. Their sizes add to $q + 1 > q = |k|$, so S and T are not disjoint, and a common element gives x, y with $ax^2 = c - by^2$.

Every nondegenerate form of rank at least 3 over $\mathbb{F}_q$ is isotropic. Diagonalize by theorem 22.2.1 as $\varphi \cong \langle a_1, \ldots, a_n \rangle$ in an orthogonal basis $w_1, \ldots, w_n$; nondegeneracy makes every a_i nonzero by the last claim of proposition 22.2.2. With $n \geq 3$, solve $a_1 x^2 + a_2 y^2 = -a_3$ by the previous paragraph and set $v := xw_1 + yw_2 + w_3$, which is nonzero because its third coordinate is 1. Then $q(v) = a_1 x^2 + a_2 y^2 + a_3 = 0$.

Consequently, in the Witt decomposition of a form over $\mathbb{F}_q$ the anisotropic summand has dimension at most 2. Both values occur: $\langle 1 \rangle$ is anisotropic of rank 1, and if $\epsilon \in \mathbb{F}_q^\times$ is a non-square then $\langle 1, -\epsilon \rangle$ has $-ab = \epsilon$ a non-square, so it is anisotropic of rank 2 by example 22.4.7.

Theorem 22.4.8 produces some number m of hyperbolic planes, and nothing in its proof says that a different sequence of choices produces the same number. A quantity that is visibly independent of all choices is available instead, and the rest of the section relates the two.

Definition 22.4.10: The Witt Index

Let k be a field, let V be a finite-dimensional k-vector space and let φ be a symmetric bilinear form on V. The *Witt index* of φ is

$$\nu(\varphi) := \max \{\dim W \mid W \subseteq V \text{ a totally isotropic subspace}\}$$

The maximum exists: the zero subspace is totally isotropic, so the set of dimensions is nonempty, and it is bounded above by $\dim V$.

The Witt index is an invariant of φ by construction, since it is defined without reference to a basis or a decomposition, and isometries carry totally isotropic subspaces to totally isotropic subspaces of the same dimension. It is zero exactly when φ is anisotropic, since a one-dimensional totally isotropic subspace is the span of an isotropic vector. The next result computes it against theorem 22.4.8.

Proposition 22.4.11: The Witt Index Counts Hyperbolic Planes

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space of dimension n and let φ be a nondegenerate symmetric bilinear form on V.

1. Let $W \subseteq V$ be totally isotropic with $\dim W = d$. Then there are hyperbolic planes $H_1, \dots, H_d$ in V, with hyperbolic pairs (e_i, f_i) such that $e_1, \dots, e_d$ is a basis of W, and a subspace U with $\varphi|_U$ nondegenerate, such that
$$V = H_1 \perp \cdots \perp H_d \perp U$$
In particular $2d \leq n$, which is also proposition 22.3.8(2) applied to the totally isotropic W.
2. In the situation of (1), the form $\varphi|_U$ is anisotropic if and only if W is maximal among the totally isotropic subspaces of V.
3. $\nu(\varphi) \leq n/2$; some decomposition as in theorem 22.4.8 has exactly $\nu(\varphi)$ hyperbolic planes; and every such decomposition has at most $\nu(\varphi)$ of them.

***Proof*:**

1. Induct on d. For $d = 0$ take $U = V$, and there is nothing to prove. Let $d \geq 1$ and choose a basis $w_1, \dots, w_d$ of W. Since W is totally isotropic and $w_1 \neq 0$, the vector w_1 is isotropic, so proposition 22.4.6 gives an f_1 making (w_1, f_1) a hyperbolic pair, with $H_1 = \operatorname{span}(w_1, f_1)$ a hyperbolic plane, $V = H_1 \perp H_1^\perp$ and $\varphi|_{H_1^\perp}$ nondegenerate.

   Consider the linear map $\lambda \colon W \to k$ defined by $\lambda(x) = \varphi(x, f_1)$. It is nonzero, since $\lambda(w_1) = \varphi(w_1, f_1) = 1$, so $\ker \lambda$ has dimension $d-1$. Moreover $\ker \lambda = W \cap H_1^\perp$: every $x \in W$ satisfies $\varphi(x, w_1) = 0$ because W is totally isotropic and $w_1 \in W$, so x lies in $H_1^\perp$ exactly when in addition $\varphi(x, f_1) = 0$, using lemma 13.3.21 to reduce orthogonality to H_1 to orthogonality to the two spanning vectors.

   Set $W_1 := W \cap H_1^\perp$, a totally isotropic subspace of $H_1^\perp$ of dimension $d-1$. The inductive hypothesis, applied to the nondegenerate form $\varphi|_{H_1^\perp}$, gives hyperbolic planes $H_2, \dots, H_d$ in $H_1^\perp$ with hyperbolic pairs (e_i, f_i) whose vectors $e_2, \dots, e_d$ form a basis of W_1, and a subspace U with $\varphi|_U$ nondegenerate and $H_1^\perp = H_2 \perp \cdots \perp H_d \perp U$. All of these lie in $H_1^\perp$ and are therefore orthogonal to H_1, so $V = H_1 \perp H_2 \perp \cdots \perp H_d \perp U$. Finally $w_1 \notin W_1$, because $\lambda(w_1) = 1$ while λ vanishes on W_1, so $w_1, e_2, \dots, e_d$ are d linearly independent vectors of W and hence a basis of it; setting $e_1 := w_1$ gives the statement. The dimension count is $n = 2d + \dim U \geq 2d$.

2. Write $\mathcal{H} := H_1 \perp \cdots \perp H_d$, so $V = \mathcal{H} \oplus U$ and $W = \operatorname{span}(e_1, \dots, e_d)$ by (1).

   Suppose first that $\varphi|_U$ is anisotropic, and let $W' \supseteq W$ be totally isotropic. Take $x \in W'$ and write $x = \sum_i (a_i e_i + b_i f_i) + u$ with $u \in U$. For each j the vector e_j lies in $W \subseteq W'$, so $\varphi(x, e_j) = 0$; on the other hand the only summand of x not orthogonal to e_j is $b_j f_j$, whence $\varphi(x, e_j) = b_j$. So every b_j vanishes and $x = \sum_i a_i e_i + u$. Expanding $q(x)$ by bilinearity, the terms $\varphi(e_i, e_j)$ vanish for all i, j and the terms $\varphi(e_i, u)$ vanish because $e_i \in \mathcal{H}$ and $u \in U$, leaving $q(x) = q(u)$. As $x \in W'$ is isotropic or zero, $q(u) = 0$, so $u = 0$ by anisotropy and $x \in W$. Hence $W' = W$ and W is maximal.

Suppose instead that $\varphi|_U$ is isotropic, say $u \in U$ is nonzero with $q(u) = 0$. Then $W + ku$ is totally isotropic: expanding $\varphi(w + au, w' + a'u)$ leaves $\varphi(w, w') = 0$, the cross terms $\varphi(w, u) = 0$ and $\varphi(u, w') = 0$ since $W \subseteq \mathcal{H}$ and $u \in U$, and $aa'q(u) = 0$. It strictly contains W, because $u \notin \mathcal{H} \supseteq W$, so W is not maximal. The two implications together give the stated equivalence.

3. Applying (1) to a totally isotropic subspace of dimension $\nu(\varphi)$ gives $2\nu(\varphi) \leq n$. That subspace is maximal, being of largest dimension, so (2) makes the corresponding U anisotropic and
$$V = H_1 \perp \cdots \perp H_{\nu(\varphi)} \perp U$$
is a decomposition as in theorem 22.4.8, with radical zero and exactly $\nu(\varphi)$ hyperbolic planes. Conversely, let $V = H_1' \perp \cdots \perp H_m' \perp V_{\text{an}}$ be any such decomposition, with hyperbolic pair (e_i', f_i') in H_i'. The vectors $e_1', \ldots, e_m'$ lie in distinct summands of a direct sum and are nonzero, hence are linearly independent, and their span is totally isotropic: $\varphi(e_i', e_j') = 0$ for $i \neq j$ by orthogonality of the summands and $\varphi(e_i', e_i') = 0$ by the definition of a hyperbolic pair. So $m \leq \nu(\varphi)$, completing the proof.

Part (3) does not say that every decomposition has $\nu(\varphi)$ hyperbolic planes. It produces one that does and bounds all the others by that number, and no argument given above closes the gap: comparing two decompositions of the same space requires an isometry between them, and producing one is what Witt cancellation supplies. Section 22.5 proves it, and with it every decomposition of a nondegenerate φ in theorem 22.4.8 has $m = \nu(\varphi)$ and an anisotropic summand determined up to isometry. Nondegeneracy is needed there: the Witt index of a degenerate form counts its radical as well, and running the same statement on a complement of the radical gives $m = \nu(\varphi) - \dim \operatorname{rad}(\varphi)$ instead, by exercise 22.4.1 (4). What is established here is that $\nu(\varphi)$ bounds the number of hyperbolic planes in any decomposition, and that the bound is attained when φ is nondegenerate. Over $\mathbb{R}$ that number can be computed directly from a diagonalization.

Example 22.4.12: The Witt Index over the Reals

Let φ be nondegenerate on a real vector space V of dimension n. By theorem 22.2.1 and proposition 22.2.2 applied with $c_i = |a_i|^{-1/2}$, there is a basis $u_1, \ldots, u_p, w_1, \ldots, w_r$ of V, orthogonal for φ, with $q(u_i) = 1$ and $q(w_j) = -1$ and $p + r = n$.

Pairing the vectors two at a time, $\operatorname{span}(u_i, w_i)$ carries the form $\langle 1, -1 \rangle$, which is a hyperbolic plane by example 22.4.5. Doing this for $i \leq \min(p, r)$ and collecting the remaining $|p - r|$ basis vectors, which all have the same value of q, gives
$$\varphi \cong \min(p, r)\, H \perp \langle \pm 1, \ldots, \pm 1 \rangle$$
with $|p - r|$ entries in the last summand, all equal to $+1$ if $p > r$ and all to -1 if $r > p$. That summand is anisotropic, a sum of $|p - r|$ squares being zero only when each is.

The Witt index is $\min(p, r)$. It is at least that, by the span of the $u_i + w_i$ for $i \leq \min(p, r)$, which are linearly independent and satisfy $q(u_i + w_i) = 1 - 1 = 0$ and $\varphi(u_i + w_i, u_j + w_j) = 0$ for $i \neq j$. For the reverse bound let W be totally isotropic and let $P := \operatorname{span}(u_1, \ldots, u_p)$. A nonzero $x \in P$ has $q(x) = \sum_i x_i^2 > 0$, so x is not isotropic and $W \cap P = 0$, forcing $\dim W \leq n - p = r$. The same argument with $N := \operatorname{span}(w_1, \ldots, w_r)$, where $q(y) = -\sum_j y_j^2 < 0$ for $y \neq 0$, gives $\dim W \leq n - r = p$. Hence $\nu(\varphi) = \min(p, r)$, in agreement with proposition 22.4.11(3).

Since $\nu(\varphi)$ and n depend only on φ, the unordered pair $\{p, r\}$ does too. Which of the two is p is not settled by this argument, and that remaining bit is Sylvester's law of inertia, which needs the order on $\mathbb{R}$ in a way the present chapter does not use.

Exercise 22.4.1

1. Let $\operatorname{char} k \neq 2$ and let $a \in k^\times$. Show that $\langle 1, -a\rangle$ is isotropic if and only if a is a square in k, and that in that case $\langle 1, -a\rangle \cong H$. Using that $\mathbb{Q}^\times/(\mathbb{Q}^\times)^2$ is infinite, deduce that $\mathbb{Q}$ carries infinitely many pairwise non-isometric anisotropic binary forms.
2. Let $\operatorname{char} k \neq 2$. Show that the hyperbolic plane represents every scalar: for each $c \in k$ there is $x \in H$ with $q(x) = c$. Deduce that a nondegenerate isotropic form on any V represents every element of k.
3. Let $\operatorname{char} k \neq 2$ and let $\varphi \cong \langle a, b\rangle$ be nondegenerate of rank 2. Using example 22.4.7, decide for which pairs (a, b) over $k = \mathbb{Q}$ the form is a hyperbolic plane, and exhibit one anisotropic and one hyperbolic example.
4. Let φ be a symmetric bilinear form on V with radical $R = \operatorname{rad}(\varphi)$, and let $\bar\varphi$ be the induced nondegenerate form on V/R from exercise 22.1.1 (5). Show that $\nu(\varphi) = \dim R + \nu(\bar\varphi)$.
5. Let φ be nondegenerate on V and let $W \subseteq V$ be totally isotropic. Show that W is maximal among totally isotropic subspaces if and only if every isotropic vector of $W^\perp$ already lies in W.
6. Show that $\nu(\varphi \perp \psi) \geq \nu(\varphi) + \nu(\psi)$ for symmetric bilinear forms φ and ψ, and give an example over $\mathbb{R}$ where the inequality is strict.
7. Let q be odd and let φ be a nondegenerate symmetric bilinear form of odd rank n over $\mathbb{F}_q$. Show that $\nu(\varphi) = (n-1)/2$, so the Witt index over a finite field is forced by the rank alone when the rank is odd.
8. Let $V = \mathbb{F}_7^3$ with φ the standard dot product, so $q(x, y, z) = x^2+y^2+z^2$. Verify that $v = (3, 2, 1)$ is isotropic, run the construction in the proof of proposition 22.4.6 with $w = (0, 0, 1)$ to produce a partner f, compute a spanning vector of $H_v^\perp$, and write out the resulting decomposition $V = H_v \perp \langle a\rangle$. Is a a square in $\mathbb{F}_7$?

22.5 Witt Cancellation and Witt's Extension Theorem

Theorem 22.4.8 splits a form into an anisotropic part, a sum of hyperbolic planes and the radical, and each step of that construction rests on a choice: which isotropic vector to complete to a hyperbolic plane, and which complement to continue in. Nothing proved so far forces two runs of the construction to return the same number of hyperbolic planes, or isometric anisotropic parts. This section proves that they do. The result that delivers it is a cancellation law for orthogonal sums: a nondegenerate summand common to both sides of an isometry may be deleted. The section then proves Witt's extension theorem, which says that an isometry between two subspaces of a nondegenerate space is always the restriction of an isometry of the whole space. Both rest on one construction, the reflection in an anisotropic vector, which this book has not yet defined.

Throughout, $q(x) = \varphi(x, x)$ is the quadratic form attached to a symmetric bilinear form φ by proposition 22.1.2, and $\varphi \perp \psi$ is the orthogonal sum of definition 22.4.1. One further fact about that operation is used repeatedly below: the bijections $\big(v, (w, x)\big) \mapsto \big((v, w), x\big)$ and $(v, w) \mapsto (w, v)$ leave the defining expression unchanged, so they are isometries, and an orthogonal sum of several forms may be regrouped and reordered freely without changing its isometry class.

Every theorem below produces an isometry of a space with itself, so those isometries need a name.

Definition 22.5.1: The Orthogonal Group of a Form

Let k be a field, let V be a finite-dimensional k-vector space and let φ be a symmetric bilinear form on V. The *orthogonal group* of φ is

$$O(\varphi) = \{\sigma \colon V \to V \mid \sigma \text{ is an isometry of } (V, \varphi) \text{ with itself}\}$$

where isometry is meant in the sense of definition 22.1.10, and the operation is composition of maps.

That this is a group takes nothing beyond the definition: id_V is an isometry; a composite of linear bijections preserving φ is again a linear bijection preserving φ; and if σ is an isometry then so is σ^{-1}, since $\varphi(\sigma^{-1}x, \sigma^{-1}y) = \varphi(\sigma\sigma^{-1}x, \sigma\sigma^{-1}y) = \varphi(x, y)$ for all $x, y \in V$.

The construction used throughout the section takes an anisotropic vector (definition 22.4.2) and produces the isometry that negates it and fixes everything orthogonal to it. Over $\mathbb{R}$ with the dot product this is the familiar mirror reflection in the hyperplane $\{v\}^\perp$, and the formula below is the one from that setting, written so that it makes sense over any field in which $q(v)$ is invertible.

Definition 22.5.2: Reflection in an Anisotropic Vector

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space with a symmetric bilinear form φ, and let $v \in V$ be anisotropic, that is $q(v) = \varphi(v, v) \neq 0$. The *reflection in* v is the map $\tau_v \colon V \to V$ given by

$$\tau_v(x) = x - \frac{2\varphi(v, x)}{\varphi(v, v)}\, v$$

The denominator is nonzero precisely because v is anisotropic, which is why the construction is available for anisotropic vectors and for no others.

The properties that make τ_v useful are all direct computations with the defining formula.

Lemma 22.5.3: Reflections Are Involutive Isometries

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space with a symmetric bilinear form φ, and let $v \in V$ be anisotropic. Then:

1. $V = kv \oplus \{v\}^\perp$;
2. τ_v is linear, $\tau_v(v) = -v$, and $\tau_v(x) = x$ for every $x \in \{v\}^\perp$;
3. τ_v preserves φ and satisfies $\tau_v \circ \tau_v = \mathrm{id}_V$; in particular $\tau_v \in O(\varphi)$ and $\tau_v^{-1} = \tau_v$;
4. $\tau_{\lambda v} = \tau_v$ for every $\lambda \in k^\times$;
5. $\det \tau_v = -1$. In particular $\tau_v \neq \mathrm{id}_V$, so τ_v has order exactly 2 in $O(\varphi)$.

***Proof*:**
Write $a = q(v) = \varphi(v, v) \neq 0$ throughout. The set $\{v\}^\perp$ is a subspace by lemma 13.3.21.

1. Every $x \in V$ decomposes as
$$x = \frac{\varphi(v,x)}{a} v + \left(x - \frac{\varphi(v,x)}{a} v\right)$$
and applying $\varphi(v, -)$ to the bracketed vector gives $\varphi(v,x) - \frac{\varphi(v,x)}{a} a = 0$, so that vector lies in $\{v\}^\perp$ and $V = kv + \{v\}^\perp$. The sum is direct: if $\lambda v \in \{v\}^\perp$ then $0 = \varphi(v, \lambda v) = \lambda a$, and $a \neq 0$ forces $\lambda = 0$.

2. Linearity holds because $x \mapsto \varphi(v,x)$ is linear and τ_v subtracts a scalar multiple of the fixed vector v. Substituting $x = v$ gives $\tau_v(v) = v - \frac{2a}{a} v = v - 2v = -v$, and if $\varphi(v,x) = 0$ then the subtracted term vanishes, so $\tau_v(x) = x$.

3. For $x, y \in V$, expanding by bilinearity and symmetry,
$$\varphi\big(\tau_v(x), \tau_v(y)\big) = \varphi(x,y) - \frac{2\varphi(v,y)}{a}\varphi(x,v) - \frac{2\varphi(v,x)}{a}\varphi(v,y) + \frac{4\varphi(v,x)\varphi(v,y)}{a^2}\, a$$
The last three terms are $-2c$, $-2c$ and $+4c$ with $c = \varphi(v,x)\varphi(v,y)/a$, so they cancel and $\varphi(\tau_v(x), \tau_v(y)) = \varphi(x,y)$. For the involution, first
$$\varphi\big(v, \tau_v(x)\big) = \varphi(v,x) - \frac{2\varphi(v,x)}{a}\, a = -\varphi(v,x)$$
so
$$\tau_v\big(\tau_v(x)\big) = \tau_v(x) - \frac{2\varphi(v, \tau_v(x))}{a}\, v = x - \frac{2\varphi(v,x)}{a}\, v + \frac{2\varphi(v,x)}{a}\, v = x$$
Hence τ_v is a linear bijection preserving φ, which is an isometry of (V, φ) with itself in the sense of definition 22.1.10, so $\tau_v \in O(\varphi)$ by definition 22.5.1 and $\tau_v^{-1} = \tau_v$.

4. For $\lambda \neq 0$ the vector λv is anisotropic, since $q(\lambda v) = \lambda^2 a \neq 0$, and
$$\tau_{\lambda v}(x) = x - \frac{2\varphi(\lambda v, x)}{\lambda^2 a}\, \lambda v = x - \frac{2\lambda^2\varphi(v,x)}{\lambda^2 a}\, v = \tau_v(x)$$

5. By (1) choose a basis $v, z_2, \ldots, z_n$ of V with $z_2, \ldots, z_n$ a basis of $\{v\}^\perp$. By (2) the matrix of τ_v in this basis is $\operatorname{diag}(-1, 1, \ldots, 1)$, whose determinant is -1. Since $\operatorname{char} k \neq 2$ this is not 1, so $\tau_v \neq \mathrm{id}_V$, and $\tau_v^2 = \mathrm{id}_V$ from (3) then makes its order exactly 2, completing the proof.

Example 22.5.4: Reflections of $\langle 1, 1\rangle$ over $\mathbb{Q}$

Let $k = \mathbb{Q}$ and let φ be the form on $V = \mathbb{Q}^2$ with matrix the identity in the standard basis e_1, e_2, so $q(x_1, x_2) = x_1^2 + x_2^2$ and $\varphi \cong \langle 1, 1\rangle$.

Take $v = e_1$, with $q(e_1) = 1$. Then $\tau_{e_1}(x) = x - 2\varphi(e_1, x)e_1 = x - 2x_1 e_1$, so $\tau_{e_1}(e_1) = -e_1$ and $\tau_{e_1}(e_2) = e_2$, and the matrix of τ_{e_1} is $\operatorname{diag}(-1, 1)$.

Take instead $v = (1,1)$, with $q(v) = 2 \neq 0$. Here $\tau_v(x) = x - \frac{2\varphi(v,x)}{2}v = x - \varphi(v,x)v$, so

$$\tau_v(e_1) = (1,0) - (1,1) = (0,-1), \qquad \tau_v(e_2) = (0,1) - (1,1) = (-1,0)$$

and the matrix of τ_v is $\left(\begin{smallmatrix} 0 & -1 \\ -1 & 0 \end{smallmatrix}\right)$. Both matrices have determinant -1 and square to the identity, as lemma 22.5.3 requires.

Their product is

$$\begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

an isometry of determinant 1 whose square is $-\mathrm{id}$ and whose fourth power is id. So $O(\langle 1,1\rangle)$ over $\mathbb{Q}$ contains an element of order 4, which is not a reflection: reflections have order 2 and determinant -1. Products of reflections are therefore strictly more general than reflections, and corollary 22.5.10 will say how much more general.

Reflections are used here for one property: they move a vector to any other vector of the same nonzero value under q. That is how every theorem below produces the isometry it needs, and it takes at most two reflections.

Lemma 22.5.5: Two Reflections Move a Vector to Any Other of the Same Value

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space with a symmetric bilinear form φ, and let $u, w \in V$ satisfy $q(u) = q(w) \neq 0$. Then there is a $\sigma \in O(\varphi)$ with $\sigma(u) = w$, and σ can be taken to be a product of at most two reflections.

Proof:
Expanding both terms by bilinearity and using $q(w) = q(u)$,

$$q(u-w) + q(u+w) = \big(q(u) - 2\varphi(u,w) + q(w)\big) + \big(q(u) + 2\varphi(u,w) + q(w)\big) = 4q(u)$$

Since $\operatorname{char} k \neq 2$, the scalar $4 = 2^2$ is nonzero, so $4q(u) \neq 0$ and $q(u-w)$ and $q(u+w)$ do not both vanish.

Case 1: $q(u-w) \neq 0$. Put $v = u - w$, an anisotropic vector. Then

$$q(v) = q(u) - 2\varphi(u,w) + q(w) = 2\big(q(u) - \varphi(u,w)\big) = 2\varphi(v,u)$$

the last equality because $\varphi(v,u) = \varphi(u,u) - \varphi(w,u) = q(u) - \varphi(u,w)$. Hence $2\varphi(v,u)/q(v) = 1$, and

$$\tau_v(u) = u - \frac{2\varphi(v,u)}{q(v)}v = u - v = w$$

so $\sigma = \tau_v$ works, and it lies in $O(\varphi)$ by lemma 22.5.3.

Case 2: $q(u-w) = 0$. Then $q(u+w) = 4q(u) \neq 0$ by the displayed identity. The vectors u and $-w$ satisfy $q(-w) = q(w) = q(u) \neq 0$ and $q\big(u - (-w)\big) = q(u+w) \neq 0$, so Case 1 applied to the pair $u, -w$ gives $\tau_{u+w}(u) = -w$. Also $q(w) \neq 0$, so τ_w is defined, and $\tau_w(-w) = -\tau_w(w) = w$ by lemma 22.5.3(2). Therefore

$$(\tau_w \circ \tau_{u+w})(u) = \tau_w(-w) = w$$

and $\sigma = \tau_w \circ \tau_{u+w}$ is a product of two reflections, lying in $O(\varphi)$ because $O(\varphi)$ is closed under composition (definition 22.5.1), as we sought to show.

Both cases occur. In example 22.5.4 the vectors $u = e_1$ and $w = e_2$ have $q(u) = q(w) = 1$ and $q(u-w) = q(1,-1) = 2 \neq 0$, so Case 1 applies and the single reflection $\tau_{(1,-1)}$ carries e_1 to e_2; indeed $\tau_{(1,-1)}(e_1) = e_1 - \frac{2 \cdot 1}{2}(1,-1) = (0,1)$. Case 2 is not an artifact of the proof: over $\mathbb{Q}$ with $\varphi \cong \langle 1, 1, -1 \rangle$ the vectors $u = e_1$ and $w = (1,1,1)$ both have $q = 1$ while $q(u-w) = q(0,-1,-1) = 0$, and there no single reflection suffices: an equality $\tau_v(u) = w$ reads $u - w = \frac{2\varphi(v,u)}{q(v)} v$, and $w \neq u$ makes the coefficient nonzero, so $q(u-w)$ would be a nonzero square multiple of $q(v) \neq 0$ and in particular nonzero, contradicting $q(u-w) = 0$.

Lemma 22.5.5 carries no nondegeneracy hypothesis on φ, which matters immediately: the cancellation theorem is proved for arbitrary φ_1 and φ_2, whose radicals are not controlled, and only the summand being cancelled is required to be nondegenerate. The proof reduces that summand to one dimension, where the lemma does the work.

Theorem 22.5.6: Witt Cancellation

Let k be a field with $\operatorname{char} k \neq 2$. Let ψ be a *nondegenerate* symmetric bilinear form on a finite-dimensional k-vector space, and let φ_1, φ_2 be symmetric bilinear forms on finite-dimensional k-vector spaces. If

$$\psi \perp \varphi_1 \cong \psi \perp \varphi_2$$

then $\varphi_1 \cong \varphi_2$.

***Proof*:**
Step 1: reduction to a one-dimensional ψ. Let ψ live on U with $\dim U = m$. By theorem 22.2.1 the space U has an orthogonal basis $u_1, \ldots, u_m$, so $\psi \cong \langle c_1, \ldots, c_m \rangle$ with $c_i = \psi(u_i, u_i)$. By the last claim of proposition 22.2.2 the number of indices with $c_i = 0$ is $\dim \operatorname{rad}(\psi)$, which is 0 because ψ is nondegenerate; hence every $c_i \neq 0$. Regrouping the orthogonal sum,

$$\psi \perp \varphi_j \cong \langle c_1 \rangle \perp \big(\langle c_2, \ldots, c_m \rangle \perp \varphi_j \big) \qquad (j = 1, 2)$$

So if the theorem holds whenever ψ is one-dimensional and nondegenerate, then cancelling $\langle c_1 \rangle$ from the hypothesis gives $\langle c_2, \ldots, c_m \rangle \perp \varphi_1 \cong \langle c_2, \ldots, c_m \rangle \perp \varphi_2$, and $m-1$ further cancellations, formally an induction on m with the case $m = 0$ reading $\varphi_1 \cong \varphi_2$, give the theorem. It therefore suffices to treat $\psi = \langle c \rangle$ with $c \in k^\times$.

Step 2: the one-dimensional case. Let φ_j live on W_j and realize $\langle c \rangle \perp \varphi_j$ on $V_j = k e_j \oplus W_j$, where $q(e_j) = c$, $\varphi(e_j, W_j) = 0$, and the form restricted to W_j is φ_j. Write $\varphi^{(j)}$ for the form on V_j. First,

$$W_j = \{e_j\}^\perp \text{ inside } V_j$$

since $W_j \subseteq \{e_j\}^\perp$ by construction, and conversely if $x = \lambda e_j + y$ with $y \in W_j$ satisfies $\varphi^{(j)}(e_j, x) = 0$, then that value is λc, and $c \neq 0$ forces $\lambda = 0$.

Let $f \colon V_1 \to V_2$ be an isometry. Put $u = f(e_1) \in V_2$. Then $q^{(2)}(u) = q^{(1)}(e_1) = c \neq 0$ and $q^{(2)}(e_2) = c$, so lemma 22.5.5 applied inside $(V_2, \varphi^{(2)})$ supplies $\sigma \in O(\varphi^{(2)})$ with $\sigma(u) = e_2$. The composite $g = \sigma \circ f \colon V_1 \to V_2$ is again an isometry, and $g(e_1) = e_2$.

Step 3: g carries W_1 onto W_2. For $x \in V_1$,

$$\varphi^{(2)}\big(e_2, g(x)\big) = \varphi^{(2)}\big(g(e_1), g(x)\big) = \varphi^{(1)}(e_1, x)$$

so $x \in \{e_1\}^{\perp}$ if and only if $g(x) \in \{e_2\}^{\perp}$. Since g is bijective, g maps $\{e_1\}^{\perp}$ onto $\{e_2\}^{\perp}$, which by Step 2 says $g(W_1) = W_2$. The restriction $g|_{W_1} : W_1 \to W_2$ is a linear isomorphism preserving the forms, that is an isometry $\varphi_1 \cong \varphi_2$, completing the proof.

The theorem is what makes the decomposition of theorem 22.4.8 independent of the choices made in producing it.

Corollary 22.5.7: The Anisotropic Part and the Witt Index Are Invariants

Let k be a field with $\operatorname{char} k \neq 2$ and let φ be a nondegenerate symmetric bilinear form on a finite-dimensional k-vector space. Suppose

$$\varphi \cong \varphi_1 \perp m_1 H \qquad \text{and} \qquad \varphi \cong \varphi_2 \perp m_2 H$$

with φ_1 and φ_2 anisotropic and $m_1, m_2 \geq 0$. Then $m_1 = m_2$ and $\varphi_1 \cong \varphi_2$.

***Proof*:**
By definition 22.4.4 a hyperbolic plane H has a basis e, f with $q(e) = q(f) = 0$ and $\varphi(e, f) = 1$, so its matrix in that basis is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, of determinant $-1 \neq 0$; by lemma 13.3.23 the form H is nondegenerate. The matrix of an orthogonal sum in the union of two bases is block diagonal with the two matrices as blocks, so its determinant is the product of theirs, and mH is nondegenerate for every $m \geq 0$ by the same lemma. Also e is a nonzero isotropic vector of H.

Assume without loss of generality that $m_1 \leq m_2$. Regrouping the orthogonal sum,

$$\varphi_1 \perp m_1 H \cong \varphi \cong \varphi_2 \perp m_2 H \cong \big(\varphi_2 \perp (m_2 - m_1)H\big) \perp m_1 H$$

Since $m_1 H$ is nondegenerate, theorem 22.5.6 cancels it from the two ends and gives

$$\varphi_1 \cong \varphi_2 \perp (m_2 - m_1)H$$

If $m_2 > m_1$, the right-hand form has the nonzero isotropic vector e of any one of its hyperbolic summands, and the preimage of e under the isometry is nonzero and isotropic for φ_1, since an isometry is injective and preserves q; that contradicts the hypothesis that φ_1 is anisotropic. Hence $m_1 = m_2$, the term $(m_2 - m_1)H$ is the form on the zero space, and $\varphi_1 \cong \varphi_2$, as we sought to show.

So the Witt index of definition 22.4.10 deserves its name. Proposition 22.4.11(3) computes $\nu(\varphi)$ as the number of hyperbolic planes in the decomposition produced by the proof of theorem 22.4.8, and corollary 22.5.7 says that number is the same in every decomposition of that shape; so $m = \nu(\varphi)$ in *any* of them, and the anisotropic part is determined up to isometry by φ alone. Two nondegenerate forms $\varphi \cong \varphi_1 \perp mH$ and $\varphi' \cong \varphi'_1 \perp m'H$, with φ_1 and φ'_1 anisotropic, are therefore isometric if and only if $m = m'$ and $\varphi_1 \cong \varphi'_1$: if $\varphi \cong \varphi'$ then φ has the two decompositions $\varphi \cong \varphi_1 \perp mH$ and $\varphi \cong \varphi'_1 \perp m'H$, so corollary 22.5.7 gives $m = m'$ and $\varphi_1 \cong \varphi'_1$, while conversely $m = m'$ and $\varphi_1 \cong \varphi'_1$ give $\varphi \cong \varphi_1 \perp mH \cong \varphi'_1 \perp m'H \cong \varphi'$. That biconditional is the reduction the classification of forms over a given field uses.

Cancellation deletes a summand from both sides of an isometry that is already given. The extension theorem is the statement that isometries are plentiful: any isometry defined on a subspace already extends to the whole space, with no compatibility condition beyond preserving the form. The subspace is allowed to be degenerate, and that is the substance of the theorem; for a subspace containing an anisotropic vector, the reduction to a smaller space is the argument already used twice above, whereas a totally isotropic subspace gives that argument nothing to work with. The following lemma is what repairs that case: it manufactures, for an isotropic vector inside a totally isotropic subspace, a partner making it half of a hyperbolic plane, chosen orthogonal to the rest of the subspace.

Lemma 22.5.8: Hyperbolic Partners for Isotropic Vectors

Let k be a field with $\operatorname{char} k \neq 2$, let φ be a nondegenerate symmetric bilinear form on a finite-dimensional k-vector space V, let $U \subseteq V$ be a subspace with $\varphi(x,y) = 0$ for all $x, y \in U$, let $u \in U$ be nonzero, and let $U_1 \subseteq U$ be a subspace with $U = ku \oplus U_1$. Then there exists $u^* \in V$ with

$$q(u^*) = 0, \qquad \varphi(u, u^*) = 1, \qquad \varphi(u^*, x) = 0 \text{ for all } x \in U_1$$

***Proof*:**
Let $u_1, \dots, u_m$ be a basis of U_1, so that $u, u_1, \dots, u_m$ is a basis of U and in particular a linearly independent family in V. Consider the linear map

$$\Phi \colon V \to k^{m+1}, \qquad \Phi(y) = \big(\varphi(u,y), \varphi(u_1,y), \dots, \varphi(u_m,y)\big)$$

Suppose Φ were not surjective. Its image is then a proper subspace of k^{m+1}, hence contained in the kernel of some nonzero linear functional (extend a basis of the image to a basis of k^{m+1} and take the member of the dual basis of proposition 13.3.5 attached to a vector outside the image): there are $\lambda_0, \dots, \lambda_m \in k$, not all zero, with $\lambda_0\varphi(u,y) + \sum_{i=1}^m \lambda_i \varphi(u_i, y) = 0$ for every $y \in V$. Bilinearity rewrites this as $\varphi(z,y) = 0$ for every $y \in V$, where $z = \lambda_0 u + \sum_i \lambda_i u_i$. As φ is symmetric, this says $z \in \operatorname{rad}(\varphi)$ (definition 13.3.22), which is zero by nondegeneracy; and $u, u_1, \dots, u_m$ being linearly independent then forces every $\lambda_j = 0$, contradicting the choice of the λ_j. So Φ is surjective.

Choose $y \in V$ with $\Phi(y) = (1, 0, \dots, 0)$, so $\varphi(u,y) = 1$ and $\varphi(u_i, y) = 0$ for each i; by bilinearity the latter gives $\varphi(x,y) = 0$ for every $x \in U_1$. Since $\operatorname{char} k \neq 2$ the scalar $q(y)/2$ is defined, and we may set

$$u^* := y - \frac{q(y)}{2}\, u$$

Because $u \in U$ and φ vanishes identically on U, we have $q(u) = 0$ and $\varphi(u,x) = 0$ for $x \in U_1$. Hence

$$\varphi(u,u^*) = \varphi(u,y) - \frac{q(y)}{2} q(u) = 1 - 0 = 1$$

$$q(u^*) = q(y) - 2 \cdot \frac{q(y)}{2}\varphi(y,u) + \frac{q(y)^2}{4} q(u) = q(y) - q(y) + 0 = 0$$

using $\varphi(y,u) = \varphi(u,y) = 1$ by symmetry. Finally, for $x \in U_1$ both $\varphi(y,x) = 0$ and $\varphi(u,x) = 0$, so $\varphi(u^*, x) = 0$, completing the proof.

Theorem 22.5.9: Witt's Extension Theorem

Let k be a field with $\operatorname{char} k \neq 2$, let φ be a nondegenerate symmetric bilinear form on a finite-dimensional k-vector space V, let $U \subseteq V$ be a subspace, and let $f\colon U \to V$ be an injective linear map with

$$\varphi\big(f(x), f(y)\big) = \varphi(x, y) \qquad \text{for all } x, y \in U$$

Then there is an $F \in O(\varphi)$ with $F|_U = f$.

***Proof*:**
Induct on $\dim V$. If $\dim V = 0$ then $U = 0$ and $F = \mathrm{id}_V$ serves. So let $\dim V = n \geq 1$ and assume the theorem for every nondegenerate symmetric bilinear form on a space of dimension smaller than n. If $U = 0$, take $F = \mathrm{id}_V$; assume $U \neq 0$.

Step 1: reduction to the case where φ does not vanish identically on U. Suppose $\varphi(x, y) = 0$ for all $x, y \in U$. Choose $u \in U$ nonzero and a subspace U_1 with $U = ku \oplus U_1$, and let $u_1, \dots, u_m$ be a basis of U_1. Lemma 22.5.8 supplies $u^* \in V$ with $q(u^*) = 0$, $\varphi(u, u^*) = 1$ and $\varphi(u^*, U_1) = 0$.

Put $u' = f(u)$ and $U_1' = f(U_1)$. Since f is injective and preserves φ, the subspace $f(U)$ satisfies $\varphi(x, y) = 0$ for all $x, y \in f(U)$, the vector u' is nonzero, and $f(U) = ku' \oplus U_1'$. A second application of lemma 22.5.8, to the subspace $f(U)$ with the vector u' and the complement U_1', supplies $u'^* \in V$ with $q(u'^*) = 0$, $\varphi(u', u'^*) = 1$ and $\varphi(u'^*, U_1') = 0$.

Because $\varphi(u, u^*) = 1$ while $\varphi(u, x) = 0$ for every $x \in U$, the vector u^* is not in U, so $\tilde{U} := U \oplus ku^*$ has $u, u^*, u_1, \dots, u_m$ as a basis. Define a linear map $\tilde{f}\colon \tilde{U} \to V$ by $\tilde{f}|_U = f$ and $\tilde{f}(u^*) = u'^*$.

The map $\tilde{f}$ preserves φ. By bilinearity it is enough to compare φ on pairs of basis vectors with φ on the pairs of their images, and the six comparisons are:

$$q(u) = 0 = q(u'), \qquad q(u^*) = 0 = q(u'^*), \qquad \varphi(u, u^*) = 1 = \varphi(u', u'^*)$$

$$\varphi(u, u_i) = 0 = \varphi\big(f(u), f(u_i)\big), \qquad \varphi(u^*, u_i) = 0 = \varphi(u'^*, f(u_i)), \qquad \varphi(u_i, u_j) = \varphi\big(f(u_i), f(u_j)\big)$$

the fourth and sixth because f preserves φ, the fifth by the two orthogonality conditions on u^* and u'^*.

The map $\tilde{f}$ is injective. Let $x = \lambda u + \mu u^* + w$ with $w \in U_1$ and $\tilde{f}(x) = 0$, that is $\lambda u' + \mu u'^* + f(w) = 0$. Applying $\varphi(u', -)$ and using $\varphi(u', u') = 0$, $\varphi(u', u'^*) = 1$ and $\varphi(u', f(w)) = \varphi(f(u), f(w)) = \varphi(u, w) = 0$ gives $\mu = 0$. Then $f(\lambda u + w) = 0$, so $\lambda u + w = 0$ by injectivity of f, so $\lambda = 0$ and $w = 0$ because $U = ku \oplus U_1$.

Finally $q(u + u^*) = q(u) + 2\varphi(u, u^*) + q(u^*) = 2 \neq 0$, so φ does not vanish identically on $\tilde{U}$. Any $F \in O(\varphi)$ with $F|_{\tilde{U}} = \tilde{f}$ satisfies $F|_U = f$, so it suffices to prove the theorem for the pair $(\tilde{U}, \tilde{f})$, which is of the kind treated next.

Step 2: the case where φ does not vanish identically on U. Some $u \in U$ has $q(u) \neq 0$: otherwise q vanishes on U and, for $x, y \in U$, $0 = q(x + y) = q(x) + 2\varphi(x, y) + q(y) = 2\varphi(x, y)$, which with $\operatorname{char} k \neq 2$ makes φ vanish identically on U.

Then $q(f(u)) = q(u) \neq 0$, so lemma 22.5.5 supplies $\sigma \in O(\varphi)$ with $\sigma(f(u)) = u$. The map $f' := \sigma \circ f$ is again an injective linear map $U \to V$ preserving φ, and $f'(u) = u$.

Set $V_1 = \{u\}^\perp$ and $U' = U \cap V_1$. Four facts about these:

1. $V = ku \oplus V_1$ with $\varphi(u, V_1) = 0$, by lemma 22.5.3(1) applied to (V, φ) and the anisotropic vector u; in particular $\dim V_1 = n - 1$.
2. $U = ku \oplus U'$, by the same part of the same lemma applied to $(U, \varphi|_U)$, whose orthogonal complement of u inside U is $U \cap \{u\}^\perp = U'$.
3. $\varphi|_{V_1}$ is nondegenerate: if $y \in V_1$ satisfies $\varphi(y, V_1) = 0$, then also $\varphi(y, u) = 0$, so $\varphi(y, V) = 0$ by (1) and bilinearity, whence $y \in \operatorname{rad}(\varphi) = 0$.
4. $f'(U') \subseteq V_1$: for $x \in U'$, $\varphi(u, f'(x)) = \varphi(f'(u), f'(x)) = \varphi(u, x) = 0$.

So $f'|_{U'} : U' \to V_1$ is an injective linear map from a subspace of V_1 into V_1 preserving $\varphi|_{V_1}$, and $\dim V_1 = n - 1$. The inductive hypothesis gives $G \in O(\varphi|_{V_1})$ with $G|_{U'} = f'|_{U'}$.

Step 3: assembling F. Define $F' : V \to V$ by $F'(\lambda u + y) = \lambda u + G(y)$ for $\lambda \in k$ and $y \in V_1$; this is well defined and bijective by (1) and the bijectivity of G. It preserves φ: for $\lambda, \mu \in k$ and $y, z \in V_1$, using $G(y), G(z) \in V_1$ and $\varphi(u, V_1) = 0$ twice,

$$\varphi\big(\lambda u + G(y), \mu u + G(z)\big) = \lambda\mu\, q(u) + \varphi\big(G(y), G(z)\big) = \lambda\mu\, q(u) + \varphi(y, z) = \varphi(\lambda u + y, \mu u + z)$$

So $F' \in O(\varphi)$. It restricts to f' on U: writing $x \in U$ as $x = \lambda u + x'$ with $x' \in U'$ by (2),

$$F'(x) = \lambda u + G(x') = \lambda u + f'(x') = \lambda f'(u) + f'(x') = f'(x)$$

Set $F = \sigma^{-1} \circ F'$, an element of $O(\varphi)$. Then $F|_U = \sigma^{-1} \circ f' = \sigma^{-1} \circ \sigma \circ f = f$, completing the proof.

The hypothesis that φ be nondegenerate on the ambient space is not removable, and it enters the proof twice: in Step 1 through lemma 22.5.8, and in Step 2 as fact (3), where $\operatorname{rad}(\varphi) = 0$ is what makes $\varphi|_{V_1}$ nondegenerate and so licenses the inductive hypothesis. What goes wrong without it is direct: an isometry of V carries $\operatorname{rad}(\varphi)$ onto itself, so a form-preserving injection sending a vector outside the radical into the radical extends to no isometry, and exercise 22.5.1 (6) exhibits one. Nondegeneracy of the *subspace* U, on the other hand, is nowhere assumed, and Step 1 is the work of doing without it.

Taking U to be a line already extends lemma 22.5.5 past its restriction to anisotropic vectors. Let φ be nondegenerate, let $c \in k$, and let v, v' be nonzero vectors with $q(v) = q(v') = c$. The map $f : kv \to V$ with $f(\lambda v) = \lambda v'$ is linear and injective, and $\varphi(f(\lambda v), f(\mu v)) = \lambda\mu\, q(v') = \lambda\mu\, q(v) = \varphi(\lambda v, \mu v)$, so theorem 22.5.9 extends it to an isometry of V carrying v to v'. So $O(\varphi)$ acts transitively on the nonzero vectors of each fixed value of q, including the value 0, where no reflection was available. The last consequence counts how many reflections it takes to build an arbitrary isometry.

Corollary 22.5.10: Reflections Generate the Orthogonal Group

Let k be a field with $\operatorname{char} k \neq 2$ and let φ be a nondegenerate symmetric bilinear form on a k-vector space V of finite dimension n. Then every $\sigma \in O(\varphi)$ is a product of at most $2n$ reflections τ_v in anisotropic vectors $v \in V$, where the empty product is read as id_V. In particular $O(\varphi)$ is generated by its reflections. The bound $2n$ is not the sharp one; see the discussion after the proof.

***Proof*:**
Induct on n. For $n = 0$ the group $O(\varphi)$ is trivial and id_V is the empty product. Let $n \geq 1$ and assume the statement for nondegenerate forms on spaces of dimension $n-1$.

First, V contains an anisotropic vector: if $q(x) = 0$ for every $x \in V$, then for all $x, y \in V$

$$0 = q(x+y) = q(x) + 2\varphi(x,y) + q(y) = 2\varphi(x,y)$$

and $\operatorname{char} k \neq 2$ makes φ the zero form, so $\operatorname{rad}(\varphi) = V \neq 0$, contradicting nondegeneracy. Fix such a u, with $q(u) \neq 0$.

Let $\sigma \in O(\varphi)$. Then $q(\sigma(u)) = q(u) \neq 0$, so lemma 22.5.5, applied to the pair $\sigma(u)$ and u, supplies $\pi \in O(\varphi)$ with $\pi(\sigma(u)) = u$ and π a product of at most two reflections. Put $\rho = \pi \circ \sigma$, so $\rho(u) = u$.

Set $V_1 = \{u\}^\perp$. As in the proof of theorem 22.5.9, $V = ku \oplus V_1$ with $\varphi(u, V_1) = 0$ by lemma 22.5.3(1), $\dim V_1 = n-1$, and $\varphi|_{V_1}$ is nondegenerate because a vector of V_1 orthogonal to V_1 is also orthogonal to u, hence to V, hence zero. Moreover $\rho(V_1) = V_1$: for $y \in V_1$, $\varphi(u, \rho(y)) = \varphi(\rho(u), \rho(y)) = \varphi(u, y) = 0$, so $\rho(V_1) \subseteq V_1$, and ρ is injective, so the inclusion is an equality by dimension count.

By the inductive hypothesis $\rho|_{V_1}$ is a product $\tau_{v_1}^{V_1} \cdots \tau_{v_r}^{V_1}$ of $r \leq 2(n-1)$ reflections of $(V_1, \varphi|_{V_1})$, with each $v_i \in V_1$ anisotropic. Each v_i is anisotropic in V as well, and the reflection τ_{v_i} of V satisfies $\tau_{v_i}(u) = u$, since $\varphi(v_i, u) = 0$, and restricts on V_1 to $\tau_{v_i}^{V_1}$, the defining formula being the same. Hence $\tau_{v_1} \cdots \tau_{v_r}$ and ρ agree on u and on V_1, so they agree on $V = ku \oplus V_1$, and ρ is a product of at most $2(n-1)$ reflections of V.

Finally $\sigma = \pi^{-1} \circ \rho$, and π^{-1} is a product of at most two reflections, since each reflection is its own inverse by lemma 22.5.3(3) and the inverse of $\tau_v \tau_w$ is $\tau_w \tau_v$. So σ is a product of at most $2 + 2(n-1) = 2n$ reflections, as we sought to show.

The sharp form of this count is the Cartan-Dieudonné theorem, proved in Artin's *Geometric Algebra*: over a field of characteristic other than 2, every isometry of an n-dimensional nondegenerate space is a product of at most n reflections. The bound proved above loses a factor of two at Case 2 of lemma 22.5.5, where two reflections are used in place of one. Recovering the sharp bound requires a separate analysis of the isometries σ for which $q(x - \sigma(x)) = 0$ for every $x \in V$, so that no single reflection returns $\sigma(x)$ to x. Such isometries exist: on $H \perp H$, with the two hyperbolic bases e_1, f_1 and e_2, f_2, the map fixing e_1 and e_2 and sending $f_1 \mapsto f_1 + e_2$ and $f_2 \mapsto f_2 - e_1$ is one. For them the reflection count is governed by $\dim \operatorname{im}(\sigma - \mathrm{id}_V)$ rather than by n. That analysis is not carried out in this book.

Exercise 22.5.1

1. Let φ be a nondegenerate symmetric bilinear form on V with $\dim V = n \geq 1$ and $\operatorname{char} k \neq 2$, and let $\sigma \in O(\varphi)$. Show that if A is the matrix of φ and S the matrix of σ in one common basis, then $S^t AS = A$ (use lemma 13.3.19), and deduce $\det \sigma = \pm 1$ with the help of lemma 13.3.23. Using $\det \tau_v = -1$ from lemma 22.5.3, deduce that $SO(\varphi) := \{\sigma \in O(\varphi) \mid \det \sigma = 1\}$ is a subgroup of index exactly 2, and that the parity of the number of reflections in a factorization of σ given by corollary 22.5.10 does not depend on the factorization.

2. Let $\operatorname{char} k \neq 2$, let φ be a symmetric bilinear form on V, and let $v, w \in V$ be anisotropic. Show that $\tau_v = \tau_w$ if and only if $kv = kw$, so that $v \mapsto \tau_v$ is a bijection from the set of anisotropic lines of V onto a set of involutions in $O(\varphi)$. Then count the reflections in $O(\langle 1, 1\rangle)$ over $\mathbb{F}_5$, by listing the six lines of $\mathbb{F}_5^2$ and deciding which are anisotropic.

3. Show that the hypothesis that ψ be nondegenerate can be removed from theorem 22.5.6: for arbitrary symmetric bilinear forms over a field with $\operatorname{char} k \neq 2$, $\psi \perp \varphi_1 \cong \psi \perp \varphi_2$ implies $\varphi_1 \cong \varphi_2$. Reduce, using theorem 22.2.1, to cancelling $\langle 0\rangle$, and for that case use that an isometry carries the radical of one form onto the radical of the other, together with the description of the radical in an orthogonal basis given by proposition 22.2.2.

4. Over $k = \mathbb{Q}$, show that $\langle 1, 1\rangle$ and $\langle -1, -1\rangle$ are not isometric by asking which nonzero rationals each represents. Deduce from theorem 22.5.6 that $\langle 1, 1, 5\rangle \not\cong \langle -1, -1, 5\rangle$, and check that these two forms have the same rank and the same discriminant, so that neither invariant of section 22.1 could have separated them.

5. Let φ be nondegenerate on V with $\operatorname{char} k \neq 2$, and recall the totally isotropic subspaces of definition 22.3.6. Call one *maximal* if no strictly larger subspace of V is totally isotropic. Using theorem 22.5.9, show that any two maximal totally isotropic subspaces of V have the same dimension. Then explain why lemma 22.5.5 gives nothing about isotropic vectors, by exhibiting two nonzero isotropic vectors u, w of $H \perp H$ with $q(u - w) = q(u + w) = 0$.

6. Let $\operatorname{char} k \neq 2$ and let $V = k^3$ carry the form whose matrix in the standard basis is $\operatorname{diag}(1, -1, 0)$. Show that $f\colon k(e_1 + e_2) \to V$ with $f(e_1 + e_2) = e_3$ is an injective linear map preserving the form, and that no isometry of V restricts to it. Conclude that the nondegeneracy hypothesis in theorem 22.5.9 cannot be dropped.

7. Let $\operatorname{char} k \neq 2$ and let $a \in k^\times$. Show that $\langle a, -a\rangle \cong H$, by exhibiting an isotropic vector and applying proposition 22.4.6. Then show that the isometry class of $\langle a, -a\rangle$ does not depend on a, even though the square class of a may vary.

8. Let $\operatorname{char} k \neq 2$ and let V be four-dimensional with basis e_1, f_1, e_2, f_2 and the symmetric bilinear form determined by $\varphi(e_1, f_1) = \varphi(e_2, f_2) = 1$, all other products of two basis vectors being zero, so that $V \cong H \perp H$. Define σ by $\sigma(e_i) = e_i$, $\sigma(f_1) = f_1 + e_2$ and $\sigma(f_2) = f_2 - e_1$. Show that $\sigma \in O(\varphi)$, that $x - \sigma(x)$ lies in the totally isotropic subspace spanned by e_1 and e_2 for every $x \in V$, and hence that $q(x - \sigma(x)) = 0$ for every x. Deduce that no reflection τ_v satisfies $\tau_v(\sigma(x)) = x$ for any x with $\sigma(x) \neq x$, so that Case 2 of lemma 22.5.5 is unavoidable for this σ.

22.6 The Witt Group

Theorem 22.4.8 writes a nondegenerate form as an anisotropic form orthogonal to a number of hyperbolic planes, and corollary 22.5.7 says that the anisotropic part is determined up to isometry. Two forms with isometric anisotropic parts therefore differ only in how many hyperbolic planes are attached to them, and this section discards that number. What remains is an abelian group under $\perp$, and a commutative ring once the tensor product of forms is available.

The construction needs no group completion. The inverse of a class is again the class of a form, because $\varphi \perp (-\varphi)$ is a sum of hyperbolic planes, and that computation is the first item below. The group is then computed for the two families of fields whose square classes are known: the algebraically closed fields, where it has two elements, and the finite fields, where it has four. The finite case answers the question left open at the end of example 22.2.5.

Throughout, k is a field with $\operatorname{char} k \neq 2$ and every form is a symmetric bilinear form on a finite-dimensional k-vector space, identified with its quadratic form through proposition 22.1.2 whenever that is convenient. The orthogonal sum $\varphi \perp \psi$ is definition 22.4.1, and everything used below about it is established there: the block-diagonal Gram matrix, the multiplicativity $\det(\varphi \perp \psi) = \det(\varphi)\det(\psi)$, that the sum is nondegenerate exactly when both summands are, and that $\perp$ descends to isometry classes and is commutative and associative up to isometry. Write $-\varphi$ for the form $(x, y) \mapsto -\varphi(x, y)$ on V. In the diagonal notation of section 22.2,

$$\langle a_1, \dots, a_m\rangle \perp \langle b_1, \dots, b_n\rangle = \langle a_1, \dots, a_m, b_1, \dots, b_n\rangle$$

and $-\langle a_1, \dots, a_n\rangle = \langle -a_1, \dots, -a_n\rangle$. Finally mH denotes the orthogonal sum of m copies of the hyperbolic plane H (definition 22.4.4), with $0H$ the zero form on the zero space.

The identification that drives everything below is that a form and its negative add up to nothing but hyperbolic planes.

Lemma 22.6.1: A Form and Its Negative Sum to Hyperbolic Planes

Let k be a field with $\operatorname{char} k \neq 2$.

1. For every $a \in k^\times$ one has $\langle a, -a\rangle \cong H$. In particular $H \cong \langle 1, -1\rangle$, so $\det H = -1$.
2. If φ is a nondegenerate form of rank n on V, then $\varphi \perp (-\varphi) \cong nH$.

***Proof*:**

1. By example 22.4.7 a nondegenerate binary form $\langle a, b\rangle$ is a hyperbolic plane exactly when $-ab$ is a square in $k^\times$. Here $b = -a$, so $-ab = a^2$ is a square and $\langle a, -a\rangle \cong H$. Taking $a = 1$ gives $H \cong \langle 1, -1\rangle$, whose matrix in an orthogonal basis is $\operatorname{diag}(1, -1)$, of determinant -1.
2. Diagonalize $\varphi \cong \langle a_1, \dots, a_n\rangle$ by theorem 22.2.1. Nondegeneracy forces every $a_i \neq 0$: by the last claim of proposition 22.2.2 the number of zero entries is the dimension of the radical, which is 0 here by definition 13.3.22. Then $-\varphi \cong \langle -a_1, \dots, -a_n\rangle$, so

$$\varphi \perp (-\varphi) \cong \langle a_1, \dots, a_n, -a_1, \dots, -a_n\rangle \cong \langle a_1, -a_1\rangle \perp \cdots \perp \langle a_n, -a_n\rangle$$

the second isometry being the permutation of an orthogonal basis that places each a_i next to its negative. Applying part (1) to each summand gives $\varphi \perp (-\varphi) \cong nH$, as we sought to show.

Every form of rank n is isometric to a form on k^n, obtained by transporting it along a choice of basis, so the isometry classes of nondegenerate forms over k constitute a set rather than a proper class. That set carries $\perp$ as a commutative associative operation with the zero form as a neutral element, and the lemma says that after hyperbolic planes are discarded every element acquires an inverse.

Definition 22.6.2: Witt Equivalence and the Witt Group

Let k be a field with $\operatorname{char} k \neq 2$. Two nondegenerate symmetric bilinear forms φ and ψ over k, possibly on spaces of different dimensions, are *Witt equivalent*, written $\varphi \sim \psi$, if there are integers $m, n \geq 0$ with

$$\varphi \perp mH \cong \psi \perp nH$$

The *Witt group* $W(k)$ is the set of equivalence classes, the class of φ being written $[\varphi]$, equipped with the operation

$$[\varphi] + [\psi] := [\varphi \perp \psi]$$

That $\sim$ is an equivalence relation and that the operation is well defined are proved in theorem 22.6.3.

Two small computations show what the relation does. Over any k one has $\langle 1 \rangle \perp \langle -1 \rangle \cong H$ by lemma 22.6.1, so $\langle 1, -1 \rangle \sim 0$: the hyperbolic plane is Witt trivial, which is the whole content of the definition. Consequently $\langle 1, 1, -1 \rangle \sim \langle 1 \rangle$, taking $m = 0$ and $n = 1$ against $\psi = \langle 1 \rangle$, since $\langle 1 \rangle \perp H \cong \langle 1, 1, -1 \rangle$. Forms of different ranks can therefore be Witt equivalent, and rank is not an invariant of a Witt class.

Theorem 22.6.3: The Witt Classes Form an Abelian Group

Let k be a field with $\operatorname{char} k \neq 2$. Witt equivalence is an equivalence relation on nondegenerate forms over k, the operation of definition 22.6.2 is well defined on classes, and $W(k)$ is an abelian group whose neutral element is the class $[0] = [H]$ of the zero form and in which $-[\varphi] = [-\varphi]$.

***Proof*:**
Step 1: $\sim$ is an equivalence relation. Reflexivity is the case $m = n = 0$, and symmetry is immediate from the symmetry of $\cong$. For transitivity, suppose $\varphi \perp mH \cong \psi \perp nH$ and $\psi \perp pH \cong \chi \perp qH$. Adding pH to the first isometry and nH to the second, which is legitimate because orthogonal sums of isometric forms are isometric, and rearranging summands by commutativity and associativity of $\perp$, gives

$$\varphi \perp (m+p)H \cong \psi \perp (n+p)H \cong \chi \perp (q+n)H$$

so $\varphi \sim \chi$.

Step 2: the operation is well defined. Let $\varphi \sim \varphi'$ and $\psi \sim \psi'$, say $\varphi \perp mH \cong \varphi' \perp m'H$ and $\psi \perp nH \cong \psi' \perp n'H$. Taking the orthogonal sum of the two isometries and rearranging summands,

$$(\varphi \perp \psi) \perp (m+n)H \cong (\varphi' \perp \psi') \perp (m'+n')H$$

so $\varphi \perp \psi \sim \varphi' \perp \psi'$. Both $\varphi \perp \psi$ and $\varphi' \perp \psi'$ are nondegenerate, since orthogonal sums of nondegenerate forms are, so the sum of two classes is again a class.

Step 3: the group axioms. Commutativity and associativity of $+$ are those of $\perp$, transported to classes by Step 2. The zero form 0 on the zero space is nondegenerate, its radical being the zero space, and $\varphi \perp 0 = \varphi$, so $[0]$ is neutral. Taking $m = 0$ and $n = 1$ in definition 22.6.2 gives $H \perp 0H \cong 0 \perp 1H$, that is $H \sim 0$, so $[H] = [0]$. Finally, if φ has rank n then $\varphi \perp (-\varphi) \cong nH$ by lemma 22.6.1, and $nH \sim 0$ directly from definition 22.6.2, taking the two integers there to be 0 and n, so

$$[\varphi] + [-\varphi] = [\varphi \perp (-\varphi)] = [nH] = [0]$$

which exhibits $[-\varphi]$ as the inverse of $[\varphi]$, completing the proof.

The group is built from forms alone: no formal differences are introduced, and no group completion of the monoid of isometry classes is taken, because the negative of a form is a form and lemma 22.6.1 makes the two cancel. What the construction has cost is the ability to see the rank, since φ and $\varphi \perp H$ have become equal. The next result says that nothing else was lost, and it is where Witt cancellation enters: cancellation plays no part in the group axioms above, and its role is to identify the classes with objects one can list.

Proposition 22.6.4: Each Witt Class Contains Exactly One Anisotropic Form

Let k be a field with $\operatorname{char} k \neq 2$ and let φ, ψ be nondegenerate forms over k, with Witt decompositions $\varphi \cong \varphi_{\mathrm{an}} \perp m_\varphi H$ and $\psi \cong \psi_{\mathrm{an}} \perp m_\psi H$ as in theorem 22.4.8. Then

$$\varphi \sim \psi \quad \text{if and only if} \quad \varphi_{\mathrm{an}} \cong \psi_{\mathrm{an}}$$

Consequently $[\varphi] \mapsto \varphi_{\mathrm{an}}$ is a bijection from $W(k)$ to the set of isometry classes of anisotropic forms over k, and $[\varphi] = 0$ if and only if $\varphi \cong m_\varphi H$.

***Proof*:**
First note that an anisotropic form is nondegenerate: a nonzero vector v of the radical satisfies $\varphi(v, v) = 0$, hence is an isotropic vector (definition 22.4.2), so the radical of an anisotropic form is zero and definition 13.3.22 applies. Both φ_{an} and ψ_{an} are therefore nondegenerate, as is H, which is what the cancellation theorem requires.

Step 1: isometric anisotropic parts give Witt equivalence. If $\varphi_{\mathrm{an}} \cong \psi_{\mathrm{an}}$ then

$$\varphi \perp m_\psi H \cong \varphi_{\mathrm{an}} \perp (m_\varphi + m_\psi)H \cong \psi_{\mathrm{an}} \perp (m_\varphi + m_\psi)H \cong \psi \perp m_\varphi H$$

so $\varphi \sim \psi$ by definition 22.6.2.

Step 2: Witt equivalence gives isometric anisotropic parts. Suppose $\varphi \perp mH \cong \psi \perp nH$. Substituting the two Witt decompositions and writing $a = m_\varphi + m$ and $b = m_\psi + n$,

$$\varphi_{\mathrm{an}} \perp aH \cong \psi_{\mathrm{an}} \perp bH$$

This is exactly the situation corollary 22.5.7 settles: two Witt decompositions of isometric forms have isometric anisotropic parts and equal hyperbolic counts. Applying it gives $a = b$ and $\varphi_{\mathrm{an}} \cong \psi_{\mathrm{an}}$.

Step 3: the two consequences. The two steps say exactly that $[\varphi] \mapsto \varphi_{\mathrm{an}}$ is well defined and injective on $W(k)$; it is surjective because an anisotropic form χ is nondegenerate with $\chi_{\mathrm{an}} = \chi$ and $m_\chi = 0$. For the last claim, $[\varphi] = [0]$ holds if and only if φ_{an} is isometric to the zero form on the zero space, that is if and only if $\varphi \cong m_\varphi H$, completing the proof.

So $W(k)$ is the set of anisotropic forms over k, given an addition that is not orthogonal sum: to add two anisotropic forms, take their orthogonal sum and discard the hyperbolic planes that appear in it. The integer m_φ discarded in the process is the Witt index of definition 22.4.10, the two agreeing by proposition 22.4.11(3), and the pair (anisotropic part, Witt index) is a complete isometry invariant of a nondegenerate form, while the class in $W(k)$ retains only the first half of that pair. The first field to compute is one over which every anisotropic form has rank at most one.

Example 22.6.5: The Witt Group of an Algebraically Closed Field
Let k be algebraically closed with $\operatorname{char} k \neq 2$; the case $k = \mathbb{C}$ is the one to keep in mind. Fix $c \in k$ with $c^2 = -1$, which exists because $x^2 + 1$ has a root.

No anisotropic form has rank 2 or more. Indeed, by example 22.2.4 a nondegenerate form of rank n is isometric to $\langle 1, \dots, 1\rangle$, and if $n \geq 2$ the vector $v = (c, 1, 0, \dots, 0)$ is nonzero and satisfies

$$q(v) = c^2 + 1 = -1 + 1 = 0$$

so the form is isotropic. The anisotropic forms are therefore the zero form and the rank one form $\langle 1\rangle$, the latter being anisotropic because $x^2 = 0$ forces $x = 0$. By proposition 22.6.4,

$$W(k) = \{\, [0],\ [\langle 1\rangle] \,\}$$

has two elements. Its group law is forced: $2[\langle 1\rangle] = [\langle 1, 1\rangle]$, and $\langle 1, 1\rangle \cong \langle 1, -1\rangle$ by proposition 22.2.2, since $-1 \cdot c^2 = 1$ rescales the second entry by the square c^2, so $\langle 1, 1\rangle \cong H$ by lemma 22.6.1 and $2[\langle 1\rangle] = 0$. Hence $W(k) \cong \mathbb{Z}/2\mathbb{Z}$, the isomorphism sending $[\varphi]$ to the rank of φ modulo 2.

Addition is not the only operation available on forms. The tensor product of the underlying spaces carries a form built from the two given ones, and it is compatible with $\perp$ and with Witt equivalence, which upgrades $W(k)$ from a group to a ring. In diagonal coordinates the operation is multiplication of the diagonal entries in all pairs, which is what makes it computable.

Proposition 22.6.6: The Tensor Product of Forms and the Witt Ring

Let k be a field with $\operatorname{char} k \neq 2$, let φ be a symmetric bilinear form on V and ψ one on W.

1. There is exactly one bilinear form $\varphi \otimes \psi$ on $V \otimes_k W$ satisfying

$$(\varphi \otimes \psi)(v \otimes w,\ v' \otimes w') = \varphi(v, v')\,\psi(w, w')$$

   for all $v, v' \in V$ and $w, w' \in W$, and it is symmetric.

2. If $\varphi \cong \langle a_1, \dots, a_m\rangle$ and $\psi \cong \langle b_1, \dots, b_n\rangle$, then $\varphi \otimes \psi$ is isometric to the diagonal form whose mn entries are the products $a_i b_j$. In particular $\varphi \otimes \psi$ is nondegenerate when φ and ψ are, and isometric inputs produce isometric outputs.

3. The rule $[\varphi] \cdot [\psi] := [\varphi \otimes \psi]$ is well defined and makes $W(k)$ a commutative ring with identity $[\langle 1\rangle]$.

***Proof*:**

1. Fix bases $v_1, \dots, v_m$ of V and $w_1, \dots, w_n$ of W. By corollary 15.2.6 the mn vectors $v_i \otimes w_j$ form a basis of $V \otimes_k W$. Let M be the $mn \times mn$ matrix indexed by pairs, with entry $\varphi(v_i, v_{i'})\psi(w_j, w_{j'})$ in position $\big((i, j), (i', j')\big)$, and define $B(x, y) := [x]^t M[y]$ using coordinates in that basis. Taking coordinates is linear and matrix multiplication is bilinear in the two coordinate vectors, so B is a bilinear form.

   To see that B has the stated values, write $v = \sum_i x_i v_i$, $v' = \sum_{i'} x'_{i'} v_{i'}$, $w = \sum_j y_j w_j$ and $w' = \sum_{j'} y'_{j'} w_{j'}$. The map $(v, w) \mapsto v \otimes w$ is bilinear by theorem 15.1.12, so $v \otimes w = \sum_{i,j} x_i y_j\,(v_i \otimes w_j)$, which is the coordinate vector of $v \otimes w$ in the chosen basis. Hence

$$\begin{aligned} B(v \otimes w, v' \otimes w') &= \sum_{i,j,i',j'} x_i y_j x'_{i'} y'_{j'}\, \varphi(v_i, v_{i'})\psi(w_j, w_{j'}) \\ &= \Big(\sum_{i,i'} x_i x'_{i'} \varphi(v_i, v_{i'})\Big)\Big(\sum_{j,j'} y_j y'_{j'} \psi(w_j, w_{j'})\Big) \\ &= \varphi(v, v')\,\psi(w, w') \end{aligned}$$

   the last line by bilinearity of φ and of ψ. For uniqueness, the simple tensors span $V \otimes_k W$ by lemma 15.1.4, and two bilinear forms agreeing on all pairs of vectors from a spanning set agree everywhere, by expanding both arguments. Symmetry follows the same way: the bilinear forms $(x, y) \mapsto B(x, y)$ and $(x, y) \mapsto B(y, x)$ agree on pairs of simple tensors because φ and ψ are symmetric, hence agree.

2. Choose the bases in (1) to be orthogonal bases realizing the two diagonalizations, which exist by theorem 22.2.1, so that $\varphi(v_i, v_{i'}) = 0$ for $i \neq i'$ with $\varphi(v_i, v_i) = a_i$, and likewise for ψ. Then for $(i, j) \neq (i', j')$,

$$(\varphi \otimes \psi)(v_i \otimes w_j,\ v_{i'} \otimes w_{j'}) = \varphi(v_i, v_{i'})\psi(w_j, w_{j'}) = 0$$

   since at least one of the two factors has distinct indices, while the value at $(i, j) = (i', j')$ is $a_i b_j$. So the basis $\{v_i \otimes w_j\}$ is orthogonal for $\varphi \otimes \psi$ with the mn diagonal entries $a_i b_j$, which is the claim. If all a_i and all b_j are nonzero then so are all a_ib_j, so the matrix of $\varphi\otimes\psi$ in this basis is diagonal with nonzero entries, hence invertible, and lemma 13.3.23 gives nondegeneracy. Finally, if $\varphi' \cong \varphi$ and $\psi' \cong \psi$, then $\varphi' \cong \langle a_1, \ldots, a_m\rangle$ and $\psi' \cong \langle b_1, \ldots, b_n\rangle$ for the very same entries, since the diagonal notation asserts an isometry class and not a chosen basis. Running the argument just given for those diagonalizations exhibits $\varphi' \otimes \psi'$ and $\varphi \otimes \psi$ as isometric to one and the same diagonal form, so isometric inputs produce isometric outputs. The multiset $\{a_ib_j\}$ is not itself an invariant of the pair of isometry classes, being pinned down only up to multiplying its entries by squares, but the isometry class it names is.

3. Write $\varphi \cong \langle a_1, \ldots, a_m\rangle$, $\psi \cong \langle b_1, \ldots, b_n\rangle$ and $\chi \cong \langle c_1, \ldots, c_p\rangle$, all nondegenerate. By (2) the products a_ib_j and b_ja_i agree, giving $\varphi\otimes\psi \cong \psi\otimes\varphi$; the products $(a_ib_j)c_l$ and $a_i(b_jc_l)$ agree, giving associativity; the entries of $\varphi\otimes(\psi\perp\chi)$ are the a_ib_j together with the a_ic_l, which are the entries of $(\varphi\otimes\psi)\perp(\varphi\otimes\chi)$, giving distributivity over $\perp$; and $\langle 1\rangle\otimes\varphi \cong \varphi$ because the products $1\cdot a_i$ are the a_i.

   It remains to check that the rule respects Witt equivalence. First, $\langle a\rangle\otimes H \cong \langle a\rangle\otimes\langle 1,-1\rangle \cong \langle a,-a\rangle \cong H$, using lemma 22.6.1 at both ends and (2) in the middle, so by distributivity

$$\psi\otimes H \cong (\langle b_1\rangle\otimes H)\perp\cdots\perp(\langle b_n\rangle\otimes H) \cong nH$$

   Now suppose $\varphi \sim \varphi'$, say $\varphi\perp pH \cong \varphi'\perp p'H$. Tensoring with ψ and using that isometric inputs give isometric outputs, then expanding by distributivity and the previous display,

$$(\varphi\otimes\psi)\perp pnH \cong (\varphi'\otimes\psi)\perp p'nH$$

   so $\varphi\otimes\psi \sim \varphi'\otimes\psi$. Commutativity gives the same conclusion in the second variable, so the product of two classes does not depend on the representatives. The ring axioms are the isometries established in the previous paragraph, read on classes, completing the proof.

$W(k)$ is called the *Witt ring* when the multiplication is in play, and the group and the ring have the same underlying set. The multiplication restricts usefully to rank one forms: $\langle a\rangle\otimes\langle b\rangle \cong \langle ab\rangle$ by part (2), so the square classes of k act on $W(k)$ through $[\langle a\rangle]$, and each $[\langle a\rangle]$ is a unit since $\langle a\rangle\otimes\langle a\rangle \cong \langle a^2\rangle \cong \langle 1\rangle$ by proposition 22.2.2.

Two invariants from section 22.1 can now be tested against Witt equivalence. Rank fails, as the computation after definition 22.6.2 shows, but rank modulo 2 survives because a hyperbolic plane has rank 2. The discriminant also fails, and for a reason worth isolating: $\det(\varphi\perp H) = -\det(\varphi)$ by lemma 22.6.1(1), so $\operatorname{disc}(\varphi\perp H)$ and $\operatorname{disc}(\varphi)$ differ by the class of -1, which is nontrivial in most fields. A sign attached to the determinant repairs this, and box 22.1.9 announced it.

Definition 22.6.7: The Signed Discriminant

Let φ be a nondegenerate symmetric bilinear form of rank n over a field k with $\operatorname{char} k \neq 2$. The *signed discriminant* of φ is the square class

$$d_{\pm}(\varphi) := (-1)^{n(n-1)/2}\operatorname{disc}(\varphi) \in k^\times/(k^\times)^2$$

with disc as in definition 22.1.7. For $n = 0$ the determinant of the empty matrix is 1, so $d_{\pm}$ of the zero form is the trivial class.

The definition depends on nothing but the isometry class of φ, since the rank does not and disc does not by proposition 22.1.8. For a diagonal form the sign multiplies the product of the entries: $d_\pm\langle a_1, \dots, a_n\rangle = (-1)^{n(n-1)/2} a_1 \cdots a_n$ modulo squares, by corollary 22.2.3. Thus $d_\pm\langle a\rangle = a$, $d_\pm\langle a, b\rangle = -ab$ and $d_\pm\langle a, b, c\rangle = -abc$.

Proposition 22.6.8: Rank Modulo Two and the Signed Discriminant Are Witt Invariants

Let k be a field with $\operatorname{char} k \neq 2$.

1. The assignment $e\big([\varphi]\big) := \dim\varphi + 2\mathbb{Z}$ is a well defined surjective ring homomorphism $e\colon W(k) \to \mathbb{Z}/2\mathbb{Z}$.
2. For nondegenerate φ of rank m and ψ of rank n,
$$d_\pm(\varphi \perp \psi) = (-1)^{mn}\, d_\pm(\varphi)\, d_\pm(\psi)$$
3. Witt equivalent forms have equal signed discriminants, so $d_\pm$ is a well defined map $W(k) \to k^\times/(k^\times)^2$.
4. Restricted to the classes of even rank, $d_\pm$ is a group homomorphism from $\big(\ker e, +\big)$ to $k^\times/(k^\times)^2$.

***Proof*:**

1. If $\varphi \perp mH \cong \psi \perp nH$ then comparing dimensions gives $\dim\varphi + 2m = \dim\psi + 2n$, so $\dim\varphi \equiv \dim\psi \pmod 2$ and e is well defined. It is additive because $\dim(\varphi \perp \psi) = \dim\varphi + \dim\psi$, and multiplicative because $\dim(V \otimes_k W) = \dim V \cdot \dim W$ by corollary 15.2.6. It sends the identity $[\langle 1\rangle]$ to $1 + 2\mathbb{Z}$, which also gives surjectivity.
2. Both sides are computed from determinants and ranks. The rank of $\varphi \perp \psi$ is $m + n$ and its determinant is $\det(\varphi)\det(\psi)$, by the block form recorded at the start of this section. So the two sides differ only in the power of -1, and
$$\frac{(m+n)(m+n-1)}{2} - \frac{m(m-1)}{2} - \frac{n(n-1)}{2} = \frac{2mn}{2} = mn$$
after expanding the numerator as $m^2 + 2mn + n^2 - m - n - m^2 + m - n^2 + n$. Raising -1 to that difference gives the stated factor.
3. By lemma 22.6.1(1) the hyperbolic plane has rank 2 and determinant -1, so $d_\pm(H) = (-1)^{2(2-1)/2} \cdot (-1) = (-1)(-1) = 1$ in $k^\times/(k^\times)^2$. Applying (2) with $\psi = H$, where $n = 2$ makes $(-1)^{mn} = 1$,
$$d_\pm(\varphi \perp H) = d_\pm(\varphi)\, d_\pm(H) = d_\pm(\varphi)$$
Iterating, $d_\pm(\varphi \perp mH) = d_\pm(\varphi)$ for every $m \geq 0$. Now if $\varphi \perp mH \cong \psi \perp nH$, then the two sides have equal rank and equal discriminant, the latter by proposition 22.1.8, hence equal signed discriminant; combining the three equalities gives $d_\pm(\varphi) = d_\pm(\psi)$.
4. If m and n are both even then $(-1)^{mn} = 1$, so (2) reads $d_\pm(\varphi \perp \psi) = d_\pm(\varphi) d_\pm(\psi)$. Since addition in $W(k)$ is induced by $\perp$ and the target group is written multiplicatively, this is the homomorphism property on $\ker e$, as we sought to show.

The restriction in (4) is not an artifact of the proof. Over $\mathbb{Q}$ one has $d_\pm\langle 1\rangle = 1$ while $d_\pm\big(\langle 1\rangle \perp \langle 1\rangle\big) = d_\pm\langle 1, 1\rangle = -1$, and -1 is not a square in $\mathbb{Q}$, so $d_\pm$ is not additive on all of $W(\mathbb{Q})$. The subgroup where it is additive has a name.

Definition 22.6.9: The Fundamental Ideal

Let k be a field with $\operatorname{char} k \neq 2$. The *fundamental ideal* of $W(k)$ is

$$I(k) := \ker\big(e\colon W(k) \to \mathbb{Z}/2\mathbb{Z}\big)$$

the set of Witt classes of even rank. It is an ideal of the Witt ring, being the kernel of the ring homomorphism of proposition 22.6.8(1), and $W(k)/I(k) \cong \mathbb{Z}/2\mathbb{Z}$.

The classes $[\langle 1, -a\rangle]$ for $a \in k^\times$ lie in $I(k)$ and have signed discriminant $-1 \cdot (1 \cdot (-a)) = a$, so $d_\pm$ maps $I(k)$ onto the whole square class group. Rank modulo 2 and the signed discriminant are thus two homomorphisms out of $W(k)$ and out of $I(k)$ respectively, and over a finite field they turn out to separate every class from every other.

Proposition 22.6.10: Rank and Discriminant Classify Forms over a Finite Field

Let q be an odd prime power and fix a non-square $\epsilon \in \mathbb{F}_q^\times$.

1. For all $a, b \in \mathbb{F}_q^\times$ and all $c \in \mathbb{F}_q$ there exist $x, y \in \mathbb{F}_q$ with $ax^2 + by^2 = c$.
2. Every nondegenerate form over $\mathbb{F}_q$ of rank at least 3 is isotropic, and every nondegenerate form of rank at least 2 represents every element of $\mathbb{F}_q^\times$.
3. Two nondegenerate forms over $\mathbb{F}_q$ are isometric if and only if they have the same rank and the same discriminant.
4. Up to isometry the anisotropic forms over $\mathbb{F}_q$ are exactly the zero form, $\langle 1\rangle$, $\langle \epsilon\rangle$ and $\langle 1, -\epsilon\rangle$.

***Proof*:**

1. This is proved in example 22.4.9, by the counting argument on $S = \{ax^2 \mid x \in \mathbb{F}_q\}$ and $T = \{c - by^2 \mid y \in \mathbb{F}_q\}$, each of size $(q+1)/2$ in a set of size q.
2. The first claim is example 22.4.9, which deduces it from (1). For the second, let φ be nondegenerate of rank $n \geq 2$ and diagonalize it by theorem 22.2.1 as $\varphi \cong \langle a_1, \ldots, a_n\rangle$ in an orthogonal basis $w_1, \ldots, w_n$, every a_i being nonzero by the last claim of proposition 22.2.2. Given $c \in \mathbb{F}_q^\times$, part (1) supplies $x, y \in \mathbb{F}_q$ with $a_1 x^2 + a_2 y^2 = c$. Put $v := xw_1 + yw_2$; then $q(v) = a_1 x^2 + a_2 y^2 = c$, which is nonzero, so $v \neq 0$ and φ represents c.
3. Isometric forms have the same rank and, by proposition 22.1.8, the same discriminant. For the converse, induct on the common rank n. For $n = 0$ both forms are the zero form on the zero space. For $n = 1$, write $\varphi \cong \langle a\rangle$ and $\psi \cong \langle b\rangle$; equality of the discriminants means $b = ac^2$ for some $c \in \mathbb{F}_q^\times$ by corollary 22.2.3 and definition 22.1.6, and then $\langle a\rangle \cong \langle b\rangle$ by proposition 22.2.2.

   Let $n \geq 2$. Diagonalizing φ produces a vector v with $c := \varphi(v, v) \neq 0$, and by (2) the form

ψ also represents c, say $\psi(v', v') = c$. A vector of nonzero square splits off: for x in the space of φ,

$$x = \frac{\varphi(v,x)}{c} v + \left(x - \frac{\varphi(v,x)}{c} v \right)$$

where applying $\varphi(v, -)$ to the bracket gives $\varphi(v,x) - \frac{\varphi(v,x)}{c} c = 0$, so the bracket lies in $\{v\}^\perp$ (definition 13.3.20), a subspace by lemma 13.3.21; and if $\lambda v \in \{v\}^\perp$ then $\lambda c = 0$, so $\lambda = 0$. Hence the space is the direct sum of kv and $\{v\}^\perp$, these are orthogonal, and $\varphi \cong \langle c \rangle \perp \varphi'$ with φ' the restriction to $\{v\}^\perp$. The same argument gives $\psi \cong \langle c \rangle \perp \psi'$. Both φ' and ψ' have rank $n-1$ and are nondegenerate, since $c \det(\varphi') = \det(\varphi) \neq 0$ and likewise for ψ. Their discriminants agree: in the square class group, $\operatorname{disc}(\varphi') = c^{-1} \operatorname{disc}(\varphi) = c^{-1} \operatorname{disc}(\psi) = \operatorname{disc}(\psi')$. By the inductive hypothesis $\varphi' \cong \psi'$, and taking the orthogonal sum with the identity of $\langle c \rangle$ gives $\varphi \cong \psi$.

4. An anisotropic form has rank at most 2 by (2). The zero form is anisotropic vacuously. In rank 1, every $\langle a \rangle$ is anisotropic, and by (3) the isometry class is determined by the discriminant, which is the class of a; the two square classes of $\mathbb{F}_q$ are those of 1 and ϵ by example 22.2.5. In rank 2, the form $\langle a, b \rangle$ is isotropic exactly when $-ab$ is a square: given $ax^2 + by^2 = 0$ with $(x, y) \neq (0, 0)$, the case $y = 0$ would force $ax^2 = 0$ and hence $x = 0$, so $y \neq 0$ and $-ab = a^2(x/y)^2$ is a square; conversely if $-ab = t^2$ then $(x, y) = (t, a)$ is nonzero and $at^2 + ba^2 = a(t^2 + ab) = 0$. So $\langle a, b \rangle$ is anisotropic exactly when $-ab$ is a non-square, that is when $\operatorname{disc}\langle a, b \rangle = ab$ is the class of $-\epsilon$. By (3) that single condition on the discriminant pins down one isometry class in rank 2, and $\langle 1, -\epsilon \rangle$ is in it, completing the proof.

Part (3) is the affirmative answer promised at the end of example 22.2.5: over $\mathbb{F}_q$ the rank and the discriminant are a complete system of invariants, so the two forms $\langle 1, 1 \rangle$ and $\langle 1, 2 \rangle$ exhibited there over $\mathbb{F}_5$ fail to be isometric for the only reason available. Part (4) turns proposition 22.6.4 into a count.

Example 22.6.11: The Witt Group of a Finite Field

Let q be odd and $\epsilon \in \mathbb{F}_q^\times$ a non-square. By proposition 22.6.4 the elements of $W(\mathbb{F}_q)$ correspond to isometry classes of anisotropic forms, and proposition 22.6.10(4) lists four of them, so

$$W(\mathbb{F}_q) = \{ [0],\ [\langle 1 \rangle],\ [\langle \epsilon \rangle],\ [\langle 1, -\epsilon \rangle] \}$$

has exactly four elements. Which group of order four it is depends on q modulo 4, through whether -1 is a square.

The case $q \equiv 1 \pmod 4$. Then -1 is a square, say $-1 = c^2$: the group $\mathbb{F}_q^\times$ is cyclic by theorem 11.3.14, of order $q - 1$, which is divisible by 4 in this case, so it has an element of order 4, whose square has order 2 and hence equals -1, the unique element of order 2. For any $a \in \mathbb{F}_q^\times$, proposition 22.2.2 gives $\langle a \rangle \cong \langle ac^2 \rangle = \langle -a \rangle$, so every form satisfies $\varphi \cong -\varphi$ after diagonalizing, and

$$2[\varphi] = [\varphi] + [-\varphi] = 0$$

by theorem 22.6.3. A group of order 4 in which every element has order dividing 2 is $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$.

The case $q \equiv 3 \pmod 4$. Then -1 is a non-square, so $\epsilon = -1$ is an admissible choice, and $\langle 1, 1 \rangle$ is anisotropic by the criterion in the proof of proposition 22.6.10(4), since $-1 \cdot 1 = -1$ is a non-square. Hence $2[\langle 1 \rangle] = [\langle 1, 1 \rangle] \neq 0$ by proposition 22.6.4. On the other hand $\langle 1, 1, 1, 1 \rangle$ and

$2H \cong \langle 1,-1,1,-1\rangle$ both have rank 4 and discriminant the class of 1, so they are isometric by proposition 22.6.10(3), giving $4[\langle 1\rangle] = [2H] = 0$. So $[\langle 1\rangle]$ has order 4 in a group of order 4, and $W(\mathbb{F}_q) \cong \mathbb{Z}/4\mathbb{Z}$.

The invariants separate the four classes. Writing each class through its anisotropic representative and applying proposition 22.6.8, the rank modulo 2 and the signed discriminant take the values

	$[0]$	$[\langle 1\rangle]$	$[\langle \epsilon\rangle]$	$[\langle 1,-\epsilon\rangle]$
e	0	1	1	0
$d_\pm$	1	1	ϵ	ϵ

the last entry because $d_\pm\langle 1,-\epsilon\rangle = -(1\cdot(-\epsilon)) = \epsilon$. The four pairs are distinct, so a Witt class over a finite field is determined by its rank modulo 2 together with its signed discriminant.

A worked instance. Take $q = 5$. The squares in $\mathbb{F}_5^\times$ are 1 and 4, so $\epsilon = 2$ is a non-square and $-1 = 4 = 2^2$ is a square, putting this in the first case: $W(\mathbb{F}_5) \cong \mathbb{Z}/2\mathbb{Z}\times\mathbb{Z}/2\mathbb{Z}$, with anisotropic representatives 0, $\langle 1\rangle$, $\langle 2\rangle$ and $\langle 1,-2\rangle = \langle 1,3\rangle$. The two forms of example 22.2.5 land in different classes: $\langle 1,1\rangle \cong \langle 1,-1\rangle \cong H$ is Witt trivial, while $[\langle 1,2\rangle] = [\langle 1\rangle] + [\langle 2\rangle]$ has signed discriminant $-2 = 3$, a non-square, so it is not the class of 0.

Exercise 22.6.1

1. Take $k = \mathbb{F}_7$. List the square classes, determine the four anisotropic forms over $\mathbb{F}_7$ up to isometry, and identify $W(\mathbb{F}_7)$ as an abstract group. Which of the four classes is $3[\langle 1\rangle]$?
2. Let $\operatorname{char} k \neq 2$ and let φ be nondegenerate over k. Show that $[\varphi] = 0$ in $W(k)$ if and only if $\varphi \cong mH$ for some $m \geq 0$, and deduce that a nondegenerate form of odd rank is never Witt trivial. Conclude that $W(k)$ has at least two elements for every such k.
3. Let φ and ψ be nondegenerate forms over k with $[\varphi] = [\psi]$ and $\dim\varphi = \dim\psi$. Show that $\varphi \cong \psi$. Give an example over some field showing that the hypothesis on the dimensions cannot be dropped.
4. Suppose -1 is a square in k, where $\operatorname{char} k \neq 2$. Show that $\varphi \cong -\varphi$ for every form over k, hence that $2[\varphi] = 0$ for every $[\varphi] \in W(k)$, so that $W(k)$ is a vector space over $\mathbb{F}_2$. Check that example 22.6.5 is an instance.
5. Show that $a \mapsto [\langle a\rangle]$ induces a well defined group homomorphism from $k^\times/(k^\times)^2$ to the group of units of the Witt ring, and that it is injective for every field k with $\operatorname{char} k \neq 2$. (For injectivity, identify the anisotropic part of $\langle a\rangle$.)
6. Show that $d_\pm\colon I(k) \to k^\times/(k^\times)^2$ is surjective for every k with $\operatorname{char} k \neq 2$. Then compute $I(\mathbb{F}_q)$ for q odd and show that $d_\pm$ is an isomorphism of groups $I(\mathbb{F}_q) \xrightarrow{\sim} \mathbb{F}_q^\times/(\mathbb{F}_q^\times)^2$.
7. Show that $I(k)$ is generated as an abelian group by the classes $[\langle 1,-a\rangle]$ with a ranging over $k^\times$. (Start by expressing $[\langle a\rangle] - [\langle 1\rangle]$ as one of these generators up to sign.)
8. Show that the form $\langle 1,1,\ldots,1\rangle$ of rank n is anisotropic over $\mathbb{Q}$ for every n, and deduce that the classes $n[\langle 1\rangle]$ for $n \geq 0$ are pairwise distinct, so that $W(\mathbb{Q})$ is infinite and $[\langle 1\rangle]$ has infinite order. Contrast this with example 22.6.11.

22.7 The Clifford Algebra

Every construction so far has compared one form with another. This section attaches to a single form an associative algebra, built so that the form becomes the operation of squaring: inside it the equation $v^2 = q(v)$ holds for every $v \in V$. That equation is meaningless in V, where there is no product, so the object carrying it must be an algebra containing V, and section 16.3 is where algebras containing a given vector space are constructed.

The construction below is a quotient of $\mathcal{T}(V)$ by one family of relations, and for $q = 0$ it is the exterior algebra. What is proved here is that the quotient has dimension 2^n rather than collapsing, that maps out of it are prescribed by their restriction to V, and that although the $\mathbb{Z}$-grading of $\mathcal{T}(V)$ does not survive, its reduction modulo 2 does.

Definition 16.3.7 formed $\bigwedge(V)$ by killing the elements $v \otimes v$ of $\mathcal{T}(V)$, which forces $v^2 = 0$ in the quotient. Killing $v \otimes v - q(v)$ instead forces $v^2 = q(v)$. Assume $q \neq 0$ and choose v with $q(v) \neq 0$. The element $v \otimes v - q(v)$ is then a sum of a nonzero term of degree 2 and a nonzero term of degree 0, so it is not homogeneous, and the ideal generated by these elements is not a graded ideal in the sense of definition 16.2.3: were it graded, the two homogeneous components of $v \otimes v - q(v)$ would lie in it separately, so the invertible scalar $q(v)$, and with it 1, would lie in it and the quotient would be 0, contradicting theorem 22.7.5. For $q \neq 0$ the images of the $\mathcal{T}^d(V)$ therefore do not make the quotient a graded ring (definition 16.2.1); only in the excluded case $q = 0$, where the ideal is the one of definition 16.3.7 and is graded, does the $\mathbb{Z}$-grading survive (example 22.7.2). Proposition 22.7.7 says exactly how much of the grading is left in general.

Definition 22.7.1: Clifford Algebra

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space, and let q be a quadratic form on V (definition 22.1.1). Let $I(q) \subseteq \mathcal{T}(V)$ be the two-sided ideal of the tensor algebra (definition 16.3.1) generated by the elements

$$v \otimes v - q(v) \cdot 1 \qquad (v \in V)$$

where $q(v) \cdot 1$ lies in $\mathcal{T}^0(V) = k$. The *Clifford algebra* of q is the quotient k-algebra

$$C(q) := \mathcal{T}(V)/I(q)$$

and $\iota \colon V \to C(q)$ denotes the composite of the inclusion $V = \mathcal{T}^1(V) \subseteq \mathcal{T}(V)$ with the projection $\pi \colon \mathcal{T}(V) \to C(q)$.

Write φ for the symmetric bilinear form attached to q by proposition 22.1.2, so that $\varphi(v, v) = q(v)$. Two identities in $C(q)$ are used in everything below. The first is the defining relation

$$\iota(v)^2 = q(v)$$

which holds because π is an algebra homomorphism, so that $\iota(v)^2 = \pi(v \otimes v) = \pi\big(q(v) \cdot 1\big) = q(v)$, the middle equality holding because the two arguments differ by a generator of $I(q)$. The second identity is obtained by applying the first to $v + w$. Bilinearity of φ gives $q(v+w) = \varphi(v+w, v+w) = q(v) + 2\varphi(v, w) + q(w)$, while expanding the square in $C(q)$ gives

$$\iota(v+w)^2 = \big(\iota(v) + \iota(w)\big)^2 = \iota(v)^2 + \iota(v)\iota(w) + \iota(w)\iota(v) + \iota(w)^2$$

using that ι is linear. Equating the two and cancelling $\iota(v)^2 = q(v)$ and $\iota(w)^2 = q(w)$ leaves

$$\iota(v)\iota(w) + \iota(w)\iota(v) = 2\varphi(v, w) \tag{22.3}$$

Since $\operatorname{char} k \neq 2$, the right-hand side vanishes exactly when v and w are orthogonal (definition 13.3.20), so orthogonality of vectors becomes anticommutation of their images. This is the mechanism that turns a choice of orthogonal basis, which theorem 22.2.1 always supplies, into a presentation of $C(q)$ by generators and relations.

Example 22.7.2: The Clifford Algebra of the Zero Form

Let k be a field with $\operatorname{char} k \neq 2$ and take $q = 0$ on a k-vector space V of dimension n. The generators of $I(0)$ are the elements $v \otimes v - 0 = v \otimes v$ for $v \in V$, which are precisely the generators of the ideal $\mathcal{A}(V)$ of definition 16.3.7. The two ideals therefore coincide, and

$$C(0) = \mathcal{T}(V)/\mathcal{A}(V) = \bigwedge(V)$$

not merely up to isomorphism but as the same quotient. Its dimension is

$$\dim_k \bigwedge(V) = \sum_{r=0}^{n} \binom{n}{r} = 2^n$$

since $\bigwedge^r(V)$ is free of rank $\binom{n}{r}$ by theorem 16.4.3 and vanishes for $r > n$. Note that nothing in definition 22.7.1 asked q to be nondegenerate, and for $V \neq 0$ the zero form has radical all of V.

The definition determines the algebra but leaves two questions open: how large it is, and how to produce a homomorphism out of it. The second is answered first, and the answer then supplies the first, because the way to bound the dimension of $C(q)$ from below is to map it onto something of known dimension.

Proposition 22.7.3: The Universal Property of the Clifford Algebra

Let k be a field with $\operatorname{char} k \neq 2$, let V be a finite-dimensional k-vector space, and let q be a quadratic form on V.

1. For every k-algebra A and every k-linear map $f\colon V \to A$ satisfying $f(v)^2 = q(v) \cdot 1_A$ for all $v \in V$, there is a unique k-algebra homomorphism $F\colon C(q) \to A$ with $F \circ \iota = f$.
2. Let q' be a quadratic form on V', with associated symmetric bilinear forms φ and φ', and let $g\colon (V, \varphi) \to (V', \varphi')$ be an isometry (definition 22.1.10). Then there is a unique k-algebra isomorphism $C(g)\colon C(q) \to C(q')$ with $C(g)\big(\iota(v)\big) = \iota'\big(g(v)\big)$ for all $v \in V$. In particular isometric forms have isomorphic Clifford algebras.

Proof:

1. *Existence.* Take $R = k$ and $M = V$ in theorem 16.3.2(2): its hypotheses ask for a k-algebra and a k-module homomorphism from V into it, which are A and f. So it supplies a unique k-algebra homomorphism $\Psi\colon \mathcal{T}(V) \to A$ with $\Psi|_V = f$. On a generator of $I(q)$,

$$\Psi\big(v \otimes v - q(v) \cdot 1\big) = \Psi(v)\Psi(v) - q(v)\Psi(1) = f(v)^2 - q(v) \cdot 1_A = 0$$

by the hypothesis on f. Every element of $I(q)$ is a finite sum of products $x\gamma y$ with $x, y \in \mathcal{T}(V)$ and γ one of those generators, and $\Psi(x\gamma y) = \Psi(x)\Psi(\gamma)\Psi(y) = 0$, so $I(q) \subseteq \ker\Psi$. Hence

$$F\big(x + I(q)\big) := \Psi(x)$$

is well defined: two representatives of the same class differ by an element of $I(q)$, on which Ψ vanishes. It is k-linear, multiplicative and unital because Ψ is and because $\pi\colon \mathcal{T}(V) \to C(q)$ is a surjective algebra homomorphism with $F \circ \pi = \Psi$. Finally $F \circ \iota = \Psi|_V = f$.

Uniqueness. The algebra $C(q)$ is generated as a k-algebra by $\iota(V)$: the simple tensors $v_1 \otimes \cdots \otimes v_m$ generate $\mathcal{T}^m(V)$ as a k-module by lemma 15.1.4, hence together with 1 they span $\mathcal{T}(V)$, and π is surjective and sends $v_1 \otimes \cdots \otimes v_m$ to $\iota(v_1)\cdots\iota(v_m)$. Now if F_1, F_2 are algebra homomorphisms out of $C(q)$ agreeing on $\iota(V)$, the set on which they agree is closed under sums, products and scalars and contains 1, so it is a subalgebra containing a generating set, hence all of $C(q)$. So F is unique.

2. An isometry satisfies $\varphi'(g(v), g(v)) = \varphi(v, v)$, that is $q'(g(v)) = q(v)$. So the k-linear map $f := \iota' \circ g\colon V \to C(q')$ satisfies

$$f(v)^2 = \iota'\big(g(v)\big)^2 = q'\big(g(v)\big) = q(v)$$

and part (1) gives a unique algebra homomorphism $C(g)$ with $C(g) \circ \iota = \iota' \circ g$. The inverse map g^{-1} is again an isometry, since applying $\varphi'(g(-), g(-)) = \varphi(-, -)$ to the vectors $g^{-1}(x), g^{-1}(y)$ gives $\varphi'(x, y) = \varphi(g^{-1}x, g^{-1}y)$, so the same construction produces $C(g^{-1})\colon C(q') \to C(q)$. The composite $C(g^{-1}) \circ C(g)$ is an algebra homomorphism $C(q) \to C(q)$ carrying $\iota(v)$ to $\iota(g^{-1}g(v)) = \iota(v)$, and the identity of $C(q)$ carries $\iota(v)$ to $\iota(v)$ as well. Both therefore solve the problem of part (1) for $A = C(q)$ and $f = \iota$, whose hypothesis $\iota(v)^2 = q(v)$ holds, so uniqueness forces $C(g^{-1}) \circ C(g) = \mathrm{id}_{C(q)}$. Exchanging the roles of g and g^{-1} gives $C(g) \circ C(g^{-1}) = \mathrm{id}_{C(q')}$, so $C(g)$ is an isomorphism, completing the proof.

Part (1) is the statement that prescribing an algebra homomorphism out of $C(q)$ costs exactly one k-linear map $V \to A$ whose values square to the scalars $q(v)$; the relations impose nothing further. Part (2) is what makes $C(q)$ an invariant of the isometry class rather than of a chosen presentation, so it may be computed from any convenient diagonalization $\langle a_1, \ldots, a_n\rangle$ produced by theorem 22.2.1. The smallest case already shows that the answer depends on the field.

Example 22.7.4: Clifford Algebras of a Line

Let k be a field with $\operatorname{char} k \neq 2$, let $\dim_k V = 1$, say $V = kv$, and let $a := q(v)$, so that $q \cong \langle a\rangle$. Then

$$C(q) \cong k[x]/(x^2 - a)$$

To see this, write $A := k[x]/(x^2 - a)$ and let $\bar{x}$ be the class of x. The map $f\colon V \to A$ sending $\lambda v \mapsto \lambda\bar{x}$ is k-linear, and $f(\lambda v)^2 = \lambda^2\bar{x}^2 = \lambda^2 a = q(\lambda v)$ by definition 22.1.1(1), so proposition 22.7.3(1) gives an algebra homomorphism $F\colon C(q) \to A$ with $F(\iota(v)) = \bar{x}$. In the other direction, evaluation at $\iota(v)$ is an algebra homomorphism $k[x] \to C(q)$, since the powers of $\iota(v)$ commute with one another and k is central in $C(q)$; it kills $x^2 - a$ because $\iota(v)^2 = q(v) = a$, so it factors through a homomorphism $G\colon A \to C(q)$ with $G(\bar{x}) = \iota(v)$. Now $F \circ G$ is an algebra endomorphism of A fixing $\bar{x}$, and the elements it fixes form a subalgebra, which therefore contains the algebra generated by $\bar{x}$, namely all of A; so $F \circ G = \mathrm{id}_A$. Likewise $G \circ F$ is an algebra endomorphism of $C(q)$ fixing $\iota(V)$ pointwise, hence equals $\mathrm{id}_{C(q)}$ by the uniqueness clause of proposition 22.7.3(1). So F is an isomorphism.

Three cases occur, according to the square class of a (definition 22.1.6).

1. $a = 0$. Then $C(q) \cong k[x]/(x^2)$, the algebra of dual numbers, in agreement with example 22.7.2, which identifies it with $\bigwedge(V)$.
2. $a = c^2$ with $c \in k^\times$. Then $x^2 - a = (x-c)(x+c)$ is a product of two distinct monic irreducibles, distinct because $c \neq -c$ when $\operatorname{char} k \neq 2$, so proposition 11.1.6 gives

$$C(q) \cong k[x]/(x-c) \times k[x]/(x+c) \cong k \times k$$

   an algebra with zero divisors: $(\bar{x}-c)(\bar{x}+c) = 0$.
3. $a \in k^\times$ is not a square. Then $C(q)$ is a field, the quadratic extension of k obtained by adjoining a square root of a. Indeed $(u + w\bar{x})(u - w\bar{x}) = u^2 - w^2 a$ for $u, w \in k$, and this is nonzero unless $u = w = 0$: if $w \neq 0$ then $u^2 = w^2 a$ would make $a = (u/w)^2$ a square, and if $w = 0$ then $u \neq 0$ gives $u^2 \neq 0$. So every nonzero element of $C(q)$ has the inverse $(u - w\bar{x})/(u^2 - w^2 a)$.

Over $k = \mathbb{R}$ the three cases are $\mathbb{R}[x]/(x^2)$, $\mathbb{R} \times \mathbb{R}$ and $\mathbb{C}$, the last being $C(\langle -1 \rangle)$.

All three algebras above have dimension $2 = 2^1$, and the same count holds in every dimension. Proving it is the one place where the construction has to be shown not to collapse: nothing said so far rules out $C(q) = 0$, since a quotient by a large ideal can kill everything. The proof below produces an explicit $C(q)$-module of dimension 2^n, and the independence of the monomials of $C(q)$ follows from the independence of that module's basis.

Theorem 22.7.5: The Monomial Basis of $C(q)$

Let k be a field with $\operatorname{char} k \neq 2$, let V be a k-vector space of dimension n, let q be a quadratic form on V, and let $e_1, \ldots, e_n$ be an orthogonal basis of V for the associated symmetric bilinear form φ, with $a_i := q(e_i)$. For a subset $S = \{i_1 < i_2 < \cdots < i_r\}$ of $\{1, \ldots, n\}$ write

$$e_S := \iota(e_{i_1})\iota(e_{i_2}) \cdots \iota(e_{i_r}) \in C(q), \qquad e_\emptyset := 1$$

Then the 2^n elements e_S form a k-basis of $C(q)$. In particular $\dim_k C(q) = 2^n$ and $\iota\colon V \to C(q)$ is injective.

***Proof*:**
An orthogonal basis exists by theorem 22.2.1, whose hypotheses are the standing ones here. Throughout, ι is suppressed from the notation for products, so e_i denotes $\iota(e_i) \in C(q)$.

Step 1: the relations. By (22.3) applied to $v = w = e_i$ and to $v = e_i$, $w = e_j$ with $i \neq j$,

$$e_i^2 = q(e_i) = a_i, \qquad e_i e_j = -e_j e_i \quad (i \neq j)$$

the second because $\varphi(e_i, e_j) = 0$ for $i \neq j$ by the choice of basis. Also, for $v = \sum_i c_i e_i$, expanding

φ by bilinearity and using orthogonality gives

$$q(v) = \varphi(v, v) = \sum_i c_i^2 a_i \tag{22.4}$$

Step 2: the e_S span $C(q)$. As established in the uniqueness half of the proof of proposition 22.7.3, $C(q)$ is spanned as a k-vector space by 1 together with the products $\iota(v_1)\cdots\iota(v_m)$ with $v_t \in V$. Expanding each v_t in the basis $e_1, \ldots, e_n$ and multiplying out, which is legitimate because multiplication in $C(q)$ is k-bilinear, shows that the products $e_{j_1}e_{j_2}\cdots e_{j_m}$ of basis vectors already span.

It remains to reduce such a product to a scalar multiple of some e_S, which is done by induction on m. For $m = 0$ the product is $1 = e_\emptyset$. If the indices $j_1, \ldots, j_m$ are pairwise distinct, then finitely many interchanges of adjacent factors sort them into increasing order, each interchange multiplying the product by -1 by Step 1, so the product equals $\pm e_S$ with $S = \{j_1, \ldots, j_m\}$. If two indices coincide, choose a pair $j_s = j_t = i$ with $s < t$ and $t - s$ minimal; then $j_u \neq i$ for $s < u < t$, so moving the factor e_{j_t} leftwards past those $t - s - 1$ factors changes the product only by a sign and makes the two occurrences of e_i adjacent. Replacing e_ie_i by the scalar a_i produces a scalar multiple of a product of length $m - 2$, which the inductive hypothesis handles. Hence the e_S span, and $\dim_k C(q) \leq 2^n$.

Step 3: a module of dimension 2^n. Let M be the k-vector space with basis $\{u_S \mid S \subseteq \{1, \ldots, n\}\}$, so $\dim_k M = 2^n$. For an index i and a subset S write $S\triangle i$ for the symmetric difference, that is $S \cup \{i\}$ if $i \notin S$ and $S \setminus \{i\}$ if $i \in S$, and set

$$d(i, S) := \#\{l \in S \mid l < i\}, \qquad \sigma(i, S) := (-1)^{d(i,S)}, \qquad c_i(S) := \begin{cases} a_i & i \in S \\ 1 & i \notin S \end{cases}$$

Define $E_i \in \operatorname{End}_k(M)$ on the basis by

$$E_i(u_S) := c_i(S)\,\sigma(i, S)\,u_{S\triangle i}$$

Three facts about these coefficients are what the computation uses. First, $\sigma(i, S\triangle j) = \sigma(i, S)$ whenever $j \geq i$, since $d(i, -)$ counts only elements smaller than i and is therefore unchanged by inserting or deleting j. Second, $\sigma(j, S\triangle i) = -\sigma(j, S)$ whenever $i < j$, since $d(j, -)$ then changes by exactly one. Third, $c_i(S\triangle j) = c_i(S)$ for $j \neq i$, since membership of i is unchanged, while $c_i(S)c_i(S\triangle i) = a_i$, one of the two factors being a_i and the other 1.

Applying E_i twice and using the first and third facts,

$$E_i^2(u_S) = c_i(S)\sigma(i, S)\,c_i(S\triangle i)\sigma(i, S\triangle i)\,u_S = a_i\,\sigma(i, S)^2\,u_S = a_i\,u_S$$

so $E_i^2 = a_i\,\mathrm{id}_M$. For $i < j$, the same facts give

$$E_iE_j(u_S) = c_j(S)\sigma(j, S)\,c_i(S\triangle j)\sigma(i, S\triangle j)\,u_{S\triangle\{i,j\}} = c_i(S)c_j(S)\sigma(i, S)\sigma(j, S)\,u_{S\triangle\{i,j\}}$$

whereas, the second fact now contributing a sign,

$$E_jE_i(u_S) = c_i(S)\sigma(i, S)\,c_j(S\triangle i)\sigma(j, S\triangle i)\,u_{S\triangle\{i,j\}} = -\,c_i(S)c_j(S)\sigma(i, S)\sigma(j, S)\,u_{S\triangle\{i,j\}}$$

so $E_iE_j = -E_jE_i$ for $i \neq j$.

Step 4: the e_S are independent. Let $\rho\colon V \to \mathrm{End}_k(M)$ be the k-linear map with $\rho(e_i) = E_i$. For $v = \sum_i c_i e_i$, expanding the square and grouping the cross terms in pairs,

$$\rho(v)^2 = \sum_i c_i^2 E_i^2 + \sum_{i<j} c_i c_j \big(E_i E_j + E_j E_i\big) = \Big(\sum_i c_i^2 a_i\Big)\mathrm{id}_M = q(v)\,\mathrm{id}_M$$

by Step 3 and (22.4). So proposition 22.7.3(1), applied to the k-algebra $A = \mathrm{End}_k(M)$, yields an algebra homomorphism $\Phi\colon C(q) \to \mathrm{End}_k(M)$ with $\Phi(e_i) = E_i$.

Evaluate $\Phi(e_S)$ at $u_\emptyset$ for $S = \{i_1 < \cdots < i_r\}$, by descending induction on t on the claim that $E_{i_{t+1}} \cdots E_{i_r}(u_\emptyset) = u_T$ with $T = \{i_{t+1}, \ldots, i_r\}$. For $t = r$ the product is empty and the claim reads $u_\emptyset = u_\emptyset$. Given it for t, every element of T exceeds i_t, so $d(i_t, T) = 0$ and $\sigma(i_t, T) = 1$, while $i_t \notin T$ gives $c_{i_t}(T) = 1$; hence $E_{i_t}(u_T) = u_{T\cup\{i_t\}}$, which is the claim for $t-1$. At $t = 0$ it reads $\Phi(e_S)(u_\emptyset) = u_S$. Now if $\sum_S \lambda_S e_S = 0$ in $C(q)$, applying Φ and evaluating at $u_\emptyset$ gives $\sum_S \lambda_S u_S = 0$ in M, and the u_S are a basis, so every $\lambda_S = 0$.

The e_S therefore span and are independent, so they are a basis and $\dim_k C(q) = 2^n$. The images $\iota(e_1), \ldots, \iota(e_n)$ are the basis elements e_S with $\#S = 1$, hence linearly independent, so the linear map ι carries a basis of V to an independent set and is injective, completing the proof.

Two consequences are recorded before any further computation. First, ι being injective, V is identified with its image from here on and the symbol ι is dropped: a vector $v \in V$ is treated as an element of $C(q)$ with $v^2 = q(v)$. Second, $C(q)$ and $\bigwedge(V)$ have the same dimension for every q, by theorem 22.7.5 and example 22.7.2, and the same monomials index a basis of each; the multiplications differ, since squares of vectors are 0 in one and $q(v)$ in the other. For $n \geq 2$ neither algebra is commutative: $e_1e_2 = -e_2e_1$ in both, and $e_1e_2 \neq 0$ because it is a basis element (theorem 22.7.5 and theorem 16.4.3), so $e_1e_2 = e_2e_1$ would give $2e_1e_2 = 0$ against $\operatorname{char} k \neq 2$.

Example 22.7.6: The Quaternions as a Clifford Algebra

Let $V = \mathbb{R}^2$ and $q = \langle -1, -1\rangle$, with orthogonal basis e_1, e_2 and $q(e_1) = q(e_2) = -1$. By theorem 22.7.5 the algebra $C(q)$ has basis $1, e_1, e_2, e_1e_2$. Writing $\omega := e_1e_2$ and using $e_2e_1 = -e_1e_2$ to move factors past one another,

$$e_1^2 = e_2^2 = -1, \qquad \omega^2 = e_1e_2e_1e_2 = -e_1e_1e_2e_2 = -(-1)(-1) = -1$$

$$e_1e_2 = \omega, \qquad e_2\omega = e_2e_1e_2 = -e_1e_2e_2 = e_1, \qquad \omega e_1 = e_1e_2e_1 = -e_1e_1e_2 = e_2$$

These are the relations $i^2 = j^2 = k^2 = -1$, $ij = k$, $jk = i$, $ki = j$ satisfied by the quaternion units, so $C(q)$ and the quaternions $\mathbb{H}$ are the same algebra; $\mathbb{H}$ appears in theorem 20.2.3 as one of the three associative real division algebras, though that theorem supplies no basis or multiplication rule, so both are recalled here. To see it as an isomorphism rather than a coincidence of tables, recall that $\mathbb{H}$ is the 4-dimensional $\mathbb{R}$-algebra with basis $1, i, j, k$ and $ij = k = -ji$. Those two relations already force the rest of the table: putting $k = ij$ and using associativity,

$$jk = j(ij) = (ji)j = -ij^2 = i, \qquad ki = (ij)i = i(ji) = -i^2 j = j$$

and in the same way $ik = i(ij) = i^2 j = -j$ and $kj = (ij)j = ij^2 = -i$, so the products computed in $C(q)$ above are exactly the quaternion products, and they agree with the relations displayed for Q_8 in section 1.2.4. Now let $f\colon V \to \mathbb{H}$ be the $\mathbb{R}$-linear map with $f(e_1) = i$ and $f(e_2) = j$. For $v = c_1e_1 + c_2e_2$,

$$f(v)^2 = c_1^2 i^2 + c_1c_2(ij + ji) + c_2^2 j^2 = -(c_1^2 + c_2^2) = q(v)$$

so proposition 22.7.3(1) gives an algebra homomorphism $F\colon C(q) \to \mathbb{H}$ with $F(e_1) = i$ and $F(e_2) = j$. Its image is a subalgebra containing i, j and hence $ij = k$, so it contains the spanning set $1, i, j, k$ and F is surjective; both algebras have dimension 4 over $\mathbb{R}$, so

$$C(\langle -1, -1\rangle) \cong \mathbb{H}$$

Compare example 22.7.4, where $C(\langle -1\rangle) \cong \mathbb{C}$: the first two entries of a negative definite real form produce the complex numbers and then the quaternions.

The $\mathbb{Z}$-grading of $\mathcal{T}(V)$ was lost when the inhomogeneous relations were imposed, but the parity of a monomial survived the reduction in Step 2 of theorem 22.7.5: cancelling a repeated index removes two factors at a time. The following proposition makes that observation into a decomposition of the algebra, obtained not from the monomials but from the universal property, which is what makes it independent of the chosen orthogonal basis.

Proposition 22.7.7: The Parity Grading and the Even Subalgebra

Let k be a field with $\operatorname{char} k \neq 2$, let V be a k-vector space of dimension n, and let q be a quadratic form on V.

1. There is a unique k-algebra automorphism $\alpha\colon C(q) \to C(q)$ with $\alpha(v) = -v$ for all $v \in V$, and $\alpha^2 = \mathrm{id}$.
2. Setting $C^0(q) := \{x \in C(q) \mid \alpha(x) = x\}$ and $C^1(q) := \{x \in C(q) \mid \alpha(x) = -x\}$,
$$C(q) = C^0(q) \oplus C^1(q), \qquad C^\epsilon(q)\, C^\delta(q) \subseteq C^{\epsilon+\delta}(q)$$
the superscripts being read modulo 2. In particular $C^0(q)$ is a subalgebra, the *even part* of $C(q)$, and $V \subseteq C^1(q)$.
3. With the notation of theorem 22.7.5, $C^0(q)$ has basis the e_S with $\#S$ even and $C^1(q)$ has basis the e_S with $\#S$ odd. For $n \geq 1$ both have dimension 2^{n-1}.

Proof:

1. The map $f\colon V \to C(q)$ with $f(v) = -v$ is k-linear and satisfies $f(v)^2 = (-v)^2 = v^2 = q(v)$, so proposition 22.7.3(1) with $A = C(q)$ gives a unique algebra homomorphism α with $\alpha(v) = -v$ on V. Then $\alpha \circ \alpha$ is an algebra homomorphism $C(q) \to C(q)$ restricting on V to $v \mapsto -(-v) = v$, and $\mathrm{id}_{C(q)}$ restricts to that same map; the uniqueness clause of the same proposition, applied to $f = \iota$, forces $\alpha^2 = \mathrm{id}$. Hence α is bijective, so it is an automorphism.
2. For $x \in C(q)$ write
$$x = \tfrac{1}{2}\big(x + \alpha(x)\big) + \tfrac{1}{2}\big(x - \alpha(x)\big)$$
which is legitimate since $\operatorname{char} k \neq 2$. Applying α and using $\alpha^2 = \mathrm{id}$ shows the first summand is fixed by α and the second is negated, so $C(q) = C^0(q) + C^1(q)$. If x lies in both then $x = -x$, so $2x = 0$ and $x = 0$; the sum is direct. For the product rule, let $x \in C^\epsilon(q)$ and $y \in C^\delta(q)$. Then $\alpha(xy) = \alpha(x)\alpha(y) = (-1)^\epsilon(-1)^\delta xy = (-1)^{\epsilon+\delta}xy$, which is the stated containment. Taking $\epsilon = \delta = 0$ shows $C^0(q)$ is closed under multiplication, and $\alpha(1) = 1$ puts 1 in it, so it is a subalgebra. Finally $\alpha(v) = -v$ for $v \in V$ is the statement $V \subseteq C^1(q)$.

3. Since α is an algebra homomorphism, $\alpha(e_S) = \alpha(e_{i_1}) \cdots \alpha(e_{i_r}) = (-1)^r e_S$ for S of size r. Writing an arbitrary $x = \sum_S \lambda_S e_S$ in the basis of theorem 22.7.5,

$$\alpha(x) = \sum_S (-1)^{\#S} \lambda_S e_S$$

and comparing coefficients, $\alpha(x) = x$ holds if and only if $\lambda_S = 0$ for every S of odd size, while $\alpha(x) = -x$ holds if and only if $\lambda_S = 0$ for every S of even size. So the even monomials are a basis of $C^0(q)$ and the odd ones a basis of $C^1(q)$. Their numbers are equal for $n \geq 1$, since

$$\sum_{r \text{ even}} \binom{n}{r} - \sum_{r \text{ odd}} \binom{n}{r} = (1-1)^n = 0$$

by the binomial theorem, and they sum to 2^n, so each is 2^{n-1}, as we sought to show.

The decomposition is a $\mathbb{Z}/2\mathbb{Z}$-grading, and $C^0(q)$ is a subalgebra of half the dimension of $C(q)$. In example 22.7.6 it has basis $1, e_1e_2$ with $(e_1e_2)^2 = -1$, so evaluation at e_1e_2 is a surjective algebra homomorphism $\mathbb{R}[x] \to C^0$ killing $x^2 + 1$, and comparing dimensions gives

$$C^0(\langle -1, -1 \rangle) \cong \mathbb{R}[x]/(x^2+1) \cong \mathbb{C}$$

sitting inside $\mathbb{H}$ as the subalgebra spanned by 1 and one imaginary unit. The general rank-two computation, which recovers $\operatorname{disc}(q)$ of definition 22.1.7 from the even part, is the third exercise below.

Exercise 22.7.1

1. Let $\operatorname{char} k \neq 2$, let q be a quadratic form on V and regard $V \subseteq C(q)$ as in theorem 22.7.5. Show that a vector $v \in V$ is invertible in $C(q)$ if and only if $q(v) \neq 0$, and that its inverse is then $q(v)^{-1}v$. Deduce that if $q(v) = 0$ for some nonzero $v \in V$, then $C(q)$ is not a division algebra.

2. Let $\operatorname{char} k \neq 2$ and let $q = \langle 1, -1 \rangle$ on k^2. Show that $C(q) \cong M_2(k)$. (Send e_1 and e_2 to two explicit matrices, check the hypothesis of proposition 22.7.3(1) for every vector rather than only for e_1 and e_2, and finish with theorem 22.7.5.)

3. Let $\operatorname{char} k \neq 2$ and let $q \cong \langle a, b \rangle$ be nondegenerate of rank 2. Show that $C^0(q) \cong k[x]/(x^2+ab)$, and that this algebra is a field exactly when $-ab$ is not a square in k. Using corollary 22.2.3, express the condition in terms of $\operatorname{disc}(q)$, and check the answer against example 22.7.6.

4. Let $\operatorname{char} k \neq 2$ and let $q \cong \langle a_1, \ldots, a_n \rangle$ be nondegenerate, so every $a_i \neq 0$, and set $\omega := e_1e_2 \cdots e_n$ for an orthogonal basis as in theorem 22.7.5. Show that $\omega e_i = (-1)^{n-1} e_i \omega$ for every i, and deduce that ω lies in the centre of $C(q)$ if and only if n is odd.

5. Let $\operatorname{char} k \neq 2$ and let $C(g)$ be as in proposition 22.7.3(2). Show that $C(\mathrm{id}_V) = \mathrm{id}_{C(q)}$ and that $C(h \circ g) = C(h) \circ C(g)$ for isometries g and h. Deduce that $g \mapsto C(g)$ is a group homomorphism from the orthogonal group $O(\varphi)$ of definition 22.1.10 to the group of k-algebra automorphisms of $C(q)$, and that every automorphism in its image commutes with the α of proposition 22.7.7 and therefore preserves $C^0(q)$ and $C^1(q)$.

6. Let $\operatorname{char} k \neq 2$ and let $C(q)^{\mathrm{op}}$ denote the k-algebra with the same underlying vector space as $C(q)$ and multiplication $x * y := yx$. Show that there is a unique k-algebra homomorphism

$t\colon C(q) \to C(q)^{\mathrm{op}}$ with $t(v) = v$ for all $v \in V$, that the resulting map on $C(q)$ satisfies $t(xy) = t(y)t(x)$ and $t^2 = \mathrm{id}$, and that $t(e_{i_1}e_{i_2}\cdots e_{i_r}) = (-1)^{r(r-1)/2}e_{i_1}e_{i_2}\cdots e_{i_r}$ for $i_1 < \cdots < i_r$.

7. Let $\operatorname{char} k \neq 2$ and let q be a quadratic form on V. Show that $C^0(q)$ is spanned as a k-vector space by the products $v_1v_2\cdots v_{2m}$ of an even number of vectors of V, and hence that it is generated as a k-algebra by the products vw with $v, w \in V$.

Part V

Commutative Algebra

In this part of the book, we are no longer studying a new object as the central focus. Rather, it is the basic language that deals with *algebraic number theory* and *algebraic geometry*; this is the language of commutative algebra. Commutative algebra is an extension of ring theory where it is always assumed that the ring R is commutative. As shall be shown soon, this theory will prove to be very useful in developing two major studies of mathematics:

1. *Algebraic Geometry*: At the heart of Algebraic Geometry is the realization that all commutative rings have a corresponding *geometric object* (known as an *affine scheme*). We have already encountered the simplest of schemes in section 13.2.4 with the classification of hyper-planes of a finitely dimensional vector-space. Recall that each hyper-plane is associated the solution (or kernel) of linear equations. Schemes generalize this notion a great deal by working with polynomials over general commutative rings instead of restriting to linear equations (which are polynomials of degree 1), and by allowing the resulting geometric object to be "glued together" from kernels of polynomials instead of being the solution to polynomials. In *Algebraic Geometry* [5] the reader can see how to associate a scheme to every commutative ring, and the theory behind that correspondence.

2. *Algebraic Number Theory*: Studying fields allowed us to study the solutions to polynomials over fields. However, fields are very restrictive (dually very versatile) algebraic structures that allowed for some very powerful results. When trying to replicate the same strategies for solving polynomial equations over more general rings, many of these strategies fall apart. To properly generlize this, we shall need to invent a new theory, namely *algebraic number theory* is exactly this theory. In chapter 50, we shall explore some results such as quadratic reciprocity and classifying all Abelian extensions (i.e. Kronnecker-Weber's Theorem). Most of the time, we focus on solutions to equation over $\mathbb{Z}$, as $\mathbb{Z}$ is the initial object of ring, or more concretely $\mathbb{Z}$ is an object that appears very naturally in the world.

In this chapter, some basic topological notions will be used. The geometric intuition presented in this chapter will be lost on those who have not taken or learned some basic topology (up to the separation axioms, in particular T_1 and T_2, and compactness/connectedness). Appendix C serves as a review of what topological concepts will be used in this chapter.

chapter 31 and chapter 50 can be thought of as covering the more "classical" versions of heir respective field. For example, modern algebraic geometry shall start with schemes, while algebraic number theory is developed over local fields and uses techniques from complex analysis. Most of the motivation for these developments come form more concrete questions that naturally arose when studying polynomials and their solutions. The reader shall certainly gain a lot by understanding the core ideas behind these two chapters before tackling their more abstract modernization's. The reader wishing to follow up these chapters with a more in-depth covering can checkout [5] for the continuation of this book towards Algebraic Geometry and [39] for a continuation of this book towards Class Field Theory.

Note that algebraic geometry is *not* algebraic topology. In algebraic topology, we usually start with a topological space (or manifold) and associate to it an algebraic object to find properties of the topological/geometrical object. In Algebraic Geometry, we start with a commutative ring (or a collection of commutative rings), and create a geometric object that can be used to study the ring.

23

Noetherian Rings, Hilbert's Basis Theorem, and Localization

As with groups an modules, all R-algebras are quotient of a polynomial ring over many variables. If the polynomial ring is over finitely many variables. The fact that all algebras are quotient of polynomial rings will let the study of geometry and algebra.

Next, we recall some important definition and results that shall be central to the following section:

23.1 Noetherian Rings and Modules

Definition 23.1.1: Noetherian Ring

Let R be a commutative ring. Then if R satisfies the ascending chain condition on Ideals, then R is Noetherian. In particular, if $\mathcal{I}$ is a collection of ideals ordered by inclusion $(I_1 \subseteq I_2 \subseteq \cdots I_k \cdots)$, then there exists an m such that for all $n \geq m$, $I_m = I_{m+1} = \cdots$.

Proposition 23.1.2: Extension of Noetherian Rings

Let R be a Noetherian ring. Then R/I is Noetherian for any ideal I. Conversely, if I and R/I is Noetherian, then R is Noetherian.

***Proof*:**
Ideals of R/I are exactly the ideals of R containing I, so an ascending chain in R/I pulls back to an ascending chain in R, which stabilizes; thus R/I is Noetherian. Conversely, suppose I and R/I are Noetherian and let $J_1 \subseteq J_2 \subseteq \cdots$ be ideals of R. The chains $J_n \cap I$ (in I) and $(J_n + I)/I$ (in R/I) both stabilize, say for $n \geq m$. For such n, if $x \in J_{n+1}$ write $x = j + a$ with $j \in J_n$, $a \in I$ (possible since $J_n + I = J_{n+1} + I$); then $a = x - j \in J_{n+1} \cap I = J_n \cap I \subseteq J_n$, so $x \in J_n$. Hence $J_n = J_{n+1}$ and R is Noetherian.

As a consequence the image of any Noetherian ring is Noetherian.

Proposition 23.1.3: Equivalence of Noetherian Ring

Let R be a commutative ring. Then the following are equivalent

1. R is Noetherian
2. every nonempty collection of ideals of R has a maximal element under inclusion
3. every ideal of R is finitely generated

***Proof*:**
(1) $\Rightarrow$ (2): a nonempty collection of ideals with no maximal element would yield a strictly ascending chain, contradicting the ascending chain condition. (2) $\Rightarrow$ (3): given an ideal J, the collection of finitely generated subideals of J has a maximal element J_0; if $J_0 \neq J$, then for $x \in J \setminus J_0$ the ideal $J_0 + (x)$ is finitely generated and strictly larger, a contradiction, so $J = J_0$ is finitely generated. (3) $\Rightarrow$ (1): for an ascending chain $J_1 \subseteq J_2 \subseteq \cdots$, the union $J = \bigcup_n J_n$ is an ideal, hence finitely generated; its finitely many generators lie in some J_m, so $J = J_m$ and the chain stabilizes.

Example 23.1.4: Exercise
Show that if R is a Noetherian ring and M is a finitely generated R-module, then M is Noetherian (Hint: remember the universal property of free-modules)

The maximal-element form of the condition, part (2) above, is the one that does the work in practice. Here is a first instance, and the finiteness statement the factorization theory of Dedekind domains rests on: an ideal of a Noetherian ring need not factor into primes, but it always *contains* a product of them.

Proposition 23.1.5: Every Proper Ideal Contains a Product of Primes

Let R be a Noetherian ring and let $I \subsetneq R$ be a proper ideal. Then there are finitely many prime ideals $\mathfrak{p}_1, \ldots, \mathfrak{p}_r$, each containing I, with

$$\mathfrak{p}_1\mathfrak{p}_2 \cdots \mathfrak{p}_r \subseteq I$$

***Proof*:**
Let Σ be the collection of proper ideals of R admitting no such family of primes, and suppose $\Sigma \neq \emptyset$. Since R is Noetherian, Σ has a maximal element I by proposition 23.1.3(2).

Step 1: the maximal counterexample is not prime. Were I prime, $r = 1$ and $\mathfrak{p}_1 = I$ would satisfy the conclusion. So there are $a, b \in R \setminus I$ with $ab \in I$. Put $J = I + (a)$ and $J' = I + (b)$; both strictly contain I. Since $ab \in I$ and I is an ideal,

$$JJ' = (I + (a))(I + (b)) \subseteq I \cdot I + I(b) + (a)I + (ab) \subseteq I$$

Step 2: both are proper. If $J = R$ then $J' = JJ' \subseteq I$, contradicting $J' \supsetneq I$; symmetrically $J' \neq R$. So J and J' are proper ideals strictly containing I.

Step 3: descend. By maximality of I in Σ, neither J nor J' lies in Σ, so there are primes $\mathfrak{p}_1, \dots, \mathfrak{p}_s \supseteq J$ with $\mathfrak{p}_1 \cdots \mathfrak{p}_s \subseteq J$ and primes $\mathfrak{q}_1, \dots, \mathfrak{q}_t \supseteq J'$ with $\mathfrak{q}_1 \cdots \mathfrak{q}_t \subseteq J'$. Then

$$\mathfrak{p}_1 \cdots \mathfrak{p}_s \mathfrak{q}_1 \cdots \mathfrak{q}_t \subseteq JJ' \subseteq I$$

and each of these primes contains J or J', hence contains I. So $I \notin \Sigma$, a contradiction, and $\Sigma = \emptyset$ as we sought to show.

Over a domain the primes so produced are automatically nonzero, since they contain I. That is the form the theory of Dedekind domains actually consumes:

Corollary 23.1.6: Nonzero Ideals Contain Products of Nonzero Primes

Let R be a Noetherian domain and let $I \subsetneq R$ be a nonzero proper ideal. Then I contains a product of finitely many *nonzero* prime ideals, each containing I.

***Proof*:**
Take $\mathfrak{p}_1, \dots, \mathfrak{p}_r$ as in proposition 23.1.5. Each $\mathfrak{p}_i$ contains I, and $I \neq 0$, so each $\mathfrak{p}_i$ is nonzero.

We will soon encounter rings that satisfy the descending chain condition (commonly abbreviated to D.C.C). Such rings are called *Artinian rings*. For the following result, let us upgrade definition 3.7.6 for modules:

Definition 23.1.7: Chain of Modules and Composition Series

Let M be a module. Then a *chain* of submodule of M is a sequence (M_i) of submodules st

$$M = M_0 \supsetneq M_1 \supsetneq \cdots \supsetneq M_n = 0$$

where the length of the chain is the number of $\supsetneq$. A maximal chain is called a *composition series* of M (equivalently, each M_{i-1}/M_i is *simple*. IF the chain is of infinite length, we shall say that M does not have a composition series.

Proposition 23.1.8: Finite Length, then Length is Invariant

Let M have a composition series of length n. Then every composition series of M has length n, and every chain in M can be extended to a composition series.

***Proof*:**
Let $\ell(M)$ denote the least length of composition series of a module M To get the desired result, let us prove a few results:

1. $N \subseteq M \Rightarrow \ell(N) \leq \ell(M)$, with equality iff $N = M$. Let (M_i) be a composition series of M of minimum length, and take $N_i = N \cap M_i$. Then $N_{i-1}/N_i \subseteq M_{i-1}/M_i$, which is simple, so each N_{i-1}/N_i is 0 or all of M_{i-1}/M_i; dropping repetitions gives a composition series of N of length $\leq \ell(M)$, and $\ell(N) = \ell(M)$ forces $N_i = M_i$ for all i, i.e. $N = M$

2. each $M_i \subsetneq M$ have length $\leq \ell(M)$. To see this, we may make a new chain with M_0 as the starting point:
$$M = M_0 \supsetneq M_1 \supsetneq \cdots \supsetneq M_k = 0$$
which by part 1 give us:
$$\ell(M) = \ell(M_0) \geq \ell(M_1) \geq \cdots \geq \ell(M_k) = 0$$

3. Take any composition series of M. Then if it has length k, it must be that $k \leq \ell(M)$ by part (2). As $\ell(M)$ is the least length of a composition series, also $k \geq \ell(M)$, so $k = \ell(M)$. Hence, all composition series have the same length.

Finally, consider any chain for M. If its length is $\ell(M)$, by (2) it must be a composition series, if its length is less than $\ell(M)<$ it cannot be a composition series, and hence cannot be maximal. There does exists a lengthening by a new term, which as the number of possible terms that can be added is of finite length we may continue until we have a series of length $\ell(M)$, completing the proof.

23.2 Hilbert Basis Theorem

Recall from theorem 11.1.1 that if F is a field, then $F[x]$ is a Euclidean domain. By corollary 11.2.4, $F[x_1, x_2, \ldots]$ is a Unique Factorization Domain. However, of all the condition's on rings we have covered they are not necessarily stronger than Unique Factorization Domains (with the counter-example being example 11.2.5 where $\mathbb{Z}[x, y]$ is a UFD but not a PID). If we loosen the condition from the ideals be generated by a single element to being generated by *finitely many* elements (i.e. a Noetherian ring), then we in fact get that extending by an indeterminate x does not affect the finiteness condition on ideals.

Theorem 23.2.1: Hilbert's Basis Theorem (HBT)

Let R be a Noetherian ring. Then $R[x]$ is a Noetherian ring

If you know some linear algebra, the term "basis" is not like the term basis in linear algerba. It is because of an archaic use of the word basis when Hilbert formulated the theorem near the end of the 19th century, where it had a closer to "generation" than basis.

***Proof*:**

Recall that if $p(x) = a_nx^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0$, then a_n is the leading coefficient of $p(x)$. This terminology will often be used in this proof.

Let $I \subseteq R[x]$ be an ideal. The trick is to somehow make I linked to an ideal of R (which is finitely generated since R is Noetherian). Let L be the set of all leading coefficients of the ideal I. Then L is an ideal. First, $0 \in I$, so $0 \in L$. Next, take $f, g \in I$ be two polynomials in I so that $f = ax^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0$ and $g = bx^m + b_{n-1}x^{m-1} + \cdots + b_1x + b_0$ with leading coefficients a and b and degrees n and m respectively, with $n \geq m$, so that $a, b \in L$. Multiplying the lower-degree polynomial by a power of x to equalize degrees, $rx^{n-m}g \in I$ has degree n and leading coefficient rb, so $f - rx^{n-m}g \in I$ has degree-n coefficient $a - rb$; hence $a - rb \in L$ whenever it is nonzero. Thus L is closed under subtraction and absorbs multiplication by R, so L is an ideal. Now, since R is a Noetherian ring and L is an ideal of R, L is finitely generated, say $L = \langle a_1, a_2, ..., a_n \rangle$. Then for each a_i, there is a polynomial f_i that has a_i as it's coefficient. Let's say e_i is the degree of f_i, so that the set $e_1, e_2, ..., e_n$ represents the degree's of the polynomials representing the generators of L. Let $N = \max\{e_1, e_2, ..., e_n\}$.

Next, we will construct a couple of smaller ideals. Let $d \in \{0, 1, 2, ..., N-1\}$ (i.e. d is strictly smaller than the largest degree N) and define $L_d \subseteq L$ to be the set of all leading coefficients of polynomials of I of degree d, together with 0. Then L_d is also an ideal of R as can be checked by a similar method as last proof. Since R is Noetherian, there exists a set of generators for L_d, say $L_d = \{b_{d,1}, b_{d,2}, ..., b_{d,k_d}\}$. For each generator of L_d, there is a polynomial $f_{d,i} \in I$ of degree d that has the generator $b_{d,i}$ as its leading coefficient.

Now, we will show that

$$I = \langle f_1, f_2, ..., f_n, f_{1,1}, f_{1,2}, ...f_{1,k_1}, f_{2,1}, ..., f_{N-1,k_{N-1}} \rangle$$

that is, I is generated by the polynomial f_i and the polynomials $f_{d,i}$. Since there are finitely many of them, I would be finitely generating completing the proof. To show this, let I' represent the right hand side. Then $I' \subseteq I$, since every generator of I' is in I, and I' is the smallest set that contains those generators. So, let's prove $I \subseteq I'$, and take a $f \in I$.

If $\deg(f) \geq N$, then since $f \in I$, it's leading coefficient (say a) is in L: $a \in L$. Then since L is finitely generated, it is an R-linear combination of the generators of L: $r_1a_1 + r_2a_2 + \cdots + r_na_n$. From this, we can define a new polynomial $g_1 = r_1x^{d-e_1}f_1 + r_2x^{d-e_2}f_2 + \cdots + r_nx^{d-e_n}f_n$ with the same leading coefficient a of f that is in I'. Then

$$f - g_1$$

is a polynomial in I of degree less than $\deg(f)$. If $\deg(f - g_1)$ is still greater than or equal to N, then repeat the same process, making the polynomial $(f - g_1) - g_2$. Continue on this way till we get a polynomial of degree less than N:

$$f - g_1 - g_2 - \cdots - g_\ell = f - (g_1 + g_2 + \cdots + g_\ell)$$

Let's label this above polynomial f'. Note that the sum of the g_i's can be re-written as an R-linear combination of elements of I' since they all belong to I':

$$f - (\alpha_1 f_1 + \alpha_2 f_2 + \cdots + \alpha_n f_n)$$

Now, $\deg(f') < N$. Since $f' \in I'$, it's leading coefficient (say a) is in L_d: $a \in L_d$. Then since L_d is finitely generated, it is an R-linear combination of the generators of L_d: $a = r_1 b_{d,1} + r_2 b_{d,2} + \cdots + r_{k_d} b_{d,k_d}$. From this, we can define a new polynomial $h_1 = r_1 f_{d,1} + r_2 f_{d,2} + \cdots + r_{k_d} f_{d,k_d}$ with the same leading coefficient as f' that is in I'. Then

$$f' - h_1$$

Is of degree less than f'. Just as before, we can continue this procedure, which will terminate once the degree reaches 0:

$$f' - h_1 - h_2 - \cdots - h_p = f' - (h_1 + h_2 + \cdots + h_p)$$

Note that $\sum_i h_i$ can be decomposed into a sum of polynomials with leading coefficients from L_d:

$$f' - (\beta_{1,1} f_{1,1} + \beta_{1,2} f_{1,2} + \cdots + \beta k, k_d f_{k,k_d})$$

Since our algorithm terminated after we have subtacted the constant (that is, the leading term of L_0), we are left with:

$$f - (g_1 + g_2 + \cdots + g_\ell + h_1 + h_2 + \cdots + h_p) = 0$$

which implies $f = g_1 + g_2 + \cdots + g_\ell + h_1 + h_2 + \cdots + h_p$. Re-writing slightly, we get that

$$f = \alpha_1 f_1 + \alpha_2 f_2 + \cdots + \alpha_n f_n + \beta_{1,1} f_{1,1} + \beta_{1,2} f_{1,2} + \cdots + \beta k, k_d f_{k,k_d}$$

which shows that f is a combination of elements of I' and so $f \in I'$. Since f was arbitrary, we cna conclude that $I \subseteq I'$.

Along with the quick assertion earlier that $I' \subseteq I$, that shows us that $I = I'$, showing that I was finitely generated. Since I was an arbitrary ideal, we are left with saying that every ideal of $R[x]$ is finitely generated, showing that $R[x]$ is also Noetherian, as we sought to show.

The result is not necessarily true if R is not Noetherian

In the exercises there will be the outlining of an alternative proof which will give a different insight in the exercises.

Corollary 23.2.2: HBT on multi-variable Polynomials

Let R be a Noetherian ring. Then $R[x_1, x_2, ..., x_n]$ is a Noetherian ring

***Proof*:**
Since R is Noetherian, by the Hilbert Basis Theorem, $R[x_1]$ is Noetherian. Since $R[x_1]$ is Noetherian, $(R[x_1])[x_2] = R[x_1, x_2]$ is Noetherian. Continuing inductively, we see that $R[x_1, x_2, ..., x_n]$ is Noetherian, as we sought to show

Corollary 23.2.3: f.g. K-algebra then Finitely Presented

Let R be a finitely generated k-algebra. Then R is *finitely presented*, meaning

$$R \cong \frac{k[x_1, ..., x_n]}{(f_1, ..., f_m)} = \frac{k[x_1, ..., x_n]}{I}$$

where I is finitely generated.

***Proof*:**
As R is finitely generated as a k algebra:

$$R \cong \frac{k[x_1, ..., x_n]}{I}$$

for some finitely many variable $x_1, ..., x_n$ and an ideal $I \subseteq R$. By corollary 23.2.2 R is Noetherian, hence I is *finitely generated*: $I = (f_1, ..., f_m)$. But then R is finitely presented, completing the proof.

You can now return to example 10.1.18 to fully appreciate how there exist Atomic Domains which are not Noetherian Domains.

This theorem is very powerful. Since $R[x]$ is an ideal of itself, it is also finitely generated and the polynomials which generate it finitely can be characterized by their leading coefficients. In section 23.3, we will expand this theory further find a computational way of getting these polynomials.

Since a field is Noetherian (only ideal is (1) and (0), both clearly finite), Hilbert's Basis Theorem and induction immediately give:

Corollary 23.2.4: HBT on Polynomial Rings of Several Variables

Every ideal in the polynomial ring $F[x_1, x_2, ..., x_n]$ with coefficients from a field F is finitely generated

***Proof*:**
A field is Noetherian, so by corollary 23.2.2 the ring $F[x_1, \dots, x_n]$ is Noetherian; every ideal is therefore finitely generated by proposition 23.1.3.

Recall that finitely generated R-algebras are quotient of polynomial rings R. By HBT, we have the following

Corollary 23.2.5: Finitely Generated Algebras Are Noetherian

Let R be Noetherian and let A be a finitely generated R-algebra. Then A is Noetherian.

***Proof*:**
Write $A \cong R[x_1, \dots, x_n]/I$ as a quotient of a polynomial ring. By corollary 23.2.2 the polynomial ring is Noetherian, and by proposition 23.1.2 so is its quotient A.

Polynomial rings being over a Noetherian ring being Noetherian is central to to the study of algebras thanks to the universal property of Algebras

(A word on how Artinian rings are the opposite with D.C.C. We won't study them till chapter 28, since they sort of seem like a "oh wow, Noetherian rings can do so much, what about the opposite?" and then we realise that Artinian ring implies Noetherian ring, and it has so much structure that we can easily classify them all with no further fought, so we'll just leave that for later. All in all, the Noetherian condition turns out to be "more interesting")

23.2.6 Without Assuming Noetherian Let $R = k[x_1, ..., x_n, ...]$ and $A = R/(x_1, ..., x_n, ...)$. Then A is finitely generated, but the ideal is not finitely generated. In algebraic geometry, there is often the need to work with rings that look like quotients of polynomial rings (ex. polynomial rings over local rings). Thus, it common to work with *finitely presented* rings.

Exercise 23.2.1

1. Alternative HBT: (the one uses Diksons lemma)
2. Consider the chain $k[[x]]] \subseteq k[[x^{1/2}]] \subseteq k[[x^{1/6}]] \subseteq \cdots \subseteq k[[x^{1/n!}]]$. Taking the union of all of these forms an object called the *Puisseaux series*. Is the Puisseaux seris a ring, and if so is the Puisseaux series Noetherian?
3. Let S be a finitely generated R-algebra, where R is Noetherian. Prove that S is Noetherian.
4. We know that ideals of $k[x]$ are generated by 1 element if k is a field. By Hilbert's basis theorem, we know that every ideal of $k[x, y]$ is finitely generated. Is it true that ideals of $k[x, y]$ is generated by at most 2 elements if k is a field?
5. Which of the following are Noetherian Rings:
    1. $\mathbb{Z}[x, 1/x]$ as a subring of $\mathbb{Q}$
    2. $R := \mathbb{R} + x\mathbb{C}[x]$
    3. $R := k + xL[x]$ where $[L : k] < \infty$ is a finite field extension
    4. $R := k + xk[x, y]$ as a subring of $k[x, y]$, k a field.
6. Let M be an R-module over a Noetherian ring R. Show that there exists a $x \in M$ such that $\mathrm{Ann}_R(x)$ is a prime ideal (large hint: consider the set $\mathcal{S} = \{\mathrm{Ann}_A(x) \mid x \in M\}$ of ideals, and use the fact that R is Noetherian to conclude $\mathcal{S}$ has a maximal element. Is this element prime?)

23.3 Gröbner Bases

Hilbert's basis theorem guarantees that every ideal of $k[x_1, \ldots, x_n]$ is finitely generated, but its proof is not constructive: it exhibits no canonical generating set and no way to decide whether a given polynomial lies in an ideal. *Gröbner bases* repair both defects. They provide, for each ideal and each choice of monomial order, a distinguished finite generating set against which a multivariate division algorithm gives unique remainders, turning ideal membership into a finite computation. This is the computational basis of commutative algebra and algebraic geometry; the standard reference is Cox, Little, and O'Shea, *Ideals, Varieties, and Algorithms.*

Fix the polynomial ring $S = k[x_1, \dots, x_n]$ over a field k, and write a monomial as $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$ for $\alpha \in \mathbb{N}^n$.

Definition 23.3.1: Monomial Order

A *monomial order* on S is a total order $\preceq$ on the monomials of S (equivalently on $\mathbb{N}^n$) such that

1. $\preceq$ is a well-order: every nonempty set of monomials has a least element; and
2. it is compatible with multiplication: if $x^\alpha \preceq x^\beta$ then $x^\gamma x^\alpha \preceq x^\gamma x^\beta$ for all $\gamma \in \mathbb{N}^n$.

The prototype is the *lexicographic order*: $x^\alpha \succ x^\beta$ when the leftmost nonzero entry of $\alpha - \beta$ is positive. The *graded* and *graded reverse* lexicographic orders first compare total degree $|\alpha| = \sum_i \alpha_i$ and break ties lexicographically; the latter is usually fastest in practice. Fixing a monomial order, every nonzero $f \in S$ has a largest monomial.

Definition 23.3.2: Leading Term

Let $\preceq$ be a monomial order and $0 \neq f \in S$. The *multidegree* $\operatorname{multideg}(f)$ is the $\preceq$-largest α with x^α occurring in f; the corresponding term is the *leading term* $\operatorname{LT}(f)$ and its monomial the *leading monomial* $\operatorname{LM}(f)$. For an ideal I, its *leading term ideal* is $\operatorname{LT}(I) = (\operatorname{LT}(f) : 0 \neq f \in I)$, a monomial ideal.

Compatibility makes leading terms multiplicative, $\operatorname{LT}(fg) = \operatorname{LT}(f)\operatorname{LT}(g)$, and the well-order axiom is exactly what makes the following algorithm terminate.

Theorem 23.3.3: Multivariate Division Algorithm

Fix a monomial order and an ordered tuple $(g_1, \dots, g_s)$ of nonzero polynomials. Then every $f \in S$ can be written

$$f = q_1 g_1 + \cdots + q_s g_s + r$$

where no monomial of the remainder r is divisible by any $\operatorname{LM}(g_i)$. It is produced by repeatedly subtracting the appropriate multiple of some g_i whenever $\operatorname{LM}(g_i)$ divides the current leading monomial, and otherwise moving the leading term into r.

***Proof*:**
Each step strictly lowers the $\preceq$-largest monomial not yet moved into r, so by the well-order property the process terminates; the stated condition on r holds by construction.

The remainder generally depends on the *order* of the g_i, and $r = 0$ is sufficient but not necessary for $f \in (g_1, \dots, g_s)$. Both defects vanish for a special generating set.

Definition 23.3.4: Gröbner Basis

Let $I \subseteq S$ be a nonzero ideal and $\preceq$ a monomial order. A finite set $G = \{g_1, \ldots, g_s\} \subseteq I$ is a *Gröbner basis* of I if the leading terms of G generate the leading term ideal:

$$\mathrm{LT}(I) = (\mathrm{LT}(g_1), \ldots, \mathrm{LT}(g_s))$$

Theorem 23.3.5: Existence and Membership

Every nonzero ideal $I \subseteq S$ has a Gröbner basis for any monomial order, and any Gröbner basis of I generates I. Dividing $f \in S$ by a Gröbner basis of I gives a remainder that is independent of the order of the divisors and is zero if and only if $f \in I$.

***Proof*:**
The monomial ideal $\mathrm{LT}(I)$ is finitely generated by finitely many $\mathrm{LT}(f_i)$ with $f_i \in I$ (*Dickson's lemma*, equivalently theorem 23.2.1); these f_i are a Gröbner basis. If G is a Gröbner basis and $f \in I$, division gives $f = \sum q_i g_i + r$ with $r \in I$ and no monomial of r divisible by any $\mathrm{LM}(g_i)$; were $r \neq 0$, then $\mathrm{LT}(r) \in \mathrm{LT}(I) = (\mathrm{LM}(g_i))$ would be divisible by some $\mathrm{LM}(g_i)$, a contradiction. Hence $r = 0$ and $f \in (G)$, so G generates I and membership is detected by the remainder. Two remainders of the same f differ by an element of I with no monomial divisible by a leading term, hence by 0; the remainder is unique.

Thus a Gröbner basis solves the *ideal membership problem*: $f \in I$ iff its Gröbner-basis remainder is 0. To compute one, we measure the failure of a generating set to be Gröbner through cancellations of leading terms.

Definition 23.3.6: S-polynomial

For nonzero $f, g \in S$ with $L = \mathrm{lcm}(\mathrm{LM}(f), \mathrm{LM}(g))$, the *S-polynomial* is

$$S(f,g) = \frac{L}{\mathrm{LT}(f)} f - \frac{L}{\mathrm{LT}(g)} g,$$

built so the leading terms of the two products cancel.

Theorem 23.3.7: Buchberger's Criterion

A finite generating set $G = \{g_1, \ldots, g_s\}$ of an ideal I is a Gröbner basis if and only if, for every pair $i \neq j$, the remainder of $S(g_i, g_j)$ on division by G is zero.

***Proof*:**
Necessity is immediate, since $S(g_i, g_j) \in I$ has zero remainder by theorem 23.3.5. For sufficiency, the content is that every cancellation of leading terms among the g_i is an S-polynomial syzygy; when all S-polynomial remainders vanish this forces $\mathrm{LT}(I) = (\mathrm{LM}(g_i))$. The details are in Cox, Little, and O'Shea.

The criterion is a decision procedure, and completing a set to satisfy it is an algorithm.

Theorem 23.3.8: Buchberger's Algorithm

Given generators $\{f_1, \dots, f_m\}$ of I, start with $G = \{f_1, \dots, f_m\}$; repeatedly compute the remainder r of each $S(g_i, g_j)$ on division by G, adjoining r to G whenever $r \neq 0$; stop when all S-polynomial remainders are zero. This terminates and returns a Gröbner basis of I.

***Proof*:**
Each adjoined remainder r has leading monomial outside the current $(\mathrm{LM}(g))$, so the leading term ideals strictly increase; by the ascending chain condition in the Noetherian ring S (theorem 23.2.1) this stabilizes, so finitely many elements are added and the loop halts. On termination all S-polynomial remainders vanish, so G is a Gröbner basis by theorem 23.3.7.

Discarding redundant generators and scaling leading coefficients to 1 yields the unique *reduced* Gröbner basis of I for a given order, a genuine canonical form: two ideals coincide iff their reduced Gröbner bases (for the same order) are equal.

Gröbner bases make ideal membership *decidable*, but not cheap. In the worst case the degrees occurring in a reduced Gröbner basis, and hence the running time of Buchberger's algorithm, are doubly exponential in the number of variables, and ideal membership for $k[x_1, \dots, x_n]$ is EXPSPACE-complete (Mayr and Meyer). The abstract finiteness handed to us by Hilbert's basis theorem thus conceals real computational hardness: knowing that an ideal is finitely generated is a long way from being able to compute with it.

23.4 Localization

Localization shall be the generalization of section 9.5 to commutative rings and modules in general (including ones with zero-divisors). With the introduction of the tensor product, localization shall be shown to have the important property of producing *flat module*, which shall have important geometric consequences in algebraic geometry. From this, we shall define the notion of local properties and the famous Nakayama lemma which shall allow many proofs to be done "locally". Concluding this section, we shall wrap up the correspondence between primes of a ring R and primes in its integral extension.

The term "localization" comes from algebraic geometry, where this process of localizing mirrors the process of "localizing" for manifolds. If you have done some differential geometry, recall that the tangent space at a point p has *cotangent* space $\mathfrak{m}_p/\mathfrak{m}_p^2$, where $\mathfrak{m}_p$ is the maximal ideal of germs vanishing at p (the tangent space is its dual). Localizing shall correspond to this process, where "inverting" elements around a point is the same as a function on a manifold being invertible on a small enough local neighborhood where $f(p) \neq 0$. The reader may question this correspondence, for in differential geometry we are working with smooth functions over a [smooth] manifold, while in the algebraic case we simply have a [commutative] ring. However, the correspondence is more equivalent than it may at first seem. It shall be particularly clear by the end of section 32.5, where it is shown that there is a way of thinking of all commutative rings as a set of "functions" on a special geometric space (the geometric space is called an [affine] *scheme*), hence there is a direct parallel between smooth functions on the geometric object of a manifold and commutative rings where each element is interpreted as a function on a scheme.

23.4.1 Localization of Rings

This is a generalization of the constructing of ring of fraction from theorem 9.5.1 by allowing the set that's closed under multiplication D to have zero divisors. This will imply that R need not be embedded into $D^{-1}R$, but the universal property is still satisfied. Furthermore, we will have to solve the problem of elements that "should" be zero being equal to nonzero elements. If $a \in R$ and $d \in D$ where $as = 0$, then:

$$a = \frac{a}{1} = \frac{as}{s} = \frac{0}{s} = 0$$

this issue will be addressed in the proof:

Theorem 23.4.1: Universal Property of Localization

Let R be a commutative ring and D a multiplicatively closed subset containing 1. Then there is a ring $D^{-1}R$ and a homomorphism $\iota\colon R \to D^{-1}R$ with $\iota(D) \subseteq (D^{-1}R)^{\times}$ such that for every ring S and homomorphism $\psi\colon R \to S$ with $\psi(D) \subseteq S^{\times}$, there is a *unique* homomorphism $\Psi\colon D^{-1}R \to S$ making the following diagram commute:

$$\begin{tikzcd} D^{-1}R \arrow[dr, "\Psi"] & \\ R \arrow[u, "\iota"] \arrow[r, "\psi"'] & S \end{tikzcd}$$

The pair $(D^{-1}R, \iota)$ is universal among all such (S, ψ).

***Proof*:**
A lot of this proof is similar to theorem 9.5.1 (Ring of Fractions) and so it will be quickly presented pointing out where the generalization of D having zero divisors makes a difference.

Let $R \times D$ have the equivalence relation

$$(a, b) \sim (c, d) \;\Leftrightarrow\; x(ad - bc) = 0 \text{ for some } x \in D$$

Which is essentially the same as in theorem 9.5.1. The difference between the proof in the case where D does not have zero divisors' is with the fact that the terms are scaled by some $x \in D$. This is to make sure elements that are zero-divisors will belong to the [0] (as we'll show in the proceeding corollary). Usually, the equivalence class $[(r, d)]$ is denoted $\frac{r}{s}$ or r/s so that

$$\frac{a}{b} = \frac{c}{d} \text{ if and only if } x(ad - bc) = 0 \qquad \text{for some } x \in D$$

Define

$$\frac{r}{d} + \frac{s}{e} := \frac{re + sd}{de} \qquad \frac{r}{d}\frac{s}{e} := \frac{rs}{de}$$

Then these two operations form a well-defined commutative ring $(R \times D)/\sim$; this ring is denoted $D^{-1}R$. Note that $\frac{d}{1}$ is a unit in $D^{-1}R$ for every $d \in D$, with inverse $\frac{1}{d}$.

Define $\iota : R \to D^{-1}R$ by $\iota(r) = \frac{r}{1}$. This map defines a natural ring homomorphism. Using this map, if the map $\varphi : R \to S$ maps D to units, we can define the map $\Psi : D^{-1}R \to S$ by defining:

$$\Psi(\frac{r}{d}) = \psi(r)\psi(d)^{-1}$$

This map is well-defined: Notice if $\frac{r}{d} = \frac{s}{e}$ then by definition of the equivalence relation, for some $x \in D$, $x(re - sd) = 0$ Thus $\varphi(x(re - sd)) = \varphi(x)(\varphi(re) - \varphi(sd)) = 0$. Since x is a unit in S and S is a commutative ring, s is not a zero-divisor, and so $\varphi(re) - \varphi(sd) = 0$ Moving values around, we get

$$\varphi(r)\varphi(d)^{-1} = \varphi(s)\varphi(e)^{-1}$$

Thus, Ψ is a well-defined ring homomorphism. Furthermore, by construction, $\Psi \circ \iota = \varphi$

Finally, Ψ is unique. If there was another Ψ' such that $\Psi' \circ \iota = \varphi$, then:

$$\varphi(r) = \Psi'(\iota(r)) = \Psi'\left(\frac{r}{1}\right)$$

Thus Ψ' maps $\frac{r}{1}$ in the same way as Ψ. For the $\frac{1}{d}$ terms, notice that

$$\frac{1}{d} = \left(\frac{d}{1}\right)^{-1}$$

and so $\varphi(d) = \Psi'(\frac{d}{1})$, and so, by properties of ring homomorphisms

$$\Psi'\left(\frac{d}{1}\right)^{-1} = \Psi'\left(\frac{1}{d}\right)$$

showing that $\Psi' = \Psi$, fulfilling the last condition needed to prove for the universal property

As before, $D^{-1}R$ is still called the ring of fractions. However, there is a more common name with a geometric intuition:

Definition 23.4.2: Localization of R at D

Let R be a commutative ring and D be a multiplicatively closed subset of R. Then the ring $D^{-1}R$ produced in the previous theorem is the *ring of fractions of R with respect to D*, or the *localization of R at D*. This ring is also sometimes denoted $R[D^{-1}]$.
If $D = \{f^n \mid n \in \mathbb{Z}_{\geq 0}\}$ for some $f \in R$, we usually denote $D^{-1}R = R_f$.

If D is not a multiplicatively closed set, we define $R[D^{-1}] := R[\overline{D}^{-1}]$ where $\overline{D^{-1}}$ is the multiplicative closure of D.

The fact that D can contain zero divisors means that ι can now have non-trivial kernel:

Corollary 23.4.3: Kernel of ι

Let ι be the natural inclusion of R into $D^{-1}R$ for some appropriate D. Then

1. $\ker(\iota) = \{r \in R \mid xr = 0 \text{ for some } x \in D\}$. In particular, ι is an injection if and only if D doesn't contain 0 or zero-divisors
2. $D^{-1}R = 0$ if and only if D contains 0 or a nilpotent element (since D is multiplicatively closed)

***Proof*:**

1. If $\iota(r) = \frac{r}{1} = 0$, then we have that $(r, 1) \sim (0, 1)$ and so $x(1r - 0) = xr = 0$ for some $x \in D$. Thus, ι is an injection if and only if D does not contain 0 or zero-divisors
2. $D^{-1}R = 0$ if and only if $r/1 = 0/1$ for all r i.e. $(r, 1) \sim (0, 1)$ if and only if $(1, 1) \sim (0, 1)$ if and only if $x \cdot 1 = 0$. If $x = 0$, we're done, and if not then as D is multiplicatively closed then $x^n \in D$ for each $n \in \mathbb{N}$ and so if $x^n = 0$ then x is nilpotent and $x^n \cdot 1 = 0$, completing the proof.

This let's us get a sense of how adding zero-divisors to D changes the resulting localization of R at D.

Example 23.4.4: Localization
All examples in section 9.5 are valid examples, including the trivial one of any field $\mathbb{F}$, $\mathbb{Z}$ to $\mathbb{Q}$ with $D = \mathbb{Z} - \{0\}$, and $\mathbb{F}[x]$ to $\mathbb{F}(x)$ with $D = F[x] - \{0\}$. We shall give some more interesting examples here (all rings are commutative):

1. If R is an integral domain, then we can always take $D = R - \{0\}$. The ring $D^{-1}R$ is then always a field, and is called the *field of fractions of* R, and is sometimes denoted Q. Then for any smaller multiplicatively closed subset E, $E^{-1}R$ is a subring of Q with elements $r/e \in Q$ with $r \in R$ and $e \in E$
2. Let R be a ring and $f \in R$. Define $D = \{f^n \mid n \in \mathbb{Z}_{\geq 0}\}$. Then we'll denote $D^{-1}R = R_f$. Then R_f is a ring in which the element f has become a unit. In a sense, it is now possible to solve the question
$$fx - 1 = 0$$
In fact, this intuition can be made more rigorous showing that
$$R_f \cong \frac{R[x]}{fx - 1}$$
This is similar to how we worked with field extensions, and in fact is an important link to connect the intuition of localization to a geometric intuition. Keep this example in the back of your mind for now.
3. Consider $R = k[x, y]/(xy)$, take $\overline{x} \in R$, and consider $R_{\overline{x}}$. Then the the map $\iota : R \to R_{\overline{x}}$ is no longer injective as:
$$\overline{y} = \frac{\overline{xy}}{\overline{x}} = \frac{\overline{0}}{\overline{x}} = \overline{0}$$
4. This example is called *localizing at a prime*. Let R be a ring and P a prime ideal of R. Then the set $D = R - P$ is multiplicatively closed. To see that, let $x, y \in D$. If it were the case that $xy \in P$, then either $x \in P$ or $y \in P$. But then one of them wouldn't be in D, a contradiction. Thus, D is indeed multiplicatively closed. The localization $D^{-1}R$ is called the *localization of* R *at* P and is commonly denoted as R_P. In this ring, all elements not in P become units. As a simple example, take $R = \mathbb{Z}$ and $P = (p)$ for some prime p. Then by the nice divisibility properties of integers, the set $\mathbb{Z}_{(p)}$ can with a little work be shown to be:
$$\mathbb{Z}_{(p)} = \left\{ \frac{a}{b} \in \mathbb{Q} \;\middle|\; p \nmid b \right\}$$

that is, it is all elements of $\mathbb{Q}$ for which the denominator is not divisible by p. Can you prove that $\mathbb{Z}_{(p)}$ has only one maximal ideal (and hence, is a local ring)? Is this true of all localization at primes?

It is tempting to say that if $R_{(p)}$ is the localization of a ring R at the prime p and $a/b \in R_{(p)}$ if $b \notin (p)$, however this is not necessarily the case as we are dealing with an equivalence class! The reader may then ask if we can take a better representative (like the representative a/b in $\mathbb{Z}$ such that $\gcd(a, b) = 1$), however R is not necessarily a UFD and so this may not be well-defined.

5. The following examples is a way to "localise" functions. Let k be a field and V be any set. Define R to be functions from V to k containing the constant functions ($F \subseteq \mathrm{Hom}^{+\text{ constants}}_{\mathbf{Set}}(V, k)$) with $+$ and $\cdot$ defined by component-wise addition and multiplication on the image: $R = (F, +, \cdot)$. For example, take all continuous functions from $[0, 1]$ to $\mathbb{R}$. For any $a \in V$, let $M_a \subseteq R$ be the set of all functions that vanish at a: $f(a) = 0$. Then M_a is the kernel of the evaluation map from R to k:
$$\mathrm{ev}_a : R \to k \qquad f \mapsto f(a) \qquad \ker(\mathrm{ev}_a) = M_a$$
Since R contains constant functions, ev_a is surjective and so $k \cong R/M_a$. By proposition 9.4.19, M_a is a maximal idea, and hence a prime ideal. Thus, we can define the localization of R at M_a to be:
$$R_{M_a} = \left\{ \frac{f}{g} \;\middle|\; f, g \in R,\ g(a) \neq 0 \right\}$$
where ev_a is extended as:
$$(f/g)(a) = f(a)/g(a)$$
This then makes R_{M_a} a way of defining rational functions.

6. Let $R = \mathbb{C}[x]$, and take $p = (x - a)$. Since $\mathbb{C}[x]$ is a Principal Ideal Domain and $(x - a)$ is irreducible, $(x - a)$ is prime, and so we can define
$$\mathbb{C}[x]_{(x-a)} = \left\{ p(x)/q(x) \;\middle|\; x - a \nmid q(x) \right\}$$
which can be thought of all rational functions which do not vanish at a.

Localization has many nice geometric interpretations. As we will see in section 32.4, all algebraic varieties (i.e. irreducible algebraic sets) are related to the prime ideals. Hence, understanding how ideals of R correspond to ideals of $D^{-1}R$ will bring us to understanding a geometric connection.

For an ideal $I \subseteq R$, its *extension* ${}^{\iota}I$ is the ideal of $D^{-1}R$ generated by $\iota(I)$; since every such element can be written as a/d with $a \in I$ and $d \in D$, the notation $D^{-1}I$ is also used. For an ideal $J \subseteq D^{-1}R$, its *contraction* ${}^{\pi}J = \iota^{-1}(J)$ is an ideal of R, being the preimage of an ideal under the ring homomorphism ι.

Proposition 23.4.5: Ideals of Localization

Let R be a ring and $D^{-1}R$ be the localization of R at D for appropriate D. Then:

1. For every ideal $J \subseteq D^{-1}R$,
$$J = J^{ce}$$
As a consequence, every ideal of $D^{-1}R$ is an extension of an ideal in R, and every ideal of D^{-1} contracts to a distinct ideal in R

2. If $I \subseteq R$ is an ideal of R, then:
$$^{\pi}(^{\iota}I) = \{r \in R \mid dr \in I \text{ for some } d \in D\}$$
As a consequence, $I^e = D^{-1}R$ if and only if $I \cap D \neq \emptyset$

3. There is a bijection between the set of prime ideals with $P \cap D = \emptyset$ and the set of prime ideals of $D^{-1}R$:
$$\left\{\begin{matrix}\text{prime ideals of } R \text{ with} \\ P \cap D = \emptyset\end{matrix}\right\} \underset{(-)^c}{\overset{(-)^e}{\rightleftarrows}} \left\{\text{prime ideals of } D^{-1}R\right\}$$

4. If R is Noetherian, then $D^{-1}R$ is Noetherian. Similarly if R is Artinian

***Proof*:**

1. Notice that by construction, $^{\iota}(^{\pi}J) \subseteq J$. For the other direction, notice that for any $a/d \in J$ it is always the case that $a/1 = d(a/d) \in J$, that is there exists a a/d such that $d(a/d) = a/1$. Since $\iota(\pi(a/d)) = a/1$. and so by definition, of $^{\iota}(^{\pi}J)$, $(1/d)(a/1) = a/d \in {}^{\iota}(^{\pi}J)$ (since it closed by multiplication of elements from $D^{-1}R$.

2. Let $I' = \{r \in R \mid dr \in I \text{ for some } d \in D\}$ be the set in the question. We'll show $I' = {}^{\pi}(\lim I)$. For the $\subseteq$ direction, take $r \in I'$. Then by definition there exists a $d \in D$ such that $dr = a \in I$. Then $r/1 = a/d \in \lim I$, so contracting we get $r \in {}^{\pi}(\lim I)$. For the $\supseteq$ direction, take $r \in {}^{\pi}(\lim I)$. Then $r/1 = a/d \in \lim I$ for some $a \in I$ and $d \in D$. Then by the definition of the equivalence class, we have $x(dr - a) = 0$ for some $x \in D$, and hence $xdr = xa$ where $xa \in I$. Since $xd \in D$, $r \in I'$. The rest of the assertions of (2) follow quickly.

3. To map prime ideals from $D^{-1}R$ to R, recall that preimages of prime ideals are prime. Thus, by construction, the contraction must map prime ideals of $D^{-1}R$ to prime ideals that are disjoint from D.

   For the converse, let P be a prime ideal of R that is disjoint from D, and consider $Q = {}^{\iota}P$. We'll show Q is prime. Suppose $(a/d_1)(b/d_2) = (ab/d_1d_2) \in Q$. Then $ab/d_1d_2 = c/d$ for some $c \in P$ and $d \in D$. Then by definition of the equivalent relation, $x(dab - d_1d_2c) = 0$ for some $x \in D$. Since $xdab - xd_1d_2c = 0 \in P$ and P is closed under subtraction and left-multiplication of elements of R, it must be that $xdab = (xd)(ab) \in P$. Since P is disjoint from D, it must be that $ab \in P$. Since P is prime, either a or b is an element of P. Thus, either a/d_1 or b/d_2 is an element of Q, showing that Q is a prime ideal. Thus, extending prime ideals that are disjoint from D map to prime ideals in $D^{-1}R$.

Finally, by (2), since P is disjoint from D we have $P = {}^{\pi}({}^{\iota}P)$, showing that extending and contracting are inverses of each other, finishing the proof for (3).

4. Given some ascending chain of ideals in $D^{-1}R$, they contract to ascending chain of ideals in R. Since R is Noetherian, they stabilize. Thus, the ideals that get contracted must also stabilize. Similarly for Artinian Rings.

The ideal in part (2) of proposition 23.4.5 is given a name:

Definition 23.4.6: Saturated Ideal

Let R be a commutative ring, $I \subseteq R$ is an ideal and $D^{-1}R$ is the localization of R at D for appropriate D. Then *saturation* of the ideal I with respect to D is ${}^{\pi}(\lim I)$. If $I = {}^{\pi}(\lim I)$, then I is said to be *saturated* or *D-saturated* with respect to D

Geometrically, the prime-ideal bijection of proposition 23.4.5(3) identifies $\operatorname{Spec}(D^{-1}R)$ with the subspace of $\operatorname{Spec} R$ consisting of the primes disjoint from D. For $D = \{f^n \mid n \in \mathbb{Z}_{\geq 0}\}$ this is the distinguished open set $D(f) = \{\mathfrak{p} \in \operatorname{Spec} R \mid f \notin \mathfrak{p}\}$, so $\operatorname{Spec} R_f \cong D(f)$; dually $\operatorname{Spec} R/(f) \cong V(f)$, the closed set of primes containing f. Thus $\operatorname{Spec} R = D(f) \sqcup V(f)$ as sets, the two pieces being homeomorphic to $\operatorname{Spec} R_f$ and $\operatorname{Spec} R/(f)$ as subspaces (though $\operatorname{Spec} R$ is their topological coproduct only when $D(f)$ is also closed).

Proposition 23.4.7: Localization Property Preservation

Let R be a ring, $D \subseteq R$ a multiplicative set with $0 \notin D$, and $D^{-1}R$ the localization. Then the following properties of R are preserved in $D^{-1}R$:

1. no zero divisors
2. Noetherian
3. Integrally closed

For (3), R is understood to be an integrally closed domain, so that (1) makes $D^{-1}R$ a domain with the same fraction field.

***Proof*:**

1. Suppose $(a/s)(b/t) = 0$ in $D^{-1}R$. Then $uab = 0$ for some $u \in D$ by corollary 23.4.3, and $u \neq 0$ because $0 \notin D$, so $ab = 0$ in the domain R and hence $a = 0$ or $b = 0$. Thus $a/s = 0$ or $b/t = 0$.

2. Let $J \subseteq D^{-1}R$ be an ideal and put $I = \iota^{-1}(J)$, where $\iota\colon R \to D^{-1}R$. By proposition 23.4.5 every ideal of the localization is the extension of its contraction, so $J = D^{-1}I$. Since R is Noetherian, $I = (a_1, \ldots, a_n)$ for finitely many a_i, and then J is generated by $a_1/1, \ldots, a_n/1$: an element of J is a/s with $a \in I$, and writing $a = \sum r_i a_i$ gives $a/s = \sum (r_i/s)(a_i/1)$. Every ideal of $D^{-1}R$ is therefore finitely generated.

3. Write $K = \operatorname{Frac}(R)$, which by (1) is also the fraction field of $D^{-1}R$. Let $z \in K$ be integral

over $D^{-1}R$, say
$$z^n + \frac{a_{n-1}}{s_{n-1}} z^{n-1} + \cdots + \frac{a_1}{s_1} z + \frac{a_0}{s_0} = 0$$
with $a_i \in R$ and $s_i \in D$. Put $s = s_0 s_1 \cdots s_{n-1} \in D$ and multiply the relation by s^n, collecting powers of sz:
$$(sz)^n + \sum_{i=1}^{n} \frac{a_{n-i}\, s^i}{s_{n-i}} (sz)^{n-i} = 0$$
Each coefficient lies in R, since $s^i/s_{n-i} = s^{i-1} \prod_{j \neq n-i} s_j$ and $i \geq 1$. So sz is integral over R, hence $sz \in R$ because R is integrally closed, and therefore $z = (sz)/s \in D^{-1}R$, as we sought to show.

Exercise 23.4.1

1. Let R be a ring, f be an element of R ,and R_f be the localization of R at $\{f^n \mid n \in \mathbb{Z}_{\geq 0}\}$. Then
   1. $$R_f \cong \frac{R[x]}{fx-1}$$
   2. $R_f \cong R_{f^n}$ for $n \geq 1$
   3. If f is nilpotent, then $R_f = 0$
2. Let R be a normal domain and S a multiplicatively closed set. Then $S^{-1}R$ is a normal domain

23.4.2 Localization of Modules

Since every ring is a module over itself, we can see how localization works for this special case of modules. We extend the concept of localization now to more general modules. The construction is essentially the same thing: if M is an R-module, and $D \subseteq R$ is multiplicatively closed, define the same equivalence class on $M \times D$ and the operation's on $(M \times D)/\sim$ as
$$\frac{m}{d} + \frac{m'}{d'} = \frac{d'm + dm'}{dd'} \quad \text{and} \quad r \cdot \frac{m}{d} = \frac{r \cdot m}{d}$$
Then this is indeed a module with the proof proceeeding essentially the same as theorem 23.4.1, and so is left as a sanity check. Just like $R[D^{-1}]$ is the localization of R at D, we will denote $M[D^{-1}]$ to be the localization of M at D. Thus, an R-module M is extended to an $D^{-1}R$-module $M[D^{-1}]$.

Proposition 23.4.8: Zeros of $M[D^{-1}]$

Let R be a ring, $D \subseteq R$ be a multiplicatively closed subset, and M be a module over R. Then m goes to 0 in $M[U^{-1}]$ if and only if m is annihilated by an element $d \in D$. If M is finitely generated, then $M[U^{-1}] = 0$ if and only if M is annihilated by an element in D.

If R lies in a field K and M is an R-module that is contained in a k-vector space, then $\iota : M \to D^{-1}M$ is injective iff $M \xrightarrow{\cdot s} M$ is injective for all $s \in D$.

***Proof*:**
Exercise

Localization modules works well with homomorphisms: let $\varphi : M \to N$ be an R-module homomorphism. Then by the universal property, we see that this is extended to an $D^{-1}R$-module homomorphism $D^{-1}\varphi : M[D^{-1}] \to N[D^{-1}]$ by mapping:

$$D^{-1}\varphi\left(\frac{m}{d}\right) = \frac{\varphi(m)}{d}$$

Furthermore, $D^{-1}(\varphi \circ \psi) = (D^{-1}\varphi) \circ (D^{-1}\psi)$, i.e. $D^{-1}(-)$ is a functor from Mod_R to $\text{Mod}_{D^{-1}R}$. We may ask for certain properties of this functor, most basic perhaps would be if $D^{-1}(-)$ is an exact functor, that it preserves kernels and cokernels. This is the case:

Proposition 23.4.9: Localization Is Exact

Let M_1, M_2, M_3 be R-modules such that $0 \to M_1 \xrightarrow{f} M_2 \xrightarrow{g} M_3 \to 0$ is a short exact sequence. Then

$$0 \to M_1[D^{-1}] \xrightarrow{D^{-1}f} M_2[D^{-1}] \xrightarrow{D^{-1}g} M_3[D^{-1}] \to 0$$

is a short exact sequence, that is $D^{-1}(\underline{\hspace{2em}})$ is an exact functor.

***Proof*:**
Since $g \circ f = 0$, $D^{-1}g \circ D^{-1}f = D^{-1}(0) = 0$, and so $\text{im}(D^{-1}f) \subseteq \ker(D^{-1}g)$. For the reverse inclusion, let $m/d \in \ker(D^{-1}g)$ so that $g\left(\frac{m}{d}\right) = \frac{g(m)}{d} = 0$ in $M_3[D^{-1}]$. Thus, there exists an s such that $sg(m) = 0$ in M_3. Since g is an R-module homomorphism, $sg(m) = g(sm)$, and so $sm \in \ker(g) = \text{im}(f)$, implying for some $m' \in M_1$, $f(m') = sm$. Putting it all together, we get that in $M_2[D^{-1}]$:

$$\frac{m}{d} = \frac{f(m')}{ds} = (D^{-1}f)\left(\frac{m'}{ds}\right) \in \text{im}(D^{-1}f)$$

showing that $\ker(D^{-1}g) \subseteq \text{im}(D^{-1}f)$, which along with the fact that $\text{im}(D^{-1}f) \subseteq \ker(D^{-1}g)$ show's that

$$\ker(D^{-1}g) = \text{im}(D^{-1}f)$$

For exactness at the ends: if $(D^{-1}f)(m/d) = f(m)/d = 0$ then $sf(m) = f(sm) = 0$ for some $s \in D$, and injectivity of f gives $sm = 0$, so $m/d = 0$; thus $D^{-1}f$ is injective. And any m_3/d equals $(D^{-1}g)(m_2/d)$ where $g(m_2) = m_3$ (surjectivity of g), so $D^{-1}g$ is surjective. Hence the localized sequence is short exact, completing the proof.

Notice that as we are defining a $D^{-1}R$-module, we are extending scalars. If we use section 17.5, then we can use the following observation to arrive at this result more quickly:

Proposition 23.4.10: Characterization of Localization

Let M be an R-module and $M[D^{-1}]$ a localiation. Then:

$$M[D^{-1}] \cong_R D^{-1}R \otimes_R M$$

***Proof*:**
Define the map:

$$(r/d) \times m \mapsto \frac{r \cdot m}{d}$$

then it is easy to that this map is R-bilinear, and hence by the universal property of the tensor-product, there exists an R-module homomorphism:

$$f : D^{-1}R \otimes M \to M[D^{-1}]$$

It is clear that f is surjective and is uniquely defined with respect to the universal property. It remains to check that f is injective. First, show that for any element in $D^{-1}R \otimes M$, it can be written as:

$$\frac{1}{d} \otimes m$$

for some $d \in D$ and $m \in M$. Let's say $f(1/d \otimes m) = m/d = 0$. Then $sm = 0$ for some $s \in D$. Then:

$$\frac{1}{d} \otimes m = \frac{s}{ds} \otimes m = \frac{1}{ds} \otimes sm = \frac{1}{ds} \otimes 0 = 0$$

showing that f is injective, and hence an R-module isomorphism, completing the proof.

As a direct conssequence, $D^{-1}R$ is a *flat R-module.*

Corollary 23.4.11: Localization Commuting With Tensor

Let M and N be R-modules and $D \subseteq R$ multiplicatively closed. Then there is a unique isomorphism:

$$\varphi : M[D^{-1}] \otimes_{D^{-1}R} N[D^{-1}] \to (M \otimes_R N)[D^{-1}] \qquad (m/d) \otimes (n/s) \mapsto (m \otimes n)/ds$$

In particular, if $\mathfrak{p}$ is any prime ideal:

$$M_{\mathfrak{p}} \otimes_{R_{\mathfrak{p}}} N_{\mathfrak{p}} \cong (M \otimes_R N)_{\mathfrak{p}}$$

***Proof*:**
By proposition 23.4.10, localizing is base change along $R \to D^{-1}R$, so $M[D^{-1}] = D^{-1}R \otimes_R M$. Associativity of the tensor product then gives

$$M[D^{-1}] \otimes_{D^{-1}R} N[D^{-1}] \cong D^{-1}R \otimes_R (M \otimes_R N) = (M \otimes_R N)[D^{-1}],$$

and the prime-ideal case is the special case $D = R \setminus \mathfrak{p}$.

(Some more cool results from Micheal's p. 43)

23.4.3 Local Properties

Localization allows us to diminish our problem to a ring much closer to a field, in particular if we want to study a family of prime ideals contained in some prime ideal p. In fact, there are many results about rings that can be deduced by studying rings *locally*, namely by studying rings at each prime ideal[1]. This motivates the following concept:

Definition 23.4.12: Local Properties

Let P be a property of a ring (ex. commutative, free, etc.). Then a property P of a ring R (resp. of an R-module M) is called a *local property* if it respects the following:

$$R \text{ (resp. } M\text{) has property } P \Leftrightarrow R_p \text{ (resp. } M_p\text{) has property } P \text{ for each prime ideal } p \subseteq R$$

In otherwords, a property is local if we can move back and forth between studying any ring (resp. module) localized at a prime. Here are some examples of local properties:

Proposition 23.4.13: Zero Module Is A Local Property

Let M be an R-module. Then the following are equivalent:

1. $M = 0$
2. $M_p = 0$ for all prime ideals $p \subseteq R$
3. $M_m = 0$ for all maximal ideal $m \subseteq R$

***Proof*:**
Certainy (1) $\Rightarrow$ (2) $\Rightarrow$ (3). For (3) $\Rightarrow$ (1), let $0 \neq x \in M$ be a nonzero element of an R-module M with $0 \neq 1$. Let $I = \text{Ann}(x)$. Then I is contained in some maximal ideal m: $I \subseteq m$. Consider M_m. Since $M_m = 0$, $x/1 = 0$, implying $rx = 0$ for some $r \in R - m$. Howver $\text{Ann}(x) \subseteq m$, meaning no such element can exist, a contradiction, showing that $M = 0$ as we sought to show.

Another property that only needs to be verified locally is the injectivity/surjectivity of a function:

Proposition 23.4.14: Injectivity/Surjectivity/Isomorphism Is A Local Property

Let $\varphi : M \to N$ be an R-module homomorphism. Then the following are equivalent:

1. φ is an injection/surjection/isomorphism
2. $\varphi_p : M_p \to N_p$ is injection/surjection/isomorphism for all prime ideals $p \subseteq R$
3. $\varphi_m : M_m \to N_m$ is injection/surjection/isomorphism for all maximal ideals $m \subseteq R$

***Proof*:**
The proof shall be doen for injectivity, surjectivitiy follows easly and isomorphism is combining the two.

(1) $\Rightarrow$ (2) Since $0 \to M \xrightarrow{\varphi} N$ is exact, by proposition 23.4.9, $0 \to M_p \xrightarrow{\varphi_p} N_p$ is exact, hence φ_p is injective for any prime ideal $p \subseteq R$.

(2) $\Rightarrow$ (3) Every maximal idael is prime

[1] This observation is at the basis of interpreting rings as geometric objects

(3) $\Rightarrow$ (1) Let $K = \ker(\varphi)$. Then the sequence $0 \to K \to M \to N$ is exact, and hence proposition 23.4.9 $0 \to K_m \to M_m \to N_m$ is exact, therefore $K'_m \cong \ker(\varphi_m) = 0$ since φ_m is injective. Thus, by proposition 23.4.13 φ is injective.

to show surjectivity, simply reverse the arrows.

Corollary 23.4.15: Exactness Is A Local Property

Let $A \xrightarrow{f} B \xrightarrow{g} C$ be a sequence of R-module homomorphisms. Then it is exact if and only if $A_{\mathfrak{m}} \xrightarrow{f_{\mathfrak{m}}} B_{\mathfrak{m}} \xrightarrow{g_{\mathfrak{m}}} C_{\mathfrak{m}}$ is exact for every maximal ideal $\mathfrak{m} \subseteq R$.

***Proof*:**
Exactness at B says the homology $H = \ker g/\mathrm{im} f$ vanishes. Localization is exact (proposition 23.4.9), so it commutes with kernels, images, and quotients, giving $H_{\mathfrak{m}} = \ker g_{\mathfrak{m}}/\mathrm{im} f_{\mathfrak{m}}$. By proposition 23.4.13, $H = 0$ iff $H_{\mathfrak{m}} = 0$ for every maximal $\mathfrak{m}$, which is exactness of the localized sequences.

A final example that will be useful is that faltness is a local property:

Proposition 23.4.16: Flatness Is A Local Property

Let M be an R-module. Then the following are equivalent:

1. M is a flat R-module
2. M_p is a flat R_p-module for each prime ideal $p \subseteq R$
3. M_m is a flat R_m-module for each maximal ideal $m \subseteq R$

***Proof*:**
(1) $\Rightarrow$ (2) comes from pervious lemmas and (2) $\Rightarrow$ (3) is immediate. For (3) $\Rightarrow$ (1), let $N \to P$ be any R-module homomorphism and $m \subseteq R$ any maximal idea. Then:

$N \to P$ is injective	$\Rightarrow N_m \to P_m$ is injective	proposition 23.4.14
	$\Rightarrow N_m \otimes_{R_m} M_m \to P_m \otimes_{R_m} M_m$ is injective	flatness property
	$\Rightarrow (N \otimes_R M)_m \to (P \otimes_R M)_m$ is injective	corollary 23.4.11
	$\Rightarrow N \otimes_R M \to P \otimes_R M$ is injective	proposition 23.4.14

Hence, M is flat.

Proposition 23.4.17: Integral Closure Is A Local Property

Let R be an integral domain. Then the following are equivalent:

1. R is integrally closed
2. R_p is integrally closed for each prime ideal $p \subseteq R$
3. R_m is integrally closed for each maximal ideal $m \subseteq R$

***Proof*:**
exercise.

The following is a way of proving results locally:

Proposition 23.4.18: Local Properties On Modules

Let R be a subring of a field k, and let M be an R-module contained in a k-vector space V (equiv. the map $M \to M \otimes_R k$ is injective). Then:

$$M = \bigcap_{\mathfrak{m}} M_{\mathfrak{m}} = \bigcap_{\mathfrak{p}} M_{\mathfrak{p}}$$

***Proof*:**
Certainly $M \subseteq \cap_{\mathfrak{m}} M_{\mathfrak{m}}$. For the other direciton, take $x \in \cap_{\mathfrak{m}} M - \mathfrak{m}$. For each maximal ideal $\mathfrak{m}$, $x = m/s$ for some $m \in M$ and $s \in R - \mathfrak{m}$. Hence $sx \in M$. Define the ideal

$$I_a = \{a \in R \mid ax \in M\}$$

Then $as \in I_a$. But by construction $s \notin \mathfrak{m}$,hence $I_a \not\subseteq \mathfrak{m}$. But then it must be that $I_a = R$, hence $x = 1 \cdot x \in M$, the giving the result

Extending to prime ideals is left as an exercise.

Corollary 23.4.19: Local Properties Of Ideals

Let R be an integral domain. Then every ideal $I \subseteq R$ is equal to the intersection of its localizations at the maximal ideals of R, and also to the intersections of its localization at the prime ideals of R

Hence, to show a property of an ideal I in an integral domain R, it suffices to show that the properly holds for all its localization $I_{\mathfrak{p}}$ and it is preserved under intersections.

Exercise 23.4.2

1. Show that M is projective if and only if each M_p is free.

23.4.4 Local Rings

Recall that the localization of $\mathbb{Z}$ at any prime ideal (p), $\mathbb{Z}_{(p)}$, has a unique maximal ideal. It was left as an exercise to see whether any localization at a prime, R_p left R with only a single maximal ideal. This is indeed the case, meaning there is a unique field associated to R_p, letting us study R in terms of the collection of field induced by R_p. Thus, for any integral domain R, we can always produce a collection of rings that only have a single maximal ideal $\mathfrak{m}_\mathfrak{p}$. Once we interpret a ring as a geometric object $\operatorname{Spec}(R)$, we shall see that the rings $R_\mathfrak{p}$ representing the local properties of $\operatorname{Spec}(R)$, not unlike how we have stalks at a point in Differential Geometry. Due to this, it is worth-while studying rings with a unique maximal ideal:

Definition 23.4.20: Local Ring

Let R be a commutative ring. Then R is a *local ring* if it has a unique maximal ideal.

Every field is a local ring, its unique maximal ideal being (0). The definition is enlightening: if R is local with maximal ideal $\mathfrak{m}$ and $x \notin \mathfrak{m}$, then x must be a unit, since otherwise (x) is a proper ideal and so lies in a maximal ideal, forcing $x \in \mathfrak{m}$. Conversely, if the non-units of R form an ideal then that ideal is the unique maximal ideal, so R is local.

Example 23.4.21: Local Rings

1. Every field is trivially a local ring.
2. $\mathbb{Z}/p^n\mathbb{Z}$ is a local ring with $n > 1$ with maximal ideal $\overline{p}$
3. if $f \in k[x]$ is irreducible then $k[x]/(f(x)^n)$ is a local ring with maximal ideal $\overline{(f(x))}$
4. (geometric example) Let M be a smooth manifold (real or complex). Then define $\mathcal{O}_{M,x}$ to be the germ of smooth functions at x, that is, two smooth functions $f, g \in C^\infty(M)$ are in the same equivalence relation $f \sim g$ (i.e. $[f] = [g]$ are the same germ) if there exists some open set $U \subseteq M$ containing x such that $f|_U = g|_U$. Clearly, $\mathcal{O}_{M,x}$ is a ring (using the ring operation of the codomain $\mathbb{R}$ or $\mathbb{C}$). The maximal ideal of $\mathcal{O}_{M,x}$ are those functions that are 0 at x

In fact, this last example will have a direct parallel in scheme theory, see [5].

Proposition 23.4.22: Local Ring Equivalences

Let R be a commutative ring with $1 \neq 0$. Then the following are equivalent:

1. R is a local ring.
2. the sum of any two non-units is a non-unit
3. for every $x \in R$, either x is a unit or $1 - x$ is a unit
4. if a finite sum is a unit, then one of its terms is a unit

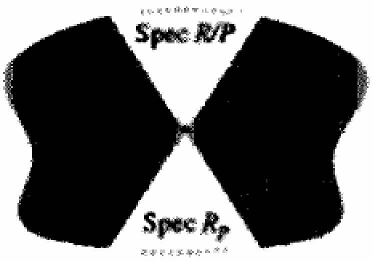
***Proof*:**
(1) $\Rightarrow$ (2): if R is local with maximal ideal $\mathfrak{m}$, an element is a non-unit iff it generates a proper ideal iff it lies in $\mathfrak{m}$, so the non-units are exactly $\mathfrak{m}$, which is closed under addition.

(2) $\Rightarrow$ (4): if a finite sum is a unit but no term is, then every term is a non-unit, so by (2) the sum is a non-unit, a contradiction.

(4) $\Rightarrow$ (3): apply (4) to $x + (1 - x) = 1$.

(3) $\Rightarrow$ (1): let $\mathfrak{m}$ be the set of non-units; it absorbs multiplication by R. If $x, y \in \mathfrak{m}$ had a unit sum $u = x + y$, then $1 = u^{-1}x + u^{-1}y$, so by (3) one of $u^{-1}x, u^{-1}y$ is a unit, making x or y a unit, a contradiction. Hence $\mathfrak{m}$ is closed under addition and is an ideal. Every proper ideal consists of non-units, hence lies in $\mathfrak{m}$, so $\mathfrak{m}$ is the unique maximal ideal and R is local.

Using localization and quotienting, we have a large amount of control over the prime ideals we want to work with: given a (commutative) ring R, if we take R_p, we eliminates all ideals except those contained in p, while R/p eliminates except those contained not contained in p (i.e. containing p). This can be visualized like so:



Hence, R_p/q^e (resp. $(R/p)_{\overline{q}}$) will only keep all the ideals between p and q, and if $p = q$, then the result is a field, known as the *residue field*:

Definition 23.4.23: Residue Field

Let R be a commutative local ring with maximal ideal m. Then R/m is called the *residue field*.

The quotient $R/\mathfrak{p}$ and the ring $R_\mathfrak{p}$ are canonically related: the ring $R_\mathfrak{p}$ can be thought of as the localization of $R/\mathfrak{p}$:

Proposition 23.4.24: Localization and Quotient Commute

Let $\mathfrak{p} \subseteq R$ be prime ideal of a ring R, and let $\mathfrak{m}_\mathfrak{p}$ be the unique maximal ideal of $R_\mathfrak{p}$. Then localizing at $\mathfrak{p}$ and then taking the field of fractions is isomorphic to taking quotient at $\mathfrak{p}$ and then localizing (at $\overline{fp} = \overline{0}$) Then there is a canonical embedding:

$$R/\mathfrak{p} \hookrightarrow R_\mathfrak{p}/\mathfrak{m}_\mathfrak{p}$$

that maps $R_\mathfrak{p}/\mathfrak{m}_\mathfrak{p}$ into the field of fractions of $R/\mathfrak{p}$

This may be visualized as the following diagram:

$$\begin{tikzcd}
 & R/\mathfrak{p} \arrow[dr, "\text{localize}"] & \\
R \arrow[ur, "\text{quotient}"] \arrow[dr, "\text{localize}"'] & & K(R/\mathfrak{p}) \cong R_\mathfrak{p}/\mathfrak{p}R_\mathfrak{p} \\
 & R_\mathfrak{p} \arrow[ur, "\text{quotient}"'] &
\end{tikzcd}$$

***Proof*:**
exercise

23.4.5 Nakayama's Lemma

(Atiyah Michael in Comm alg has some interesting results that feel are worth putting in here: p.21 on fin. gen modules)

As mentioned at the beginning, localization let's us get geometric information on a local level. Nakayama's lemma will be one way we translate that information to a global level. In this section, we will restrict to finitely generated modules (the infinite case is treated in the exercises).

Let's say M is a finitely generated module over R. If we were to localize M at a prime, we would get a local ring $R[D^{-1}]$. For simplicity, let's denote this ring G. As we've shown, G has only one maximal ideal m. Modding G by m, we get the field G/m. M over G/m is a vector-space, and so it has a basis. The heart of Nakayama's lemma is that this can be reversed: Using the basis of M over G/m, we can find a basis for M over G!

We will guild this up in three steps, which are collectively called Nakayama's Lemma:

Definition 23.4.25: Jacobson Radical

Let R be a ring. Then the *jacobson radical* of R, denoted $\text{Jac}(R)$ is the intersection fo all maximal ideals of R:

$$\text{Jac}(R) = \bigcap_{\substack{M \subseteq R \\ \text{maximal}}} M$$

(analogous to Fratini subgroup)

Proposition 23.4.26: Properties Of Jacobson Radical

Let $J \subseteq R$ be the Jacobson radical of a commutative ring R. Then:

1. If $I \subsetneq R$ is a proper ideal, then the ideal generated by I and J is also proper: $(I, J) \subsetneq R$
2. If R is Artinian, then the Jacobson radical is nilpotent: $J^n = 0$ for some n
3. $x \in J$ if and only if $1 - rx$ is a unit for every $r \in R$

***Proof*:**

1. If I is maximal, then $J \subseteq I$ and we're done, and if not then $I \subseteq M$ for some maximal ideal so $(I, J) \subseteq M \subsetneq R$

2. Let J be the jacobson radical. By the D.C.C. the following chain stabalizes
$$J \supseteq J^2 \supseteq \cdots \supseteq J^n = J^{n+1} = \cdots$$
Consider the set of all annihilators of J^n:
$$I = \{x \in R \mid xJ^n = 0\}$$
I claim that $I = (1)$, which will show that $1J^n = J^n = 0$ (i.e. J is nilpotent). For the sake of contradiction, let's say it is not I. Then pick $I' \supsetneq I$ that is minimal (i.e. there is no ideal between I' and I). Such an ideal exists by the D.C.C. condition. Then by minimality, it must be that I' is generated by adding just one more element, that is
$$I' = I + Rx \qquad x \in R,\ x \notin I$$
Thus, I'/I is a simple R-module by minimality (i.e. has no other ideals in it). However, it is easy to see that any simple R-module is of the form R/m for some maximal ideal m. Thus,
$$I'/I \cong R/m$$
multiplying both sidses by m, we "kill" the right hand side and get
$$mI' \subseteq I$$
Thus $JI' \subseteq I.$, so $xJ \in I$, and so by definition of I,
$$xJ^{n+1} = 0$$
but by assumption $xJ^{n+1} = J^n$, but that implies $x \in I$. However, $x \notin I$, a contradiction.

3. Doing the contra-positive, let's say $x \notin \text{Jac}(R)$. Then $x \notin M'$ for some maximal ideal M'. By maximality, $M + (x) = (1)$, so $y + rx = 1$, implying $1 - rx = y \in M'$, showing that $1 - rx$ cannot be a unit (this does not show "for all $r \in R$"). Conversely, if $1 - rx$ is not a unit, $1 - rx \in M$ for some M. However, $1, rx \notin M$, since if they were then $1 \in M$. Thus, $rx \notin \text{Jac}(R)$ for all r, but then $x \notin \text{Jac}(R)$.

Lemma 23.4.27: Nakayama's Lemma I

Let M be a finitely generated R-module, and suppose $\alpha \subseteq R$ is an ideal that is contained in all maximal ideals of R (i.e. $\alpha \subseteq \text{Jac}(R)$). Then:
$$\text{if } \alpha M = M \text{ then } M = \{0\}$$

***Proof*:**
We will proceed by induction on the number of generators of M. If $n = 1$, then $\langle x_1 \rangle = M$. If $\alpha M = M$, we have that:

$$x_1 = a_1 x_1 \text{ for some } a_1 \in \alpha$$

we get that $(1 - a_1)x_1 = 0$, meaning $1 - a_1$ annihilates x_1.

However, $(1 - a_1)$ is in fact a unit (as will be shown in a moment). Since it's a unit, there exists a b such that

$$0 = b \cdot 0 = b(1 - a_1)x_1 = x_1$$

Thus it must be that $x_1 = 0$, showing that $M = \{0\}$. So it's left to show that $1 - a_1$ is a unit. Let's say $(1 - a_1)$ was a proper ideal. Then it must lie in some maximal ideal. Since $a_1 \in \alpha$ and α is a subset of all maximal ideals, it must be that $1 - \alpha_1 + \alpha_1 = 1$ is in a maximal ideal, however that would make the ideal a non-proper ideal, a contradiction.

For the case of $n = k$, let $x_1, x_2, ..., x_k$ generate M, and suppose $\alpha M = M$. Then

$$x_k = a_1 x_1 + a_2 x_2 + \cdots + a_k x_k$$

so $(1 - a_k)x_k = a_1 x_1 + \cdots + a_{k-1} x_{k-1} \in \langle x_1, \ldots, x_{k-1} \rangle$. As in the base case $1 - a_k$ is a unit, hence $x_k \in \langle x_1, \ldots, x_{k-1} \rangle$, so $M = \langle x_1, \ldots, x_{k-1} \rangle$ is generated by $k-1$ elements and still satisfies $\alpha M = M$. By the induction hypothesis $M = \{0\}$, as we sought to show

If we restrict to $R = A$ being a local ring and $\alpha = m$ the maximal ideal of A, we will have the first step in constructing a basis for M over A:

Lemma 23.4.28: Nakayama's Lemma II

Let M be a finitely generated A-module over a local ring A with maximal ideal m, and let F be a submodule of M. Then:

$$\text{if } M = F + mM \text{ then } M = F$$

***Proof*:**
Take $M/F = (F + mM)/F = mM/F$ so that $M/F = mM/F$. Then by lemma 23.4.27, $M/F = \{0\}$, so that means that M moded by F makes everything 0, and so

$$M = F$$

Finally, we put these two together to create create a basis for a module over a local ring using a basis for a smaller module!

Lemma 23.4.29: Nakayama's Lemma III

Let M be a A-module over a local ring A and m the maximal ideal of A. If $x_1, x_2, ..., x_n$ generated M/mM (M mod mM), then they also generators for M

***Proof*:**
Let $F = \langle x_1, x_2, ..., x_n \rangle \subseteq M$ be the submodule generated by the x_i. Then

$$M = F + mM$$

Then by lemma 23.4.28, $M = F$, and so M has $\langle x_1, x_2, ..., x_n \rangle$ as generators, as we sought to show

Nakayama's lemma let's us reverse some constructions. As we saw in chapter 14, a [finitely generated?] projective module over a PID is free. Using Nakayama's lemma, we can show that a finitely generated module over a local ring is also free!

Theorem 23.4.30: Projective Module over Local Ring

Let M be a finitely generated projective module over a local ring A. Then M is free. In particular, If if $\{x_1, ..., x_n\}$ are elements of M who's residue class $\{\overline{x_1}, ..., \overline{x_1}\}$ form a basis for M/mM over A/m, then $x_1, ..., x_n$ is a *basis* for M over A.

Furthermore, if $\overline{x_1}, ..., \overline{x_n}$ are linearly independent over A/m, then this collection can be completed to a basis for M over A

***Proof*:**
First, Note that $M/\mathfrak{m}M$ over $A/\mathfrak{m}$ is indeed a vector space with action $(a + \mathfrak{m})(m + \mathfrak{m}M) = (am + \mathfrak{m}M)$ being well-defined.

Since $M/\mathfrak{m}M$ is a finite-dimensional $A/\mathfrak{m}$-vector space, choose $x_1, \dots, x_n \in M$ lifting a basis of it (so by Nakayama's lemma III they generate M). Let F be a free module with basis $e_1, e_2, ..., e_n$, and consider the homomorphism $f : F \to M$, $f(e_i) = x_i$. We'll show that f is in fact an isomorphism. Since $x_1, ..., x_n$ generate M mod $\mathfrak{m}M$, by Nakayama's lemma III, they generate M, and so f is surjective. Next, since M is projective, f splits, i.e., $F = P_0 \oplus P_1$ where $P_0 = \ker(f)$ and P_1 and $P_1 \cong M$ through f. We'll show $P_0 = 0$.

Take some $\sum a_i x_i \in \ker(f)$ so that $\sum a_i x_i = 0$. Then reducing to the mod, we have $\sum a_i x_i + \mathfrak{m}M = 0 + \mathfrak{m}M = \sum (a_i \mathfrak{m}) \cdot (x_i + \mathfrak{m}M) = 0 + \mathfrak{m}M$. Since the $\overline{x}_i$ form a basis for $M/\mathfrak{m}M$ over $A/\mathfrak{m}A$, it must be that $a_i \in \mathfrak{m}$. Thus, we have $\sum a_i e_i \in \mathfrak{m}F$. Therefore:

$$\ker(f) \subseteq \mathfrak{m}F = \mathfrak{m}\ker(f) \oplus \mathfrak{m}M$$

Thus, $\mathfrak{m}\ker(f) = \ker(f)$. Since $\ker(f)$ is the direct summand of finitely generated modules, it is itself finitely generated. Thus, by Nakayama's lemma, $\ker(f) = 0$, and so f is an isomorphism! Therefore, we have $F \cong M$, and so M is free!

Notice that this immediately implies that the $x_1, ..., x_n$ are linealy independent since they form a basis for M over A (since f is an isomorphism and $f(e_i) = x_i$). Finally, if we extend $\overline{x}_1, ..\overline{x}_r$ to $\overline{x}_1, ..., \overline{x}_r, ...\overline{x}_n$ to be a basis for $M/\mathfrak{m}M$, then we just showed they will indeed form a basis for M.

A cool result of this theorem is a way to show some properties f based on f on the respective local modules. Let M be module over a local ring A. Then there is an associated module $M(\mathfrak{m}) = M/\mathfrak{m}M$

Then $\_\_\_(\mathfrak{m})$ induces a functor mapping M to $M(\mathfrak{m})$ and

$$f : M \to N \quad \mapsto \quad f_{(\mathfrak{m})} : M(\mathfrak{m}) \to N(\mathfrak{m})$$

Notice that if f is surjective, then $f_{(\mathfrak{m})}$ is surjective. The magic of Nakayama's lemma is that the converse is true too!

Proposition 23.4.31: Local Homomorphisms

Let M, N be finitely generated modules over a local ring A and $f : M \to N$ be an A-module homomorphism. Then:

1. f is surjective if and only if $f_{(\mathfrak{m})}$ is surjective
2. Assume f is injective. Then if $f_{(\mathfrak{m})}$ is surjective, f is an isomorphism
3. If M and N are free and $f_{(\mathfrak{m})}$ is injective, then f is injective; and f is an isomorphism if and only if $f_{(\mathfrak{m})}$ is an isomorphism

***Proof*:**

1. Let $f : M \to N$ be an R-module homomorphism and let the inducd $f_{(m)}$ be surjective so that $f(M \bmod \mathfrak{m}M) = N \bmod \mathfrak{m}N$. Since N is finitely generated, so is any quotient of it, and so $N \bmod \mathfrak{m}N$ is finitely generated by $\{\overline{x}_1, \overline{x}_2, ..., \overline{x}_n\}$ By Nakayama's lemma, $\{x_1, x_2, ..., x_n\}$ generated N. Since $x_1, ..., x_n \in f(M)$, f is also surjective

   More consisely, since $f_{(\mathfrak{m})}$ is surjective, $N = \text{im}(f) + \mathfrak{m}N$. Thus, by Nakayama's lemma, $N = \text{im}(f)$.

2. By part (1), surjectivity of $f_{(\mathfrak{m})}$ makes f surjective; together with the assumed injectivity of f, this makes f an isomorphism.

3. Assume M and N are free and $f_{(\mathfrak{m})}M/\mathfrak{m}M \to N/\mathfrak{m}N$ is injective. Since M is free, let $\{x_1, ..., x_n\} \subseteq M$ so that $\{\overline{x}_1, ..., \overline{x}_n\}$ is a basis for $M/\mathfrak{m}M$. Then by theorem 23.4.30, $x_1, ..., x_n$ forms a basis for M. Suppose now that $f(a_1x_1 + \cdots + a_nx_n) = 0$. By definition of $f_{(\mathfrak{m})}$, $f_{(\mathfrak{m})}(\overline{a}_1\overline{x}_1 + \cdots + \overline{a}_n\overline{x}_n) = \overline{0}$. Since $f_{(\mathfrak{m})}$ is injective, we have $\overline{a}_1\overline{x}_1 + \cdots + \overline{a}_n\overline{x}_n = 0$, and since $\overline{x}_1, ..., \overline{x}_n$ is a basis, we have that the coefficients are all $\overline{0}$, that is $a_i \in \mathfrak{m}$.

   To show that $\ker(f) = 0$, we'll use Nakayama's lemma, so it suffices to show that $\ker(f) \subseteq \mathfrak{m}\ker(f)$. By what we've just shown, we have $\ker(f) \subseteq \mathfrak{m}M$. If $f_{(\mathfrak{m})}$ were surjective, then this proof is rather quick. By part (1), we have that f is surjective. Thus the following short exact sequence splits:

   $$0 \to \ker(f) \to M \to N \to 0$$

   since N is free, So $M \cong \ker(f) \oplus N$, and $\ker(f) \subseteq \mathfrak{m}M \cong \ker(f) \oplus N$, and so $\ker(f) \subseteq \mathfrak{m}\ker(f)$, and so by Nakayama's lemma $\ker(f) = 0$.

   If $f_{(\mathfrak{m})}$ is not surjective, then we need to do a little more work. We'll take advantage of the basis lifting property we proved in the previous theorem. Let $\{\overline{x}_1, ..., \overline{x}_n\}$ be a basis for $M/\mathfrak{m}M$ over $A/\mathfrak{m}A$ which induces a basis $\{x_1, .., x_n\}$ for M over A.

$\langle f_{(\mathfrak{m})}(\overline{x}_1), ..., f_{(\mathfrak{m})}(\overline{x}_n)\rangle = \text{im}(f_{(\mathfrak{m})})$ is a submodule of $N/\mathfrak{m}N$ which have that generating set as a basis (since $f_{(\mathfrak{m})}$ is injective). Thus, if:

$$\overline{a}_1 f_{(\mathfrak{m})}(\overline{x}_1) + \cdots + \overline{a}_n f_{(\mathfrak{m})}(\overline{x}_n) = 0$$

then since f is a homomorphism, we have

$$f_{(\mathfrak{m})}(\overline{a}_1\overline{x}_1 + \cdots + \overline{a}_1\overline{x}_1) = 0$$

and since these elements form a basis and f is injective, $\overline{a}_i = 0$ for all i. Now, extend this to a basis for $N/\mathfrak{m}N$ over $A/\mathfrak{m}A$:

$$\{f_{(\mathfrak{m})}(\overline{x}_1), ..., f_{(\mathfrak{m})}(\overline{x}_n), \overline{y}_1, ..., \overline{y}_m\}$$

Since N is free, this basis lifts to a basis for N over A, in particular:

$$\{f(x_1), ..., f(x_n), y_1, ..., y_m\}$$

since $f_{(\mathfrak{m})}(\overline{x}_i) = f_{(\mathfrak{m})}(x_i + \mathfrak{m}M) = f(x_i) = \mathfrak{m}N$. With this, we can now get our conclusion: since the $f(x_i)$ are linearly independent, we have that:

$$a_1 f(x_1) + \cdots + a_n f(x_n) = f(a_1x_1 + \cdots + a_nx_n) = 0$$

then it must be that the $a_i = 0$ for all the i, but then this is the condition for a function to be injective, and so f is injective, as we sought to show

Proposition 23.4.32: Projective Modules Determined by Their Reduction

Let P and P' be finitely generated projective modules over a local ring A. Then $P \cong P'$ if and only if $P/\mathfrak{m}P \cong P'/\mathfrak{m}P'$.

***Proof*:**
By theorem 23.4.30, P and P' are free, with ranks $\dim_{A/\mathfrak{m}}(P/\mathfrak{m}P)$ and $\dim_{A/\mathfrak{m}}(P'/\mathfrak{m}P')$; these ranks agree iff $P/\mathfrak{m}P \cong P'/\mathfrak{m}P'$, in which case $P \cong P'$. The converse is immediate.

Recall that if R is a finite integral domain, then it is necessarily a field (corollary 9.1.25). Naturally, this is not necessarily the case for infinite rings ($\mathbb{Z}$ being the prototypical example). We may thus take $Q = \text{Frac}(R)$, and consdier the R-module Q

Corollary 23.4.33: Infinite Generation Of Ring Of Fractions

Let R be an integral domain that is not a field, and $Q = \text{Frac}(R)$ its field of fractions. Then Q, considered as an R-module, is not finitely generated.

***Proof*:**
Suppose Q were finitely generated as an R-module. Since R is not a field, choose a nonzero maximal ideal $\mathfrak{m}$. As every nonzero element of R is already a unit in Q, we have $Q_{\mathfrak{m}} = Q$, still finitely generated over the local ring $R_{\mathfrak{m}}$. For any $0 \neq a \in \mathfrak{m}$ and $q \in Q$ we have $q = a(q/a)$ with

$a \in \mathfrak{m}R_{\mathfrak{m}}$, so $\mathfrak{m}R_{\mathfrak{m}} \cdot Q = Q$. By lemma 23.4.27, $Q = 0$, contradicting $R \subseteq Q$.

Recall that when dealing with infinite functions, we may have some strange results, like a surjection $f : M \to M$ that is not an injection. Nakayama's lemma insures we get some sanity here:

Corollary 23.4.34: Surjective Implies Injective

Let M be a finitely generated R-module. Then if $f : M \to M$ is a surjective R-module homomorphism, it is injecive.

Note that no Noetherian assumption on R or M is required.

***Proof*:**
Make M a module over $R[x]$ by letting x act as f, i.e. $x \cdot m = f(m)$. Surjectivity of f gives $(x)M = xM = M$. Since M is a finitely generated $R[x]$-module with $(x)M = M$, the determinant trick (the Cayley-Hamilton form of Nakayama's lemma) yields $q(x) \in (x)$ with $(1 - q(x))M = 0$. Write $q(x) = x\,h(x)$. For $m \in \ker f$ we have $xm = f(m) = 0$, hence $m = q(x)m = h(x)(xm) = 0$. Thus $\ker f = 0$ and f is injective.

24

Primary Decomposition and Associated Primes

The integer n factors uniquely into prime powers, and the ideal $(n) \subseteq \mathbb{Z}$ inherits the factorization: writing $n = p_1^{a_1} \cdots p_k^{a_k}$ gives $(n) = (p_1^{a_1}) \cap \cdots \cap (p_k^{a_k})$, a finite intersection of ideals each built from a single prime. Over a general ring the unique factorization of elements fails, and the factorization of ideals into primes fails with it. What survives, in every Noetherian ring, is the weaker statement that an ideal is a finite intersection of *primary* ideals, the ideal-theoretic analogue of a prime power. This is the content of the Lasker-Noether theorem, and it is the decomposition facet of the finiteness thread: the same Noetherian hypothesis that produced Hilbert's basis theorem produces here the existence and finiteness that make the theory run.

The primes attached to such a decomposition are not artifacts of the factorization but invariants of the ideal, its *associated primes*. They split into two kinds. The minimal ones record the irreducible components and are uniquely determined; the *embedded* ones sit inside those components and can shift from one decomposition to another. Read through the correspondence between primes and points, the minimal primes will become the irreducible components of a variety and the embedded primes its embedded components, a reading developed downstream in [27]. Here the account is purely ring-theoretic, and its natural home is a module: the associated primes $\mathrm{Ass}(M)$ and the support $\mathrm{Supp}(M)$ are the invariants the later chapters, and the geometry and homological volumes, reach back for.

24.1 Primary Ideals

A prime ideal $\mathfrak{p}$ is one for which $xy \in \mathfrak{p}$ forces $x \in \mathfrak{p}$ or $y \in \mathfrak{p}$. The primary ideals relax the second alternative to a power.

Definition 24.1.1: Primary Ideal

A proper ideal $\mathfrak{q} \subsetneq R$ is *primary* if, whenever $xy \in \mathfrak{q}$ with $x \notin \mathfrak{q}$, some power y^n lies in $\mathfrak{q}$.

Passing to the quotient makes the condition transparent: $\mathfrak{q}$ is primary exactly when $R/\mathfrak{q} \neq 0$ and every zero-divisor of $R/\mathfrak{q}$ is nilpotent. Indeed $xy \in \mathfrak{q}$ with $x \notin \mathfrak{q}$ says that $\bar{y}$ kills the nonzero element $\bar{x}$ of $R/\mathfrak{q}$, and $y^n \in \mathfrak{q}$ says $\bar{y}$ is nilpotent.

Proposition 24.1.2: The Radical of a Primary Ideal

If $\mathfrak{q}$ is primary then $\mathfrak{p} = \sqrt{\mathfrak{q}}$ is prime, and it is the smallest prime containing $\mathfrak{q}$. One says $\mathfrak{q}$ is $\mathfrak{p}$-*primary*.

***Proof*:**
The radical of any ideal is the intersection of the primes containing it, so $\sqrt{\mathfrak{q}}$ is contained in every prime over $\mathfrak{q}$; it suffices to show it is prime. Suppose $xy \in \sqrt{\mathfrak{q}}$, say $(xy)^m \in \mathfrak{q}$, and $x \notin \sqrt{\mathfrak{q}}$. Then no power of x lies in $\mathfrak{q}$, so from $x^m y^m \in \mathfrak{q}$ and primarity applied to $x^m \cdot y^m$ we get $(y^m)^k \in \mathfrak{q}$ for some k, whence $y \in \sqrt{\mathfrak{q}}$.

The radical being prime does *not*, by itself, make an ideal primary; the converse needs the radical to be maximal.

Lemma 24.1.3: Ideals with Maximal Radical are Primary

If $\sqrt{\mathfrak{q}} = \mathfrak{m}$ is maximal, then $\mathfrak{q}$ is primary. In particular every power $\mathfrak{m}^n$ of a maximal ideal is $\mathfrak{m}$-primary.

***Proof*:**
In $R/\mathfrak{q}$ the image of $\mathfrak{m}$ is the nilradical, since $\mathfrak{m} = \sqrt{\mathfrak{q}}$, and it is also maximal. Thus $R/\mathfrak{q}$ has a single prime ideal, so every element is either a unit or nilpotent, and every zero-divisor is nilpotent. For the last claim, $\sqrt{\mathfrak{m}^n} = \mathfrak{m}$.

Example 24.1.4: Primary and Non-Primary Ideals

1. In $\mathbb{Z}$ the primary ideals are (0) and the prime powers (p^n); this is the factorization $(n) = \bigcap (p_i^{a_i})$ read one prime at a time.
2. In $R = k[x, y]$ the ideal $\mathfrak{q} = (x, y^2)$ is primary: $R/\mathfrak{q} \cong k[y]/(y^2)$, whose only zero-divisors are the multiples of $\bar{y}$, all nilpotent. Its radical is (x, y), and $(x, y)^2 \subsetneq \mathfrak{q} \subsetneq (x, y)$, so a primary ideal need not be a power of its radical prime.
3. A power of a prime need not be primary. In $R = k[x, y, z]/(xy - z^2)$ let $\mathfrak{p} = (\bar{x}, \bar{z})$, which is prime because $R/\mathfrak{p} \cong k[y]$ is a domain. Then $\bar{x}\bar{y} = \bar{z}^2 \in \mathfrak{p}^2$, yet $\bar{x} \notin \mathfrak{p}^2$ and $\bar{y} \notin \sqrt{\mathfrak{p}^2} = \mathfrak{p}$, so $\mathfrak{p}^2$ is not primary although its radical $\mathfrak{p}$ is prime.

24.2 Primary Decomposition

Definition 24.2.1: Primary Decomposition

A *primary decomposition* of an ideal I is an expression

$$I = \mathfrak{q}_1 \cap \mathfrak{q}_2 \cap \cdots \cap \mathfrak{q}_n$$

with each $\mathfrak{q}_i$ primary. It is *minimal* if the radicals $\mathfrak{p}_i = \sqrt{\mathfrak{q}_i}$ are pairwise distinct and no $\mathfrak{q}_i$ contains the intersection of the others. An ideal admitting a primary decomposition is called *decomposable.*

Any primary decomposition can be trimmed to a minimal one, once we know that primary ideals with a common radical combine.

Lemma 24.2.2: Intersections of $\mathfrak{p}$-Primary Ideals

A finite intersection $\mathfrak{q} = \mathfrak{q}_1 \cap \cdots \cap \mathfrak{q}_m$ of $\mathfrak{p}$-primary ideals (same radical $\mathfrak{p}$) is again $\mathfrak{p}$-primary.

***Proof*:**
Radicals commute with finite intersections, so $\sqrt{\mathfrak{q}} = \bigcap \sqrt{\mathfrak{q}_i} = \mathfrak{p}$. Suppose $xy \in \mathfrak{q}$ with $y \notin \sqrt{\mathfrak{q}} = \mathfrak{p}$. For each i, $xy \in \mathfrak{q}_i$ and $y \notin \sqrt{\mathfrak{q}_i}$, so no power of y lies in $\mathfrak{q}_i$; primarity of $\mathfrak{q}_i$ then gives $x \in \mathfrak{q}_i$. Hence $x \in \mathfrak{q}$, and $\mathfrak{q}$ is primary.

Given any primary decomposition, group the $\mathfrak{q}_i$ by their radical and replace each group by its intersection, which lemma 24.2.2 keeps primary; then discard any term containing the intersection of the rest. The result is minimal, so *every decomposable ideal has a minimal primary decomposition.* The point of the next two sections is that the data surviving this trimming is intrinsic to I.

24.3 Associated Primes

The invariants are cleanest for modules, where they will also serve the later theory of depth and support.

Definition 24.3.1: Associated Prime

Let M be an R-module. A prime $\mathfrak{p}$ is an *associated prime* of M if $\mathfrak{p} = \operatorname{Ann}(x)$ for some $x \in M$; equivalently, if $R/\mathfrak{p}$ embeds in M. The set of associated primes is written $\operatorname{Ass}(M)$. The associated primes of an ideal I mean those of the module R/I.

The two forms match because a copy of $R/\mathfrak{p}$ inside M is generated by an element whose annihilator is $\mathfrak{p}$, and conversely $\operatorname{Ann}(x) = \mathfrak{p}$ makes $r \mapsto rx$ an embedding $R/\mathfrak{p} \hookrightarrow M$.

Lemma 24.3.2: Zero-Divisors and Annihilators

Let R be Noetherian and $M \neq 0$ a finitely generated module. A maximal element of the family $\{\mathrm{Ann}(x) : 0 \neq x \in M\}$ is prime, so it lies in $\mathrm{Ass}(M)$; in particular $\mathrm{Ass}(M) \neq \emptyset$.

***Proof*:**
The family is nonempty and, R being Noetherian, has a maximal member $\mathfrak{p} = \mathrm{Ann}(x)$. It is proper since $x \neq 0$. If $ab \in \mathfrak{p}$ with $b \notin \mathfrak{p}$, then $bx \neq 0$ and $\mathrm{Ann}(bx) \supseteq \mathfrak{p} + (a) \supseteq \mathfrak{p}$; maximality forces $\mathrm{Ann}(bx) = \mathfrak{p}$, so $a \in \mathrm{Ann}(bx) = \mathfrak{p}$. Thus $\mathfrak{p}$ is prime.

The associated primes are exactly the radicals appearing in a minimal decomposition.

Theorem 24.3.3: First Uniqueness Theorem

Let R be Noetherian and let I have a minimal primary decomposition $I = \mathfrak{q}_1 \cap \cdots \cap \mathfrak{q}_n$ with radicals $\mathfrak{p}_i = \sqrt{\mathfrak{q}_i}$. Then

$$\{\mathfrak{p}_1, \ldots, \mathfrak{p}_n\} = \mathrm{Ass}(R/I),$$

and in particular the set of radicals does not depend on the chosen minimal decomposition.

***Proof*:**
Work in R/I; annihilators there are the ideals $(I : x)/I$ for $x \in R$, and $\sqrt{(I : x)}$ measures which components miss x. For $x \in R$ one computes $(I : x) = \bigcap_i (\mathfrak{q}_i : x)$, and $(\mathfrak{q}_i : x) = R$ when $x \in \mathfrak{q}_i$ while $\sqrt{(\mathfrak{q}_i : x)} = \mathfrak{p}_i$ when $x \notin \mathfrak{q}_i$ (primarity: if $y(x) \in \mathfrak{q}_i$ with $x \notin \mathfrak{q}_i$ then $y \in \mathfrak{p}_i$). Hence

$$\sqrt{(I : x)} = \bigcap_{x \notin \mathfrak{q}_i} \mathfrak{p}_i$$

If this radical is itself prime it must equal some $\mathfrak{p}_i$, since a prime containing a finite intersection contains one of the factors and each $\mathfrak{p}_i$ here contains the intersection. Thus every prime of the form $\sqrt{(I : x)}$ is one of the $\mathfrak{p}_i$. Conversely, minimality provides for each i an element x_i lying in every $\mathfrak{q}_j$ with $j \neq i$ but not in $\mathfrak{q}_i$, and then $\sqrt{(I : x_i)} = \mathfrak{p}_i$. The primes among $\sqrt{(I : x)}$ are therefore exactly $\mathfrak{p}_1, \ldots, \mathfrak{p}_n$. For $\mathrm{Ass}(R/I) \subseteq \{\mathfrak{p}_i\}$: if $\mathfrak{p} \in \mathrm{Ass}(R/I)$ then $\mathfrak{p} = (I : x)/I$ is an annihilator, and being prime it equals its radical $\sqrt{(I : x)}$, hence some $\mathfrak{p}_i$. For the reverse inclusion, fix i and use minimality to pick $x_i \in \bigcap_{j \neq i} \mathfrak{q}_j$ with $x_i \notin \mathfrak{q}_i$; then $(I : x_i) = (\mathfrak{q}_i : x_i)$, which is $\mathfrak{p}_i$-primary (for $x \notin \mathfrak{q}$ with $\mathfrak{q}$ being $\mathfrak{p}$-primary, $(\mathfrak{q} : x)$ lies between $\mathfrak{q}$ and $\mathfrak{p}$, and $ab \in (\mathfrak{q} : x)$ with $a \notin (\mathfrak{q} : x)$ gives $(ax)b \in \mathfrak{q}$, $ax \notin \mathfrak{q}$, so $b \in \mathfrak{p}$). Thus the cyclic submodule $R\bar{x}_i \cong R/(\mathfrak{q}_i : x_i)$ of R/I has all its zero-divisors in $\mathfrak{p}_i$; a maximal annihilator in it is prime (lemma 24.3.2), lies in $\mathfrak{p}_i$, and, containing $(\mathfrak{q}_i : x_i)$, contains $\sqrt{(\mathfrak{q}_i : x_i)} = \mathfrak{p}_i$, so it equals $\mathfrak{p}_i$. Since annihilators in a submodule are annihilators in R/I, this gives $\mathfrak{p}_i \in \mathrm{Ass}(R/I)$, and hence equality.

24.4 The Lasker-Noether Theorem

Existence rests on two Noetherian facts: that ideals are finite intersections of irreducible ones, and that over a Noetherian ring irreducible means primary. Call a proper ideal *irreducible* if it is not the intersection of two strictly larger ideals.

Lemma 24.4.1: Irreducible Implies Primary

In a Noetherian ring every irreducible ideal is primary.

***Proof*:**
Passing to R/I, it suffices to show that the zero ideal, if irreducible, is primary; that is, that a zero-divisor of a ring in which (0) is irreducible is nilpotent. Let $xy = 0$ with $y \neq 0$. The annihilators $\mathrm{Ann}(x) \subseteq \mathrm{Ann}(x^2) \subseteq \cdots$ stabilize, say $\mathrm{Ann}(x^n) = \mathrm{Ann}(x^{n+1})$. Then $(x^n) \cap (y) = 0$: if $ax^n = by$ then $ax^{n+1} = bxy = 0$, so $a \in \mathrm{Ann}(x^{n+1}) = \mathrm{Ann}(x^n)$ and $ax^n = 0$. Since (0) is irreducible and $(y) \neq 0$, we must have $(x^n) = 0$, so x is nilpotent.

Theorem 24.4.2: Lasker-Noether

In a Noetherian ring every proper ideal is a finite intersection of irreducible ideals, and hence is decomposable. Consequently every proper ideal has a minimal primary decomposition.

***Proof*:**
Let Σ be the set of ideals that are *not* finite intersections of irreducible ideals. If $\Sigma \neq \emptyset$ it has a maximal member I by the ascending chain condition. Now I is not irreducible (an irreducible ideal is such an intersection, of length one), so $I = J \cap K$ with $J, K \supsetneq I$. By maximality J and K are each finite intersections of irreducibles, hence so is I, contradicting $I \in \Sigma$. Thus $\Sigma = \emptyset$. Each irreducible ideal is primary by lemma 24.4.1, giving a primary decomposition, which is trimmed to a minimal one by grouping common radicals and discarding redundant terms.

The finiteness of the associated primes is now immediate.

Corollary 24.4.3: Finiteness of Associated Primes

Over a Noetherian ring, $\mathrm{Ass}(R/I)$ is finite for every ideal I; more generally $\mathrm{Ass}(M)$ is finite for every finitely generated module M.

***Proof*:**
The finitely generated case includes every R/I, so we prove it. Two standard facts suffice. First, a short exact sequence $0 \to M' \to M \to M'' \to 0$ gives $\mathrm{Ass}(M) \subseteq \mathrm{Ass}(M') \cup \mathrm{Ass}(M'')$: if $\mathfrak{p} = \mathrm{Ann}(x)$ then $Rx \cong R/\mathfrak{p}$, and either $Rx \cap M' \neq 0$, so a nonzero element of the domain $R/\mathfrak{p}$ lies in M' and (being torsion-free) still has annihilator $\mathfrak{p}$, whence $\mathfrak{p} \in \mathrm{Ass}(M')$; or $Rx \cap M' = 0$, so Rx injects into M'' and $\mathfrak{p} \in \mathrm{Ass}(M'')$. Second, applying lemma 24.3.2 repeatedly to split off a submodule $\cong R/\mathfrak{p}$ and pass to the quotient produces, by the ascending chain condition, a finite filtration $0 = M_0 \subsetneq \cdots \subsetneq M_r = M$ with $M_j/M_{j-1} \cong R/\mathfrak{p}_j$. Subadditivity along it gives $\mathrm{Ass}(M) \subseteq \{\mathfrak{p}_1, \ldots, \mathfrak{p}_r\}$, a finite set; for $M = R/I$ with I proper, theorem 24.3.3 identifies it precisely as the radicals $\{\mathfrak{p}_i\}$.

24.5 Support and the Isolated Components

The associated primes live inside a coarser invariant, the support, whose minimal members are the geometrically visible components.

Two consequences are used constantly and are recorded here, the first because it is invoked by name later in this book and in [15] without ever having been stated.

Proposition 24.5.1: Prime Avoidance

Let I be an ideal of a ring R and $\mathfrak{p}_1, \dots, \mathfrak{p}_n$ prime ideals. If $I \subseteq \mathfrak{p}_1 \cup \cdots \cup \mathfrak{p}_n$ then $I \subseteq \mathfrak{p}_i$ for some i. Equivalently, if I is contained in no $\mathfrak{p}_i$, then I contains an element lying in no $\mathfrak{p}_i$.

***Proof*:**
Induct on n, the case $n = 1$ being trivial. Discarding redundant terms, assume the covering is irredundant, so that for each i there is $a_i \in I$ with $a_i \notin \mathfrak{p}_j$ for $j \neq i$; if some a_i also avoided $\mathfrak{p}_i$ we would be done, so assume $a_i \in \mathfrak{p}_i$ for every i. Consider

$$b = a_1 + a_2 a_3 \cdots a_n$$

It lies in I. If $b \in \mathfrak{p}_1$ then, since $a_1 \in \mathfrak{p}_1$, the product $a_2 \cdots a_n \in \mathfrak{p}_1$, so some $a_j \in \mathfrak{p}_1$ with $j \geq 2$, contradicting the choice of a_j. If $b \in \mathfrak{p}_i$ for some $i \geq 2$ then, since $a_2 \cdots a_n \in \mathfrak{p}_i$, we get $a_1 \in \mathfrak{p}_i$, again a contradiction. So b lies in I and in no $\mathfrak{p}_i$, contradicting the assumed covering; hence the covering was not irredundant and induction finishes the proof.

Corollary 24.5.2: The Zero-Divisors Are the Union of the Associated Primes

Let R be Noetherian and $M \neq 0$ a finitely generated module. Then

$$\{ z \in R : z \text{ is a zero-divisor on } M \} = \bigcup_{\mathfrak{p} \in \operatorname{Ass}(M)} \mathfrak{p}$$

In particular an element lying outside every associated prime of M is a non-zero divisor on M.

***Proof*:**
If $\mathfrak{p} \in \operatorname{Ass}(M)$ then $\mathfrak{p} = \operatorname{Ann}(x)$ for some $x \neq 0$, so every element of $\mathfrak{p}$ kills x and is a zero-divisor. Conversely let $zx = 0$ with $x \neq 0$, so $z \in \operatorname{Ann}(x)$. The family of annihilators $\operatorname{Ann}(y)$ for $0 \neq y \in M$ that contain $\operatorname{Ann}(x)$ is nonempty and, R being Noetherian, has a maximal element $\operatorname{Ann}(y_0)$. It is maximal in the whole family as well: an annihilator strictly containing it also contains $\operatorname{Ann}(x)$, so lies in the subfamily. By lemma 24.3.2 it is therefore prime, so $\operatorname{Ann}(y_0) \in \operatorname{Ass}(M)$, and it contains z.

Definition 24.5.3: Support

The *support* of an R-module M is $\operatorname{Supp}(M) = \{\mathfrak{p} \in \operatorname{Spec} R : M_{\mathfrak{p}} \neq 0\}$.

Proposition 24.5.4: Support of a Finitely Generated Module

If M is finitely generated then $\operatorname{Supp}(M) = V(\operatorname{Ann} M)$. In particular $\operatorname{Supp}(R/I) = V(I)$.

***Proof*:**
For finitely generated $M = (x_1, \ldots, x_m)$, the localization $M_{\mathfrak{p}}$ vanishes iff each generator dies, that is iff $\operatorname{Ann}(x_i) \not\subseteq \mathfrak{p}$ for all i. Since $\mathfrak{p}$ is prime, a containment $\bigcap_i \operatorname{Ann}(x_i) \subseteq \mathfrak{p}$ would force some $\operatorname{Ann}(x_i) \subseteq \mathfrak{p}$ (a prime containing a finite intersection contains a factor); so $M_{\mathfrak{p}} = 0$ iff $\operatorname{Ann}(M) = \bigcap_i \operatorname{Ann}(x_i) \not\subseteq \mathfrak{p}$. Thus $M_{\mathfrak{p}} \neq 0$ iff $\operatorname{Ann}(M) \subseteq \mathfrak{p}$, which is $\mathfrak{p} \in V(\operatorname{Ann} M)$.

Proposition 24.5.5: Associated Primes Sit in the Support

For finitely generated M over a Noetherian ring, $\operatorname{Ass}(M) \subseteq \operatorname{Supp}(M)$, and the two sets have the same minimal elements. For an ideal I these common minimal elements are the minimal primes over I.

***Proof*:**
If $\mathfrak{p} = \operatorname{Ann}(x) \in \operatorname{Ass}(M)$ then $R/\mathfrak{p} \hookrightarrow M$ localizes to $(R/\mathfrak{p})_{\mathfrak{p}} = \kappa(\mathfrak{p}) \neq 0 \hookrightarrow M_{\mathfrak{p}}$, so $\mathfrak{p} \in \operatorname{Supp}(M)$. For the minimal elements: $\operatorname{Supp}(M) = V(\operatorname{Ann} M)$ by proposition 24.5.4, whose minimal elements are the minimal primes over $\operatorname{Ann}(M)$. Each such minimal prime $\mathfrak{p}$ has $M_{\mathfrak{p}} \neq 0$ finitely generated over the Noetherian local ring $R_{\mathfrak{p}}$, so $\operatorname{Ass}(M_{\mathfrak{p}}) \neq \emptyset$ by lemma 24.3.2; but $\mathfrak{p}$ is minimal in $\operatorname{Supp}(M)$, so $\mathfrak{p}R_{\mathfrak{p}}$ is the only prime of $R_{\mathfrak{p}}$ in the support, forcing $\operatorname{Ass}(M_{\mathfrak{p}}) = \{\mathfrak{p}R_{\mathfrak{p}}\}$ and hence $\mathfrak{p} \in \operatorname{Ass}(M)$ (associated primes localize, as in corollary 24.6.2). So minimal elements of $\operatorname{Supp}(M)$ lie in $\operatorname{Ass}(M)$, and being minimal in the larger set they are minimal in $\operatorname{Ass}(M)$; the reverse inclusion of minimal elements is immediate from $\operatorname{Ass}(M) \subseteq \operatorname{Supp}(M)$.

The associated primes thus divide in two: the *isolated* (or minimal) primes, which are the minimal primes over I, and the *embedded* primes, which properly contain another associated prime. The isolated components are intrinsic; the embedded ones are not.

Theorem 24.5.6: Second Uniqueness Theorem

Let $I = \mathfrak{q}_1 \cap \cdots \cap \mathfrak{q}_n$ be a minimal primary decomposition with $\mathfrak{p}_i = \sqrt{\mathfrak{q}_i}$. If $\mathfrak{p}_i$ is isolated (minimal among the $\mathfrak{p}_j$), the component $\mathfrak{q}_i$ is uniquely determined by I: it is the contraction of $IR_{\mathfrak{p}_i}$ to R. Embedded components need not be unique.

***Proof*:**
Localize at an isolated prime $\mathfrak{p} = \mathfrak{p}_i$. For $j \neq i$, $\mathfrak{p}_j \not\subseteq \mathfrak{p}$ by isolation, so $\mathfrak{q}_j$ meets $R \setminus \mathfrak{p}$ and $\mathfrak{q}_j R_{\mathfrak{p}} = R_{\mathfrak{p}}$; for the index i, $\mathfrak{q}_i R_{\mathfrak{p}}$ is $\mathfrak{p}R_{\mathfrak{p}}$-primary with contraction $\mathfrak{q}_i$ (see proposition 24.6.1). Intersecting, $IR_{\mathfrak{p}} = \mathfrak{q}_i R_{\mathfrak{p}}$, so $\mathfrak{q}_i = IR_{\mathfrak{p}} \cap R$ depends only on I and $\mathfrak{p}$. Non-uniqueness of embedded components is exhibited by example 24.5.7.

Example 24.5.7: Non-Uniqueness of Embedded Components
In $R = k[x,y]$ the ideal $I = (x^2, xy)$ has radical (x) and the two minimal primary decompositions

$$I = (x) \cap (x,y)^2 = (x) \cap (x^2, y),$$

both with radicals (x) and (x,y). The isolated (x)-component is (x) in each, as theorem 24.5.6 requires. The embedded (x,y)-component is $(x,y)^2 = (x^2, xy, y^2)$ in the first and (x^2, y) in the second, so it is genuinely not determined by I.

24.6 Localization and Primary Decomposition

The behavior under localization used above is the following, and it is what recovers the isolated components.

Proposition 24.6.1: Primary Ideals under Localization

Let $S \subseteq R$ be multiplicative and $\mathfrak{q}$ a $\mathfrak{p}$-primary ideal.

1. If $S \cap \mathfrak{p} \neq \emptyset$ then $S^{-1}\mathfrak{q} = S^{-1}R$.
2. If $S \cap \mathfrak{p} = \emptyset$ then $S^{-1}\mathfrak{q}$ is $S^{-1}\mathfrak{p}$-primary and its contraction to R is $\mathfrak{q}$.

***Proof*:**
If $s \in S \cap \mathfrak{p}$ then $s^n \in \mathfrak{q}$ for some n, and s^n is a unit in $S^{-1}R$, giving (1). For (2), assume $S \cap \mathfrak{p} = \emptyset$. Since localization is exact, $S^{-1}R/S^{-1}\mathfrak{q} \cong \bar{S}^{-1}(R/\mathfrak{q})$, the localization of $R/\mathfrak{q}$ at the image $\bar{S}$ of S. The zero-divisors of $R/\mathfrak{q}$ are nilpotent, hence lie in $\mathfrak{p}/\mathfrak{q}$; as $S \cap \mathfrak{p} = \emptyset$, the elements of $\bar{S}$ avoid $\mathfrak{p}/\mathfrak{q}$ and are non-zero-divisors of $R/\mathfrak{q}$. A zero-divisor of $\bar{S}^{-1}(R/\mathfrak{q})$ then has a zero-divisor of $R/\mathfrak{q}$ for numerator, hence is nilpotent; so $S^{-1}\mathfrak{q}$ is primary, with radical $S^{-1}\mathfrak{p}$. Its contraction is $\mathfrak{q}$: if $sx \in \mathfrak{q}$ with $s \in S$, then $s \notin \mathfrak{p} = \sqrt{\mathfrak{q}}$ forces $x \in \mathfrak{q}$ by primarity.

Corollary 24.6.2: Associated Primes Localize

For a multiplicative set S and finitely generated M over a Noetherian ring,

$$\operatorname{Ass}(S^{-1}M) = \{\, S^{-1}\mathfrak{p} : \mathfrak{p} \in \operatorname{Ass}(M),\ \mathfrak{p} \cap S = \emptyset \,\}$$

Consequently, if $I = \bigcap \mathfrak{q}_i$ is a minimal decomposition, localizing at an isolated prime $\mathfrak{p}_i$ deletes every component except $\mathfrak{q}_i$, recovering $\mathfrak{q}_i = IR_{\mathfrak{p}_i} \cap R$.

***Proof*:**
For $\supseteq$: an embedding $R/\mathfrak{p} \hookrightarrow M$ with $\mathfrak{p} \cap S = \emptyset$ localizes, by exactness (proposition 23.4.9), to $S^{-1}R/S^{-1}\mathfrak{p} \hookrightarrow S^{-1}M$, and $S^{-1}\mathfrak{p}$ is prime, so $S^{-1}\mathfrak{p} \in \operatorname{Ass}(S^{-1}M)$. For $\subseteq$: let $P = \operatorname{Ann}(x/s) \in \operatorname{Ass}(S^{-1}M)$ and $\mathfrak{p} = P \cap R$, a prime with $\mathfrak{p} \cap S = \emptyset$. As R is Noetherian, $\mathfrak{p} = (a_1, \ldots, a_k)$; each $a_j/1 \in P$ kills x/s, so $t_j a_j x = 0$ in M for some $t_j \in S$, and with $t = t_1 \cdots t_k$ we get $\mathfrak{p} \subseteq \operatorname{Ann}(tx)$. Conversely, if $r \in \operatorname{Ann}(tx)$ then $r \cdot (x/s) = rtx/(ts) = 0$, so $r \in P \cap R = \mathfrak{p}$; hence

$\mathfrak{p} = \mathrm{Ann}(tx) \in \mathrm{Ass}(M)$ and $P = S^{-1}\mathfrak{p}$. The recovery statement is proposition 24.6.1(2) applied to $S = R \setminus \mathfrak{p}_i$, exactly as in the proof of theorem 24.5.6.

Read geometrically, $\mathrm{Supp}(R/I) = V(I)$ decomposes into irreducible pieces indexed by the minimal primes over I, and the isolated primary components cut out those pieces with their natural scheme structure while the embedded primes mark where that structure thickens; this translation is the subject of [27], which cites the present chapter for the algebra.

25

Completion

The next type of construction we'll do is called a *completion*. These will be in the appropriate sense "stronger" then localizations, which will result in them being more restrictive, though also more powerful. A completion of a ring in many ways parallel's the completion of the rationals numbers $\mathbb{Q}$ to the real numbers $\mathbb{R}$. In fact, defining the appropriate metric, this process is a special case of the cauchy-sequence completion of the rational numbers to the reals. Namely, the completion of a ring is the equivalence class of all Cauchy-sequences which converge to the same point. Due to the topological background needed for this perspective, we shall relegate the equivalence of what shall be explicated in this section and Cauchy-sequences to appendix C.5.

There were rings that we have observed earlier that are completions of simpler rings; we will use completions to construct rings like the ring of *formal power series* $R[[x]]$ from $R[x]$, the ring $R[x_1, x_2, ...]$, the ring with *infinitely many monomial* from $R[x_1, ..., x_n]$, and the *p-adic integers* $\mathbb{Z}_p$ from $\mathbb{Z}$..

Completions will be handy for us in many ways. One important use that we will see when looking into algebraic geometry is looking at the "singularities" of schemes (or more particularly algebraic curves). Singularities will be points that don't be had as nicely as most other points, for example in the following image (which is the zero set of the equation $y^2 - x^2\,(x+1) = 0$) does not behave well at $(0, 0)$:

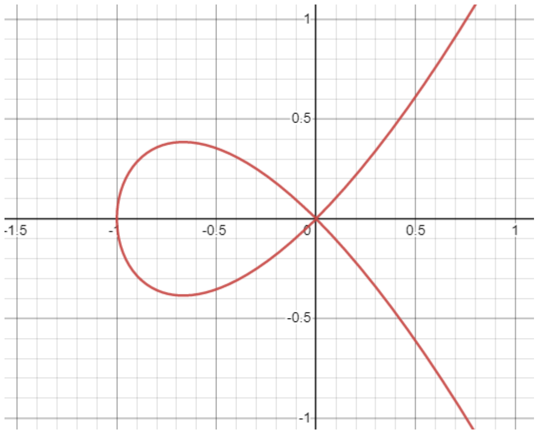


Figure 25.1: zero set of $y^2 - x^2(x+1) = 0$

This may seem similar to the geometric notion of localization, and this is indeed the case. Indeed, in the case of $\mathbb{Z}_{(p)}$ the p-adic integers are the completion of this ring, namely $\mathbb{Z}_p$ is the completion of $\mathbb{Z}_{(p)}$.

Completions shall also play a very important role in algebraic number theory. In this book, a more "classical" approach to algebraic number theory was taken, which shall give the reader great insights on the fundamental of algebraic number theory. However, a large part of *class number theory* shall rely on special completions of rings.

In this section, topological notion's will be introduced, and so an acquaintance of the material in appendix C is recommended. It should be noted that the topologies that will be discussed will be very different from that of Euclidean topologies, a new notion of size that is rather different from Euclidean distance shall be developed. The reader that is familiar with the construction of the real numbers using Cauchy sequences shall find it much easier to follow this section.

25.1 Constructing Completions

We will first define what is a "sequence". Let's say we have a collection of countable rings $R_1, R_2, ..., R_n$ and homomorphisms:

$$\cdots \xrightarrow{f_3} R_3 \xrightarrow{f_2} R_2 \xrightarrow{f_1} R_1$$

Then a sequence, or a *coherent sequence* is an element $(x_1, x_2, ...) \in \prod_{i=1}^{\infty} R_i$ where:

$$f_i(x_{i+1}) = x_i$$

If we take the special case of $I \subseteq R$ being an ideal and

$$\cdots \xrightarrow{f_3} R/(I^3) \xrightarrow{f_2} R/(I^2) \xrightarrow{f_1} R/I$$

then we will define a form of completion from these maps. For ease of notation, the sequence is usually written in the reverse order, as the reader shall understand once examples will be presented

Definition 25.1.1: Completion Of A Ring

Let R be a ring and $I \subseteq R$ be an ideal, and:

$$R/I \xleftarrow{f_1} R/(I^2) \xleftarrow{f_2} R/(I^3) \leftarrow \cdots$$

Then:

$$\hat{R} := \left\{ (a_1, a_2, ...,) \in \prod_{i=1}^{\infty} R_i \;\middle|\; f_i(a_{i+1}) = a_i \right\}$$

which is often denoted as:

$$\varprojlim R/I^n := \hat{R}$$

and is called the *limit* (or in older textbooks the *inverse limit* or *projective limit*). The collection $\{R/I^n\}$ is called the *inverse system*, with the function usually taken as implicit

A couple of remarks are in order:

1. There is a natural topology and a metric in which these elements can be thought of as Cauchy sequences and $\hat{R}$ is indeed the completion of R. If $\{R/\mathfrak{a}^n R\}$ is an inverse system with ideal $\mathfrak{a} \subseteq R$, and any $x \in R$, define a neighborhood basis (or local basis) $\{x + \mathfrak{a}^n R\}_{n=1}^{\infty}$. Then this forms a basis for a topology. This topology is called the $\mathfrak{a}$-*adic topology*, U is open in this topology if and only if for each $x \in U$, there exists a positive integer n such that

$$x + \mathfrak{a}^n R \subseteq U$$

   Then R is Hausdorff if and only if $\cap \mathfrak{a}^n R = 0$. If this is the case, define the metric $d(x, y) = 2^{-n}$ whenever $x \neq y$, where n is the largest integer with $x - y \in \mathfrak{a}^n R$ (equivalently $x - y \in \mathfrak{a}^n R \setminus \mathfrak{a}^{n+1} R$). The constant 2 does not matter, it can be replaced with any $C > 1$ and it will give the same topology.

   This exact same process can be repeated on an arbitrary R-module, where the inverse system would be $\{M/a^n M\}$, and for a given ideal $I \subseteq R$, we would define the I-adic topology on M.

2. This is a special case of a more general construction of a *limit* in the category of **Ring**. Namely, it is the limit of a special form of the diagram:

$$\cdots \to \bullet \to \bullet \to \bullet$$

   where each arrow has the coherence condition stated above.

3. The transition maps $R/\mathfrak{a}^{n+1} \to R/\mathfrak{a}^n$ of the systems built from powers of an ideal are surjective; such inverse systems are called *surjective systems*.

4. If R is a Noetherian integral domain and $I \subsetneq R$ is a proper ideal, then $\bigcap_n I^n = 0$, and hence $R \subseteq \hat{R}$. For those who shall read appendix C.4, this shows that inegral Noetherian domains are Hausdorff in the I-adic topology.

Example 25.1.2: Completion of Rings

1. Let $R = k[x]$ and $I = (x)$. Then:
$$\varprojlim (k[x]/(x)^n) = k[[x]]$$
To see this, consider:
$$\cdots k[x]/(x^3) \to k[x]/(x^2) \to k[x]/(x) = k$$
Notice that in each $k[x]/(x^k)$, can be thought of the collection of all polynomial of degree up to $k-1$. Hence, a coherent sequence $(a_1, a_2, ...)$ can be thought of as an "infinitely long polynomial" and would usually be denoted
$$\sum_k^\infty a_k x^k$$
Similarly, the reader may verify that $\widehat{k[x,y]} = k[[x,y]]$ with $I = (x,y)$
2. Let $R = \mathbb{Z}$ and $I = (10)$. Then $\varprojlim \mathbb{Z}/(10)^n$ is represented by all infinitely long numbers. Just like before, each $\mathbb{Z}/(10)^k$ can be thought of as as holding information up to the $k-1$th position. So if we take:
$$Z/(10) \leftarrow Z/(100) \leftarrow \mathbb{Z}/(1000) \leftarrow$$
and construct a coherent chain, we may chose elements like 5, 25, 425, ... and so on. The reader may see that this would represent an infinitely long number. The resulting ring is often denoted $\mathbb{Z}_{10}$ and is called the 10-adic integers. Any element of $\mathbb{Z}_{10}$ could formally be represented as
$$\sum_k^\infty a_k 10^k$$
3. Let $R_n = k[x_1, ..., x_n]$ with transition maps setting the last variable to 0. The limit $\varprojlim R_n$ strictly contains the polynomial ring $k[x_1, x_2, \dots]$: it also has elements of infinite support, such as the coherent sequence $(x_1,\, x_1 + x_2,\, \dots)$ representing $\sum_i x_i$

Completions are a way to construct rings. It would be nice if exactness interact nicely with it. If $\{A_n\}$, $\{B_n\}$, $\{C_n\}$ are three inverse systems where:

$$\begin{tikzcd}
0 \arrow[r] & A_{n+1} \arrow[r, "\psi"] \arrow[d, "\alpha"] & B_{n+1} \arrow[r, "\varphi"] \arrow[d, "\beta"] & C_{n+1} \arrow[r] \arrow[d, "\gamma"] & 0 \\
0 \arrow[r] & A'_n \arrow[r, "\psi'"] & B'_n \arrow[r, "\varphi'"] & C'_n \arrow[r] & 0
\end{tikzcd}$$

Then we'll denote it as $0 \to \{A_n\} \to \{B_n\} \to \{C_n\} \to 0$. Then we naturally get the induced homomorphisms:
$$0 \to \varprojlim A_n \to \varprojlim B_n \to \varprojlim C_n \to 0$$
however this is not always exact. The following proposition shows us when it is:

Proposition 25.1.3: Limits and Exactness for inverse Systems

Let $0 \to \{A_n\} \to \{B_n\} \to \{C_n\} \to 0$ be an exact sequence of inverse systems. Then:

$$0 \to \varprojlim A_n \to \varprojlim B_n \to \varprojlim C_n$$

is always exact. If $\{A_n\}$ is a surjective system, then:

$$0 \to \varprojlim A_n \to \varprojlim B_n \to \varprojlim C_n \to 0$$

is always exact

Hence, when working with completions induced by surjective systems, the completion functor $\widehat{(-)}$ preserves injective and surjective functions[1].

***Proof*:**
This is an application of Snakes lemma. Let $A = \prod_{n=1}^{\infty} An$, and

$$d^A : A \to A \qquad d^A(a_n) = a_n - f_{n+1}(a_{n+1})$$

Then by construction

$$\ker d^A = \varprojlim A_n$$

We may define B, C via d^B and d^C respectively. Now, as we have an exact sequence of inverse systems, we get the following diagram:

$$\begin{tikzcd}
0 \arrow[r] & A \arrow[r] \arrow[d, "d^A"] & B \arrow[r] \arrow[d, "d^B"] & C \arrow[r] \arrow[d, "d^C"] & 0 \\
0 \arrow[r] & A \arrow[r] & B \arrow[r] & C \arrow[r] & 0
\end{tikzcd}$$

Then by proposition 17.1.10 we get:

$$0 \to \ker d^A \to \ker d^B \to \ker d^C \to \text{coker} d^A \to \text{coker} d^B \to \text{coker} d^C \to 0$$

Finally, if the system is a surjective system, we can solve inuctively the equation:

$$x_n - f_{n+1}(x_{n+1}) = a_n$$

to show that d^A is surjective, completing the proof.

The following result shall be stated as it gives a very fascinating result, however for the full background the reader should read appendix C.5:

[1] In Part XI, this shall imply that the completion functor has trivial cohomology, while general inverse systems shall have non-trivial cohomology

Corollary 25.1.4: Completion of Group Exact Sequences

Let $0 \to G' \to G \xrightarrow{p} G'' \to 0$ be an exact sequence of groups. Let G have a topology given by the subgroups $\{G_n\}$, and induce the topology on G', G'' via the subgroups $\{G' \cap G_n\}$ and $\{p(G_n)\}$. Then:

$$0 \to \hat{G}' \to \hat{G} \to \hat{G}'' \to 0$$

is exact

***Proof*:**
Apply proposition 25.1.3 to

$$0 \to \frac{G'}{G' \cap G_n} \to \frac{G}{G_n} \to \frac{G''}{pG_n} \to 0$$

Corollary 25.1.5: Quotient in Completion

Let $\hat{G}_n \leqslant \hat{G}$. Then:

$$\hat{G}/\hat{G}_n \cong G/G_n$$

***Proof*:**
The quotient G/G_n carries the discrete topology (its induced filtration is eventually 0), so it equals its own completion. Applying the exact completion functor (proposition 25.1.3) to $0 \to G_n \to G \to G/G_n \to 0$ gives $0 \to \hat{G}_n \to \hat{G} \to G/G_n \to 0$, whence $\hat{G}/\hat{G}_n \cong G/G_n$.

As a consequence, in particular interest is the case of $\mathbb{Z}_{10}$ where

$$\mathbb{Z}_{10} \cong \mathbb{Z}_2 \oplus \mathbb{Z}_5$$

Hence $\mathbb{Z}_{10}$ is decomposeable to smaller rings. These rings are also in many ways nicer: notice that as a consequence of the above isomorphism that $\mathbb{Z}_{10}$ has zero divisors (any product of two non-trivial rings has zero-divisors)[2], showing that in general the completion may introduce zero-divisors, while $\mathbb{Z}_2$ and $\mathbb{Z}_5$ do not introduce zero-divisors. Furthermore, $\mathbb{Z}_p$ introduces more units (this was more evident with $k[[x]]$ where the units were explicitly found in proposition 9.2.11). For this reason, we would concentrate on the p-adic integers $\mathbb{Z}_p$. Any element of $\mathbb{Z}_p$ could be represented as

$$\sum_{k}^{\infty} a_k p^k$$

We may generalize the result for finding units in completions:

Lemma 25.1.6: Units In Completion

Let R be a ring and $\hat{R}$ a completion of R via p. Then if $u \in R/p^n$ is a unit, $u \in R/p^{2n}$ is a unit.

[2] Can you find two explicit elements?

***Proof*:**
Let u be a unit so $1 + us \in p^n$. Squaring, we get:

$$1 + u(2s + us^2) \in p^{2n}$$

Hence, it is a unit in R/p^{2n}.

The reader should use this to show that u is a unit in $\hat{R}$. This also generalizes proposition 9.2.11, for this directly shows that any power series with nonzero constant is a unit. In the case where $p = \mathfrak{m}$ is a maximal ideal (as in the case for p-adic integers and $k[x]$), we get the following result:

Lemma 25.1.7: Completion At Maximal Ideals

Let R be a ring and $\mathfrak{m}$ a maximal ideal. Then $\varprojlim R/\mathfrak{m}^n$ is a local ring, that is, it contains a single maximal ideal.

***Proof*:**
Let $z = (z_n) \in \varprojlim R/\mathfrak{m}^n$ have nonzero residue $z_1 \in R/\mathfrak{m}$. Since $\mathfrak{m}/\mathfrak{m}^n$ is the unique maximal ideal of $R/\mathfrak{m}^n$, each z_n has nonzero residue mod $\mathfrak{m}$ and so is a unit there, and the inverses z_n^{-1} are coherent; hence z is a unit. Thus the non-units are exactly $\ker(\varprojlim R/\mathfrak{m}^n \to R/\mathfrak{m})$, an ideal, so $\varprojlim R/\mathfrak{m}^n$ is local.

Thus, there is a natural map:

$$R_{\mathfrak{m}} \to \varprojlim R/\mathfrak{m}^n$$

where $R_{\mathfrak{m}}$ is the localization. Recall that in $R_{\mathfrak{m}}$, the elements are constructed by taking formal inverses, hence completion at a maximal ideal shows a "dual" way of creating units by finding them in some way "at infinity". Note that it is important that $\mathfrak{m}$ be maximal, for this will fail if an ideal is only prime (however, one may localize the ring at the prime ideal to make it maximal and then take the completion).

When working with localizaiton, we saw that a localization of an integral domain is an integral domain. This is no longer true for completion:

Example 25.1.8: Completion Looses Integral Domain
Let

$$R = \frac{k[x, y]}{(y^2 - x^3 - x^2)}$$

with k a field of characteristic 0. Then completing this ring, since completion is exact, we get:

$$\hat{R} = \frac{k[[x, y]]}{(y^2 - x^3 - x^2)} \cong \frac{k[[x, y]]}{(y - x\sqrt{1+x})(y + x\sqrt{1+x})}$$

where $\sqrt{1+x}$ is the short-hand for the power-series associated to $\sqrt{1+x}$. Then it is easy to see that this ring has zero-divisors. This shall eventually be made rather clear when a geometric perspective is taking. The ring R shall in a concrete sense have the curve $y^2 = x^3 + x^2$ associated to it:

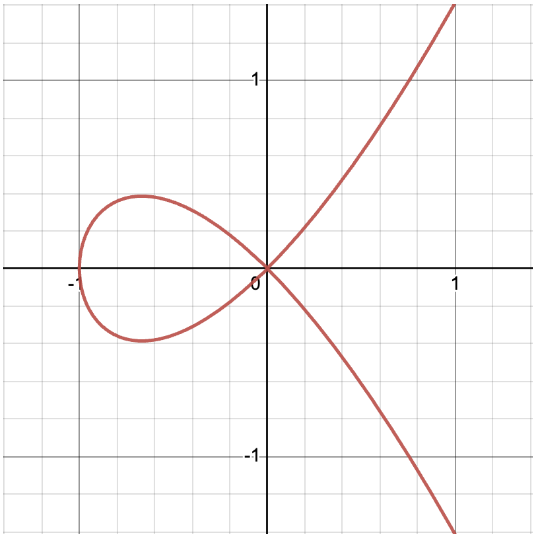

Figure 25.2: $y^2 = x^3 + x^2$

This curve shall be shown to be *irreducible* in a concrete way. The localization shall represent this curve minus some finite amount of points. The completion at (x, y) shall represent "zooming in" at the point (x, y), at which point geometric object shall roughly correspond to:

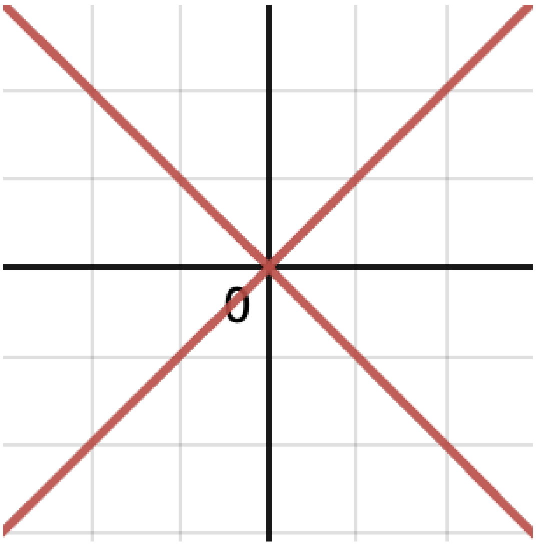

Figure 25.3: Approximate Geometric picture corresponding to $\varprojlim R/(x, y)^n$

Then this shall be shown to be decomposable in a rigorous sense into two components (the two strokes of the "x" in the above picture).

Definition 25.1.9: Separated and Complete

Let M be an R-module with the $\mathfrak{a}$-adic filtration, and let $\iota\colon M \to \hat{M} = \varprojlim M/\mathfrak{a}^n M$ be the natural map to its completion. Then M is

- *separated* if ι is injective, equivalently $\bigcap_n \mathfrak{a}^n M = 0$;
- *complete* if ι is surjective;

and *separated and complete* (usually abbreviated to just *complete*) if ι is an isomorphism, i.e. $M \cong \hat{M}$. A ring R is complete for the $\mathfrak{a}$-adic topology if it is so as a module over itself.

The two conditions genuinely differ: over a non-Noetherian ring a module can be complete without being separated. The completion $\hat{M}$ is always separated and complete, and it is the universal such object.

Proposition 25.1.10: Universal Property of Completion

Let R carry the $\mathfrak{a}$-adic topology with completion $\iota\colon R \to \hat{R}$. Then $\hat{R}$ is separated and complete, and ι is universal among continuous homomorphisms into separated complete rings: for every separated complete ring S and continuous homomorphism $f\colon R \to S$ there is a unique continuous homomorphism $\hat{f}\colon \hat{R} \to S$ with $\hat{f} \circ \iota = f$.

***Proof*:**
Continuity of f gives, after reindexing, $f(\mathfrak{a}^n) \subseteq \mathfrak{b}^n$ for a defining ideal $\mathfrak{b}$ of S, so f induces compatible maps $R/\mathfrak{a}^n \to S/\mathfrak{b}^n$. Passing to limits yields $\hat{f}\colon \hat{R} \to \hat{S} = S$ (using that S is separated and complete), and $\hat{f} \circ \iota = f$ holds on each quotient. Uniqueness follows because $\iota(R)$ is dense in $\hat{R}$ and S is separated.

Taking $\mathfrak{a}^n M$ as the filtration, a homomorphism $f\colon M \to N$ satisfies $f(\mathfrak{a}^n M) \subseteq \mathfrak{a}^n N$, so it induces maps on the quotients and lifts to $\hat{f}\colon \hat{M} \to \hat{N}$; completion is thus a functor.

25.2 Filtrations

The following construction is a more general version of an inverse system that drops many of the algebraic properties and is a more "pure topological" definition. It is being presented here for its use in the study of graded algebras, as well as it's use when defining *spectral sequences* in chapter 58

Definition 25.2.1: Filtration

Let M be an R-module. Then a *filtration* of M is an infinite chain:

$$M = M_0 \supseteq M_1 \supseteq \cdots \supseteq M_n \supseteq \cdots$$

where each M_n is a submodule of M. The chain is usually denoted (M_n). If furthermore $\mathfrak{a} \subseteq R$ is an ideal, then an $\mathfrak{a}$-filtration of M is a filtration st

$$\mathfrak{a}M_n \subseteq M_{n+1} \qquad \forall n \in \mathbb{N}$$

An $\mathfrak{a}$-filtration (M_n) is called *stable* (or $\mathfrak{a}$-*stable*) if there exists an N such that $\mathfrak{a}M_n = M_{n+1}$ for all $n \geq N$.

An $\mathfrak{a}$-stable filtration can be thought of as the generalization of a graded module which is in some way finite. The following lemma will be important to compare two $\mathfrak{a}$-stable filtrations:

Lemma 25.2.2: Comparing Stable $\mathfrak{a}$-Filtartions

Let $(M_n), (M'_n)$ be stable $\mathfrak{a}$-filtrations of M. Then they have bounded difference, that is, there exists an integer n_0 such that $M_{n+n_0} \subseteq M'_n$ and $M'_{n+n_0} \subseteq M_n$ for all $n \geq 0$.

This will imply that all stable $\mathfrak{a}$-filtrations determine the same topology on M (The $\mathfrak{a}$-topology)

***Proof*:**
It suffices to compare each stable $\mathfrak{a}$-filtration with the $\mathfrak{a}$-adic filtration $(\mathfrak{a}^n M)$. For any $\mathfrak{a}$-filtration, $\mathfrak{a}M_n \subseteq M_{n+1}$ gives $\mathfrak{a}^n M \subseteq M_n$ by induction. Stability provides an N with $M_{n+1} = \mathfrak{a}M_n$ for $n \geq N$, so $M_{n+N} = \mathfrak{a}^n M_N \subseteq \mathfrak{a}^n M$. Thus $\mathfrak{a}^n M \subseteq M_n$ and $M_{n+N} \subseteq \mathfrak{a}^n M$; doing the same for (M'_n) with some N' and combining, with $n_0 = \max(N, N')$, gives $M_{n+n_0} \subseteq M'_n$ and $M'_{n+n_0} \subseteq M_n$.

The key use of this lemma comes when defining the α-adic topology given in appendix C.4, namely all stable $\mathfrak{a}$-filtrations produce the same topology.

Exercise 25.2.1

1. Show that $\mathbb{Z}_p \cap \mathbb{Q} \cong \mathbb{Z}_{(p)}$
2. Show that $\hat{\hat{R}} \cong \hat{R}$

25.3 More on Graded Algebras

Graded algebras were initially explored in section 16.3. In this section, we expand further on graded-algebras, explore their relation to the Neotherian property, and look at some important associated graded algebras given an ideal I or module M. This exploration shall bear fruitful results that will be important in the development of *projective algebraic geometry* and *homological algebra*.

First, recall that a ring R is a graded ring if $R = \bigoplus_i R_i$ where $R_i R_j \subseteq R_{i+j}$, which makes R into an R_0-algebra, and each R_i is an R_0-module. A graded R-module is a module $M = \bigoplus_0^\infty M_i$ such that $R_m M_n \subseteq M_{m+n}$. If M is also a graded ring, then M is an R-graded algebra. Elements of M_n are called *homogeneous*, and an ideal $I \subseteq R$ is called homogeneous if $I = \bigoplus_i^\infty (R_i \cap I)$. A ring or R-module homomorphism is called graded if it respects the graded structure ($f(M_n) \subseteq N_n$). Each graded ring has an ideal $R_+ = \bigoplus_{n>0} R_n$. The elements of R_n for each n are called the *homogeneous elements*.

Proposition 25.3.1: Noetherian Graded Rings

Let R be a graded ring. Then the following are equivalent:

1. R is Noetherian
2. R_0 is Noetherian and R is a finitely generated R_0-algebra

***Proof*:**

(1) $\Rightarrow$ (2) As $R_0 \cong R/R_+$, R_0 is Noetherian. As $R_+ \subseteq R$ is an ideal of R, it is finitely generated, say $x_1, ..., x_s$. Then these elements can be used to construct homogeneous s element, let's use the same label and say they are of order $k_1, ..., k_s$ (all necessarily order greater than 0). Let $R' \subseteq R$ be the ring generated as an R_0 algebra over the homogeneous elements $x_1, ..., x_s$. Then I claim that $R = R'$, which will the proof. First, let' show $A_n \subseteq A'$ using induction. It is clear if $n = 0$. For $n > 0$, taking $y \in A_n$, as $y \in A_+$, y is a linear combination of the x_i

$$y = \sum_i^s a_i x_i$$

with $a_i \in A_{n-k_i}$ (and $A_m = 0$ of $m < 0$). Then by the inductive hypothesis, each a_i is a polynomial in the x's with coefficients in A_0. Hence, by the principle of induction, the same holds for y, we have that $A_n \subseteq A'$. As $A' \subseteq A$ by definition, we have $A = A'$, as we sought to show

(2) $\Rightarrow$ (1) Follow's from HBT

Any ring R induces a graded ring by taking $\mathfrak{a} \subseteq R$ and taking $R^* = \bigoplus_n^\infty \mathfrak{a}^n$. Similarly, any R-module M induces a graded R^*-module $M^* = \bigoplus_n M_n$ where M_n is the $\mathfrak{a}$-filtration. The "canonical" grading comes from $S = R[x_1, ..., x_n]$ with $\mathfrak{a} = (x_1, ..., x_n)$ which will produce the homogeneous grading of S.

In the case where R is Noetherian and $\mathfrak{a}$ is finitely generated (say by $x_1, ..., x_s$), then R^* is a quotient of the polynomial ring $R[x_1, ..., x_s]$ (with the x_i in degree 1), hence Noetherian by proposition 25.3.1.

Proposition 25.3.2: Topology of Noetherian Graded Module

Let R be a Noetherian ring, M a finitely generated R-module, (M_n) an $\mathfrak{a}$-filtration of M. Then the following are equivalent:

1. M^* is a finitely generated R^*-module
2. The filtration (M_n) is stable

***Proof*:**
This is about creating the right conditions to see the filter is stable. Take $Q_n = \bigoplus_{r=0}^{n} M_r$. As each M_r is finitely generated, Q_n is finitely generated. Then Q_n forms a subgroup of M^* but not in general a R^*-submodule. We may however use it to generate one:

$$M_n^* = M_0 \oplus \cdots M_n \oplus \mathfrak{a}M_n \oplus \mathfrak{a}^2 M_n \oplus \cdots \oplus \mathfrak{a}^r M_n \oplus \cdots$$

Now, as Q_n is finitely generated as an R-module, M_n^* is finitely generated as an R^*-module, and the M_n^* form an ascending chain whose unions is M^*.

Finally, we now have that as R^* is Noetherian ,M^* is finitely generated as an R^*-module if and only if the chain stops ($M^* = M_{n_0}^*$) if and only if the filtration is stable.

Corollary 25.3.3: Graded Noetherian then Component Noetherian

Let R be graded and Noetherian, and suppose M is a finitely generated graded R-module. Then M_n is a finitely-generated R_0-module for all $n \in \mathbb{N}$

***Proof*:**
Let

$$d_j = \deg m_j$$

Then every element of $m \in M_n$ can be written as:

$$m = \sum_j f_j(x) m_j \qquad f_j(x) \in R$$

where f_j is homogeneous of degree $n - d_j$ (and is zero if $n < d_j$). Hence, M_n is finitely generated as an R_0-module generated by all $g_j(x)m_j$ where $g_j(x)$ is a monomial in x_i of total degree $n - d_j$, as we sought to show.

25.4 Artin-Rees Lemma

The Artin-Rees lemma is a central result that will allow us to compare the induced and $\mathfrak{a}$-adic topology on a submodule, giving us insight on their topologies.

Theorem 25.4.1: Artin-Rees Lemma

Let R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal, M a finitely generated R-module, and (M_n) a stable $\mathfrak{a}$-filtration of M. Then if $M' \subseteq M$ is a submodule of M, $(M' \cap M_n)$ is a stable $\mathfrak{a}$-filtration of M'

***Proof*:**
As $\mathfrak{a}(M' \cap M_n) \subseteq \mathfrak{a}M' \cap \mathfrak{a}M_n \subseteq M' \cap M_{n+1}$, $(M' \cap M_n)$ is an $\mathfrak{a}$-filtration, and so it defines a graded R^*-module which is a submodule of M^*, and so it is finitely generated, letting us apply by proposition 25.3.2 to completing the proof.

Corollary 25.4.2: Graded Sub-module, Computational Shortcut

Let R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal, M a finitely generated R-module, and $M' \subseteq M$ a submodule. Then there exists a k such that

$$(\mathfrak{a}^n M) \cap M' = \mathfrak{a}^{n-k}\left((\mathfrak{a}^k M) \cap M'\right)$$

for all $n \geq k$

***Proof*:**
By the Artin-Rees lemma (theorem 25.4.1), $(\mathfrak{a}^n M \cap M')$ is a stable $\mathfrak{a}$-filtration of M', so there is a k with $\mathfrak{a}(\mathfrak{a}^n M \cap M') = \mathfrak{a}^{n+1} M \cap M'$ for all $n \geq k$; iterating gives $\mathfrak{a}^n M \cap M' = \mathfrak{a}^{n-k}(\mathfrak{a}^k M \cap M')$ for $n \geq k$.

Theorem 25.4.3: Submodule Adic Topology Equivalence

Let R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal, M a finitely generated R-module, $M' \subseteq M$ a submodule. Then the filtrations

$$\mathfrak{a}^n M' \qquad \text{and} \qquad (\mathfrak{a}^n M) \cap M'$$

have bounded difference, hence the $\mathfrak{a}$-topology of M' coincides with the induced topology given by the $\mathfrak{a}$-topology of M

***Proof*:**
Direct result of corollary 25.4.2 and theorem 25.4.1.

Corollary 25.4.4: Module Completion Preserves Exactness

Let

$$0 \to M' \to M \to M'' \to 0$$

be a short exact sequence of finitely generated R-modules over a Noetherian ring R. Then if $\mathfrak{a} \subseteq R$ is an ideal, the $\mathfrak{a}$-adic completion functor preserves exactness:

$$0 \to \hat{M}' \to \hat{M} \to \hat{M}'' \to 0$$

***Proof*:**
Theorem 25.4.3 provides the condition needed to use corollary 25.1.4.

Next, as we have a natural homomorphism $R \to \hat{R}$, we can think of $\hat{R}$ as an R-algebra, and hence we have an extension of scalars of an R-module M given to an $\hat{R}$-module $\hat{R} \otimes_R M$. This gives a natural sequence of maps that we may want to understand:

$$\hat{R} \otimes_R M \to \hat{R} \otimes_R \hat{M} \to \hat{R} \otimes_{\hat{R}} \hat{M} = \hat{M}$$

In general, these maps are neither injective nor surjective. Under nicer conditions, we have a better control:

Proposition 25.4.5: Module Completion as Tensor Product

Let R be any ring. Then if$M$ is finitely generated,

$$\hat{R} \otimes_R M \twoheadrightarrow \hat{M}$$

is surjective. If furthermore R is Neotherian, then:

$$\hat{R} \otimes_R M \cong \hat{M}$$

***Proof*:**
Let $F \cong R^n$ so that $M \cong F/N$ for appropriate N. The conclusion can be drawn from the following commutative diagram:

$$\begin{tikzcd}
 & \hat{R} \otimes_R N \arrow[r] \arrow[d, "\gamma"] & \hat{R} \otimes_R F \arrow[r] \arrow[d, "\beta"] & \hat{R} \otimes_R M \arrow[r] \arrow[d, "\alpha"] & 0 \\
0 \arrow[r] & \hat{N} \arrow[r] & \hat{F} \arrow[r, "\delta"] & \hat{M} \arrow[r] & 0
\end{tikzcd}$$

where the top line is given by the right-exactness of the tensor product, and the bellow line is given by corollary 25.1.4. Note that as completion commutes with finite direct sums (use corollary 25.1.4), we have that $\hat{R} \otimes_R F \cong \hat{F}$, and so α is surjective, giving us the first part. If R is Noetherian, hen N is finitely generated and so γ is surjective, and so we get exactness of the bottom line. Then by chasing the diagram we will get hat α is injective, and hence an isomorphism, completing the proof.

From this, we get that when R is Noetherian, the extension of scalar functor $\widehat{(-)}$ is equivalent to the functor $\hat{R} \otimes_R (-)$ from the category of R-modules to the category of $\hat{R}$-modules is exact. As a consequence:

Corollary 25.4.6: Flatness of Completion

Let R be a Neotherian ring, $\mathfrak{a} \subseteq R$ an ideal, $\hat{R}$ the $\mathfrak{a}$-adic completing of R. Then $\hat{R}$ is a flat R-algebra.

***Proof*:**
direct result of above discussion.

Proposition 25.4.7: Properties of Adic Completion

Let R be Noetherian and $\hat{R}$ its $\mathfrak{a}$-adic completion. Then:

1. $\hat{\mathfrak{a}} = \hat{R}\mathfrak{a} = \hat{R} \otimes_R \mathfrak{a}$
2. $\widehat{\mathfrak{a}^n} = \hat{\mathfrak{a}}^n$
3. $\mathfrak{a}^n/\mathfrak{a}^{n+1} \cong \hat{\mathfrak{a}}^n/\hat{\mathfrak{a}}^{n+1}$
4. $\hat{\mathfrak{a}}$ is contained in the Jacobson radical of $\hat{R}$

***Proof*:**
exercise (or see Atiyah p.109)

We shall show the last one. By (2) and the fact that $\hat{\hat{R}} \cong \hat{R}$, we see that $\hat{R}$ is complete in the $\mathfrak{a}$-adic topology. Hence for any $x \in \hat{\mathfrak{a}}$,

$$(1-x)^{-1} = 1 + x + x^2 + \cdots$$

converges in $\hat{R}$, and so $1-x$ is a unit. Then this implies that $\hat{\mathfrak{a}}$ is contained in the Jacobson radical of $\hat{R}$, completing the proof.

Let us next characterize the kernel of the map $M \to \hat{M}$

Theorem 25.4.8: Krull's Theorem

LEt R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal, M a finitely generated R-module, and $\hat{M}$ the $\mathfrak{a}$-completion of M, Then the kernel

$$E = \bigcap_{n=1}^{\infty} \mathfrak{a}^n M$$

given by the map $M \to \hat{M}$ consist of all $x \in M$ that are annihilated by some element $1 + \mathfrak{a}$.

***Proof*:**
It suffices to show that $(1-\alpha)E = 0$. IT is clear that if $(1-\alpha)x = 0$

$$x = \alpha x = \alpha^2 x = \cdots \in \bigcap_{n=1}^{\infty} \mathfrak{a}^n M = E$$

Hence we shall show the converse. By the Artin-Rees consequence (corollary 25.4.2) applied to $E \subseteq M$, there is a k with $\mathfrak{a}^n M \cap E = \mathfrak{a}^{n-k}(\mathfrak{a}^k M \cap E)$ for $n \geq k$. Since $E \subseteq \mathfrak{a}^n M$ for all n, the left-hand side is E and the right-hand side is $\mathfrak{a}^{n-k}E$, so $E = \mathfrak{a}^{n-k}E \subseteq \mathfrak{a}E$, giving $\mathfrak{a}E = E$. As M is finitely generated over the Noetherian ring R, E is finitely generated, so the determinant form of Nakayama's lemma yields $\alpha \in \mathfrak{a}$ with $(1-\alpha)E = 0$, completing the proof.

Proposition 25.4.9: Localization is A Subring of Completion

Let R be Noetherian and let $S = 1 + \mathfrak{a}$. Then

$$S^{-1}R \hookrightarrow \hat{R}$$

***Proof*:**
The map $R \to \hat{R}$ and $R \to S^{-1}R$ have the same kernel, and for any $\alpha \in \hat{\mathfrak{a}}$ we have

$$(1-\alpha)^{-1} = 1 + \alpha + \alpha^2 + \cdots$$

converges in $\hat{A}$, and hence all S become a unit in $\hat{A}$. By the universal property of $S^{-1}A$, there is a natural homomorphism $S^{-1}A \to \hat{A}$ which is injective by theorem 25.4.8.

The Noetherian condition is necessary, an easy example lies within the realm of analysis:

Example 25.4.10: Localization and Completion Without Noetherian Property
Take R to be the collection of smooth functions on $\mathbb{R}$, $C^\infty(\mathbb{R})$. Let $\mathfrak{a}$ be the ideal of all f which vanish at 0. This ideal is maximal as $R/\mathfrak{a} \cong \mathbb{R}$. Then $\mathfrak{a}$ is generated by x (if you know some multi-variable calculus prove that any f that vanishes at 0 can be written as $f(x) = xg(x)$ for g smooth, it is a variation of Hadamard's lemma), and $E = \bigcap_{n=1}^{\infty} \mathfrak{a}^n$ is the set of all $f \in R$ such that all derivatives vanish at the origin. On the other hand, f is annihilated by some element $1+\alpha$ for $\alpha \in \mathfrak{a}$ iff f vanishes identically in some neighborhood of 0. Now, the function e^{-1/x^2} has vanishing derivative at 0, but is not identically zero near 0. Hence the kernels of the $R \to \hat{R}$ and $\mathbb{R} \to S^{-1}R$ with $S = 1 + \mathfrak{a}$ do not coincide.

This can also be a way of showing that R cannot be Noetherian.

Corollary 25.4.11: Krull Theorem, Noetherian Domain

Let R be a Noetherian domain and $(1) \neq \mathfrak{a} \subseteq R$ an ideal. Then

$$\bigcap \mathfrak{a}^n = 0$$

***Proof*:**
By Krull's theorem (theorem 25.4.8), $\bigcap \mathfrak{a}^n$ consists of the x annihilated by some $1+\alpha$ with $\alpha \in \mathfrak{a}$. Since $\mathfrak{a}$ is proper, $-1 \notin \mathfrak{a}$, so $1+\alpha \neq 0$; as R is a domain, $(1+\alpha)x = 0$ forces $x = 0$, whence $\bigcap \mathfrak{a}^n = 0$.

Corollary 25.4.12: Krull Theorem, Hausdorff Topology

Let R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal contained in the Jacobson radical, and M a finitely generated R-module. Then the $\mathfrak{a}$-topology of M is Hausdroff, i.e.

$$\bigcap \mathfrak{a}^n M = 0$$

***Proof*:**
Since $\mathfrak{a} \subseteq \text{Jac}(R)$, every element of $1+\mathfrak{a}$ is a unit (proposition 23.4.26). By Krull's theorem (theorem 25.4.8), each element of $\bigcap \mathfrak{a}^n M$ is annihilated by such a unit, hence is 0.

Corollary 25.4.13: Krull Theorem, Kernel Into Localization

Let R be a Noetherian ring, $\mathfrak{p} \subseteq R$ a prime ideal. Then the intersection of all $\mathfrak{p}$-primary ideals of A is the kernel of $A \to A_{\mathfrak{p}}$

***Proof*:**
Write $K = \ker(A \to A_{\mathfrak{p}}) = \{a \in A \mid sa = 0 \text{ for some } s \notin \mathfrak{p}\}$. Every $\mathfrak{p}$-primary ideal $\mathfrak{q}$ contains K: if $sa = 0 \in \mathfrak{q}$ with $s \notin \mathfrak{p} = \sqrt{\mathfrak{q}}$, then $a \in \mathfrak{q}$; hence $K \subseteq \bigcap\{\mathfrak{p}\text{-primary}\}$. Conversely the symbolic powers $\mathfrak{p}^{(n)} = (\mathfrak{p}^n A_{\mathfrak{p}}) \cap A$ are $\mathfrak{p}$-primary, and since $\mathfrak{p}A_{\mathfrak{p}}$ lies in the Jacobson radical of $A_{\mathfrak{p}}$, corollary 25.4.12 gives $\bigcap_n \mathfrak{p}^n A_{\mathfrak{p}} = 0$, whence $\bigcap_n \mathfrak{p}^{(n)} = K$. Thus $\bigcap\{\mathfrak{p}\text{-primary}\} \subseteq \bigcap_n \mathfrak{p}^{(n)} = K$, and the two inclusions give equality.

25.5 Associated Graded Rings: Noetherian Closed under Completion

The following will let us show another way of characterizing complete rings, and let us prove that the completion of a Noetherian ring is Noetherian.

Definition 25.5.1: Associated Graded Ring

Let R be a ring and $\mathfrak{a} \subseteq R$ an ideal. Then the *associated graded ring* is

$$G_{\mathfrak{a}}(R) = \bigoplus_{n=0}^{\infty} \mathfrak{a}^n/\mathfrak{a}^{n+1}$$

where $\mathfrak{a}^0 = R$. If unambiguous, $G(R)$ will be written instead of $G_{\mathfrak{a}}(R)$. For an R-module M with an $\mathfrak{a}$-filtration (M_n), the graded $G(R)$-module is given by:

$$G(M) = \bigoplus_{n=0}^{\infty} M_n/M_{n+1} = \bigoplus_{n=0}^{\infty} G_n(M)$$

Multiplication is certainly well-defined: for each $x_n \in \mathfrak{a}^n$, $\overline{x}_n$ is the image of x_n in $\mathfrak{a}^n/\mathfrak{a}^{n+1}$. Then $\overline{x}_m\overline{x}_m$ is $\overline{x_m x_n}$ which is the image of $x_m x_n$ in $\mathfrak{a}^{m+n}/\mathfrak{a}^{m+n+1}$ (if the reader is not convinced, check to see if this is well-defined).

Proposition 25.5.2: Properties of Associated Graded Rings

Let R be a Noetherian ring and $\mathfrak{a} \subseteq R$ an ideal. Then:

1. $G_{\mathfrak{a}}(R)$ is Noetherian
2. $G_{\mathfrak{a}}(R)$ is isomorphic to $G_{\hat{\mathfrak{a}}}(\hat{R})$ as graded rings
3. If M is a finitely generated R-module and (M_n) is a stable $\mathfrak{a}$-filtration of M, then $G(M)$ is a finitely generated graded $G_{\mathfrak{a}}(R)$-module

***Proof*:**

1. $G_{\mathfrak{a}}(R)$ is generated as an algebra over the Noetherian ring $R/\mathfrak{a}$ by the images of generators of $\mathfrak{a}$ in $\mathfrak{a}/\mathfrak{a}^2$, hence is Noetherian by HBT (theorem 23.2.1).
2. By proposition 25.4.7(3), $\mathfrak{a}^n/\mathfrak{a}^{n+1} \cong \hat{\mathfrak{a}}^n/\hat{\mathfrak{a}}^{n+1}$ in each degree, and these degreewise isomorphisms respect multiplication, giving $G_{\mathfrak{a}}(R) \cong G_{\hat{\mathfrak{a}}}(\hat{R})$.
3. Pick N with $\mathfrak{a}M_n = M_{n+1}$ for $n \geq N$ (stability). Then $G(M)$ is generated over $G_{\mathfrak{a}}(R)$ by the finitely many pieces M_n/M_{n+1} with $n \leq N$, each finitely generated over $R/\mathfrak{a}$ (corollary 25.3.3); hence $G(M)$ is finitely generated over $G_{\mathfrak{a}}(R)$.

The most important case of an associated graded ring is the one where the ideal is generated by a regular sequence: there the associated graded ring is as simple as it could be, a polynomial ring, and the geometric consequence is that the normal cone of a regularly embedded subscheme is a vector bundle rather than a general cone.

Theorem 25.5.3: Associated Graded Ring of a Regular Sequence

Let A be a Noetherian ring and let $x_1, \ldots, x_d \in A$ be a regular sequence ([15, Regular Sequence], a co-requisite of this book: x_i is a nonzerodivisor on $A/(x_1, \ldots, x_{i-1})$ for each i, and $A/(x_1, \ldots, x_d) \neq 0$). Let $\mathfrak{a} = (x_1, \ldots, x_d)$. Then the $(A/\mathfrak{a})$-algebra homomorphism

$$(A/\mathfrak{a})[T_1, \ldots, T_d] \longrightarrow G_{\mathfrak{a}}(A), \qquad T_i \longmapsto \overline{x_i} \in \mathfrak{a}/\mathfrak{a}^2$$

is an isomorphism of graded rings. In particular $\mathfrak{a}^n/\mathfrak{a}^{n+1}$ is a free $A/\mathfrak{a}$-module on the monomials of degree n in the $\overline{x_i}$.

***Proof*:**
Surjectivity. The ideal $\mathfrak{a}^n$ is generated by the degree-n monomials in the x_i, so $\mathfrak{a}^n/\mathfrak{a}^{n+1}$ is generated as an $A/\mathfrak{a}$-module by their classes, which are the images of the degree-n monomials in the T_i. Surjectivity in each degree follows.

Injectivity, by induction on d. For $d = 0$ the ideal is zero and both sides are A.

Suppose $d \geq 1$ and the statement holds for shorter regular sequences. Let $F \in (A/\mathfrak{a})[T_1, \ldots, T_d]$ be homogeneous of degree n with $F(\overline{x}) \in \mathfrak{a}^{n+1}$; the claim is that all coefficients of F vanish in $A/\mathfrak{a}$. Lift the coefficients to A and write F for a lift, so $F(x_1, \ldots, x_d) \in \mathfrak{a}^{n+1}$.

Group F by its T_d-degree, $F = \sum_j T_d^j G_j(T_1, \ldots, T_{d-1})$ with G_j homogeneous of degree $n - j$. Reducing modulo x_d kills every term with $j > 0$, so $G_0(\overline{x_1}, \ldots, \overline{x_{d-1}}) \in \overline{\mathfrak{a}}^{n+1}$ in $A/(x_d)$, where $x_1, \ldots, x_{d-1}$ is again a regular sequence and generates $\overline{\mathfrak{a}}$. By the inductive hypothesis applied in $A/(x_d)$, every coefficient of G_0 lies in $\mathfrak{a} + (x_d) = \mathfrak{a}$, which is the required vanishing for the $j = 0$ part.

Hence $F - G_0 = T_d \cdot H$ for a homogeneous H of degree $n-1$, and $x_d \cdot H(x) = F(x) - G_0(x) \in \mathfrak{a}^{n+1}$. Since $G_0(x) \in \mathfrak{a}^{n+1}$ we get $x_d H(x) \in \mathfrak{a}^{n+1}$. Now $\mathfrak{a}^{n+1} = x_d \mathfrak{a}^n + \mathfrak{a}'^{n+1}$ where $\mathfrak{a}'$ is generated by $x_1, \ldots, x_{d-1}$; writing $x_d H(x) = x_d a + b$ with $a \in \mathfrak{a}^n$ and $b \in \mathfrak{a}'^{n+1}$ gives $x_d(H(x) - a) = b$. Because x_d is a nonzerodivisor modulo $\mathfrak{a}'$ and $b \in \mathfrak{a}'^{n+1} \subseteq \mathfrak{a}'$, this forces $H(x) - a \in \mathfrak{a}^n$, hence $H(x) \in \mathfrak{a}^n$. The inductive hypothesis in degree $n-1$, applied to H, then gives that all coefficients of H lie in $\mathfrak{a}$, completing the induction and the proof.

Lemma 25.5.4: Associated Graded Ideal and Completion Map Relation

Let $\varphi : A \to B$ be a homomorphism of filtered groups ($\varphi(A_n) \subseteq B_n$), and let $G(\varphi) : G(A) \to G(B)$, $\hat{\varphi}\hat{A} \to \hat{B}$ be the induced homomorphisms of the associated graded group and complete group respectively. Then:

1. $G(\varphi)$ is injective $\Rightarrow$ $\hat{\varphi}$ is injective
2. $G(\varphi)$ is surjective $\Rightarrow$ $\hat{\varphi}$ is surjective

***Proof*:**
The key is to look at the following commutative diagram of exact sequences:

$$\begin{tikzcd} 0 \arrow[r] & A_n/A_{n+1} \arrow[r] \arrow[d, "G_n(\varphi)"] & A/A_{n+1} \arrow[r] \arrow[d, "\alpha_{n+1}"] & A/A_n \arrow[r] \arrow[d, "\alpha_n"] & 0 \\ 0 \arrow[r] & B_n/B_{n+1} \arrow[r] & B/B_{n+1} \arrow[r] & B/B_n \arrow[r] & 0 \end{tikzcd}$$

which by the snake lemma gives us the usual:

$$0 \to \ker G_n(\varphi) \to \ker \alpha_{n+1} \to \ker \alpha_n \to \text{coker} G_n(\varphi) \to \text{coker}\alpha_{n+1} \to \text{coker}\alpha_n \to 0$$

Now, by induction on n, we see that:

1. $\ker \alpha_n = 0$
2. $\text{coker}\alpha_n = 0$

taking the limit of the homomorphisms α_n and applying proposition 25.1.3 completes the proof.

Proposition 25.5.5: Partial Converse of proposition 25.5.2(3)

Let R be a ring, $\mathfrak{a} \subseteq R$ an ideal, M an R-module, and (M_n) an $\mathfrak{a}$-filtration of M. Suppose R is complete in the $\mathfrak{a}$-topology, M is Hausdorff in its filtration topology ($\bigcap_n M_n = 0$), and $G(M)$ is a finitely generated $G(R)$-module.

Then M is a finitely generated R-module.

***Proof*:**
As $G(M)$ is finitely generated, pick some finite set of generators. Split them up into the homogeneous components, say ζ_i (with $1 \leq i \leq \nu$) where ζ_i has degree $n(i)$, and is the image of some $x_i \in M_{n(i)}$. Let F^i be the module with the stable $\mathfrak{a}$-filtration given by $F^i_K = \mathfrak{a}^{k+n(i)}$ and let $F = \bigoplus_{i=1}^r F^i$. Then the mapping that takes the generator 1 of each F^i to x_i gives a homomorphism of filtered groups

$$\varphi : F \to M$$

Hence it induces a homomorphism of $G(A)$-modules. By construction this map is surjective. Hence by lemma 25.5.4 $\hat{\varphi}$ is surjective. Now consider the diagram:

$$\begin{tikzcd} F \arrow[r, "\varphi"] \arrow[d, "\alpha"'] & M \arrow[d, "\beta"] \\ \hat{F} \arrow[r, "\hat{\varphi}"] & \hat{M} \end{tikzcd}$$

As F is free and $A = \hat{A}$, α is an isomorphism. Next, as M is Hausdorff, β is injective. . As $\hat{\varphi}$ is surjective, φ is surjective, and so $x_1, ..., x_r$ generate M as an A-module completing the proof.

Corollary 25.5.6: Partial Converse in Noetherian Case

Let R be a ring, $\mathfrak{a} \subseteq R$ an ideal, M an R-module, and (M_n) an $\mathfrak{a}$-filtration of M. Suppose R is complete in the $\mathfrak{a}$-topology, M is Hausdorff in its filtration topology ($\bigcap_n M_n = 0$), and $G(M)$ is a finitely generated $G(R)$-module.

Then if $G(M)$ is a Noetherian $G(R)$-module, then M is a Noetherian R-module.

***Proof*:**
If we show that every submodule $M' \subseteq M$ is finitely generated, we're done. Let $M'_n = M' \cap M_n$. Then (M'_n) is an $\mathfrak{a}$-filtration of M', and the embedding $M'_n \to M_N$ induces an injective homomorphism:

$$M'_n/M'_{n+1} \to M_n/M_{n+1}$$

Hence we gt a embedding of $G(M')$ in $G(M)$, $G(M)$ is Noetherian, $G(M')$ is finitely generated, and so M' is Hausdroff. As $\cap M'_n \subseteq \cap M_N = 0$, we get that M' is finitely generated, as we sought to show.

Theorem 25.5.7: Noetherian Closed Under Completion

Let R be a Noetherian ring and $\mathfrak{a} \subseteq R$ an ideal. Then the $\mathfrak{a}$-completion $\hat{R}$ of R is Noetherian

***Proof*:**
As:

$$G_{\mathfrak{a}}(R) = G_{\hat{\mathfrak{a}}}(\hat{R})$$

is Noetherian, apply corollary 25.5.6 to the complete ring $\hat{R}$ and taking $M = \hat{R}$.

Corollary 25.5.8: Power Series Ring is Noetherian

Let R be a Noetherian ring, and let $S = R[[x_1, ..., x_n]]$ be the power series ring in n variables. Then S is Noetherian.

***Proof*:**
The ring $R[x_1, ..., x_n]$ is Noetherian by Hilbert's Basis Theorem, and S is the completion for the $(x_1, ..., x_n)$-adic topology.

Completion also leaves the dimension of a Noetherian local ring unchanged, which is how dimension is often computed by passing to the simpler complete ring.

Corollary 25.5.9: Completion Preserves Dimension

Let $(R, \mathfrak{m})$ be a Noetherian local ring with $\mathfrak{m}$-adic completion $\hat{R}$. Then $\dim \hat{R} = \dim R$.

***Proof*:**
By proposition 25.5.2(2), $G_{\mathfrak{m}}(R) \cong G_{\hat{\mathfrak{m}}}(\hat{R})$ as graded rings, and corollary 25.1.5 gives $R/\mathfrak{m}^n \cong \hat{R}/\hat{\mathfrak{m}}^n$; hence the Hilbert-Samuel functions $n \mapsto \ell(R/\mathfrak{m}^n)$ and $n \mapsto \ell(\hat{R}/\hat{\mathfrak{m}}^n)$ coincide. Since the Krull dimension of a Noetherian local ring is the degree of its Hilbert-Samuel polynomial (chapter 29), $\dim R = \dim \hat{R}$.

25.6 The Cohen Structure Theorem

Completion gives the local structure of a ring coordinates: a complete Noetherian local ring containing its residue field is a quotient of a power series ring, the algebraic form of a formal coordinate chart around a point.

Theorem 25.6.1: Cohen Structure Theorem, Equicharacteristic Case

Let $(R, \mathfrak{m})$ be a complete Noetherian local ring containing a field k with $R/\mathfrak{m} = k$. Then $R \cong k[[x_1, \ldots, x_n]]/I$ for an ideal I, where $n = \dim_k \mathfrak{m}/\mathfrak{m}^2$ is the minimal number of generators of $\mathfrak{m}$.

***Proof*:**
Choose $y_1, \ldots, y_n \in \mathfrak{m}$ whose residues form a k-basis of $\mathfrak{m}/\mathfrak{m}^2$; by Nakayama's lemma (lemma 23.4.27) they generate $\mathfrak{m}$. The composite $k \hookrightarrow R \twoheadrightarrow R/\mathfrak{m} = k$ is the identity, making R a k-algebra, so we may define

$$\varphi \colon k[[x_1, \ldots, x_n]] \to R, \qquad \sum_\alpha c_\alpha x^\alpha \mapsto \sum_\alpha c_\alpha y^\alpha,$$

the sum on the right converging because $y^\alpha \in \mathfrak{m}^{|\alpha|}$ and R is $\mathfrak{m}$-adically complete (definition 25.1.9); φ is a k-algebra homomorphism. For surjectivity, reduce modulo $\mathfrak{m}^m$. Each graded piece $\mathfrak{m}^j/\mathfrak{m}^{j+1}$ is spanned over k by the degree-j monomials in the residues $\bar{y}_i$, since multiplication gives a surjection $\mathrm{Sym}^j(\mathfrak{m}/\mathfrak{m}^2) \twoheadrightarrow \mathfrak{m}^j/\mathfrak{m}^{j+1}$ and $\mathfrak{m}/\mathfrak{m}^2$ is spanned by the $\bar{y}_i$. Hence $R/\mathfrak{m}^m$, whose composition factors are the $\mathfrak{m}^j/\mathfrak{m}^{j+1}$ for $j < m$, is spanned over k by monomials in the y_i of degree $< m$, all in the image of φ; so φ is surjective modulo every $\mathfrak{m}^m$. As $R = \varprojlim R/\mathfrak{m}^m$ and $k[[x_1, \ldots, x_n]]$ is complete, φ is surjective. Thus $R \cong k[[x_1, \ldots, x_n]]/I$ with $I = \ker \varphi$, and $n = \dim_k \mathfrak{m}/\mathfrak{m}^2$ is minimal by the choice of the y_i.

The hypothesis $R/\mathfrak{m} = k$ is the equicharacteristic case with trivial residue extension, the form deformation theory over a field uses. In general Cohen's theorem first produces a *coefficient field* $k \hookrightarrow R$ lifting the residue field (equicharacteristic case) or, in mixed characteristic, a complete discrete valuation coefficient ring; that mixed-characteristic theory, through Witt vectors, is developed in [19].

25.7 Weierstrass Preparation and Division

The Cohen structure theorem realizes a complete local ring as a quotient of a power series ring; the *Weierstrass* theorems describe the internal structure of the power series ring itself, showing that division by a sufficiently generic series behaves like polynomial division. Fix a complete local ring $(R, \mathfrak{m})$ (for instance $R = k[[x_1, \ldots, x_{n-1}]]$) and one further variable x.

Definition 25.7.1: Regular Power Series

A power series $f = \sum_{i \geq 0} a_i x^i \in R[[x]]$ is *regular of order* d in x if $a_0, \ldots, a_{d-1} \in \mathfrak{m}$ and a_d is a unit; equivalently, its image in $(R/\mathfrak{m})[[x]]$ is x^d times a unit.

Theorem 25.7.2: Weierstrass Division Theorem

Let $(R, \mathfrak{m})$ be complete and $f \in R[[x]]$ regular of order d in x. Then every $g \in R[[x]]$ can be written uniquely as

$$g = qf + r, \qquad q \in R[[x]], \quad r \in R[x], \ \deg r < d$$

Theorem 25.7.3: Weierstrass Preparation Theorem

Let $(R, \mathfrak{m})$ be complete and $f \in R[[x]]$ regular of order d in x. Then $f = u\,\omega$ uniquely, where $u \in R[[x]]$ is a unit and

$$\omega = x^d + b_{d-1}x^{d-1} + \cdots + b_0, \qquad b_i \in \mathfrak{m},$$

is a monic *Weierstrass polynomial.*

***Proof*:**
Preparation follows from division: apply theorem 25.7.2 to $g = x^d$, writing $x^d = qf + r$ with $\deg r < d$; reducing modulo $\mathfrak{m}$ shows q is a unit and $\omega := x^d - r$ is a Weierstrass polynomial, so $f = u\omega$ with $u = q^{-1}$. Division itself is proved by successive approximation: writing $f = P + x^d U$ with $P = \sum_{i<d} a_i x^i \in \mathfrak{m}[x]$ and $U = a_d + a_{d+1}x + \cdots$ a unit, the operator returning the low-degree remainder of $g - (\text{quotient part})f$ is a contraction for the $\mathfrak{m}$-adic topology, and completeness of R makes the resulting series for q and r converge; uniqueness holds because a Weierstrass polynomial is a non-zero-divisor. See Zariski-Samuel or Eisenbud, Ch. 7.

Iterating in $x_1, \ldots, x_n$ pins down the local structure of $k[[x_1, \ldots, x_n]]$: it is a regular local ring of dimension n in which, after a generic linear change of coordinates, ideals are generated by Weierstrass polynomials, the algebraic counterpart of resolving a formal germ into a finite branched cover of a coordinate subspace. This underlies formal and analytic local geometry, intersection multiplicities, and Puiseux expansions used downstream.

26

Ring Extension and Integral Extension

In this section, we generalize the notion of extension from fields to commutative rings. Just like how $k \subseteq F$ can be seen as a field extension, if we let k and R be rings instead, we will et the accompying notion of ring extension:

26.1 Ring and Integral Extensions

Definition 26.1.1: Ring Extension

Let S be a commutative ring and $R \subseteq S$ a subring. Then we say that S is a *ring extension* of R. Equivalently, if there exists an injective ring homomorphism $\varphi : R \to S$, then S is a ring extension of R.

Unlike fields, we must specify the homomorphism to be injective, since ring homomorphisms need not be injective. The notation S/R is also used just as in field, though more scarcely. Just like how any field extension F/k makes F into a k-vector-space and we have special k-homomorphisms letting k-commute between the homomorphism, a ring extension S/R have an analogue: in fact, a k-homomorphism is *precisely* a k-algebra homomorphism!

Recall that any *R-algebra* can be defined as a ring homomorphism $\varphi : R \to S$, *provided* that $\varphi(R) \subseteq Z(S)$. Since we are working with commutative rings, this is *always* the case, and so we can always thing of a ring extension S over R is an R-algebra! This is why we focus on *commutative rings*. There is a similar notion of ring extension for non-commutative which is closer to the notion of group extension (i.e. a short exact sequence extending the object), however ring extensions don't break down into nice building blocks since kernels of rings are not rings, which means we would have to extend a ring R by an abelian group (i.e. two-sided ideal) I. This very much changes how we would study rings. However, we can always study the structure of any commutative ring S by how behaves as an R-algebra similarly to how we studied fields, which is what we'll do in these chapters.

26.1.2 Advanced Intuition Integral extensions shall correspond to *proper maps* of morphisms. Non-integral extensions shall never be proper, thus geometrically exhibiting greatly different behaviour. In particular, taking base change if necessary, the image of closed sets (essentially zero-sets of polynomials) need not be closed.

Perhaps the first notion we might want to genelize is the equivalent of an *algebraic element*, since they capture the relations within a ring extension with respect to the base ring. The following is the exactly this generlization:

Definition 26.1.3: Integral Elements

Let $R \subseteq S$.

1. An element $s \in S$ is called an *integral over R* if s is the root of a monic polynomial over $R[x]$:
$$s^n + r_{n-1}s^{n-1} + \cdots + r_1 s + r_0 = 0 \qquad r_i \in R$$
2. S is called *integral over R* or an *integral extension of R* if every element of S is integral over R. The integral closure of an integral domain is also called the *normalization of R*. Sometimes, the integral extension will be written as S/R
3. The set $\overline{R}^S$ containing all the elements of S that are integral over R is called the *integral closure of R*
4. If $R = \overline{R}^S$, then R is said to be *integrally closed over S*.
5. If R is an integral domain that is integrally closed in it's field of fractions F, $\overline{R}^F$, then R is called *normal domain.*

The fact that the polynomial it satisfies has to be monic can be thought of as not wanting to add relations that produce "units" or unlit-like elements (ex. $3x - 1 = 0$ implies there is a new element that behaves like $1/3$). For a more specific motivation, we can think of the following: If $f(x) \in R[x]$ is a polynomial of minimal degree with root r, and $h(x) \in R[x]$ is another monic polynomials with minimal degree with root r, then we would want that $h(x)|f(x)$, just like for minimal polynomials over fields. In the process of doing so, we would require the coefficient of the leading terms to divide. Since they can be arbitrary, we would require the coefficients of these polynomial to be units, or just 1, in order for the division to follow through. It follows that it is a natural condition that all polynomials be monic for an integral extension.

Another motivation comes from Gauss's lemma: over a UFD R with fraction field K, a primitive polynomial of $R[x]$ is irreducible in $R[x]$ if and only if it is irreducible in $K[x]$. Monic polynomials are primitive, so factorization of monic polynomials over R mirrors factorization over K; this parallel between $R[x]$ and $K[x]$ becomes important in [7].

Integral elements share many of the same properties as algebraic elements:

Proposition 26.1.4: Integral Element Equivalences

Let $R \subseteq S$ be a subring of S. Then the following are equivalent:

1. s is integral over R
2. $R[s]$ is a finitely generated R-module
3. The element s is in T for some subring T where $R \subseteq T \subseteq S$, that is a finitely generated R-module

***Proof*:**

$1 \Rightarrow 2$ Recall that $R[s]$ can be expressed as all R-linear combinations of powers of s. Since s is integral over R:

$$s^n + r_n s^{n-1} + \cdots + r_1 s + r_0 = 0$$

in particular:

$$s^n = -(r_n s^{n-1} + \cdots + r_1 s + r_0)$$

It follows that for all $m \geq n$, s^m can be expressed in terms of $1, s, \ldots, s^{n-1}$ (for the same reasons as we've shown for algebraic elements). Hence:

$$R[s] = R + Rs + \cdots + Rs^{n-1}$$

Notice here how if the polynomial was not monic, we might not have been able to isolae s^n, causing complications.

$2 \Rightarrow 3$ Let $T = R[s]$. Then the reuslt immediately follows

$3 \Rightarrow 1$ We take advantage of rational canonical forms and Cramer's rule (remember that if R is an integarl domain, we can take it's field of fractions, and the resulting matri multiplication remains the same). Since T is finitely generated, let $v_1, v_2, ..., v_n$ be a finite generating set. Since $s \in T$ and T is a ring, $sv_i \in T$ for all $1 \leq i \leq n$. Thus:

$$sv_i = \sum_j a_{ij} v_j$$

Giving us the equation n:

$$\sum_j (\delta_{ij} s - a_{ij}) v_j = 0 \qquad 1 \leq i \leq n$$

where δ_{ij} is one when $i = j$ and 0 otherwise (i.e. the Kronecker delta). Letting B be the matrix such that the entries are $B_{ij} = \delta_{ij} s - a_{ij}$ and letting v be the $n \times 1$ matrix whose entries are $v_1, ..., v_n$, we get:

$$Bv = 0$$

Thus, by Cramer's rule:

$$(\det B) v_i = 0 \qquad 1 \leq i \leq n$$

Now, since 1 is an R-linear combination of $v_1, v_2, ..., v_n$,

$$\det B = (\det B)1 = (\det B)\sum_i a_i v_i = \sum a_i((\det B)v_i) = 0$$

i.e. $\det B = 0$. Now, B is by definition $B = sI - A$ (where $A_{ij} = a_{ij}$). Thus, s is the root of a monic polynomial $\det(xI - A) \in R[x]$, namely the characteristic polynomial of A, and so is the root of a monic polynomial with coefficients in R, giving (1)

Corollary 26.1.5: Transitivity of Integrality

Let $R \subseteq S \subseteq T$ be rings. If T is integral over S and S is integral over R, then T is integral over R.

***Proof*:**
Let $t \in T$, a root of a monic $x^n + a_{n-1}x^{n-1} + \cdots + a_0 \in S[x]$. Each a_i is integral over R, so in the tower $R \subseteq R[a_0] \subseteq \cdots \subseteq R[a_0, \ldots, a_{n-1}] =: R'$ every step is module-finite (proposition 26.1.4), hence R' is a finitely generated R-module. As t is integral over R', $R'[t]$ is module-finite over R', hence over R; by proposition 26.1.4 (applied to the subring $R'[t]$), t is integral over R.

Corollary 26.1.6: Integral Elements Form Rings

Let $R \subseteq S$ be a subring of S, and $s, t \in S$. Then:

1. If s and t are integral over R, so is $s \pm t$ and st
2. $\overline{R}^S$ is a subring of S containing R, and is integrally closed[a]

[a] If we were working over rng's, $\overline{R}^S$ need not be integrally closed

***Proof*:**
Let s, t be integral over R, sy that by proposition 26.1.4 $R[s]$ and $R[t]$ are finitely generated R-modules, say:

$$R[s] = Rs_1 + \cdots + Rs_n$$
$$R[t] = Rt_1 + \cdots + Rt_m$$

Then:

$$R[s, t] = Rs_1t_1 + \cdots + Rs_it_j + \cdots + Rs_nt_m$$

is a ring containing $s \pm t$ and st that is also a finitely generated R-module, so $s \pm t$ and st are integral over R. Thus $\overline{R}^S$ is a subring of S containing R; it is integrally closed in S, since any $s \in S$ integral over $\overline{R}^S$ is integral over R by transitivity (corollary 26.1.5), hence lies in $\overline{R}^S$.

In particular, taking the integral closure is idempotent: $\overline{(\overline{R}^S)}^S = \overline{R}^S$, since integrality is transitive (corollary 26.1.5).

Note that integral closure is dependent on the ring over which we are closing; we do not have the equivalent notion of "integral closure of R" without specifying a ring over which it is integrally closed (Why?)

Corollary 26.1.7: Module-Finite versus Finite-Type-and-Integral

Let S be an R-algebra. Then S is a finitely generated R-module if and only if S is of finite type over R and integral over R.

Notice how if S is not integral, then it is possible that S is of finite type over R but not finitely generated over R, the most cannonical example being $R[x]$ over R (since $R[x]$ is finitely generated as an R-algebra by 1 and x, but $1, x, x^2, \dots$ is an infinite set that is a basis for $R[x]$)

***Proof*:**
If S is a finitely generated R-module it is of finite type, and every element is integral (proposition 26.1.4). Conversely, let $S = R[s_1, \dots, s_n]$ be of finite type with each s_i integral over R. In the tower

$$R \subseteq R[s_1] \subseteq R[s_1, s_2] \subseteq \cdots \subseteq R[s_1, \dots, s_n] = S$$

each step $R[s_1, \dots, s_{i-1}][s_i]$ is module-finite, since s_i is integral over the smaller ring (proposition 26.1.4); a module-finite extension of a module-finite extension is module-finite, so S is a finitely generated R-module.

Before giving examples, we'll show that we have been studying special types of integral closures when we worked with field exensions in Part IV:

Proposition 26.1.8: Integral Extension over Fields

Let S/R be an integral extension where S is an integral domain. Then R is a field if and only if S is a field

Note that if S was not an integral domain or commutative, this theorem does not work: Take $M_2(k)$ over any field. Then $M_2(k)$ is a 4-dimensional k-algebar, but certianly not a field (it contains zero-divisors, and is not commutative).

***Proof*:**

($\Rightarrow$) Let R be a field and take $0 \neq s \in S$. Since s is integral over R, we have:

$$s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0 = 0 \qquad a_i \in R$$

Without loss of generality, let $a_0 \neq 0$; otherwise, factor an s, and using the fact that S is an integral domain, we see that either $s = 0$ or $s^{n-1} + \cdots + a_1 = 0$, and since $s \neq 0$, then we simply choose $s^{n-1} + \cdots + a_1 = 0$ to be our equation. Thus, moving a_0 and factoring s we get:

$$s(s^{n-1} + \cdots + a_1) = -a_0$$

Since R is a field, $\frac{-1}{a_0} \in R$, so:

$$s \cdot \big((-1/a_0)(s^{n-1} + \cdots + a_1)\big) = 1$$

showing that s has a multiplictative inverse. Since s was arbitrary, we have that S is a field.

($\Leftarrow$) Let S be a field and take $0 \neq r \in R$ (automatically implying that R is an integral domain). Since $r \in R$, $r \in S$, and so $r^{-1} \in S$. Since S is an integral extension of R:

$$r^{-n} + a_{n-1}r^{-(n-1)} + \cdots + a_1 r^{-1} + a_0 = 0$$

Multiply the entire expression by r^{n-1}, and move all the terms except the r^{-1} terms to the right hand side to get:

$$r^{-1} = -(a_{n-1} + \cdots + a_1 r^{n-2} + a_0 r^{n-1})$$

which is a linear combination of elements in R, showing that $r^{-1} \in R$, and so R is a field.

Thus, any algebraic field extension is an integral extension.

Example 26.1.9: Integral Extensions

1. As we've just shown, all algebraic extensions of fields are integral extensions.

2. Let R be a Unique Factorization Domain and let $F = \text{Frac}(R)$. Then $\overline{R}^F = R$. The $\supseteq$ direction is obvious, so consider the $\subseteq$ direciton: suppose that $a/b \in \overline{R}^F$ with $\gcd(a, b) = 1$. Then by definition
$$\left(\frac{a}{b}\right)^n + r_{n-1}\left(\frac{a}{b}\right)^{n-1} + \cdots + r_1\frac{a}{b} + r_0 = 0$$
Then:
$$a^n = b(-r_{n-1}a^{n-1} - \cdots - r_1 ab^{n-2} - r_0 b^{n-1})$$
so $b\big|a^n$, and hence $b\big|a$. Since $\gcd(a, b) = 1$, it must thus be that b is a unit, and hence we have that $a/b \in R$, showing that $\overline{R}^F = R$. Hence, all UFD's are normal domains. This should make intuitive sense, since any element $a/b \in \text{Frac}(R)$ would satisfy the equation $bx - a = 0$, which is not-monic.

   More generally, any polynomial ring over a UFD R, $R[x_1, ..., x_n]$ is integrally closed over it's field of fractions $R(x_1, ..., x_n)$ ([25]), showing every polynomial ring over an Unique Factorization Domain is a normal domain.

3. Let S be integral over R and $I \subseteq S$ be an ideal. Then S/I is integral over $R/(R \cap I)$. To see this, notice that a monic polynomial over R where $s \in S$ is a root, when reduced modulo I gives a monic polynomial over $R/(R \cap I)$ where $\overline{s} \in S/I$ is a root.

4. Let k be any field and take $k[x, y]$ (which is integrally closd since it's a UFD). Take the prime ideal $(x^2 - y^3) \subseteq k[x, y]$ (see Dummit and Foote, §9.1, Exercise 14). Consider the integral domain
$$R = k[x, y]/(x^2 - y^3) = k[\overline{x}, \overline{y}]$$
Notice that R is *not* normal: the element $\overline{x}/\overline{y}$ is the solution to the equation
$$\left(\frac{\overline{x}}{\overline{y}}\right)^3 - \overline{x} = 0$$

but evidently $\overline{x}/\overline{y} \notin R$. Thus, R cannot be a Unique Factorization Domain.

If you wish to practice, another example is $\mathbb{Z}[\sqrt{-3}]$. It's integral closure over it's field of fraction's is:

$$\mathbb{Z}\left[\frac{1+\sqrt{-3}}{2}\right]$$

Corollary 26.1.10: Normalization Commutes with Localization

Let R be a domain with fraction field K, $D \subseteq R$ a multiplicative set, and $\overline{R}$ the integral closure of R in K. Then, computing integral closures inside K, $\overline{D^{-1}R} = D^{-1}\overline{R}$.

***Proof*:**
If $x \in \overline{R}$ satisfies $x^n + a_{n-1}x^{n-1} + \cdots + a_0 = 0$ with $a_i \in R$, the same relation holds over $D^{-1}R$, so $D^{-1}\overline{R} \subseteq \overline{D^{-1}R}$. Conversely, if $y \in K$ is integral over $D^{-1}R$, then clearing the denominators in its integral relation shows sy is integral over R for some $s \in D$, so $sy \in \overline{R}$ and $y = (sy)/s \in D^{-1}\overline{R}$. In particular R is normal iff $R_{\mathfrak{m}}$ is normal for every maximal ideal $\mathfrak{m}$.

Locality shows where to compute an integral closure but not whether the answer is manageable. The integral closure of a Noetherian domain in its fraction field can fail to be a finite module, and can even fail to be Noetherian, so finiteness is a genuine theorem and not a formality. For the rings that geometry actually produces, finitely generated algebras over a field, it holds; this is what makes the normalization of a variety a variety again rather than an unwieldy limit.

Theorem 26.1.11: Finiteness of Integral Closure

Let k be a field, let A be a domain that is finitely generated as a k-algebra, and let L be a finite field extension of $\mathrm{Frac}(A)$. Then the integral closure of A in L is a finite A-module. In particular it is a Noetherian ring and is finitely generated as a k-algebra, and taking $L = \mathrm{Frac}(A)$, the normalization $\overline{A}$ of A is a finite A-module.

***Proof*:**
The argument is given in full for k perfect, which is the case every consumer in this series needs; the imperfect case is discussed after the proof.

Step 1: reduce to a polynomial ring. By Noether normalization (theorem 29.1.1) there is a polynomial subalgebra $B = k[x_1, \dots, x_d] \subseteq A$ with A finite, hence integral, over B. An element of L integral over A is then integral over B by transitivity of integral dependence, and conversely $B \subseteq A$, so the integral closures of A and of B in L coincide; it suffices to prove the theorem for B. Note that $\mathrm{Frac}(B) \subseteq \mathrm{Frac}(A) \subseteq L$ with both extensions finite, so $L/\mathrm{Frac}(B)$ is finite. The ring B is a unique factorization domain and hence normal (example 26.1.9).

Step 2: arrange separability. Because k is perfect, the finitely generated field extension L/k is separably generated: some subset of any finite generating set is a transcendence basis $x_1, \dots, x_d$ for which L is a finite separable extension of $k(x_1, \dots, x_d)$. This is proved in *Core Algebra* [25]. Choosing the Noether normalization of Step 1 compatibly with such a basis, we may assume

$L/\mathrm{Frac}(B)$ is separable.

Step 3: the trace form pins the integral closure inside a free module. Let C denote the integral closure of B in L and put $F = \mathrm{Frac}(B)$. Choose an F-basis $e_1, \ldots, e_n$ of L consisting of elements integral over B; this is possible because any F-basis can be scaled into C, an element of L being algebraic over F and hence integral after multiplication by a suitable element of B clearing denominators in its minimal polynomial. Since L/F is separable, the trace form is nondegenerate and there is a dual basis $e_1^*, \ldots, e_n^*$ of L over F with $\mathrm{tr}_{L/F}(e_i e_j^*) = \delta_{ij}$, by *Core Algebra* [25].

Let $c \in C$ and write $c = \sum_j \lambda_j e_j^*$ with $\lambda_j \in F$. Then $\lambda_j = \mathrm{tr}_{L/F}(c\, e_j)$. Now $c\, e_j$ is a product of elements integral over B, hence integral over B, and the trace of an element integral over B lies in B: the trace is, up to sign, a coefficient of the characteristic polynomial of multiplication by that element, which is a power of its minimal polynomial, and the minimal polynomial of an integral element has coefficients in B because B is integrally closed in F. So $\lambda_j \in B$ for every j, and

$$C \;\subseteq\; Be_1^* + \cdots + Be_n^*$$

Step 4: conclude. The right-hand side is a free B-module of rank n, and B is Noetherian by Hilbert's basis theorem, so its submodule C is a finite B-module. Since B is a finitely generated k-algebra, C is a finitely generated k-algebra and a Noetherian ring, as we sought to show.

26.1.12 Note: The Imperfect Case Step 2 is the only place perfectness is used, and it cannot be avoided there: over an imperfect field a finitely generated extension need not be separably generated (*Core Algebra* [25] records a counterexample), so the trace form can degenerate and the argument above stops. The theorem is nonetheless true over any field. The standard route replaces k by a finite purely inseparable extension over which the situation becomes separably generated, and then descends; see Matsumura [37], or [51, Tag 0335], where the result appears in the form that a finite type algebra over a field is a Nagata ring, hence Japanese, which is exactly the finiteness asserted here. No book in this series currently consumes the imperfect case.

26.2 Extension and Contraction of Ideals

Probably the biggest difference between fields and rings is that ideals are nontrivial. Thus, it is meaningful to ask what happens to ideals in (general) ring extensions. Recall that if $f : R \to S$ is a ring homomorphism, and $J \subseteq S$ is an ideal, $f^{-1}(J)$ is an ideal. However, if $I \subseteq R$ is an ideal, $f(I)$ need not be an ideal (take $\mathbb{Z} \hookrightarrow \mathbb{Q}$ with any non-trivial ideal of $\mathbb{Z}$). The next best thing would be to define the smallest ideal of S containing $f(I)$:

Definition 26.2.1: Extension and Contraction

Let $\varphi : R \to S$ be a homomorphism between commutative rings and let $I \subseteq R$, $J \subseteq S$.

1. The *extension* of I to S is the ideal $\varphi(I)S$, commonly denoted I^e
2. The *contraction* of J in R is the ideal $\varphi^{-1}(J)$, commonly denoted J^c

In the case where φ is the natural inclusion $\iota : R \to S$, then the extension of I is IS, and the contraction of J is $J \cap R$. If $I \subseteq R$, there are multiple extension of R, say S/R and T/R, then the extension of I is sometiems denoted I_S or I_T to emphasize to what ring I is being extended too S or T respectively.

Proposition 26.2.2: Properties of Extensions and Contractions

1. $I \subseteq IS \cap R$, or more generally that I is contained in the contraction of its extension to S ($I \subseteq I^{ec}$)
2. $(J \cap R)S \subseteq J$, or more genrally that J is contained in the extension of its contraction in R ($J \supseteq J^{ce}$)
3. $I^e = I^{ece}$
4. $J^c = J^{cec}$
5. If J is prime, J^c is prime. If I is prime, I^e need not be prime (consider $\mathbb{Z} \hookrightarrow \mathbb{Q}$). If $\varphi : R \to S$ is surjective and I is a prime ideal containing $\ker\varphi$, then I^e is prime.
6. If J is maximal, J^c need not be maximal, and similarly if I is maximal then I^e need not be maximal.

***Proof*:**
(1) holds since $I \subseteq \varphi^{-1}(\varphi(I)S) = I^{ec}$, and (2) since $I^{ce} = \varphi(\varphi^{-1}(J))S \subseteq J$. Applying (1) to I^e gives $I^e \subseteq I^{ece}$, and applying $(-)^e$ to (2) gives $I^{ece} \subseteq I^e$, so (3) holds; (4) is dual. For (5): $J^c = \varphi^{-1}(J)$ is prime as a preimage of a prime; over $\mathbb{Z} \hookrightarrow \mathbb{Q}$ the nonzero prime (p) has $(p)^e = \mathbb{Q}$, not a proper ideal; and if φ is surjective with prime $I \supseteq \ker\varphi$, then $I^e = \varphi(I)$ and $S/I^e \cong R/I$ is a domain. (6) is $\mathbb{Z} \hookrightarrow \mathbb{Q}$ again, where (0) is maximal in $\mathbb{Q}$ but not in $\mathbb{Z}$.

Lemma 26.2.3: Extension And Contraction With Common Operations

Let $\mathfrak{a}_1, \mathfrak{a}_2 \subseteq A$ be ideals of A and $\mathfrak{b}_1, \mathfrak{b}_2 \subseteq B$ be ideals of B. Then:

$$
\begin{aligned}
(\mathfrak{a}_1+\mathfrak{a}_2)^e &= \mathfrak{a}_1^e+\mathfrak{a}_2^e & (\mathfrak{b}_1+\mathfrak{b}_2)^c &\supseteq \mathfrak{b}_1^c+\mathfrak{b}_2^c \\
(\mathfrak{a}_1\cap\mathfrak{a}_2)^e &\subseteq \mathfrak{a}_1^e\cap\mathfrak{a}_2^e & (\mathfrak{b}_1\cap\mathfrak{b}_2)^c &= \mathfrak{b}_1^c\cap\mathfrak{b}_2^c \\
(\mathfrak{a}_1\mathfrak{a}_2)^e &= \mathfrak{a}_1^e\mathfrak{a}_2^e & (\mathfrak{b}_1\mathfrak{b}_2)^c &\supseteq \mathfrak{b}_1^c\mathfrak{b}_2^c \\
(\mathfrak{a}_1:\mathfrak{a}_2)^e &\subseteq (\mathfrak{a}_1^e:\mathfrak{a}_2^e) & (\mathfrak{b}_1:\mathfrak{b}_2)^c &\subseteq (\mathfrak{b}_1^c:\mathfrak{b}_2^c) \\
\sqrt{\mathfrak{a}}^e &\subseteq \sqrt{\mathfrak{a}^e} & \sqrt{\mathfrak{b}}^c &= \sqrt{\mathfrak{b}^c}
\end{aligned}
$$

***Proof*:**
Each identity is routine from the definitions of extension and contraction (Atiyah-Macdonald, Chapter 1); the inclusions that are not equalities are strict already for $\mathbb{Z} \hookrightarrow \mathbb{Q}$.

If $\varphi : R \to S$ is a ring homomorphism, we may decompose φ into the following:

$$R \xrightarrow{p} \varphi(R) \xhookrightarrow{j} S$$

where p maps R surjectively onto $\varphi(R)$, and j injects into S. Relating the ideals of R to the ideals of $\varphi(R)$ is very easy:

Proposition 26.2.4: Correspondence Between Ideals And Image Of Ideals

Let $\varphi : R \to S$ be a ring homomorphism. Then there exists a bijective correspondence:

$$\{I \subseteq \varphi(R)\} \underset{\varphi(-)}{\overset{(-)^c}{\rightleftarrows}} \{\ker(\varphi) \subseteq J \subseteq R\}$$

Furthermore, prime ideals of $\varphi(R)$ correspond to prime ideals of R containing $\ker(\varphi)$.

***Proof*:**
Since $\varphi(R) \cong R/\ker\varphi$, this is the correspondence theorem for the quotient $R \twoheadrightarrow R/\ker\varphi$: ideals of $R/\ker\varphi$ correspond to ideals of R containing $\ker\varphi$ via image and preimage, and primes correspond to primes.

On the other hand, the correspondence between $\varphi(R)$ and S is much harder, and is covered in section 26.3 when S/R is an integral extension. As shown in proposition 26.2.2, every prime ideal "lies over" another prime ideal. This motivates the following vocuabilary:

Definition 26.2.5: Lying Over

Let $I \subseteq S$ be an ideal and S/R an integral extension. If $J = I \cap R$, I is said to be *lying over* J.

Example 26.2.6: Extending ideals
Take $\varphi : \mathbb{Z} \to \mathbb{Z}[i]$ to be the inclusion. Then a prime ideal $(p) \subseteq \mathbb{Z}$ may or may not remain prime when extended to $\mathbb{Z}[i]$. Using Fermat's theorem of sums of squares (theorem 10.3.3), it can be deduced that:

1. $(2)^e = (1+i)^2$
2. If $p \equiv 1 \bmod 4$, then p^e is the product of two distinct prime ideals (ex. $(5)^e = (2+i)(2-i)$)
3. if $p \equiv 3 \bmod 4$, then p^e is prime in $\mathbb{Z}[i]$

In general, it is rather hard to determine when $\varphi(p)$ is prime when p is prime. If $\varphi : R \to S$ is an integarl extension, then the situation becomes much better, however it will require the notion of *localization* which shall be covered in the next section. One special case is note mentioning:

Proposition 26.2.7: Maximal Ideals Lying Over

Let S/R be an integral extension and $\mathfrak{m} \subseteq S$ a prime ideal. Then $\mathfrak{m} \cap R$ is maximal if and only if $\mathfrak{m}$ is maximal.

***Proof*:**
Consider the integral domain $S/\mathfrak{m}$. Then $S/\mathfrak{m}$ is an integral extension of $R/(\mathfrak{m} \cap R)$. Then by proposition 26.1.8, $S/\mathfrak{m}$ is a field if and only if $R/(\mathfrak{m} \cap R)$ is a field. But then $\mathfrak{m}$ is maximal if and only if $\mathfrak{m} \cap R$ is maximal.

26.3 Integral Extensions and Prime Ideals

We return to the question of the extension of ideals, in particular prime ideals, given S/R. The going-down half rests on the following, where integrality over an *ideal* I means being a root of a monic $x^n + a_{n-1}x^{n-1} + \cdots + a_0$ with all $a_i \in I$.

Lemma 26.3.1: Integral over an Ideal

Let R be a normal domain with fraction field K, let $S \supseteq R$ be a domain, and let $I \subseteq R$ be an ideal. If $x \in S$ is integral over I, then x is algebraic over K and the non-leading coefficients of its minimal polynomial over K lie in $\sqrt{I}$.

***Proof*:**
The integral relation shows x is algebraic over K; let $m(t) = t^r + c_{r-1}t^{r-1} + \cdots + c_0$ be its minimal polynomial over K. In a splitting field the conjugate roots $x = x_1, \ldots, x_r$ of m each satisfy the same relation with coefficients in I, so all x_j are integral over I; hence so are the c_i, being (up to sign) elementary symmetric functions of the x_j. Each $c_i \in K$ is integral over R, so $c_i \in R$ since R is normal; and $c_i \in R$ integral over I satisfies $c_i^m + b_{m-1}c_i^{m-1} + \cdots + b_0 = 0$ with $b_j \in I$, giving $c_i^m \in I$, i.e. $c_i \in \sqrt{I}$.

Theorem 26.3.2: Integral Extension Prime Correspondence (Cohen-Seidenberg Theorem)

Let S be an integral extension of the integral domain R

1. (**Lying-over Property**) Let $\mathfrak{p} \subseteq R$ be a prime ideal. Then there is a prime ideal $P \subseteq S$ such that $\mathfrak{p} = P \cap R$. Furthermore, $\mathfrak{p}$ is maximal if and only if P is maximal.
2. (**Going-up Property**) Let $p_1 \subseteq p_2 \subseteq \cdots \subseteq p_n$ be a chain of prime ideals of R, and suppose there exists a chain $q_1 \subseteq q_2 \subseteq \cdots \subseteq q_m$, $(m < n)$ such that $p_i = q_i \cap R$. Then there exists prime ideals $q_{m+1}, ..., q_n$ that complete the chain: $q_m \subseteq q_{m+1} \subseteq \cdots \subseteq q_n$, $p_i = q_i \cap R$ for all i.
3. (**Going-down Property**) Suppose in addition that S is a domain. If R is a normal domain, $p_1 \supseteq p_2 \supseteq \cdots \supseteq p_n$ be a chain of prime ideals of R, and suppose there exists a chain $q_1 \supseteq q_2 \supseteq \cdots \supseteq q_m$, $(m < n)$ such that $p_i = q_i \cap R$. Then there exists prime ideals $q_{m+1}, ..., q_n$ that complete the chain: $q_m \supseteq q_{m+1} \supseteq \cdots \supseteq q_n$, $p_i = q_i \cap R$ for all i.
4. (**Incomparability property**) Let q_1 and q_2 lie over p. Then either $q_1 = q_2$, or they do not contain each other: $q_1 \not\subseteq q_2$ and $q_2 \not\subseteq q_1$

***Proof*:**

1. We'll take advantage of the corresponence theorem for rings and their localization. Let $D = R - P$. Then as we saw, D is multiplicatively closed, and so $R[D^{-1}]$ is well-defined. Since D is also a multiplicatvely closed set of S, $S[D^{-1}]$ is also well-defined. Furthermore, $S[D^{-1}]/R[D^{-1}]$ is an integral extensions of $R[D^{-1}]$: for any $s \in S[D^{-1}]$, if $s \in S$, clearly S is still integral. If $t = \frac{s}{d}$ for some $s \in S$ and $d \in D$, then letting
$$s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0 = 0$$
This equation is still zero if we multiply by d^{-n}:
$$\frac{s^n}{d^n} + \frac{a_{n-1}s^{n-1}}{d^n} + \cdots + \frac{a_1 s}{d^n} + \frac{a_0}{d^n} = 0$$
and shuffling the coefficients we get:
$$\frac{s^n}{d^n} + \frac{da_{n-1}s^{n-1}}{d^{n-1}} + \cdots + \frac{d^{n-1}a_1 s}{d} + \frac{a_0}{d^n} = 0$$
and replacing each $d^{n-i}a_i = b_i$, and $s/d = t$,
$$t^n + b_{n-1}t^{n-1} + \cdots + b_1 t + b_0 = 0$$
showing that t is integral over $R[D^{-1}]$, and so $S[D^{-1}]$ is an integral extension of $R[D^{-1}]$. Let $m \subseteq S[D^{-1}]$ be a maximal ideal. Then by the corresponence of ideals from a ring and it's localization, we have that $m \cap R_p$ is a maximal ideal in R_p, and $m \cap R_p$ is the extension of P to the local ring R_p, so it contracts to p. It might be easier to see if we

have a visual:

$$\begin{array}{ccc} S & \xrightarrow{\pi} & S[D^{-1}] \\ {\scriptstyle\iota}\uparrow & & {\scriptstyle\iota}\uparrow \\ R & \xrightarrow{\pi} & R[D^{-1}] = R_p \end{array}$$

The maximal ideal m is maximal in $S[D^{-1}]$, it's pre-image is a maximal ideal of $R[D^{-1}]$, and the pre-image of that map is p, showing that $p = m \cap R$, as we sought to show.

2. This can be reducd to showing that if $p_1 \subseteq p_2$ and q_1 lies above p_1 such that $p_1 = q_1 \cap R$, then there exists a q_2 that lies above p_2 ($q_2 = p_2 \cap R$) and $q_1 \subseteq q_2$. First, let $\overline{S} = S/q_1$ and $\overline{R} = R/p_1$. Then $\overline{S}/\overline{R}$ is an integral extension by similar reasoning to what we've shown in part 1. By the ideal-correspondence for the quotient $R \to R/p_1$ (proposition 26.2.4), p_2/p_1 is a prime ideal of $\overline{R}$. Then by part (1), we have that there exists an ideal $q_2/q_1 \subseteq \overline{S}$ that lies abouve p_2/p_1, in particular:
$$q_2/q_1 \cap \overline{R} = p_2/p_1$$
At this point we are essentially done: taking the pre-image of q_2/q_1, we get q_2, and by the correspondence theorem we get
$$q_2 \cap R = p_2$$

3. It suffices to find, given $p_1 \supseteq p_2$ in R and q_1 over p_1, a prime $q_2 \subseteq q_1$ over p_2. Localize S at the multiplicative set $S \setminus q_1$; it is enough that $p_2 S_{q_1} \cap R = p_2$, for then a prime of S_{q_1} over p_2 contracts to the desired $q_2 \subseteq q_1$. The inclusion $\supseteq$ is clear. For $\subseteq$, take $x \in p_2 S_{q_1} \cap R$ and write $x = y/s$ with $y \in p_2 S$, $s \in S \setminus q_1$. Now $y \in p_2 S$ is integral over p_2, so by lemma 26.3.1 its minimal polynomial over $K = \mathrm{Frac}(R)$ has non-leading coefficients in $\sqrt{p_2} = p_2$: say $y^r + u_{r-1} y^{r-1} + \cdots + u_0 = 0$ with $u_i \in p_2$. Then $s = y/x$ has minimal polynomial $s^r + v_{r-1} s^{r-1} + \cdots + v_0$ with $v_i = u_i / x^{r-i} \in R$ (as s is integral over the normal R), and $x^{r-i} v_i = u_i \in p_2$. Were $x \notin p_2$, each $v_i \in p_2$, so $s^r = -(v_{r-1} s^{r-1} + \cdots + v_0) \in p_2 S \subseteq q_1$, forcing $s \in q_1$, a contradiction. Hence $x \in p_2$, giving $p_2 S_{q_1} \cap R = p_2$.

4. For the sake of contradiction, let $q_1 \subseteq q_2$, and let both lie over p: $q_1 \cap R = q_2 \cap R = p$. Consider $\overline{S} = S/q_1$ and $\overline{R} = R/p$. Then as we've shown earlier, $\overline{S}/\overline{R}$ is an integral extension, and $q_2/q_1 \subseteq \overline{S}$ is a prime ideal. Consider:
$$(q_2/q_1) \cap \overline{R} = (q_2 \cap R)/(R \cap q_1) = (R \cap q_1)/(R \cap q_1) = \{\overline{0}\}$$
Now $\overline{S}$ is a domain integral over the domain $\overline{R}$, and the prime q_2/q_1 meets $\overline{R}$ only in $\{0\}$. If $q_2/q_1 \neq 0$, pick $0 \neq \bar{x} \in q_2/q_1$ satisfying an integral relation $\bar{x}^n + \overline{a}_{n-1} \bar{x}^{n-1} + \cdots + \overline{a}_0 = 0$ of least degree; then $\overline{a}_0 = -\bar{x}(\bar{x}^{n-1} + \cdots + \overline{a}_1) \in (q_2/q_1) \cap \overline{R} = \{0\}$, so $\overline{a}_0 = 0$, and cancelling $\bar{x}$ (valid in the domain $\overline{S}$) contradicts minimality. Hence $q_2/q_1 = \{0\}$, i.e. $q_2 = q_1$.

Exercise 26.3.1

1. Let $I \subseteq R$ be an ideal and R a ring. Then if we consider integral extension of *rngs*, show that I^{n+1}/I^n is an integral extension.

2. Let $I \subseteq R$, $f : R \to S$ an integral extension and $I^e \subseteq S$ the extension of S. Then:

$$S/I^e \cong S \otimes_R R/I$$

Valuation Ring and Local Rings

Recall from the theory of absolute values ([19]) that an absolute value defines a notion of size on a field. On a finite field the only absolute value is the trivial one ($|x| = 1$ for $x \neq 0$), and by Ostrowski's theorem the only absolute values on $\mathbb{Q}$ up to equivalence are the p-adic $|-|_p$ and the usual $|-|_\infty$. These were defined using a constant c^{-m}; the choice of constant does not affect the topology, so what really matters is the exponent m. This section defines a function capturing that exponent, a useful link between geometric and algebraic intuition on certain fields.

27.1 Valuations

Definition 27.1.1: $\mathbb{R}$-Valuation

Let K be a field. Append ∞ to $\mathbb{R}$ and preserve the total ordering by adding the properties that $g \leq \infty$ for all $g \in \mathbb{R}$ and $g + \infty = \infty + g = \infty + \infty = \infty$. Then a function $\nu : K \to \mathbb{R} \cup \{\infty\}$ is called a $\mathbb{R}$-*valuation* if

1. $\nu(K^\times) \subseteq \mathbb{R}$ and $\nu|_{K^\times} : K^\times \to \mathbb{R}$ is a group-homomorphism, that is $\nu(x \cdot y) = \nu(x) + \nu(y)$.
2. $\nu(x + y) \geq \min\{\nu(x), \nu(y)\}$
3. $\nu(x) = \infty$ if and only if $x = 0$

It may be more clear that $\mathbb{R}$-valuations come as a generalization of non-Archimedean absolute values from the original definition given by Emil Artin (and hence why these are called valuations). To make sense of this definition, we shall introduce the slightly more general notion of a totally ordered abelian group.

Definition 27.1.2: Totally Ordered [Abelian] Group

Let G be an abelian group. Then G is said to be a *totally ordered group*, or simply an *ordered group* if $\leq$ is a total ordering on G that is translation invariant, that is for all $x, y, z \in G$ where $x \leq y$:

$$zx \leq zy$$

An abelian group admits a translation-invariant total order if and only if it is torsion-free. General ordered groups genuinely extend the real-valued case, but for our purposes valuations into $\mathbb{Z}$ or $\mathbb{R}$ suffice; the general notion mainly serves to connect $\mathbb{R}$-valuations to non-Archimedean absolute values ([19]):

Example 27.1.3: Value Groups

The field of *Puiseux series* $\bigcup_{n\geq 1} k((x^{1/n}))$ carries a valuation with value group $\mathbb{Q}$, given by $\nu(x^a) = a$. More generally, Hahn series over a totally ordered group Γ realize Γ as a value group.

Now, in definition 27.1.1, the $(\mathbb{R}, +)$ can be replaced with $(G, *)$. The following shows how this links to absolute values:

Definition 27.1.4: G-Valuation Equivalent Definition

Let K be a field. Append 0 to G and preserve the total ordering by adding the properties that $0 \leq g$ for all $g \in G$ and $0 * g = g * 0 = 0 * 0 = 0$. Then a function $\nu : K \to G \cup \{0\}$ is called a *G-valuation* if

1. $\nu(K^\times) \subseteq G$ and $\nu|_{K^\times} : K^\times \to G$ is a group-homomorphism, that is $\nu(x \cdot y) = \nu(x) * \nu(y)$.
2. $\nu(x + y) \leq \max\{\nu(x), \nu(y)\}$
3. $\nu(x) = 0$ if and only if $x = 0$

The image of $\nu(K^\times)$ is called the *value group*.

If $G = \mathbb{Z}$, or equivalently in the $\mathbb{R}$-valuation definition, when $v(K^*) \subseteq \mathbb{Z}$, a special name is given:

Definition 27.1.5: Discrete Valuation

Let K be a field. Then a function $\nu : K \to \mathbb{Z} \cup \{\infty\}$ is called a *discrete valuation* if

1. $\nu(x \cdot y) = \nu(x) + \nu(y)$
2. $\nu(x + y) \geq \min\{\nu(x), \nu(y)\}$
3. $\nu(x) = \infty$ if and only if $x = 0$

Example 27.1.6: Valuations

1. Given any non-Archimedean absolute value v_p with values in $(\mathbb{R}^+, \cdot)$, we get a $\mathbb{R}^+$ valuation. Hence, each v_p is a valuation on $\mathbb{Q}$ in the equivalent definition, and v_∞, v_0 are valuations on $k(x)$ for any field k.

Given a field k, it may be asked what valuations may be put on it. This is in correspondence with certain sub-rings of k:

Definition 27.1.7: Valuation Ring

Let ν be a valuation on K. Then

$$\mathcal{O}_K = \{x \in K \mid \nu(x) \geq 0\}$$

forms a ring, called the *Valuation Ring.* If ν is a discrete valuation, the ring is called a *discrete valuation ring.*

The reader should verify this is indeed a ring.

Proposition 27.1.8: Valuation Ring Properties

Let k be a field with valuation ν and let $\mathcal{O}_k$ be the valuation ring associated to it. Then:

1. Given $x \in k \setminus \{0\}$, either $x \in \mathcal{O}_k$ or $x^{-1} \in \mathcal{O}_k$ (where both are possible at once). As a consequence, k is a field of fractions of $\mathcal{O}_k$. [a]
2. The group of units is $\mathcal{O}_K^* = \{x \in k \mid \nu(x) = 0\}$ (equiv. $\nu(x) = 1$)
3. $\mathcal{O}_k$ has exactly one maximal ideal $\mathfrak{m}_v = \{x \in k \mid v(x) > 0\} = \mathcal{O}_k \setminus \mathcal{O}_k^*$ (equiv $v(x) < 1$)
4. The ideal of $\mathcal{O}_k$ form a total ordering under $\subseteq$
5. The ring $\mathcal{O}_k$ is integrally closed (i.e. a normal domain)

[a] Note that the either-or implies a general Γ-valuation!

***Proof*:**
(1) For $x \neq 0$, either $\nu(x) \geq 0$ or $\nu(x^{-1}) = -\nu(x) \geq 0$, so $x \in \mathcal{O}_k$ or $x^{-1} \in \mathcal{O}_k$; hence $k = \mathrm{Frac}(\mathcal{O}_k)$. (2) x is a unit iff $x, x^{-1} \in \mathcal{O}_k$ iff $\nu(x) = 0$. (3) By (2) the non-units form $\mathfrak{m}_\nu = \{x \mid \nu(x) > 0\}$, which is an ideal ($\nu(x+y) \geq \min(\nu(x), \nu(y)) > 0$ and $\nu(rx) \geq \nu(x) > 0$); being exactly the non-units, it is the unique maximal ideal.

For 4, first show it on principal ideals, namely if $(a), (b) \subseteq \mathcal{O}_K$, then $(a) \subseteq (b)$ or $(b) \subseteq (a)$. Do this by noticing that either $ab^{-1} \in \mathcal{O}_K$ or $a^{-1}b \in \mathcal{O}_K$. For general ideals, if $\mathfrak{a}$ and $\mathfrak{b}$ are ideals that are not ordered, then there exists $a \in \mathfrak{a} \setminus \mathfrak{b}$ and $b \in \mathfrak{b} \setminus \mathfrak{a}$. Consider $(a), (b)$ which must be ordered namely $(a) \subseteq (b)$ or $(b) \subseteq (a)$. Say $(a) \subseteq (b)$. Then $(a) \cap (b) = (a)$. But then $a \in (b)$ meaning $a = bx$ for some $x \in \mathcal{O}_K$. But as $bx \in \mathfrak{b}$, this would imply $a \notin \mathfrak{a} \setminus \mathfrak{b}$, a contradiction.

We shall show that $\mathcal{O}_K$ is integrally closed. Say that $x \in K$ is integral over $\mathcal{O}_K$, for the sake of contradiction say $x \notin \mathcal{O}_K$. As it is integral:

$$x^n + a_1 x^{n-1} + \cdots + a_n = 0$$

with $a_i \in \mathcal{O}_K$. If $x \notin \mathcal{O}_K$ then $\nu(x) < 0$, so $x^{-1} \in \mathcal{O}_K$; dividing the relation by x^{n-1} gives

$$x = -(a_1 + a_2 x^{-1} + \cdots + a_n x^{-(n-1)}),$$

whose right-hand side lies in $\mathcal{O}_K$ (each $x^{-j} \in \mathcal{O}_K$), forcing $x \in \mathcal{O}_K$, a contradiction, completing the proof.

These properties in fact characterize valuation rings:

Proposition 27.1.9: Characterizing Valuation Ring

Let k be a field, $R \subseteq k$ a sub-ring, and R^* the group of units of R. Then the following are equivalent:

1. R is a valuation ring of k
2. $k = \mathrm{Frac}(R)$ and the ideals of R form a chain under inclusion
3. for every $x \in k \setminus \{0\}$, either $x \in R$ or $x^{-1} \in R$

Then $G = (k \setminus \{0\})/R^*$ is a totally ordered abelian group and

$$\nu_R : x \mapsto xR^*$$

is a valuation on k. The induced valuation ring is R. As a consequence, two valuations on the same field are equivalent if and only if they have the same valuation ring.

***Proof*:**
(1) $\Rightarrow$ (3) is proposition 27.1.8(1), and (1) $\Rightarrow$ (2) its parts (1) and (4). For (3) $\Rightarrow$ (2): (3) gives $k = \mathrm{Frac}(R)$, and any two ideals $\mathfrak{a}, \mathfrak{b}$ are comparable, for if $a \in \mathfrak{a} \setminus \mathfrak{b}$ and $b \in \mathfrak{b}$ then $a/b \notin R$ (else $a \in (b) \subseteq \mathfrak{b}$), so $b/a \in R$ and $b \in (a) \subseteq \mathfrak{a}$, giving $\mathfrak{b} \subseteq \mathfrak{a}$. For (2) $\Rightarrow$ (3): for $x = a/b \in k^\times$ the principal ideals $(a), (b)$ are comparable, so $a/b \in R$ or $b/a \in R$. Given (3), $G = k^\times/R^*$ is totally ordered by $xR^* \leq yR^* \Leftrightarrow y/x \in R$, and $\nu_R(x) = xR^*$ is a valuation whose ring is $\{x \in k \mid \nu_R(x) \geq 0\} = R$; a valuation is determined up to equivalence by its ring.

27.2 Discrete Valuation Ring

Limiting to discrete valuation rings, then there is a smallest positive value s such that:

$$\nu(K^*) = s\mathbb{Z}$$

We can normalize this result and get an equivalent ν where $\nu(K^*) = \mathbb{Z}$ and $\mathcal{O}_K$, $\mathcal{O}_K^*$, and $\mathfrak{p}$ are the same. Then there must be an element such that

$$\nu(\pi) = 1$$

Labelling this element as π, we can use it to show that any $x \in K \setminus \{0\}$ can be written as :

$$x = u\pi^m$$

for a unit $u \in K^\times$ $(\nu(u) = 0)$. To see this, let

$$\nu(x) = m \Rightarrow \nu(x\pi^{-m}) = 0 \Rightarrow u = x\pi^{-m} \in \mathcal{O}_K^*$$

which gives the result, where $m = \nu(x) \in \mathbb{Z}$. This in fact characterizes DVRs:

Proposition 27.2.1: Characterizing DVR

Let R be an integral domain and $k = \mathrm{Frac}(R)$. Then R is the valuation ring of a discrete valuation ν on k if and only if R is a PID with a unique nonzero prime ideal.

***Proof*:**
($\Rightarrow$) Normalize ν so $\nu(k^\times) = \mathbb{Z}$, with uniformizer π ($\nu(\pi) = 1$). Every nonzero $x \in R$ is $u\pi^n$ with u a unit and $n = \nu(x) \geq 0$, so every nonzero ideal equals $(\pi^n) = \mathfrak{m}^n$ for the least n occurring; thus R is a PID with unique nonzero prime $\mathfrak{m} = (\pi)$. ($\Leftarrow$) If R is a PID with unique nonzero prime (π), each nonzero $x \in R$ factors uniquely as $u\pi^n$; setting $\nu(x) = n$ and extending by $\nu(a/b) = \nu(a) - \nu(b)$ gives a discrete valuation on k with valuation ring R.

The DVRs are exactly the "nicest" one-dimensional local rings, characterized among Noetherian local domains of dimension one in several equivalent ways:

Theorem 27.2.2: Characterizations of a DVR

Let $(R, \mathfrak{m})$ be a Noetherian local domain of Krull dimension 1 with fraction field k. The following are equivalent:

1. R is a discrete valuation ring;
2. R is integrally closed (normal);
3. $\mathfrak{m}$ is principal;
4. every nonzero ideal of R is a power of $\mathfrak{m}$;
5. R is a regular local ring, i.e. $\dim_{R/\mathfrak{m}} \mathfrak{m}/\mathfrak{m}^2 = 1$.

***Proof*:**
(1) $\Rightarrow$ (2) is proposition 27.1.8(5), and (3) $\Leftrightarrow$ (5) holds since, by Nakayama (lemma 23.4.29), $\mathfrak{m}$ is principal iff $\dim_{R/\mathfrak{m}} \mathfrak{m}/\mathfrak{m}^2 = 1$. For (2) $\Rightarrow$ (3): pick $0 \neq a \in \mathfrak{m}$; as $\dim R = 1$, $\mathfrak{m}$ is the only prime over (a), so $\mathfrak{m}^n \subseteq (a)$ for some least n. Choose $b \in \mathfrak{m}^{n-1} \setminus (a)$ and put $t = a/b \in k$; then $b\mathfrak{m} \subseteq \mathfrak{m}^n \subseteq (a)$ gives $t^{-1}\mathfrak{m} = (b/a)\mathfrak{m} \subseteq R$. If $t^{-1}\mathfrak{m} \subseteq \mathfrak{m}$, the finitely generated faithful module $\mathfrak{m}$ would be stable under t^{-1}, making t^{-1} integral over R (determinant trick) and hence $t^{-1} \in R$ by normality, contradicting $b \notin (a)$. So $t^{-1}\mathfrak{m} = R$, i.e. $\mathfrak{m} = tR$ is principal. (3) $\Rightarrow$ (4): writing $\mathfrak{m} = (\pi)$, Krull's intersection theorem (corollary 25.4.11) gives $\bigcap_n \mathfrak{m}^n = 0$, so any nonzero ideal is $(\pi^n) = \mathfrak{m}^n$ for the largest n with the ideal $\subseteq \mathfrak{m}^n$. (4) $\Rightarrow$ (1): defining $\nu(x) = n$ where $(x) = \mathfrak{m}^n$ gives a discrete valuation on k with valuation ring R.

Example 27.2.3: Discrete Valuation Ring

1. The ring of p-adic integers $\mathbb{Z}_p$ is a discrete valuation ring.
2. For any prime p, $\mathbb{Z}_{(p)}$ the localization of $\mathbb{Z}$ at the prime (p) is a discrete valuation ring.

3. The ring $k[[x]]$ of formal power series is a DVR with unique non-zero prime ideal (x).
4. (If you know some analysis) The ring of convergent power series over $\mathbb{R}$ or $\mathbb{C}$ (those with a positive radius of convergence) is a DVR.
5. (If you know some complex analysis) Let X be a connected Riemann surface and let $M(X)$ be the field of meromorphic functions $X \to \mathbb{C} \cup \{\infty\}$. For each point $p \in X$, define a discrete valuation on $M(X)$ where
$$\nu_p(f) = i$$
where i is the largest number st
$$\frac{f(z)}{(z-p)^i}$$
can be extended to a holomorphic function (i.e. the order of the root/pole).

It shall be seen in algebraic geometry ([5]) that DVRs appear naturally in the study of smooth projective algebraic curves".

Proposition 27.2.4: Representation Of Elements Of a Complete DVR

Let k be a field with *complete* DVR $\mathcal{O}_k$, uniformizer π, and let $\mathcal{T} \subseteq \mathcal{O}_k$ contain 0 and exactly one element of every coset of $\mathfrak{m}$. Then every element $x \in \mathcal{O}_k$ is a unique convergent series
$$\sum_{i \geq 0} r_i \pi^i$$
with coefficients $r_i \in \mathcal{T}$, and every nonzero $x \in k$ is a unique Laurent series $\sum_{i \geq m} r_i \pi^i$ with $r_i \in \mathcal{T}$ for all $i \geq m$ and $r_m \neq 0$

***Proof*:**
By completeness, build the series by repeatedly subtracting coset representatives: let $r_0 \in \mathcal{T}$ represent x mod $\mathfrak{m}$, so $x - r_0 \in \mathfrak{m} = (\pi)$; write $x - r_0 = \pi x_1$ and repeat with x_1. The partial sums $\sum_{i<N} r_i \pi^i$ are Cauchy and converge to x, and the r_i are forced as coset representatives, giving uniqueness. The Laurent case follows by factoring out π^m with $m = \nu(x)$.

Valuation rings are the maximal objects in the domination order, which yields a clean description of integral closure.

Proposition 27.2.5: Domination and Existence of Valuation Rings

Let k be a field. Every local subring $A \subseteq k$ is dominated by a valuation ring $\mathcal{O}$ of k (that is, $A \subseteq \mathcal{O}$ and $\mathfrak{m}_{\mathcal{O}} \cap A = \mathfrak{m}_A$). Consequently, for a domain A with fraction field k, the integral closure of A in k is the intersection of the valuation rings of k containing A:
$$\overline{A} = \bigcap_{A \subseteq \mathcal{O}} \mathcal{O},$$
so A is integrally closed iff it is an intersection of valuation rings.

***Proof*:**
Order the local subrings of k dominating A by domination; the union of a chain dominates A, so by Zorn there is a maximal one $\mathcal{O}$. It is a valuation ring: suppose $x \in k$ with $x, x^{-1} \notin \mathcal{O}$. Not both of $\mathfrak{m}_{\mathcal{O}}\mathcal{O}[x]$ and $\mathfrak{m}_{\mathcal{O}}\mathcal{O}[x^{-1}]$ are the unit ideal, for otherwise $1 = \sum_{i \leq n} a_i x^i = \sum_{j \leq m} b_j x^{-j}$ with $a_i, b_j \in \mathfrak{m}_{\mathcal{O}}$ and n, m minimal, and eliminating the top power of x between the two relations lowers one of the degrees, a contradiction. Say $\mathfrak{m}_{\mathcal{O}}\mathcal{O}[x] \neq \mathcal{O}[x]$ and let $\mathfrak{n}$ be a maximal ideal of $\mathcal{O}[x]$ containing it; then $\mathcal{O}[x]_{\mathfrak{n}}$ is a local ring strictly dominating $\mathcal{O}$ (it contains $x \notin \mathcal{O}$), contradicting maximality. Every valuation ring is integrally closed (proposition 27.1.8), so $\overline{A} \subseteq \bigcap \mathcal{O}$. Conversely, if $x \in k$ is not integral over A, then x^{-1} is a non-unit of $A[x^{-1}]$, hence lies in a maximal ideal $\mathfrak{n}$; the localization $A[x^{-1}]_{\mathfrak{n}}$ is dominated by a valuation ring $\mathcal{O} \supseteq A$ with $x^{-1} \in \mathfrak{m}_{\mathcal{O}}$, so $\nu(x) < 0$ and $x \notin \mathcal{O}$. Thus $\bigcap \mathcal{O} \subseteq \overline{A}$.

Proposition 27.2.6: Extension of Valuations

Let $K \subseteq L$ be a field extension and ν a valuation on K with valuation ring $\mathcal{O}_\nu$. Then ν extends to a valuation on L.

***Proof*:**
The local ring $\mathcal{O}_\nu \subseteq L$ is dominated by a valuation ring $\mathcal{O}$ of L (proposition 27.2.5). Then $\mathcal{O} \cap K$ is a valuation ring of K dominating $\mathcal{O}_\nu$, hence equals $\mathcal{O}_\nu$, so the valuation of $\mathcal{O}$ restricts to ν on K.

Exercise 27.2.1

1. Show that an abelian group admits a translation-invariant total order if and only if it is torsion-free.
2. Let $\mathcal{O}$ be a DVR with unique prime $\mathfrak{p}$. Show that $\mathfrak{p}^n/\mathfrak{p}^{n+1} \cong \mathcal{O}/\mathfrak{p}$ for $n \geq 0$
3. Let $x \in \mathfrak{m}$ be a non-unit of a complete DVR $\mathcal{O}$. Show that $1 - x$ is a unit, its inverse being the convergent series $\sum_{n \geq 0} x^n$.

28

Artinian Rings

Being Noetherian brings a consistent notion of finiteness to rings, letting us define concepts like dimension. It is natural to ask what the dual *descending chain condition* yields. This chapter studies rings and modules satisfying the D.C.C.; it turns out to be far more restrictive than the A.C.C., forcing an Artinian ring to be zero-dimensional and, in fact, a finite product of local Artinian rings.

28.1 Artinian Rings and Modules

Definition 28.1.1: Artinian module and ring

Let M be a R-module. Then if M satisfies the *descending chain condition* on submodules, it is an *artinian module*. More precisely, for any collection of submodules such that

$$M_1 \supseteq M_2 \supseteq \cdots \supseteq M_k \supseteq \cdots$$

then for some n, we get $M_n = M_{n+1} = \cdots$.
If we let $M = R$ be a module over itself, then we say that R is an *Artinian ring*.

Naturally, an Artinian ring has the D.C.C. condition on its ideals.

Proposition 28.1.2: Artinian Module Equivalent

M is Artinian if and only if every non-empty set of submodules of M contains a minimal element under inclusion

***Proof*:**
If M satisfies the D.C.C. and a nonempty set $\mathcal{S}$ of submodules had no minimal element, choose $M_1 \in \mathcal{S}$ and inductively $M_{i+1} \subsetneq M_i$ in $\mathcal{S}$, an infinite strictly descending chain, a contradiction. Conversely, if every nonempty set has a minimal element, a descending chain $M_1 \supseteq M_2 \supseteq \cdots$ has a minimal M_n, whence $M_n = M_{n+1} = \cdots$.

Just like Noetherian modules, a quotient of an Artinian module is Artinian.

Lemma 28.1.3: Artinian Module Closed Under Quotient

Let M be an Artinian module and $N \subseteq M$. Then M/N is also Artinian

***Proof*:**
A descending chain of submodules of M/N pulls back, via the correspondence for $M \twoheadrightarrow M/N$, to a descending chain of submodules of M containing N, which stabilizes; hence the chain in M/N stabilizes.

Example 28.1.4: Artinian, But Not Noetherian Module
Take $\mathbb{Z}[1/2]/\mathbb{Z}$ as a $\mathbb{Z}$-module. Its submodules form the increasing chain

$$0 \subsetneq \tfrac{1}{2}\mathbb{Z}/\mathbb{Z} \subsetneq \tfrac{1}{4}\mathbb{Z}/\mathbb{Z} \subsetneq \cdots, \qquad \tfrac{1}{2^n}\mathbb{Z}/\mathbb{Z} \cong \mathbb{Z}/2^n\mathbb{Z},$$

and these are all of its submodules. Any descending chain among them is eventually constant, so the module is Artinian, while the increasing chain shows it is not Noetherian. (It is a module, not a ring.)

However, unlike Noetherian rings, Artinian rings need to satisfy stronger properties on their ideals:

Proposition 28.1.5: Artinian, Prime $\Rightarrow$ Maximal

Let R be an Artinian ring and $P \subseteq R$ be a prime ideal. Then P is maximal

Notice how this differs from Noetherian rings: $\mathbb{Z}[x]$ is Noetherian, (x) is prime, but not maximal since $(x) \subsetneq (2, x)$. Thus, being Artinian immediately imposes stronger conditions on its ideals.

***Proof*:**
Consider R/P, which is also artinian by lemma 28.1.3. We'll show $R/P = F$ is a field. COnsider $x \in F \setminus \{0\}$. Then by the descendign chain condition:

$$(x) \supseteq (x^2) \supseteq \cdots$$

must staxalize, that is for some n:

$$(x^n) = (x^{n+1})$$

which implies $x^n = x^{n+1}c$. By the Cancellion law, we get $1 = xc$, showing that x is in fact a unit. Since every element is a unit in F, we have that F is in fact a field, and so P is maximal, as we sought to show.

Theorem 28.1.6: Structure Theorem for Artinian Rings

Let R be an Artinian ring. Then:

1. There are only finitely many maximal ideals
2. The quotient $R/(\text{Jac}(R))$ is the direct product of a finite number of fields, where if there are n maximal ideals, we have a direct product of n fields R/M_i.
3. Every prime ideal of R is maximal. Thus $\text{kdim}(R) = 0$. As a consequence, $\text{Jac}(R) = \text{Nil}(R)$ and is a nilpotent ideal, $(\text{Jac}(R))^n = 0$ for some $n \geq 1$
4. R is isomorphic to a direct product of a finite number of local artinian rings
5. Every Artinian ring is Noetherian

Note that the last conditions is not true for Artinian Modules.

***Proof*:**

1. Consider the chain:
$$m_1 \supseteq m_1 \cap m_2 \supseteq \cdots$$
I first claim that each inclusion of this chain is proper. To see this, recall that if m_i and m_j are non-equal maximal ideal, it must be that $m_i + m_j = 1$. Thus, any collection of maximal ideals has this pair-wise condition. By the Chinese Remainder Theorem:
$$R/(m_1 \cap \cdots \cap m_n) \cong R/m_1 \times R/m_2 \times \cdots \times R/m_n$$
Now simply see that the element $(\overline{0}, ..., \overline{0}, \overline{1})$ is non-zero, and hence not contain in $m_1 \cap \cdots \cap m_n$, showing that each inclusion *must* be proper! Thus, by the D.C.C., the above chain must stabalize, meaning there can only be finitely many maximal ideals.
2. The proof follows immediately from the previous observation of the CRT
3. First, $J := \text{Jac}(R)$ is nilpotent: by the D.C.C. the chain $J \supseteq J^2 \supseteq \cdots$ stabilizes, say $J^k = J^{k+1}$. If $J^k \neq 0$, the nonempty set of ideals I with $IJ^k \neq 0$ has a minimal element I_0; pick $a \in I_0$ with $aJ^k \neq 0$, so $(a) \subseteq I_0$ is in the set and $(a) = I_0$ by minimality. Then $((a)J)J^k = (a)J^{k+1} = (a)J^k \neq 0$ and $(a)J \subseteq (a)$, so $(a)J = (a)$ by minimality, and Nakayama (lemma 23.4.27, as $J \subseteq \text{Jac}(R)$) forces $(a) = 0$, a contradiction. Hence $J^k = 0$, so $J \subseteq \sqrt{(0)} = \text{Nil}(R)$; the reverse inclusion always holds, giving $\text{Jac}(R) = \text{Nil}(R)$. Now let P be prime. As $P \supseteq \text{Nil}(R) = J$, its image in $R/J \cong k_1 \times \cdots \times k_n$ is a prime; since ideals of a product are products of ideals, that image is $k_1 \times \cdots \times 0 \times \cdots \times k_n$, which is maximal, so P is maximal by the correspondence theorem. Thus every prime is maximal and $\text{kdim} R = 0$.
4. Let $m_1, ..., m_n$ be the maximal ideals of R and let k be such that $(\text{Jac}(R))^k = 0$. Then
$$\prod_i^n M_i^k \subseteq \left(\prod_i^n M_i\right)^k \subseteq (\text{Jac}(R))^k = 0$$

Thus, by the CRT
$$R \cong (R/M_1^k) \times \cdots \times (R/M_n^k)$$
Notice that each R/M_i^k is an artinian with unique maximal ideal M_i/M_i^k.

5. By part (4) it suffices to show local Artinian rings are Noetherian. Let $\mathfrak{m}$ be the maximal ideal; then $\mathfrak{m} = \mathrm{Jac}(R)$ and $\mathfrak{m}^k = 0$ for some k (part 3), giving the filtration $R \supseteq \mathfrak{m} \supseteq \mathfrak{m}^2 \supseteq \cdots \supseteq \mathfrak{m}^k = 0$. Each quotient $\mathfrak{m}^i/\mathfrak{m}^{i+1}$ is a vector space over the field $R/\mathfrak{m}$ satisfying the D.C.C., hence finite-dimensional (lemma 28.1.11) and of finite length; concatenating their composition series gives one for R, so R is Noetherian.

Corollary 28.1.7: Uniqueness of the Local Decomposition

The decomposition of an Artinian ring $R \cong \prod_{i=1}^n R_i$ into local Artinian rings is unique up to reordering: the factors are the localizations $R_i \cong R_{\mathfrak{m}_i}$ at the maximal ideals (which here coincide with the completions $\hat{R}_{\mathfrak{m}_i}$), corresponding to the primitive idempotents of R.

***Proof*:**
In a product $\prod R_j$ of local rings the idempotents are the tuples of 0s and 1s, the primitive ones being the standard vectors e_i; hence the factors $R_i = e_i R$ are intrinsic. Localizing at $\mathfrak{m}_i$ kills every e_j with $j \neq i$ (each $1 - e_j \notin \mathfrak{m}_i$ becomes a unit and $e_j(1-e_j) = 0$), leaving R_i, so $R_{\mathfrak{m}_i} \cong R_i$; and R_i, being local Artinian, is complete.

Corollary 28.1.8: Reduced Artinian Rings

An Artinian ring is reduced if and only if it is a finite product of fields.

***Proof*:**
A finite product of fields is reduced. Conversely, if R is reduced Artinian then $\mathrm{Nil}(R) = 0$, so by the structure theorem $R \cong \prod_i R/\mathfrak{m}_i^k$ with $\bigcap_i \mathfrak{m}_i^k = \mathrm{Nil}(R) = 0$; reducedness forces each local factor to have zero nilradical, i.e. $\mathfrak{m}_i^k = 0$ collapses to $\mathfrak{m}_i = 0$ there, so each factor is the field $R/\mathfrak{m}_i$.

Corollary 28.1.9: Artinian Ring Equivalent Condition I

Let R be a ring. Then R is Artinian if and only if R is Noetherian and $\dim(R) = 0$

***Proof*:**
R Artinian implies R Noetherian (theorem 28.1.6) with all primes maximal, i.e. $\dim R = 0$. For the converse, let R be Noetherian with $\dim R = 0$. Its minimal primes $\mathfrak{m}_1, \ldots, \mathfrak{m}_n$ are finite in number (Noetherian) and all maximal ($\dim R = 0$), and $\mathrm{Nil}(R) = \mathfrak{m}_1 \cap \cdots \cap \mathfrak{m}_n$ is nilpotent (finitely generated), so $(\mathfrak{m}_1 \cdots \mathfrak{m}_n)^k \subseteq \mathrm{Nil}(R)^k = 0$ for some k. By the Chinese Remainder Theorem $R \cong \prod_i R/\mathfrak{m}_i^k$, each factor Noetherian local with nilpotent maximal ideal, hence of finite length and Artinian; so R is Artinian.

Corollary 28.1.10: Artinian Ring Equivalent Condition II

Let k be a field and R a finitely generated k-algebra. Then R is artinian if and only if R is finitely generated as a k-module.

***Proof*:**
If R is a finite-dimensional k-vector space, its ideals are k-subspaces, so the D.C.C. holds and R is Artinian. Conversely, if R is Artinian then $\dim R = 0$ (theorem 28.1.6), and a finitely generated k-algebra of dimension 0 is a finite k-module (chapter 29).

For artinian modules over a field $R = k$, there is a clean characterization:

Lemma 28.1.11: Artin+Noetherian Module

Let M be a vector space over k. Then the following are equivalent:

1. M satisfies the A.C.C.
2. M satisfies the D.C.C.
3. M is finite-dimensional

***Proof*:**
Naturally, (3) implies both (1) and (2). Conversely, assume $\dim_k(M) = \infty$, so pick some infinite collection of linearly independent vectors. Then we have an infinite strict chain:

$$\langle e_1 \rangle \subsetneq \langle e_1, e_2 \rangle \cdots$$

and an infinite descending chain:

$$\langle e_1, e_2, \ldots \rangle \supsetneq \langle e_2, e_3, \ldots \rangle \supsetneq \cdots$$

completing the proof

Example 28.1.12: Artinian Rings

1. Let $N > 1$ be an integer and $R = \mathbb{Z}/N\mathbb{Z}$. Since R is finite it is Artinian. If $N = p_1^{\alpha_1} \cdots p_r^{\alpha_r}$ for distinct primes p_i and $\alpha_i \geq 1$, then by the Chinese Remainder Theorem

$$\mathbb{Z}/N\mathbb{Z} \cong (\mathbb{Z}/p_1^{\alpha_1}\mathbb{Z}) \times (\mathbb{Z}/p_2^{\alpha_2}\mathbb{Z}) \times \cdots \times (\mathbb{Z}/p_r^{\alpha_r}\mathbb{Z})$$

   where each $\mathbb{Z}/p_i^{\alpha_i}\mathbb{Z}$ is a local Artinian ring with maximal ideal $(p_i)/(p_i^{\alpha_i})$. The Jacobson radical of R is $(p_1 p_2 \cdots p_r)$.

2. Let R be a finite dimensional k-algebra over some field k (it need not be commutative!). Then R is an Artinian ring, since any descending chain of R is a descending chain of k-subspces of R, which is bounded by $\dim_k(R)$. Note that if R is not commutative, R is not the finite direct product of local artinian rings, but the finite product of indecomposable artinian rings (i.e. artinian rings which cannot be split into direct sum of submodules).

3. Let $k[x]$ be the polynomial ring over a field k and $f \in k[x]$ be a nonzero polynomial. Then if $f(x) = f_1^{n_1}(x) \cdots f_k^{n_k}(x)$, by the CRT we have:

$$k[x]/(f(x)) \cong k[x]/(f_1^{n_1}(x)) \times \cdots \times k[x]/(f_k^{n_k}(x))$$

which is artinian, since $k[x]/(f(x))$ is a finite dimensional k-module (each $k[x]/(f_i^{n_i}(x))$ is a local artinian ring, with maximla ideal $(f_i(x))/(f_i^{n_i}(x))$). If $n_i = 1$ for all i, $k[x]/(f(x))$ is a product of fields, and if furtheremore there was only 1 n_i (i.e. $i \in \{1\}$), then $k[x]/(f(x))$ would be a field extension

We shall give names to modules that satisfy both the Artinian and Noetherian condition:

Definition 28.1.13: Modules of Finite Length

Let M be an R-module that is Noetherian and Artinian. Then M is an R-module of *finite length*.

By proposition 23.1.8 each finite-length module has a well-defined length $\ell(M) \in \mathbb{N}$. In fact the composition factors themselves are determined:

Theorem 28.1.14: Jordan-Hölder

Let M be a module of finite length. Then any two composition series of M have the same length and the same multiset of simple quotients, up to isomorphism and reordering.

***Proof*:**
Length invariance is proposition 23.1.8. Induct on $\ell(M)$ for the factors: given two composition series with maximal submodules M_1, M_1', either $M_1 = M_1'$ (apply the inductive hypothesis to M_1), or $M_1 + M_1' = M$, whence $M/M_1 \cong M_1'/(M_1 \cap M_1')$ and $M/M_1' \cong M_1/(M_1 \cap M_1')$; inserting a composition series of $M_1 \cap M_1'$ into each shows the two factor multisets agree.

Example 28.1.15: Module of Finite Length
The simplest example would be when $R = k$ is a field, which gives vector-spaces. In this case, for any V

$$\ell(V) = \dim_k(V)$$

Proposition 28.1.16: Finite Length Additive Under Extensions

Let

$$0 \to M' \to M \to M'' \to 0$$

Be a short exact sequence of finite length modules. Then:

$$\ell(M) = \ell(M') + \ell(M'')$$

***Proof*:**
Concatenating a composition series $0 = M'_0 \subsetneq \cdots \subsetneq M'_{\ell(M')} = M'$ of M' with the preimage in M of a composition series of $M'' = M/M'$ yields a composition series of M of length $\ell(M') + \ell(M'')$; by invariance of length (proposition 23.1.8) this is $\ell(M)$.

For a finite-length module the length is computed locally, and the module splits as a direct sum over its (finitely many, maximal) associated points.

Proposition 28.1.17: Length, Support, and Local Decomposition

Let M be a finite-length R-module. Then $\mathrm{Supp}(M)$ is a finite set of maximal ideals, the natural map $M \to \bigoplus_{\mathfrak{m} \in \mathrm{Supp}(M)} M_{\mathfrak{m}}$ is an isomorphism, and

$$\ell_R(M) = \sum_{\mathfrak{m} \in \mathrm{Supp}(M)} \ell_{R_{\mathfrak{m}}}(M_{\mathfrak{m}})$$

***Proof*:**
A composition series of M has simple factors $R/\mathfrak{m}_i$ with the $\mathfrak{m}_i$ maximal, so $\mathrm{Supp}(M) = \{\mathfrak{m}_i\}$ is a finite set of maximal ideals and some product $\mathfrak{m}_1^{a_1} \cdots \mathfrak{m}_r^{a_r}$ annihilates M. Thus M is a module over the Artinian ring $R/\operatorname{Ann}(M) \cong \prod_i R/\mathfrak{m}_i^{a_i}$, which gives the direct-sum decomposition $M \cong \bigoplus_i M_{\mathfrak{m}_i}$. Localizing a composition series at $\mathfrak{m}$ deletes the factors $R/\mathfrak{m}'$ with $\mathfrak{m}' \neq \mathfrak{m}$ and preserves those with $\mathfrak{m}' = \mathfrak{m}$, so $\ell_{R_{\mathfrak{m}}}(M_{\mathfrak{m}})$ counts the factors isomorphic to $R/\mathfrak{m}$; summing over $\mathfrak{m}$ gives $\ell_R(M)$.

Proposition 28.1.18: Length Along a Flat Local Homomorphism

Let $\varphi\colon (A, \mathfrak{m}) \to (B, \mathfrak{n})$ be a flat local homomorphism of Noetherian local rings whose closed fibre $B/\mathfrak{m}B$ has finite length over B, and let M be an A-module of finite length. Then $M \otimes_A B$ has finite length over B, and

$$\ell_B(M \otimes_A B) \;=\; \ell_A(M) \cdot \ell_B(B/\mathfrak{m}B)$$

In particular, if A is Artinian then $\ell_B(B) = \ell_A(A) \cdot \ell_B(B/\mathfrak{m}B)$.

***Proof*:**
Induct on $n = \ell_A(M)$. If $n = 0$ then $M = 0$ and both sides vanish. If $n = 1$ then M is simple, so $M \cong A/\mathfrak{m}$ because A is local, and $M \otimes_A B \cong B/\mathfrak{m}B$, whose length is $\ell_B(B/\mathfrak{m}B)$ by hypothesis; this is the claimed product since $\ell_A(M) = 1$.

For $n > 1$, choose a submodule $M' \subseteq M$ with $\ell_A(M') = n - 1$ and $M/M' \cong A/\mathfrak{m}$, which exists by taking a composition series. Tensoring

$$0 \to M' \to M \to A/\mathfrak{m} \to 0$$

with B over A leaves it exact, since B is flat over A. Length is additive on short exact sequences (proposition 28.1.16), so

$$\ell_B(M \otimes_A B) = \ell_B(M' \otimes_A B) + \ell_B(B/\mathfrak{m}B) = (n-1)\ell_B(B/\mathfrak{m}B) + \ell_B(B/\mathfrak{m}B)$$

using the inductive hypothesis, and the right side is $n \cdot \ell_B(B/\mathfrak{m}B)$, as we sought to show.

The multiplicativity is the algebraic content behind the geometric statement that a flat morphism pulls the fundamental cycle of the base back to the fundamental cycle of the total space: the multiplicity with which a component occurs is multiplied by the length of the fibre, uniformly.

Proposition 28.1.19: Finiteness over an Artinian Ring

Let R be an Artinian ring and M an R-module. Then M is finitely generated iff it has finite length iff it is Noetherian iff it is Artinian. In particular R has finite length over itself.

***Proof*:**
Finite length trivially implies the other three. If M is finitely generated it is a quotient of some R^n; since R has finite length over itself (its composition series comes from the filtration by the $\mathfrak{m}_i^j$), so do R^n and its quotient M. A Noetherian module is finitely generated, hence of finite length by the above. An Artinian module M over the Artinian R also has finite length: with $J = \mathrm{Jac}(R)$ and $J^k = 0$, the filtration $M \supseteq JM \supseteq \cdots \supseteq J^k M = 0$ has each piece $J^i M/J^{i+1}M$ a module over the product of fields R/J satisfying the D.C.C., hence a finite direct sum of simple modules.

Exercise 28.1.1

1. Let M be a Noetherian and Artinian A-module, $\varphi : M \to M$ an A-module homomorphism. Show that there exists an $n \geq 0$ such that $M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$.
2. Let M be an R-module. Then M is of finite length iff it has a composition series.

29

Dimension Theory

How large is a ring? For the coordinate ring of a variety the answer should be the variety's dimension, and the algebra offers three ways to measure it, each capturing a different intuition. One counts how many independent parameters the ring carries: the length of the longest chain of prime ideals, since primes correspond to irreducible closed subsets and a chain of them is a tower of nested subvarieties. A second counts how many equations it takes to cut the ring down to something finite: a zero-dimensional, Artinian quotient. A third reads the dimension off a growth rate, the rate at which $R/\mathfrak{m}^n$ grows with n. The central result of the chapter, the *dimension theorem*, is that these three numbers coincide. It is the payoff of the finiteness and locality threads: the Noetherian hypothesis makes the growth rate polynomial, localization concentrates the question at a single prime, and Noether normalization ties the whole theory back to the transparent case of a polynomial ring.

The geometric cash-out (that the Krull dimension of a coordinate ring is the topological dimension of its variety, that a hypersurface drops dimension by one) is developed in [27], which cites this chapter for the ring theory.

29.1 Noether Normalization

The theory rests on the fact that a finitely generated algebra over a field is only finitely far from a polynomial ring.

Theorem 29.1.1: Noether Normalization

Let k be a field and $A = k[r_1, \ldots, r_n]$ a finitely generated k-algebra. Then there are elements $y_1, \ldots, y_q \in A$, algebraically independent over k, such that A is a finite (module-finite) extension of $k[y_1, \ldots, y_q]$.

***Proof*:**
Induct on n, the number of generators. If $r_1, \ldots, r_n$ are algebraically independent, take $y_i = r_i$ and $A = k[y_1, \ldots, y_n]$. Otherwise a nonzero $f \in k[x_1, \ldots, x_n]$ satisfies $f(r_1, \ldots, r_n) = 0$; let d exceed every exponent appearing in f, and set

$$x_i' = x_i - x_n^{d^i} \quad (1 \le i \le n-1)$$

Rewriting f in the variables $x_1', \ldots, x_{n-1}', x_n$, each monomial $x_1^{a_1} \cdots x_n^{a_n}$ of f contributes a top x_n-power $x_n^{a_1 d + a_2 d^2 + \cdots + a_{n-1} d^{n-1} + a_n}$; base-$d$ uniqueness makes these exponents distinct across monomials, so f becomes, up to a nonzero scalar from k, monic in x_n of some degree N with coefficients in $k[x_1', \ldots, x_{n-1}']$. Putting $s_i = r_i - r_n^{d^i}$, the relation $f(r_1, \ldots, r_n) = 0$ exhibits r_n as a root of a monic polynomial over $B = k[s_1, \ldots, s_{n-1}]$, so r_n is integral over B; each $r_i = s_i + r_n^{d^i}$ is then integral over $B[r_n]$, and by transitivity A is integral, hence (being finitely generated) module-finite, over B. As B is generated by $n-1$ elements, induction gives a polynomial subalgebra $k[y_1, \ldots, y_q] \subseteq B$ over which B, and therefore A, is module-finite.

The number q is an invariant: it equals the transcendence degree of A over k when A is a domain, as theorem 29.6.2 will record once dimension is in hand.

29.2 Krull Dimension

Definition 29.2.1: Krull Dimension and Height

The *height* of a prime $\mathfrak{p}$, written $\operatorname{ht}\mathfrak{p}$, is the supremum of lengths r of chains $\mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_r = \mathfrak{p}$ of primes descending from $\mathfrak{p}$. The *Krull dimension* $\dim R$ is the supremum of $\operatorname{ht}\mathfrak{p}$ over all primes $\mathfrak{p}$, equivalently the supremum of lengths of chains of primes in R.

A field has dimension 0; a principal ideal domain that is not a field has dimension 1, its chains being $0 \subsetneq (\pi)$ for irreducible π. For a local ring $(R, \mathfrak{m})$ the dimension is $\operatorname{ht}\mathfrak{m}$, since $\mathfrak{m}$ contains every prime. The chain $0 \subsetneq (x_1) \subsetneq (x_1, x_2) \subsetneq \cdots \subsetneq (x_1, \ldots, x_n)$ in $k[x_1, \ldots, x_n]$ shows $\dim k[x_1, \ldots, x_n] \ge n$; equality is theorem 29.6.2.

Dimension is controlled locally: $\dim R = \sup_{\mathfrak{m}} \dim R_{\mathfrak{m}}$ over maximal ideals, because a chain of primes below $\mathfrak{p}$ survives in $R_{\mathfrak{p}}$. The substance of the theory is therefore the local case, to which the next two sections are devoted.

29.3 The Hilbert-Samuel Function

Throughout this section $(R, \mathfrak{m})$ is a Noetherian local ring and $\mathfrak{q}$ an $\mathfrak{m}$-*primary* ideal, so that $\mathfrak{m}^r \subseteq \mathfrak{q} \subseteq \mathfrak{m}$ for some r and $R/\mathfrak{q}$ is Artinian. We measure R through the lengths $\ell(R/\mathfrak{q}^n)$. The tool is the associated graded ring $\operatorname{gr}_{\mathfrak{q}} R = \bigoplus_{n \ge 0} \mathfrak{q}^n/\mathfrak{q}^{n+1}$, a Noetherian graded ring, finitely generated over the Artinian ring $R/\mathfrak{q}$ by the finitely many degree-one elements $\mathfrak{q}/\mathfrak{q}^2$.

Lemma 29.3.1: Hilbert Polynomial of a Graded Module

Let $S = S_0[t_1, \ldots, t_s]$ be a graded ring, finitely generated over an Artinian ring S_0 by degree-one elements t_i, and $N = \bigoplus_n N_n$ a finitely generated graded S-module. Then $\ell(N_n)$ is finite for each n and agrees, for $n \gg 0$, with a polynomial in n of degree $\leq s-1$ (rational coefficients).

***Proof*:**
Each N_n is a finitely generated S_0-module, hence of finite length. Induct on s. If $s = 0$ then $S = S_0$ and N, being finitely generated, is concentrated in finitely many degrees, so $\ell(N_n) = 0$ for $n \gg 0$ (a polynomial of degree ≤ -1). For the step, multiplication by t_s gives an exact sequence of $S_0[t_1, \ldots, t_{s-1}]$-modules in each degree,

$$0 \to K_n \to N_n \xrightarrow{t_s} N_{n+1} \to (N/t_sN)_{n+1} \to 0,$$

where $K = (0 :_N t_s)$ and N/t_sN are finitely generated and killed by t_s, hence graded modules over $S_0[t_1, \ldots, t_{s-1}]$. Additivity of length gives $\ell(N_{n+1}) - \ell(N_n) = \ell\big((N/t_sN)_{n+1}\big) - \ell(K_n)$, which by induction agrees with a polynomial of degree $\leq s-2$ for $n \gg 0$. A function whose first difference is eventually a polynomial of degree $\leq s-2$ is itself eventually a polynomial of degree $\leq s-1$.

Proposition 29.3.2: The Hilbert-Samuel Polynomial

For a finitely generated R-module M, the *characteristic function* $\chi^M_{\mathfrak{q}}(n) = \ell(M/\mathfrak{q}^nM)$ agrees for $n \gg 0$ with a polynomial in n of degree $\leq s$, where s is the least number of generators of $\mathfrak{q}$. Moreover $\deg \chi^M_{\mathfrak{q}} = \deg \chi^M_{\mathfrak{m}}$, so the degree is independent of the $\mathfrak{m}$-primary ideal $\mathfrak{q}$.

***Proof*:**
The associated graded module $\mathrm{gr}(M) = \bigoplus_n \mathfrak{q}^nM/\mathfrak{q}^{n+1}M$ is a finitely generated graded module over $\mathrm{gr}_{\mathfrak{q}} R$, itself generated over the Artinian ring $R/\mathfrak{q}$ by the s degree-one generators of $\mathfrak{q}/\mathfrak{q}^2$. By lemma 29.3.1, $\ell(\mathfrak{q}^nM/\mathfrak{q}^{n+1}M)$ is eventually a polynomial of degree $\leq s-1$. Since $\chi^M_{\mathfrak{q}}(n) = \ell(M/\mathfrak{q}^nM) = \sum_{r=0}^{n-1} \ell(\mathfrak{q}^rM/\mathfrak{q}^{r+1}M)$, summing raises the degree by one: $\chi^M_{\mathfrak{q}}$ is eventually a polynomial of degree $\leq s$. For the last claim, $\mathfrak{m}^r \subseteq \mathfrak{q} \subseteq \mathfrak{m}$ gives $\mathfrak{m}^{rn} \subseteq \mathfrak{q}^n \subseteq \mathfrak{m}^n$, hence $\chi^M_{\mathfrak{m}}(n) \leq \chi^M_{\mathfrak{q}}(n) \leq \chi^M_{\mathfrak{m}}(rn)$ for all n; the outer terms are polynomials of equal degree, so the middle one shares it.

Write $d(M) = \deg \chi^M_{\mathfrak{m}}(n)$ and $d(R) = \deg \chi_{\mathfrak{m}}(n)$ where $\chi_{\mathfrak{m}}(n) = \ell(R/\mathfrak{m}^n)$. The next proposition is the inductive engine.

Proposition 29.3.3: Dropping the Degree by a Non-Zero-Divisor

If $x \in \mathfrak{m}$ is not a zero-divisor on M, then $d(M/xM) \leq d(M) - 1$.

***Proof*:**
Set $M' = M/xM$. Additivity of length in $0 \to (xM + \mathfrak{q}^n M)/\mathfrak{q}^n M \to M/\mathfrak{q}^n M \to M'/\mathfrak{q}^n M' \to 0$ gives $\chi_{\mathfrak{q}}^{M'}(n) = \chi_{\mathfrak{q}}^{M}(n) - g(n)$, where $g(n) = \ell\big(xM/(xM \cap \mathfrak{q}^n M)\big)$. As x is a non-zero-divisor, $M \xrightarrow{x} xM$ is an isomorphism carrying $\mathfrak{q}^n M$ onto $\mathfrak{q}^n(xM)$, so $\ell(xM/\mathfrak{q}^n(xM)) = \chi_{\mathfrak{q}}^{M}(n)$. Now $\mathfrak{q}^n(xM) \subseteq xM \cap \mathfrak{q}^n M$, and by the Artin-Rees lemma (theorem 25.4.1) the filtration $\{xM \cap \mathfrak{q}^n M\}$ is $\mathfrak{q}$-stable, so $xM \cap \mathfrak{q}^n M \subseteq \mathfrak{q}^{n-c}(xM)$ for some c and all $n \geq c$. Taking lengths,

$$\chi_{\mathfrak{q}}^{M}(n-c) \leq g(n) \leq \chi_{\mathfrak{q}}^{M}(n)$$

Both bounds are $\chi_{\mathfrak{q}}^{M}$ evaluated at $n-c$ and n, so g agrees for large n with a polynomial of degree $d(M)$ and the same leading coefficient as $\chi_{\mathfrak{q}}^{M}$. Hence $\chi_{\mathfrak{q}}^{M'} = \chi_{\mathfrak{q}}^{M} - g$ has degree $\leq d(M) - 1$.

29.4 The Dimension Theorem

Theorem 29.4.1: Dimension Theorem

For a Noetherian local ring $(R, \mathfrak{m})$ the following three numbers coincide:

$$d(R) = \delta(R) = \dim R,$$

where $d(R) = \deg \ell(R/\mathfrak{m}^n)$, and $\delta(R)$ is the least number of generators of an $\mathfrak{m}$-primary ideal.

***Proof*:**
We show $d(R) \leq \delta(R) \leq \dim R \leq d(R)$.

$d(R) \leq \delta(R)$. If $\mathfrak{q}$ is $\mathfrak{m}$-primary and generated by $s = \delta(R)$ elements, then $\deg \chi_{\mathfrak{q}} \leq s$ by proposition 29.3.2, and $\deg \chi_{\mathfrak{q}} = \deg \chi_{\mathfrak{m}} = d(R)$; so $d(R) \leq \delta(R)$.

$\dim R \leq d(R)$. Induct on $d(R)$. If $d(R) = 0$ then $\ell(R/\mathfrak{m}^n)$ is eventually constant, so $\mathfrak{m}^n = \mathfrak{m}^{n+1}$ for some n; Nakayama's lemma (lemma 23.4.27) gives $\mathfrak{m}^n = 0$, so R is Artinian and $\dim R = 0$. Suppose $d(R) = d > 0$ and let $\mathfrak{p}_0 \subsetneq \cdots \subsetneq \mathfrak{p}_r$ be a chain of primes; we bound r. We may take $\mathfrak{p}_0$ minimal, and choosing $x \in \mathfrak{p}_1 \setminus \mathfrak{p}_0$, the ring $\bar{R} = R/\mathfrak{p}_0$ is a domain in which x is a nonzero, hence non-zero-divisor, element. By proposition 29.3.3, $d(\bar{R}/x\bar{R}) \leq d(\bar{R}) - 1 \leq d(R) - 1$ (the last as $\bar{R}$ is a quotient of R, whose characteristic polynomial dominates). The chain $\mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_r$ descends to a chain of length $r-1$ in $\bar{R}/x\bar{R}$, so by induction $r - 1 \leq d(R) - 1$, i.e. $r \leq d(R)$. Hence $\dim R \leq d(R)$.

$\delta(R) \leq \dim R$. Let $d = \dim R$; we build an $\mathfrak{m}$-primary ideal from d elements. Choose $x_1, \ldots, x_d \in \mathfrak{m}$ so that x_i lies in no minimal prime of $(x_1, \ldots, x_{i-1})$; this is possible by prime avoidance, as there are only finitely many such minimal primes (corollary 24.4.3), unless one of them is $\mathfrak{m}$ itself, in which case $(x_1, \ldots, x_{i-1})$ is already $\mathfrak{m}$-primary and fewer elements suffice. An induction then shows every prime $\mathfrak{p} \supseteq (x_1, \ldots, x_i)$ has $\operatorname{ht} \mathfrak{p} \geq i$: such $\mathfrak{p}$ contains a minimal prime $\mathfrak{p}'$ of $(x_1, \ldots, x_{i-1})$, which has $\operatorname{ht} \mathfrak{p}' \geq i - 1$ by induction, and $\mathfrak{p} \neq \mathfrak{p}'$ because $x_i \in \mathfrak{p} \setminus \mathfrak{p}'$, so $\operatorname{ht} \mathfrak{p} \geq \operatorname{ht} \mathfrak{p}' + 1 \geq i$. At $i = d$ every prime over $(x_1, \ldots, x_d)$ has height $\geq d = \operatorname{ht} \mathfrak{m}$; since $\mathfrak{m}$ is the only prime of that height in the local ring R, the ideal $(x_1, \ldots, x_d)$ is $\mathfrak{m}$-primary. Thus $\delta(R) \leq d$.

Krull's height theorem, proved next, is now a corollary of the dimension theorem, with no circularity:

its proof invokes only the equalities just established.

29.5 Systems of Parameters and Krull's Principal Ideal Theorem

Definition 29.5.1: System of Parameters

A *system of parameters* for a Noetherian local ring $(R, \mathfrak{m})$ of dimension d is a set of d elements generating an $\mathfrak{m}$-primary ideal. The dimension theorem guarantees one exists, and d is the least possible number of such generators.

Theorem 29.5.2: Krull's Height Theorem

Let R be Noetherian and $\mathfrak{a} = (x_1, \dots, x_c)$ generated by c elements. Then every prime $\mathfrak{p}$ minimal over $\mathfrak{a}$ has $\operatorname{ht}\mathfrak{p} \le c$. In particular (the *Hauptidealsatz*, $c = 1$) a prime minimal over a single nonunit x has height at most 1.

***Proof*:**
Localizing at $\mathfrak{p}$, we may assume $(R, \mathfrak{p})$ is local and $\mathfrak{p}$ is minimal over $\mathfrak{a}$, so that $\mathfrak{a}$ is $\mathfrak{p}$-primary and $\operatorname{ht}\mathfrak{p} = \dim R$. Then $\mathfrak{a}$ is an $\mathfrak{p}$-primary ideal with c generators, so $\dim R = \delta(R) \le c$ by the inequality $\dim R \le d(R) \le \delta(R)$ established in theorem 29.4.1; here only $\dim R \le d(R)$ and $d(R) \le \delta(R)$ are used, and $\delta(R) \le c$ because $\mathfrak{a}$ itself is $\mathfrak{p}$-primary with c generators.

A converse rounds out the picture: in a Noetherian ring a prime of height c is minimal over some ideal generated by c elements, so height is exactly the least number of generators needed to cut out a prime as a component. The Hauptidealsatz is the algebraic form of the geometric principle that one equation cuts dimension by one: passing to $R/(x)$ for x a non-unit non-zero-divisor lowers dimension by exactly one,

$$\dim R/(x) = \dim R - 1,$$

the inequality $\ge$ from theorem 29.5.2 and $\le$ from proposition 29.3.3.

29.6 Dimension and Transcendence Degree

Noether normalization now identifies the dimension of a geometric ring with a transcendence degree, and pins down the dimension of affine space. The engine is that a proper prime quotient of a finitely generated domain loses transcendence degree.

Lemma 29.6.1: Transcendence Degree Drops on a Prime Quotient

Let A be a finitely generated domain over a field k and $\mathfrak{p} \ne 0$ a prime of A. Then $\operatorname{trdeg}_k \operatorname{Frac}(A/\mathfrak{p}) < \operatorname{trdeg}_k \operatorname{Frac}(A)$.

***Proof*:**
Throughout, transcendence bases and the transcendence degree of a field extension are those of *Core Algebra* [25], where in particular the degree is shown to be well-defined.

Put $d = \operatorname{trdeg}_k A$ and $e = \operatorname{trdeg}_k A/\mathfrak{p} \leq d$, and suppose $e = d$. Choose $x_1, \dots, x_d \in A$ whose images in $A/\mathfrak{p}$ form a transcendence basis; they are algebraically independent in A, hence (as $d = \operatorname{trdeg} A$) a transcendence basis of A as well, so every element of A is algebraic over $B = k[x_1, \dots, x_d]$. Pick $0 \neq a \in \mathfrak{p}$. An algebraic relation for a over $\operatorname{Frac}(B)$, cleared of denominators and divided by the largest power of a that factors out (valid as A is a domain), becomes $c_0 + c_1 a + \cdots + c_m a^m = 0$ with $c_i \in B$ and $c_0 \neq 0$; then $c_0 = -a(c_1 + \cdots + c_m a^{m-1}) \in \mathfrak{p}$. But $\mathfrak{p} \cap B = 0$, since a nonzero element of $\mathfrak{p} \cap B$ would be a nontrivial algebraic relation among the algebraically independent images $\bar{x}_i$ in $A/\mathfrak{p}$. This contradicts $c_0 \neq 0$, so $e < d$.

Theorem 29.6.2: Dimension of Finitely Generated Algebras

Let A be a finitely generated algebra over a field k that is a domain. Then

$$\dim A = \operatorname{trdeg}_k \operatorname{Frac}(A),$$

and in particular $\dim k[x_1, \dots, x_n] = n$. More generally the number q in Noether normalization (theorem 29.1.1) equals $\dim A$.

***Proof*:**
By theorem 29.1.1, A is module-finite, hence integral, over a polynomial subalgebra $k[y_1, \dots, y_q]$ with the y_i algebraically independent, so $q = \operatorname{trdeg}_k \operatorname{Frac}(A)$; integral extensions preserve Krull dimension (theorem 26.3.2 supplies lying-over, going-up, and incomparability), so $\dim A = \dim k[y_1, \dots, y_q]$. We prove the general claim $\dim B \leq \operatorname{trdeg}_k \operatorname{Frac}(B)$ for every finitely generated domain B over k, by induction on transcendence degree. Given a chain $0 = \mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_r$ in B, the tail descends to a chain of length $r - 1$ in the finitely generated domain $B/\mathfrak{p}_1$, whose transcendence degree is at most $\operatorname{trdeg} B - 1$ by lemma 29.6.1; induction gives $r - 1 \leq \operatorname{trdeg} B - 1$, so $r \leq \operatorname{trdeg} B$. Applied to $B = k[y_1, \dots, y_q]$ this yields $\dim k[y_1, \dots, y_q] \leq q$, while the chain of definition 29.2.1 gives $\geq q$. Hence $\dim A = \dim k[y_1, \dots, y_q] = q = \operatorname{trdeg}_k \operatorname{Frac}(A)$.

The equality $\dim A = \operatorname{trdeg}_k \operatorname{Frac}(A)$ is the algebraic form of the statement that dimension counts independent coordinates; in [27] it becomes the assertion that the dimension of an irreducible affine variety is the transcendence degree of its function field.

29.7 Regular Local Rings

The dimension theorem produced three numbers and showed them equal. A fourth is always available for a local ring and is never smaller: the least number of generators of the maximal ideal, which by Nakayama is the dimension of $\mathfrak{m}/\mathfrak{m}^2$ as a vector space over the residue field. Rings for which the fourth number agrees with the other three are the regular ones, and they are the subject of this section.

The inequality has a geometric reading that fixes the terminology. For a variety X and a point p, the vector space $(\mathfrak{m}_p/\mathfrak{m}_p^2)^\vee$ is the tangent space at p, so the inequality says a variety has at least as many tangent directions at a point as it has dimensions, and regularity is the case where it has exactly as many. That reading, and the identification of regular local rings with the smooth points of a variety, is [27]; what follows is the ring theory it cites.

Corollary 29.7.1: Dimension and Embedding Dimension

Let $(R, \mathfrak{m})$ be a Noetherian local ring with residue field $k = R/\mathfrak{m}$. Then

$$\dim R \leq \dim_k \mathfrak{m}/\mathfrak{m}^2$$

***Proof*:**
Put $s = \dim_k \mathfrak{m}/\mathfrak{m}^2$ and choose $x_1, \ldots, x_s \in \mathfrak{m}$ whose images form a k-basis of $\mathfrak{m}/\mathfrak{m}^2$. By Nakayama's lemma (lemma 23.4.27) they generate $\mathfrak{m}$, which is $\mathfrak{m}$-primary, so $\delta(R) \leq s$. The dimension theorem (theorem 29.4.1) gives $\dim R = \delta(R) \leq s$, as we sought to show.

The same argument identifies $\dim_k \mathfrak{m}/\mathfrak{m}^2$ with the least number of generators of $\mathfrak{m}$: Nakayama makes any lift of a basis a generating set, and no smaller set can generate, since a generating set spans $\mathfrak{m}/\mathfrak{m}^2$. This is the number called the *embedding dimension*, and corollary 29.7.1 says it bounds the dimension from above.

Definition 29.7.2: Regular Local Ring

A Noetherian local ring $(R, \mathfrak{m})$ with residue field k is *regular* if

$$\dim R = \dim_k \mathfrak{m}/\mathfrak{m}^2,$$

equivalently if $\mathfrak{m}$ can be generated by $\dim R$ elements. Such a generating set is a *regular system of parameters*: it is a system of parameters (definition 29.5.1) that generates $\mathfrak{m}$ itself rather than merely an $\mathfrak{m}$-primary ideal.

Regularity is therefore the statement that the maximal ideal is as small as the dimension permits. The next theorem replaces that numerical condition by a structural one, and the structural form is what every later argument uses: the associated graded ring, which for a general local ring records how the powers of $\mathfrak{m}$ shrink, is for a regular local ring a polynomial ring on the regular system of parameters. Following this chapter's convention it is written $\operatorname{gr}_{\mathfrak{m}} R$; it is the ring called $G_{\mathfrak{m}}(R)$ in definition 25.5.1.

Theorem 29.7.3: Characterizations of a Regular Local Ring

Let $(R, \mathfrak{m})$ be a Noetherian local ring of dimension d with residue field k. The following are equivalent.

1. R is regular.
2. $\mathfrak{m}$ is generated by d elements.
3. $\operatorname{gr}_{\mathfrak{m}} R \cong k[t_1, \ldots, t_d]$ as graded k-algebras.

***Proof*:**

(1) $\iff$ (2) The least number of generators of $\mathfrak{m}$ is $\dim_k \mathfrak{m}/\mathfrak{m}^2$, as recorded after corollary 29.7.1, and that number is at least d by the same corollary. So $\mathfrak{m}$ is generated by d elements exactly when $\dim_k \mathfrak{m}/\mathfrak{m}^2 = d$, which is definition 29.7.2.

(2) $\Rightarrow$ (3) Let $x_1, \dots, x_d$ generate $\mathfrak{m}$ and let

$$\varphi\colon k[t_1, \dots, t_d] \to \operatorname{gr}_{\mathfrak{m}} R, \qquad t_i \mapsto x_i + \mathfrak{m}^2 \in \mathfrak{m}/\mathfrak{m}^2$$

be the graded k-algebra map they determine. It is surjective, because $\mathfrak{m}^n$ is generated by the degree-n monomials in the x_i, so $\mathfrak{m}^n/\mathfrak{m}^{n+1}$ is spanned over k by their classes. If $d = 0$ then $\mathfrak{m} = \mathfrak{m}^2$, Nakayama gives $\mathfrak{m} = 0$, and both sides are k; assume $d \geq 1$.

Suppose $\ker\varphi \neq 0$. The kernel of a graded map is graded, so it contains a nonzero homogeneous F of some degree e. For $n \geq e$ multiplication by F is an injection $k[t]_{n-e} \hookrightarrow k[t]_n$, the polynomial ring being a domain, and $(\operatorname{gr}_{\mathfrak{m}} R)_n$ is a quotient of $k[t]_n/F\,k[t]_{n-e}$. Hence

$$\dim_k \mathfrak{m}^n/\mathfrak{m}^{n+1} \leq \binom{n+d-1}{d-1} - \binom{n-e+d-1}{d-1}$$

Both binomials are polynomials in n of degree $d-1$ with the same leading coefficient $1/(d-1)!$, so their difference has degree at most $d-2$.

Since $R/\mathfrak{m} = k$, the length $\ell(\mathfrak{m}^r/\mathfrak{m}^{r+1})$ is its k-dimension, and

$$\ell(R/\mathfrak{m}^n) = \sum_{r=0}^{n-1} \ell(\mathfrak{m}^r/\mathfrak{m}^{r+1})$$

Summing a function that is eventually bounded by a polynomial of degree at most $d-2$ produces one eventually bounded by a polynomial of degree at most $d-1$; the finitely many terms with $r < e$ contribute a constant and do not affect the degree. So $d(R) \leq d-1$. But $d(R) = \dim R = d$ by theorem 29.4.1, a contradiction. Therefore $\ker\varphi = 0$ and φ is an isomorphism.

(3) $\Rightarrow$ (1) Comparing degree-one pieces, $\mathfrak{m}/\mathfrak{m}^2 \cong k^d$, so $\dim_k \mathfrak{m}/\mathfrak{m}^2 = d = \dim R$.

This closes the cycle, completing the proof.

Criterion (3) is the one that travels. Everything below is extracted from it by the same mechanism: a property of the polynomial ring $\operatorname{gr}_{\mathfrak{m}} R$ is transferred back to R along the filtration by powers of $\mathfrak{m}$, and the transfer works because Krull's theorem makes the filtration separated. The first instance is that a regular local ring has no zero-divisors, which is not visible from the numerical definition at all.

Lemma 29.7.4: A Graded Domain Lifts

Let $(R, \mathfrak{m})$ be a local ring with $\bigcap_{n\geq 0} \mathfrak{m}^n = 0$. If $\operatorname{gr}_{\mathfrak{m}} R$ is an integral domain, then so is R.

***Proof*:**
Let $a, b \in R$ be nonzero. Because $\bigcap_n \mathfrak{m}^n = 0$, neither lies in every power of $\mathfrak{m}$, so there are largest integers $r, s \geq 0$ with $a \in \mathfrak{m}^r$ and $b \in \mathfrak{m}^s$ (reading $\mathfrak{m}^0 = R$); thus $a \notin \mathfrak{m}^{r+1}$ and $b \notin \mathfrak{m}^{s+1}$. Their classes $a^* = a + \mathfrak{m}^{r+1}$ and $b^* = b + \mathfrak{m}^{s+1}$ are then nonzero in the graded pieces $(\operatorname{gr}_{\mathfrak{m}} R)_r$ and $(\operatorname{gr}_{\mathfrak{m}} R)_s$.

Since $\operatorname{gr}_{\mathfrak{m}} R$ is a domain, $a^*b^* \neq 0$ in $(\operatorname{gr}_{\mathfrak{m}} R)_{r+s}$, which says exactly that $ab \notin \mathfrak{m}^{r+s+1}$. In particular $ab \neq 0$, completing the proof.

Corollary 29.7.5: A Regular Local Ring Is a Domain

Every regular local ring is an integral domain.

***Proof*:**
Let $(R, \mathfrak{m})$ be regular of dimension d. In a local ring $\mathfrak{m}$ is the Jacobson radical, so corollary 25.4.12 applies and gives $\bigcap_n \mathfrak{m}^n = 0$. By theorem 29.7.3(3) the ring $\operatorname{gr}_{\mathfrak{m}} R$ is a polynomial ring over a field, hence a domain, and lemma 29.7.4 transfers this to R, as we sought to show.

Regularity is also insensitive to completion, for the same reason: passing to $\hat{R}$ changes neither the associated graded ring nor the dimension, and criterion (3) sees nothing else. This is what makes it legitimate to test regularity after completing, where the Cohen structure theorem (theorem 25.6.1) puts formal coordinates on the ring.

Proposition 29.7.6: Regularity and Completion

Let $(R, \mathfrak{m})$ be a Noetherian local ring and $\hat{R}$ its $\mathfrak{m}$-adic completion. Then R is regular if and only if $\hat{R}$ is regular.

***Proof*:**
The ring $\hat{R}$ is Noetherian by theorem 25.5.7, and it is local with maximal ideal $\hat{\mathfrak{m}}$ and the same residue field, since $R/\mathfrak{m}^n \cong \hat{R}/\hat{\mathfrak{m}}^n$ for every n. By proposition 25.5.2(2) the two associated graded rings agree, $\operatorname{gr}_{\mathfrak{m}} R \cong \operatorname{gr}_{\hat{\mathfrak{m}}} \hat{R}$, and by corollary 25.5.9 the two dimensions agree. Criterion (3) of theorem 29.7.3 is a statement about those two data alone, so it holds for R exactly when it holds for $\hat{R}$, completing the proof.

Example 29.7.7: Regular and Singular Local Rings

1. *Formal power series.* Let $R = k[[x_1, \ldots, x_n]]$, the completion of $A = k[x_1, \ldots, x_n]_{(x_1, \ldots, x_n)}$ (example 25.1.2). Then $\mathfrak{m} = (x_1, \ldots, x_n)$ and $\mathfrak{m}/\mathfrak{m}^2$ has the n classes $\bar{x}_i$ as a basis, so the embedding dimension is n. The dimension is also n: $\dim A = n$ because $\dim k[x_1, \ldots, x_n] = n$ by theorem 29.6.2 and localizing at a maximal ideal of height n retains it, and $\dim R = \dim A$ by corollary 25.5.9. So R is regular, with $x_1, \ldots, x_n$ a regular system of parameters, and $\operatorname{gr}_{\mathfrak{m}} R \cong k[t_1, \ldots, t_n]$ recovers the fact that a power series has a well-defined lowest-degree homogeneous part.

2. *Discrete valuation rings.* A Noetherian local domain of dimension 1 is regular exactly when

$\mathfrak{m}$ is principal, which by theorem 27.2.2 is exactly when it is a discrete valuation ring. So in dimension one, regular, normal and discrete-valuation all coincide; this is the case [27] uses to identify the smooth points of a curve.

3. *The cusp.* Let $A = k[x, y]/(y^2 - x^3)$ and $R = A_{\mathfrak{m}}$ with $\mathfrak{m} = (\bar{x}, \bar{y})$. Then $\dim R = 1$, since A is a one-dimensional domain by theorem 29.6.2 ($\mathrm{Frac}(A) = k(t)$ under $\bar{x} \mapsto t^2$, $\bar{y} \mapsto t^3$) and $\mathfrak{m}$ is maximal. But the defining relation $y^2 - x^3$ lies in $(x, y)^2$, so it imposes no linear condition: writing $\mathfrak{n} = (x, y) \subseteq k[x, y]$, one has $\mathfrak{m}/\mathfrak{m}^2 \cong \mathfrak{n}/(\mathfrak{n}^2 + (y^2 - x^3)) = \mathfrak{n}/\mathfrak{n}^2$, which is two-dimensional. So the embedding dimension is $2 > 1 = \dim R$ and R is not regular. This is the algebraic signature of the cusp of the curve $y^2 = x^3$ at the origin.

4. *A regular ring of dimension zero.* If $\dim R = 0$ then regularity forces $\mathfrak{m} = \mathfrak{m}^2$, hence $\mathfrak{m} = 0$ by Nakayama, so the regular local rings of dimension zero are exactly the fields. Contrast the Artinian local ring $k[x]/(x^2)$, which has dimension 0 and embedding dimension 1, so it is not regular; by corollary 29.7.5 it could not be, having the zero-divisor $\bar{x}$.

29.8 Regular Local Rings Are Factorial

Section 29.7 characterized regularity three ways and drew one consequence from the graded criterion, that a regular local ring is a domain. The theorem of this section is deeper and is not suggested by any of the three criteria: a regular local ring has unique factorization. It is due to Auslander and Buchsbaum, and the proof is an induction on dimension that leaves the ring at every step, passing to a localization in which the dimension has dropped.

Two criteria carry the induction, and both are worth having on their own. The first converts factoriality into a statement about height-one primes, which is what makes it accessible to dimension theory at all. The second says factoriality may be checked after inverting a single prime element. Read geometrically the theorem says that on a smooth variety every codimension-one subvariety is cut out near each point by one equation, which is how [27] uses it.

Lemma 29.8.1: Factoriality by Height-One Primes

Let R be a Noetherian domain. Then R is a unique factorization domain if and only if every prime of height one is principal.

***Proof*:**
($\Rightarrow$) Let $\mathfrak{p}$ have height one and pick $a \in \mathfrak{p}$ nonzero; a is a nonunit because $\mathfrak{p}$ is proper. Factor $a = p_1 \cdots p_r$ into irreducibles. As $\mathfrak{p}$ is prime, some $p_i \in \mathfrak{p}$, and in a unique factorization domain an irreducible element is prime (proposition 10.1.29), so (p_i) is a nonzero prime with $0 \subsetneq (p_i) \subseteq \mathfrak{p}$. A strict inclusion $(p_i) \subsetneq \mathfrak{p}$ would exhibit a chain of length two descending from $\mathfrak{p}$, contradicting $\operatorname{ht}\mathfrak{p} = 1$. Hence $\mathfrak{p} = (p_i)$.

($\Leftarrow$) A Noetherian ring satisfies the ascending chain condition on ideals, in particular on principal ideals, so by theorem 10.1.30 it suffices to show every irreducible element is prime. Let a be irreducible. Then (a) is a proper nonzero ideal, so it has a minimal prime $\mathfrak{p}$. Krull's height theorem (theorem 29.5.2) with $c = 1$ gives $\operatorname{ht}\mathfrak{p} \leq 1$, and $\mathfrak{p} \neq 0$ since $0 \neq a \in \mathfrak{p}$, so $\operatorname{ht}\mathfrak{p} = 1$. By hypothesis $\mathfrak{p} = (p)$ for some p, and $a \in (p)$ gives $a = pb$. Here p is a nonunit, so irreducibility of a forces b to be a unit; therefore $(a) = (p) = \mathfrak{p}$ is prime and a is a prime element, completing the proof.

The criterion is what ties factoriality to the rest of this chapter: height is a dimension-theoretic invariant, and Krull's height theorem is exactly what produced the height-one prime in the second half. The next lemma is the descent step. Inverting one prime element destroys only the primes containing it, and those form a single height-one class that can be checked by hand.

Lemma 29.8.2: Nagata's Criterion

Let R be a Noetherian domain and $x \in R$ a prime element. If the localization $R_x = R[1/x]$ is a unique factorization domain, then so is R.

***Proof*:**
Both R and R_x are Noetherian domains, the latter by proposition 23.4.7(1),(2), so lemma 29.8.1 applies to each. Let $\mathfrak{p} \subseteq R$ be a prime of height one; it suffices to show $\mathfrak{p}$ is principal.

Case $x \in \mathfrak{p}$. Then $0 \subsetneq (x) \subseteq \mathfrak{p}$ with (x) prime, and $\operatorname{ht}\mathfrak{p} = 1$ forces $\mathfrak{p} = (x)$.

Case $x \notin \mathfrak{p}$. The primes of R_x are the extensions of the primes of R not meeting $\{x^n \mid n \geq 0\}$, and the correspondence preserves inclusions (proposition 23.4.5), so $\mathfrak{p}R_x$ is a prime of height one. As R_x is a unique factorization domain, lemma 29.8.1 makes $\mathfrak{p}R_x$ principal. Multiplying a generator by a power of the unit x we may take the generator to be some $a \in R$, and then $a \in \mathfrak{p}R_x \cap R = \mathfrak{p}$, the contraction of the extension of $\mathfrak{p}$ being $\mathfrak{p}$ again since $\mathfrak{p}$ misses the powers of x.

We may further assume $x \nmid a$. If $a = xa'$ then $a' \in \mathfrak{p}$, because $a \in \mathfrak{p}$, $x \notin \mathfrak{p}$ and $\mathfrak{p}$ is prime; and a' still generates $\mathfrak{p}R_x$, since x is a unit there. This replacement cannot repeat indefinitely: it would place a in $\bigcap_n (x^n)$, which is 0 by corollary 25.4.11, while $a \neq 0$.

Now $\mathfrak{p} = (a)$. One inclusion is $a \in \mathfrak{p}$. For the other, let $b \in \mathfrak{p}$. Then $b \in \mathfrak{p}R_x = aR_x$, so $x^n b = ac$ for some $c \in R$ and $n \geq 0$. If $n \geq 1$ then x divides ac; as x is prime and $x \nmid a$, it divides c, and cancelling x from both sides (legitimate in a domain) lowers n by one. Iterating gives $b \in (a)$. So every height-one prime of R is principal, and lemma 29.8.1 makes R a unique factorization domain, completing the proof.

What remains is to produce a generator for a height-one prime after inverting x, and this is where the induction's homological input enters. The prime will be visibly principal at every localization, and the problem is to pass from that local information to a single global generator. The next two lemmas do so; the first is elementary, and the second is the one place this section imports a fact it does not prove.

Lemma 29.8.3: A Finite Free Resolution Makes a Projective Module Stably Free

Let S be a ring and P a finitely generated projective S-module admitting a resolution $0 \to F_n \to \cdots \to F_0 \to P \to 0$ by finitely generated free modules. Then P is *stably free*: $P \oplus S^a \cong S^b$ for some $a, b \geq 0$.

***Proof*:**
Induct on n. If $n = 0$ then $P \cong F_0$ is free. For $n \geq 1$ put $K = \ker(F_0 \to P)$. Since P is projective the sequence $0 \to K \to F_0 \to P \to 0$ splits, so $F_0 \cong P \oplus K$; in particular K is a direct summand of a finitely generated free module, hence finitely generated projective, and $0 \to F_n \to \cdots \to F_1 \to K \to 0$ is a free resolution of length $n-1$. By induction $K \oplus S^a \cong S^b$ for some a, b. Then

$$P \oplus S^b \cong P \oplus K \oplus S^a \cong F_0 \oplus S^a$$

which is free, as we sought to show.

Lemma 29.8.4: A Locally Principal Ideal of Finite Global Dimension Is Principal

Let S be a Noetherian domain of finite global dimension and $I \subseteq S$ a nonzero ideal such that $I_\mathfrak{q}$ is a principal ideal of $S_\mathfrak{q}$ for every prime $\mathfrak{q}$ of S. Then I is principal.

***Proof*:**
Step 1: I is invertible, hence projective. Work inside $K = \mathrm{Frac}(S)$ and put $I^{-1} = \{z \in K \mid zI \subseteq S\}$, an S-submodule of K containing S. The product II^{-1} is an ideal of S; it equals S, because for each prime $\mathfrak{q}$ the localization $I_\mathfrak{q}$ is generated by one element $t_\mathfrak{q} \neq 0$, so $t_\mathfrak{q}^{-1} \in (I^{-1})_\mathfrak{q}$ and $(II^{-1})_\mathfrak{q} \ni t_\mathfrak{q} t_\mathfrak{q}^{-1} = 1$, and an ideal that is the unit ideal at every prime is the unit ideal (proposition 23.4.13 applied to S/II^{-1}). Choose $a_1, \ldots, a_r \in I$ and $b_1, \ldots, b_r \in I^{-1}$ with $\sum_i a_i b_i = 1$. Then $x \mapsto (b_1 x, \ldots, b_r x)$ is an S-module map $I \to S^r$, and composing with $(s_1, \ldots, s_r) \mapsto \sum_i s_i a_i$ returns x. So I is a direct summand of S^r, hence finitely generated projective, and $I_\mathfrak{q} \cong S_\mathfrak{q}$ at every prime.

Step 2: I is stably free. Finite global dimension gives I a finite resolution by finitely generated free modules, so lemma 29.8.3 applies: $I \oplus S^a \cong S^b$ for some a, b. Localizing at any prime and comparing ranks gives $1 + a = b$, so the relation reads $I \oplus S^a \cong S^{a+1}$.

Step 3: rank one and stably free give free. This is corollary 16.4.6, applied to I: it is finitely generated projective with $I_\mathfrak{q} \cong S_\mathfrak{q}$ at every prime, and Step 2 supplies the required relation. So $I \cong S$ as an S-module, and the image of 1 under such an isomorphism generates I, completing the proof.

Theorem 29.8.5: Regular Local Rings Are Factorial

Every regular local ring is a unique factorization domain.

***Proof*:**
Let $(R, \mathfrak{m})$ be regular of dimension d; induct on d.

Base cases. If $d = 0$ then R is a field (example 29.7.7), which has no nonzero nonunits and is trivially factorial. If $d = 1$ then R is a Noetherian local domain whose maximal ideal is principal, hence a discrete valuation ring (theorem 27.2.2); its only height-one prime is $\mathfrak{m}$, which is principal, so lemma 29.8.1 applies.

Producing a prime element. Let $d \geq 2$. By corollary 29.7.5 R is a domain. Choose $x \in \mathfrak{m} \setminus \mathfrak{m}^2$. Its class is nonzero in $\mathfrak{m}/\mathfrak{m}^2$, so it extends to a basis, and lifting gives a minimal generating set $x, x_2, \ldots, x_d$ of $\mathfrak{m}$. Then $\mathfrak{m}/(x)$ is generated by the $d-1$ classes of $x_2, \ldots, x_d$, while

$\dim R/(x) = d-1$ because x is a nonzero nonunit in a domain (the consequence of theorem 29.5.2 recorded after it). So $R/(x)$ is regular by theorem 29.7.3(2), hence a domain by corollary 29.7.5, and therefore x is a prime element of R.

Reduction to a localization. By lemma 29.8.2 it is enough that $S = R_x$ is a unique factorization domain, and by lemma 29.8.1 it is enough that every height-one prime of S is principal. Note S is a Noetherian domain by proposition 23.4.7.

Global dimension is finite along the way. The Auslander-Buchsbaum-Serre theorem (theorem 57.2.8) makes $\operatorname{gldim} R$ finite, R being regular. Global dimension does not rise under localization: an S'-module over a localization S' of R is the localization of itself viewed as an R-module, and localizing an R-projective resolution gives an S'-projective resolution of the same length, localization being exact (proposition 23.4.9) and carrying projectives to projectives. Hence $\operatorname{gldim} S \leq \operatorname{gldim} R < \infty$, and likewise for every $R_{\mathfrak{p}}$.

The localizations are smaller regular rings. Let $\mathfrak{q}$ be a prime of S and $\mathfrak{p}$ the corresponding prime of R, so $S_{\mathfrak{q}} \cong R_{\mathfrak{p}}$ and $x \notin \mathfrak{p}$. Then $\mathfrak{p} \subsetneq \mathfrak{m}$, so $\dim R_{\mathfrak{p}} = \operatorname{ht} \mathfrak{p} < d$. Since $\operatorname{gldim} R_{\mathfrak{p}}$ is finite, the Auslander-Buchsbaum-Serre theorem in the other direction makes $R_{\mathfrak{p}}$ regular, and the induction hypothesis makes it a unique factorization domain.

Conclusion. Let $\mathfrak{P}$ be a height-one prime of S. For a prime $\mathfrak{q}$ of S, either $\mathfrak{P} \not\subseteq \mathfrak{q}$, in which case $\mathfrak{P}S_{\mathfrak{q}} = S_{\mathfrak{q}}$ is principal, or $\mathfrak{P} \subseteq \mathfrak{q}$, in which case $\mathfrak{P}S_{\mathfrak{q}}$ is a height-one prime of the unique factorization domain $S_{\mathfrak{q}}$ and is principal by lemma 29.8.1. So $\mathfrak{P}$ is a nonzero locally principal ideal of a Noetherian domain of finite global dimension, and lemma 29.8.4 makes it principal. Therefore S is a unique factorization domain, and lemma 29.8.2 carries this back to R, completing the proof.

Factoriality is the strongest of the standard finiteness conditions a local ring can carry, and the two weaker ones follow from it at once. The first is integral closure.

Corollary 29.8.6: A Unique Factorization Domain Is Integrally Closed

Every unique factorization domain is integrally closed in its fraction field.

***Proof*:**
Let R be a unique factorization domain with fraction field K and let $z \in K$ be integral over R. Write $z = a/b$ with $a, b \in R$, $b \neq 0$, sharing no irreducible factor, which unique factorization permits. From $z^n + c_{n-1}z^{n-1} + \cdots + c_0 = 0$ with $c_i \in R$, multiplying by b^n gives

$$a^n = -b\left(c_{n-1}a^{n-1} + c_{n-2}a^{n-2}b + \cdots + c_0 b^{n-1}\right)$$

So every irreducible factor p of b divides a^n, and p is prime (proposition 10.1.29), so p divides a, contrary to the choice of a and b. Hence b has no irreducible factor at all, so it is a unit and $z = ab^{-1} \in R$, as we sought to show.

Corollary 29.8.7: A Regular Local Ring Is Normal

Every regular local ring is a normal domain, and in particular is regular in codimension one.

***Proof*:**
Combine theorem 29.8.5 with corollary 29.8.6; the ring is a domain by corollary 29.7.5. For the last clause, a localization of a normal domain is normal by proposition 23.4.7(3), completing the proof.

Example 29.8.8: Normal but Not Factorial
Neither implication in

$$\text{regular} \Rightarrow \text{factorial} \Rightarrow \text{normal}$$

reverses. Let k have characteristic $\neq 2$ and let $B = k[u^2, uv, v^2] \subseteq k[u, v]$, the subring of polynomials of even total degree. Sending $x \mapsto u^2$, $y \mapsto v^2$, $z \mapsto uv$ identifies B with $k[x, y, z]/(xy - z^2)$, so B is the coordinate ring of the quadric cone.

B is normal. Let σ be the involution $u \mapsto -u$, $v \mapsto -v$ of $k[u, v]$. Its fixed ring is the even part, which is B, and its fixed field inside $k(u, v)$ is $\mathrm{Frac}(B) = k(u^2, u/v)$. Let $w \in \mathrm{Frac}(B)$ be integral over B. Then w is integral over $k[u, v]$, which is a unique factorization domain (corollary 11.2.4) and hence integrally closed by corollary 29.8.6; so $w \in k[u, v]$. Being in $\mathrm{Frac}(B)$, w is fixed by σ, so $w \in k[u, v]^\sigma = B$.

B is not factorial. In B the identity $u^2 \cdot v^2 = (uv)^2$ gives two factorizations of one element into irreducibles: each of u^2, v^2, uv has degree two, which is the least positive degree occurring in B, so none of them factors further in B, and no two of them are associates ($B^\times = k^\times$).

B is not regular. Localize at $\mathfrak{m} = (u^2, uv, v^2)$. The fraction field $k(u^2, u/v)$ has transcendence degree two over k, so $\dim B_\mathfrak{m} = 2$ by theorem 29.6.2, while $\mathfrak{m}/\mathfrak{m}^2$ has the three classes of u^2, uv, v^2 as a basis, $\mathfrak{m}^2$ being spanned by the monomials of degree four. So the embedding dimension is $3 > 2$.

The three computations are consistent with the displayed implications and show both are strict: $B_\mathfrak{m}$ is normal and not factorial, and by theorem 29.8.5 a non-factorial ring cannot be regular, which the third computation confirms directly.

29.9 Normal Domains in Codimension One

A normal domain is determined by its behaviour in codimension one. That is the content of this section, and it is what makes normality a condition one can check by looking only at the height-one primes: the ring is the intersection of the discrete valuation rings sitting at them. The result is used by the homological characterizations of normality in *Homological Algebra* [15] and by the divisor theory of [27] and [5].

Everything rests on one fact about principal ideals, which is where normality enters.

Lemma 29.9.1: Associated Primes of a Principal Ideal Have Height One

Let R be a Noetherian normal domain and $b \in R$ a nonzero nonunit. Then every associated prime of (b) has height one.

***Proof*:**
Let $\mathfrak{p} \in \operatorname{Ass}(R/(b))$. Associated primes localize (corollary 24.6.2), so $\mathfrak{p}R_\mathfrak{p} \in \operatorname{Ass}\big(R_\mathfrak{p}/bR_\mathfrak{p}\big)$, and $R_\mathfrak{p}$ is again a Noetherian normal domain by proposition 23.4.7. Since $\operatorname{ht}\mathfrak{p} = \operatorname{kdim} R_\mathfrak{p}$, it suffices to treat the case where $(R, \mathfrak{m})$ is local with $\mathfrak{m} \in \operatorname{Ass}(R/(b))$ and to show $\operatorname{kdim} R = 1$.

By definition 24.3.1 there is $a \in R$ with $\mathfrak{m} = \operatorname{Ann}(\overline{a}) = (b : a)$, where $\overline{a}$ is the class of a in $R/(b)$; in particular $a \notin (b)$, since otherwise the annihilator would be all of R. Put $x = a/b \in \operatorname{Frac}(R)$, so $x \notin R$. For every $r \in \mathfrak{m}$ one has $ra \in (b)$, hence $rx = ra/b \in R$: that is, $x\mathfrak{m} \subseteq R$, and $x\mathfrak{m}$ is an R-submodule of R, so an ideal.

Case 1: $x\mathfrak{m} \subseteq \mathfrak{m}$. Then $x^n\mathfrak{m} \subseteq \mathfrak{m}$ for every n, so $R[x]\mathfrak{m} \subseteq \mathfrak{m} \subseteq R$. Choose $0 \neq c \in \mathfrak{m}$, which exists as $b \in \mathfrak{m}$ is nonzero. Then $cR[x] \subseteq R$, so $R[x] \subseteq c^{-1}R$, a cyclic R-module; as R is Noetherian, the submodule $R[x]$ is a finitely generated R-module, and proposition 26.1.4(2) makes x integral over R. Normality gives $x \in R$, contradicting $x \notin R$.

Case 2: $x\mathfrak{m} \not\subseteq \mathfrak{m}$. Then the ideal $x\mathfrak{m}$ is not contained in the unique maximal ideal, so $x\mathfrak{m} = R$. Pick $t \in \mathfrak{m}$ with $xt = 1$. For any $p \in \mathfrak{m}$ we have $xp \in R$ and $p = t\,(xp)$, so $\mathfrak{m} = tR$ is principal, and it is nonzero. A Noetherian local domain whose maximal ideal is principal and nonzero is a discrete valuation ring by theorem 27.2.2, hence of dimension one.

Case 1 is impossible, so Case 2 holds and $\operatorname{kdim} R = 1$, as we sought to show.

Theorem 29.9.2: A Normal Domain Is the Intersection of Its Height-One Localizations

Let R be a Noetherian normal domain with fraction field K. Then $R_\mathfrak{p}$ is a discrete valuation ring for every prime $\mathfrak{p}$ of height one, and

$$R = \bigcap_{\operatorname{ht}\mathfrak{p}=1} R_\mathfrak{p}$$

the intersection taken inside K.

***Proof*:**
For $\operatorname{ht}\mathfrak{p} = 1$ the ring $R_\mathfrak{p}$ is a Noetherian local domain of dimension one, normal by proposition 23.4.7, hence a discrete valuation ring by theorem 27.2.2.

The inclusion $R \subseteq \bigcap R_\mathfrak{p}$ is immediate. For the reverse, let x lie in every $R_\mathfrak{p}$ and write $x = a/b$ with $a, b \in R$ and $b \neq 0$. If b is a unit then $x \in R$, so assume otherwise and suppose $a \notin (b)$, aiming at a contradiction.

The class $\overline{a} \in R/(b)$ is then nonzero, and $I = \operatorname{Ann}(\overline{a}) = (b : a)$ is a proper ideal every element of which kills $\overline{a}$, hence is a zero-divisor on $R/(b)$. By corollary 24.5.2 the zero-divisors on $R/(b)$ are the union of the associated primes of (b), of which there are finitely many (corollary 24.4.3), so prime avoidance (proposition 24.5.1) places $I \subseteq \mathfrak{q}$ for a single $\mathfrak{q} \in \operatorname{Ass}(R/(b))$. By lemma 29.9.1, $\operatorname{ht}\mathfrak{q} = 1$.

Now $x \in R_\mathfrak{q}$ by hypothesis, so $a/b = c/s$ for some $c \in R$ and $s \notin \mathfrak{q}$, whence $sa \in bR$ and $s \in (b : a) = I \subseteq \mathfrak{q}$. That contradicts $s \notin \mathfrak{q}$. Therefore $a \in (b)$ and $x \in R$, completing the proof.

The theorem is the reason divisor theory works on a normal variety: a rational function regular at every codimension-one point is regular, so a function is controlled by its orders of vanishing along the height-one primes alone. That reading, and the class group it supports, is [27].

30

Flatness and Faithfully-Flat Descent

Flatness is the algebraic form of continuous variation. A flat module is one against which tensoring preserves injections, so that submodule relations survive base change; for a ring map $R \to S$ it says the fibers of $\operatorname{Spec} S \to \operatorname{Spec} R$ vary without jumping. When in addition the base change loses no information (when it is *faithfully flat*), one can argue in reverse: a property that holds after tensoring up already held below. This is *descent*, and it is the reason the local models of a space determine the space. The chapter records the ring-theoretic core that the geometry books cash out as faithfully-flat and fppf descent, closing with the local criterion that detects flatness one fiber at a time, the tool deformation theory runs on.

Basic flatness is assumed from [25]; the homological criterion and its local refinement are proved in [15] and cited here.

30.1 Flat Modules

Recall from [25] that an R-module M is *flat* if $- \otimes_R M$ is exact, equivalently if it preserves injections; a ring map $R \to S$ is flat if S is flat as an R-module. Flatness is preserved under base change and composition, and is detected locally: M is flat over R iff $M_{\mathfrak{p}}$ is flat over $R_{\mathfrak{p}}$ for every prime $\mathfrak{p}$ (proposition 23.4.16). Localizations are flat, and for a Noetherian local ring the completion is flat (corollary 25.4.6). The homological measure of the failure of flatness is Tor: M is flat iff $\operatorname{Tor}_1^R(M, N) = 0$ for all N, and it suffices to test $N = R/\mathfrak{a}$ on finitely generated ideals; this is proved in [15] and used freely below.

30.2 Faithfully Flat Modules and Algebras

Definition 30.2.1: Faithfully Flat

An R-module M is *faithfully flat* if it is flat and, for every R-module N, the vanishing $N \otimes_R M = 0$ forces $N = 0$. A ring map $R \to S$ is faithfully flat if S is faithfully flat as an R-module.

Proposition 30.2.2: Characterizations of Faithful Flatness

For a flat R-module M the following are equivalent:

1. M is faithfully flat;
2. a sequence of R-modules is exact iff it stays exact after $- \otimes_R M$;
3. $\mathfrak{m}M \neq M$ for every maximal ideal $\mathfrak{m}$, i.e. $M \otimes_R \kappa(\mathfrak{m}) \neq 0$ for all $\mathfrak{m}$.

For a flat ring map $R \to S$ these are equivalent to $\operatorname{Spec} S \to \operatorname{Spec} R$ being surjective.

***Proof*:**
(1) $\Rightarrow$ (2): flatness already preserves exactness; conversely if $C_\bullet \otimes M$ is exact then $H(C_\bullet) \otimes M = H(C_\bullet \otimes M) = 0$ (a flat functor commutes with homology), so $H(C_\bullet) = 0$ by (1). (2) $\Rightarrow$ (3): the sequence $0 \to R/\mathfrak{m} \to 0$ is not exact, so by (2) it remains non-exact after $- \otimes M$, forcing $M/\mathfrak{m}M = (R/\mathfrak{m}) \otimes M \neq 0$. (3) $\Rightarrow$ (1): let $N \neq 0$ and $0 \neq x \in N$, so $Rx \cong R/\mathfrak{a}$ with $\mathfrak{a} = \operatorname{Ann}(x) \subseteq \mathfrak{m}$ for some maximal $\mathfrak{m}$. Tensoring with the flat M: the inclusion $Rx \hookrightarrow N$ gives an injection $Rx \otimes M \hookrightarrow N \otimes M$, while the surjection $R/\mathfrak{a} \to R/\mathfrak{m}$ gives a surjection $Rx \otimes M = M/\mathfrak{a}M \twoheadrightarrow M/\mathfrak{m}M \neq 0$; hence $Rx \otimes M \neq 0$, so $N \otimes M \neq 0$. For a flat ring map these are further equivalent to surjectivity of $\operatorname{Spec} S \to \operatorname{Spec} R$: (1) gives $S \otimes_R \kappa(\mathfrak{p}) \neq 0$ for every prime $\mathfrak{p}$, so every fibre is nonempty and the map is surjective; conversely a surjective map hits every maximal ideal, which is (3).

Corollary 30.2.3: Faithfully Flat Maps are Injective

A faithfully flat ring map $R \to S$ is injective, and $\mathfrak{a} = \mathfrak{a}S \cap R$ for every ideal $\mathfrak{a}$ of R.

***Proof*:**
Apply faithful flatness to the kernel K of $R \to S$: tensoring $0 \to K \to R \to S$ with the flat S gives $K \otimes_R S = \ker(S \to S \otimes_R S)$, the map being $s \mapsto 1 \otimes s$, which is split by the multiplication $S \otimes_R S \to S$; so $K \otimes S = 0$, whence $K = 0$. For the second claim, the map $R/\mathfrak{a} \to (R/\mathfrak{a}) \otimes_R S = S/\mathfrak{a}S$ has kernel $(\mathfrak{a}S \cap R)/\mathfrak{a}$; since $S/\mathfrak{a}S$ is faithfully flat over $R/\mathfrak{a}$ (base change of a faithfully flat map), it is injective by the first part, so $\mathfrak{a}S \cap R = \mathfrak{a}$.

Localization $R \to R_f$ is flat but rarely faithfully flat (its image in $\operatorname{Spec} R$ omits $V(f)$); by contrast a nonzero free module is faithfully flat, a finite free ring extension is faithfully flat, and for a Noetherian local ring the completion $R \to \hat{R}$ is faithfully flat.

30.3 Faithfully-Flat Descent

Faithful flatness lets a property established upstairs be brought back down.

Proposition 30.3.1: Descent of Module Properties

Let $R \to S$ be faithfully flat and M an R-module. Then M is finitely generated (respectively finitely presented, flat, or finitely generated projective) over R iff $M \otimes_R S$ has the corresponding property over S.

***Proof*:**
Necessity is base change. For sufficiency: if $M \otimes S$ is generated by finitely many elements, clear denominators so they are images of $m_i \otimes 1$; the cokernel C of $R^n \xrightarrow{(m_i)} M$ satisfies $C \otimes S = 0$, so $C = 0$ and M is finitely generated. Given that, finite presentation descends by applying the same to the kernel of $R^n \to M$ (finitely generated as $\ker \otimes S = \ker(S^n \to M \otimes S)$ is). Flatness descends because $\mathrm{Tor}_1^R(M, N) \otimes S = \mathrm{Tor}_1^S(M \otimes S, N \otimes S) = 0$ for all N, whence $\mathrm{Tor}_1^R(M, N) = 0$ by faithful flatness. Finitely generated projective descends since it equals finitely presented plus flat.

The deeper statement recovers a module, not merely a property, from data upstairs. Write $S^{\otimes 2} = S \otimes_R S$ and $S^{\otimes 3} = S \otimes_R S \otimes_R S$, with the two coprojections $p_1, p_2 \colon S \to S^{\otimes 2}$.

Theorem 30.3.2: Faithfully-Flat Descent for Modules

Let $R \to S$ be faithfully flat. Then $M \mapsto M \otimes_R S$ is an equivalence from R-modules to the category of *descent data*: pairs (N, φ) with N an S-module and $\varphi \colon p_1^* N \xrightarrow{\sim} p_2^* N$ an isomorphism over $S^{\otimes 2}$ satisfying the cocycle condition over $S^{\otimes 3}$. The inverse sends (N, φ) to the equalizer of φ-twisted coprojections $N \rightrightarrows N \otimes_S S^{\otimes 2}$.

***Proof*:**
The heart is the exactness, for every R-module M, of the *Amitsur complex*

$$0 \to M \to M \otimes_R S \to M \otimes_R S^{\otimes 2},$$

the second map being $m \otimes s \mapsto m \otimes (p_1 - p_2)(s)$. It suffices to check this after the faithfully flat base change $S \otimes_R -$, where the augmented complex acquires the contracting homotopy $s_0 \otimes s_1 \otimes \cdots \mapsto (s_0 s_1) \otimes s_2 \otimes \cdots$ (multiplication of the first two tensor factors), which shows exactness. Faithful flatness then gives exactness over R. Applying this with the canonical datum shows $M \otimes S$ recovers M as the stated equalizer, so the functor is fully faithful; the cocycle condition is exactly what makes the equalizer of a general (N, φ) an R-module whose base change is (N, φ), giving essential surjectivity.

This is the affine case of the descent that lets sheaves and torsors be glued along faithfully flat (fppf) covers, developed in [23].

30.4 The Local Criterion for Flatness

For finitely generated modules over a Noetherian local ring, flatness collapses to a single Tor, and this is what makes flatness checkable in families.

Theorem 30.4.1: Local Criterion for Flatness

Let $(R, \mathfrak{m})$ be a Noetherian local ring with residue field κ and M a finitely generated R-module. Then

$$M \text{ flat} \iff M \text{ free} \iff \mathrm{Tor}_1^R(\kappa, M) = 0$$

More generally, for a local homomorphism $(R, \mathfrak{m}) \to (S, \mathfrak{n})$ of Noetherian local rings and a finitely generated S-module M, one has M flat over R iff $\mathrm{Tor}_1^R(\kappa, M) = 0$; over an Artinian local base this is the criterion by which flatness of a deformation is tested one infinitesimal step at a time.

The equivalences and the general criterion are proved homologically in [15, Local Criterion for Flatness], which owns this theorem (DECISIONS 2026-08-17); here the point is that they reduce flatness (a condition on all modules) to the vanishing of one Tor against the residue field, and it is in this form that [23] invokes flatness over Artinian bases.

30.5 Fitting Ideals

The Fitting ideals of a finitely presented module refine the notion of rank: they cut out the loci where the number of generators jumps, commute with base change, and are the standard tool behind flattening stratifications.

Definition 30.5.1: Fitting Ideals

Let M be a finitely presented R-module with presentation $R^m \xrightarrow{A} R^n \to M \to 0$, so A is an $n \times m$ matrix. For $i \geq 0$ the *i-th Fitting ideal* $\mathrm{Fitt}_i(M)$ is generated by the $(n-i) \times (n-i)$ minors of A, with the conventions $\mathrm{Fitt}_i(M) = R$ when $n - i \leq 0$ and $\mathrm{Fitt}_i(M) = 0$ when $n - i > m$.

Proposition 30.5.2: Properties of Fitting Ideals

The Fitting ideals are independent of the chosen presentation, and:

1. $\mathrm{Fitt}_0(M) \subseteq \mathrm{Fitt}_1(M) \subseteq \cdots$, with $\mathrm{Fitt}_i(M) = R$ for $i \geq n$;
2. base change: $\mathrm{Fitt}_i(M \otimes_R R') = \mathrm{Fitt}_i(M)R'$ for any $R \to R'$;
3. $\mathrm{Fitt}_0(M) \subseteq \mathrm{Ann}(M)$ and $\mathrm{Ann}(M)^n \subseteq \mathrm{Fitt}_0(M)$;
4. for a prime $\mathfrak{p}$, the minimal number of generators of $M_{\mathfrak{p}}$ is $> d$ iff $\mathrm{Fitt}_d(M) \subseteq \mathfrak{p}$.

***Proof*:**
Any two finite presentations of M are related by adding free summands and invertible row/column operations, under which the ideal of $(n-i)$-minors is unchanged (a standard determinantal computation), giving well-definedness; base change is immediate since the minors of A map to those of $A \otimes R'$. The chain and the values for $i \geq n$ are clear. For (3), Cramer's rule applied to A gives $\mathrm{Fitt}_0(M)\, M = 0$, and expanding determinants shows $\mathrm{Ann}(M)^n \subseteq \mathrm{Fitt}_0(M)$. For (4), by Nakayama the minimal number of generators of $M_{\mathfrak{p}}$ equals $\dim_{\kappa(\mathfrak{p})} M \otimes \kappa(\mathfrak{p}) = n - \mathrm{rank}(A \bmod \mathfrak{p})$, and $\mathrm{Fitt}_d(M) \not\subseteq \mathfrak{p}$ says exactly that some $(n-d)$-minor is a unit mod $\mathfrak{p}$, i.e. $\mathrm{rank}(A \bmod \mathfrak{p}) \geq n - d$.

Thus the rank-jump locus $V(\mathrm{Fitt}_d(M)) = \{\mathfrak{p} \mid M_{\mathfrak{p}} \text{ needs} > d \text{ generators}\}$ is closed and base-change compatible, giving the flattening stratification used to build Quot and Hilbert schemes ([23]); $V(\mathrm{Fitt}_0(M))$ cuts out the support of M (with its Fitting scheme structure; the scheme-theoretic support proper is $V(\mathrm{Ann}\, M)$, with the same underlying closed set). Over a domain, a finitely presented M is locally free of rank r iff $\mathrm{Fitt}_{r-1}(M) = 0$ and $\mathrm{Fitt}_r(M) = R$, i.e. iff $\mathrm{Fitt}_r(M) = R$ and A has constant rank $n - r$.

30.6 Generic Flatness

Away from a proper closed subset of the base, a coherent family becomes flat. This Grothendieck finiteness underlies dimension counts in families and the construction of moduli.

Theorem 30.6.1: Generic Flatness

Let R be a Noetherian integral domain, S a finitely generated R-algebra, and M a finitely generated S-module. Then there is a nonzero $f \in R$ such that M_f is a free R_f-module (in particular flat over R_f).

***Proof*:**
We sketch the standard argument (Eisenbud, *Commutative Algebra*, Theorem 14.4; equivalently the Stacks Project generic-flatness lemma). By dévissage a finite filtration of M with quotients $S/\mathfrak{p}_i$ ($\mathfrak{p}_i \subseteq S$ prime) reduces the claim to $M = S/\mathfrak{p}$, since a module filtered by pieces that are free after localizing is itself free after localizing. If $\mathfrak{q} := \ker(R \to S/\mathfrak{p})$ is nonzero, then $\mathfrak{q}$ annihilates M, so $M_f = 0$ is free for any $0 \neq f \in \mathfrak{q}$. Otherwise $R \hookrightarrow S/\mathfrak{p}$ is a domain of finite type over R; by Noether normalization $(S/\mathfrak{p}) \otimes_R K$ is a *finite* module (not in general free) over a polynomial ring $K[t_1, \ldots, t_d]$, where $K = \mathrm{Frac}(R)$, and spreading out gives $0 \neq f_0$ with S_{f_0} finite over $R_{f_0}[t_1, \ldots, t_d]$. A Noetherian induction on the relative dimension d then trivializes, after inverting finitely many further elements of R, the torsion pieces of this finite module, producing a single f with M_f free over R_f.

Part VI

Affine Varieties

A shape cut out by polynomial equations is determined by the polynomial functions on it. This Part makes that statement into a dictionary: to each algebraic set in affine space is attached a ring, its coordinate ring, and the geometry of the set is recoverable from the algebra of the ring. Points become maximal ideals, irreducible subsets become primes, and the maps between varieties become homomorphisms between the rings. The dictionary is global: every entry in it is an invariant of the whole variety, and Part VII takes up the invariants attached to a single point.

The ground field is algebraically closed throughout, from chapter 32 onward; the Nullstellensatz, which is what makes the dictionary exact rather than approximate, is false without it. The commutative algebra the Part rests on is cited to *Commutative Algebra* [10] rather than rebuilt.

31

Algebraic Sets and the Zariski Topology

The dictionary this book is about begins with a single construction: to a set of polynomials, associate the points at which they all vanish. This chapter sets up that construction and its converse, which sends a set of points to the polynomials vanishing on it, and finds that the two are almost inverse to each other. The gap between "almost" and "exactly" is what chapter 32 closes.

Along the way the vanishing sets turn out to be the closed sets of a topology, the Zariski topology, which is coarse enough to be unlike any topology from analysis and fine enough to carry the whole theory. The chapter ends with the maps that respect it.

31.1 Affine Space and Regular Functions

In this whole chapter, R is a commutative ring and k be a field.

So far when polynomials were encountered, they were treated as a commutative ring with an indeterminate extension (or equivalently, they can be thought of as a ring over a free monoid). There is a natural way of thinking about any such polynomial as a function (which is probably how most first encounter polynomials): if $f \in k[x_1, x_2, ..., x_n]$, then if $(a_1, a_2, ..., a_n) \in k^n$, let $f(a_1, a_2, ..., a_n) \in k$ be the element which you get when replacing each x_i with a_i. Then we can make f into a function through the following map[1,2]:

$$k[x_1, ..., x_n] \to \mathrm{Hom}_{\mathbf{Set}}(k^n, k) \qquad f \mapsto ((a_1, ...a_n) \mapsto f(a_1, ..., a_n)) \tag{31.1}$$

where we shall consider the constants $c \in k[x_1, ..., x_n]$ to map to the functions that shall return the value of $c \in k$:

$$c \mapsto ((a_1, ..., a_n) \mapsto c)$$

Note that the codomain of the function in (31.1) is be the hom-set over the category **Set**, and not any other category we've extensively worked over so far (**Grp**, **Ring**, **Alg**, etc.); this was done since there are many non-linear functions representing non-linear polynomials (a simple example would be $x^2 \in k[x]$). On the other hand, the image of the above function is not just a collection of all set functions as they must all satisfy polynomials relations (can you find a set-function that is not given/representable by a polynomial?[3] The subset given by the function in (31.1) shall be called the set of *regular functions*: $\mathrm{Hom}_{\mathbf{Reg}}(k^n, k)$. Before properly boxing this definition, we shall take some more time pondering what the domain of the hom-set should be, namely we shall want the domain to represent Cartesian space without the extra algebraic structure that is usually implied by the notation k^n. For example, k^n usually denotes the n-dimensional vector-space over k with an origin, and more generally we think of k^n as having addition and scalar multiplication satisfying the axioms of a vector-space. Vector-spaces are "defined" for linear polynomials, with subspaces that are naturally "linear" (recall that subspaces are given by solutions of linear polynomials, see theorem 13.2.26)[4]. We shall want a new type of space for which subspaces are solutions to general polynomial equations.

Definition 31.1.1: Affine Space

Let $(k, +, \cdot)$ be any field. Then the collection of the n-tuples of k^n as a set shall be called *affine space*. Its elements shall be called *points* and the space shall be denoted $\mathbb{A}^n_k$.

Hence, a field can be thought of as $(\mathbb{A}^1_k, +, \cdot)$. The space $\mathbb{A}^n_k$ is called *affine* space rather than just "space" as there shall be an equally important (or arguably more important) space called *projective space* that shall be introduced in chapter 38[5]. The term affine can also be thought of as emphasizing the lack of importance of the origin (recall that a linear transformation that doesn't need to map the origin to itself was called affine).

With affine space established, let us now define the image of the function in (31.1):

---

[1] For those familiar with algebraic geometry, this map can be thought of as selecting the global sections of $\mathbb{A}^n_k$. By the Nullstellensatz, $k^n = \mathrm{Spec}\,(k[x_1, .., x_n])$, and by the representability of affine schemes $\Gamma(\mathrm{Spec}\,(R)) \cong \mathrm{Hom}_{\mathrm{Reg}}(\mathrm{Spec}\,(R), A^1_k)$

[2] advanced comment: if k is not algebraically closed, we are missing points, and hence this technically is *not* a representable functor and is not the sheaf obtains from embedding Var_k into $\mathbf{Sch}_k$

[3] Over finite fields, and only over finite fields, every set function is given by a polynomial: interpolate, using that $a^{|k|} = a$ for every $a \in k$.

[4] In [26], we shall show that the vector-space structure can be recovered using Hopf Algebras, but this adds more structure to the algebraic set

[5] More generally, we shall see that affine space will be the representation space for schemes which generalizes affine space, something which chapter 49 points the reader toward

Definition 31.1.2: Regular Function [on Affine Space]

Let F represent the function in (31.1):

$$F : k[x_1, ..., x_n] \to \mathrm{Hom}_{\mathbf{Set}}(k^n, k) \qquad f \mapsto ((a_1, ...a_n) \mapsto f(a_1, ..., a_n))$$

Then the collection $\mathrm{im}(F)$ is called the *regular functions*, and is usually denoted $\Gamma(\mathbb{A}^n_k)$, $k[\mathbb{A}^n_k]$, or $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{A}^n_k, \mathbb{A}^1_k)$.

Each of these notations for the collection of regular functions have its use. The $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{A}^n_k, \mathbb{A}^1_k)$ notion makes it clear what the domain and codomain is, which shall be particularly important once we take different codomain. The $k[\mathbb{A}^n_k]$ notation is particularly useful when we shall take subsets $V \subseteq \mathbb{A}^n_k$ and denote all regular functions on V as $k[V]$; in this case this notation emphasizes that we are working over the particular field k. This shall be useful for there are circumstances where we change which field we are working over[6]. The $\Gamma(\mathbb{A}^n_k)$ notation comes from modern algebraic geometry where gamma is used hint that these are the *global section* over $\mathbb{A}^n_k$ (see [5] for a full explanation). As this chapter is gearing up the reader for modern algebraic geometry, we shall preferentially use the $\Gamma(\mathbb{A}^n_k)$ notation to acclimate the reader. It should be pointed out that another common notation is $\mathcal{O}_{\mathbb{A}^n_k}(\mathbb{A}^n_k)$ which is more useful when it is important to keep track of regular functions on open subsets of $\mathbb{A}^n_k$ (once we define a topology on $\mathbb{A}^n_k$) in which case we shall have the collection of regular function on $U \subseteq \mathbb{A}^n_k$ be written as $\mathcal{O}_{\mathbb{A}^n_k}(U)$. This is not useful to us in this chapter, and so shall not be used.

The set $\Gamma(\mathbb{A}^n_k)$ forms a natural k-algebra structure given by point-wise operations:

$$f + g \equiv f(a) + g(a) \qquad fg \equiv f(a)g(a) \qquad c \cdot f = cf(a) \qquad \forall a \in k \tag{31.2}$$

With this k-algebra structure, it can be shown that $k[x_1, ..., x_n] \cong_k \mathrm{Hom}_{\mathbf{Reg}}(\mathbb{A}^n_k, \mathbb{A}^1_k)$, and so the two sets are often used interchangeably. If the distinction needs to be made clear between the element x_i and the function x_i, we shall write

$$k[X_1, ..., X_n] = \mathrm{Hom}_{\mathbf{Reg}}(\mathbb{A}^n_k, \mathbb{A}^1_k) = k[\mathbb{A}^k_n]$$

where each X_i is a regular function that is the projection onto the ith coordinate, and call an element of $k[X_1, ..., X_n]$ a *polynomial function* or *polynomial map*. This distinction shall become more important once there can be multiple polynomials that will be associated to the same regular function, which shall be the case in section 32.1. When it is clear from context, we may denote a polynomial or a regular function by $f(x)$ and $f(X)$ respectively where x is understood to be the indeterminate variables and X is understood to be the regular functions $X_1, ..., X_n$.

Due to this isomorphism, we can define a function from $k[x_1, ..., x_n]$ to k directly by directly substituting the values for the indeterminates with a point in the affine space. Namely, for each $a \in \mathbb{A}^n_k$, we take:

$$\mathrm{ev}^k_a : k[x_1, ..., x_n] \to k \qquad f(x) \mapsto f(a)$$

where x and a is understood to be n-tuples of indeterminates and values respectively. These are all k-algebra homomorphisms, for

$$\mathrm{ev}^k_a(f(x) + cg(x)) = \mathrm{ev}^k_a(f(x)) + c \cdot \mathrm{ev}^k_a(g(x)) \qquad \mathrm{ev}^k_a(f(x)g(x)) = \mathrm{ev}^k_a(f(x)\mathrm{ev}^k_a(g(x))$$

[6] A good example of the use of group cohomology is measure how much an isomorphism $k[V] \cong k[W]$ is preserved/fails when consider $\overline{k}[V]$ and $\overline{k}[W]$

The subscript of the evaluation function represents the point of evaluation, while the superscript represents the values we choose to plug for every indeterminate, where the values are usually the same as the base field, however they may differ, for example it is common to take $\mathbb{Z}$ or $\mathbb{Q}$[7]. Thus, a regular function can be thought of as the collection of evaluation functions on a polynomial.

31.1.3 Foreshadowing If you know elementary analysis or calculus, then you are probably aware that the types of functions we most commonly use are *continuous*. Continuous functions are a very important tool in analysing the properties of the space we're studying (ex. $\mathbb{R}$, $\mathbb{R}^n$, $L^2(\mathbb{R})$, etc.), continuous functions can be thought of as the natural types of functions that preserve some local properties of the space. In Algebra, we can think of polynomial functions as the natural types of functions. This comparison between continuous functions mapping to $\mathbb{R}$ and polynomial functions mapping to k will in fact be incredibly precise, as we will see in the last section of this chapter.

31.2 Algebraic Sets and Vanishing Ideals

31.2.1 Quick Side-Note A common misconception, born from a strong reliance on graphs in most first-year undergraduate calculus/analysis classes, is to intuitively associate the zero-set of a function with the *graph* of a function.
For example, $f(x) = x$ has a zero-set containing only the point 0, while the function $F(x, y) = x - y$ has a zero-set that forms the graph $\Gamma(f)$. This distinction may seem trivial, but it is surprisingly easy to conflate the two concepts when moving into higher dimensions.

Graphs can be thought of as the collection of the solutions of $f(x_1, \ldots, x_n) = y_0$ as the constant term y_0 varies.

From such polynomials functions, we can create many interesting shapes depending on the zeros', or locus, of polynomial:

[7]These shall be called $\mathbb{Z}$-valued and $\mathbb{Q}$-valued points of the polynomial, or more precisely the variety (as we shall soon see)

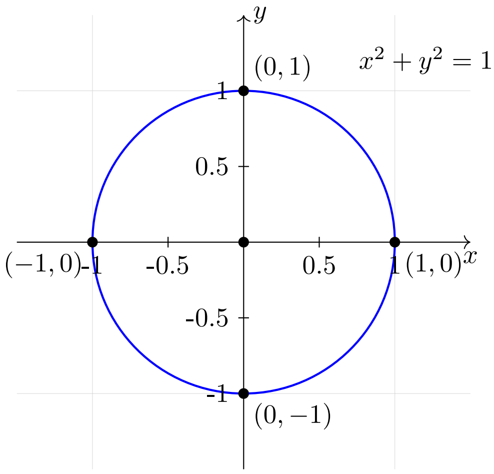

Figure 31.1: Circle represented by the equation $x^2+y^2-1=0$

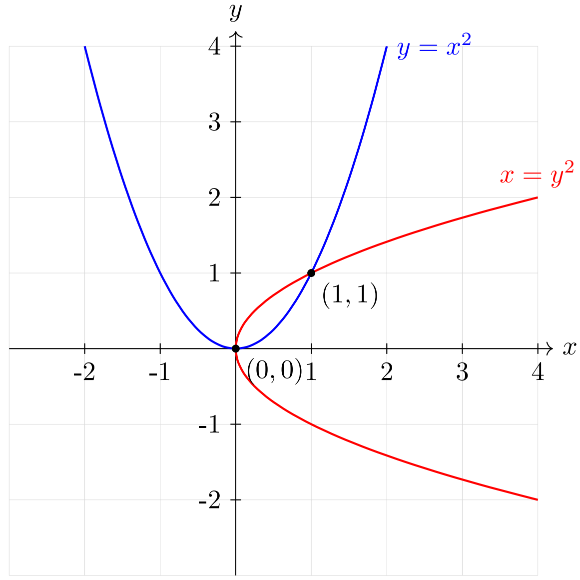
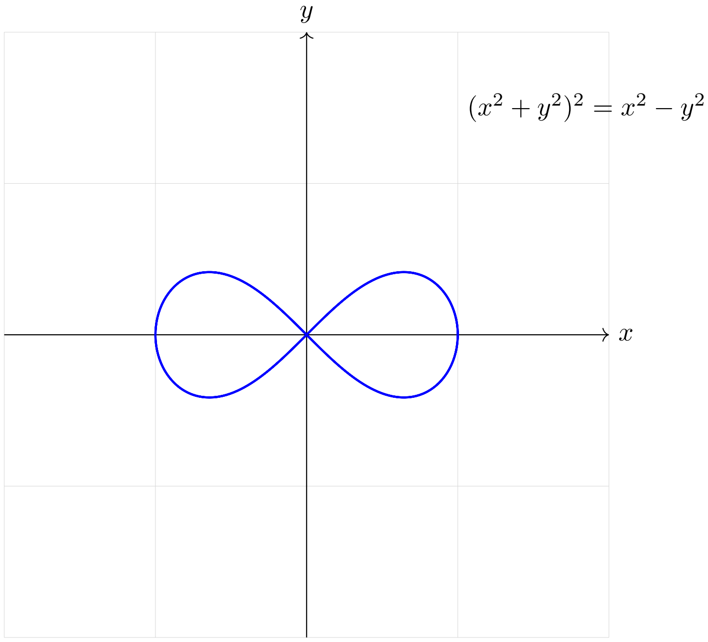
Example 31.2.2: Zeros' of Polynomials

1. The polynomial $x^2+y^2-1 \in \mathbb{R}[x,y]$ gives the circle of fig. 31.1. More precisely, the polynomial shall be associated to an element of $\Gamma(\mathbb{A}_k^n)$, where plugin in any point on from $\mathbb{A}_{\mathbb{R}}^2$ that is on the circle (ex. $(1,0)$ or $(\sqrt{2}/2, \sqrt{2}/2)$ shall give 0.

2. Take $y-x^2 \in \mathbb{R}[x,y]$. Then this shall give the usual parabola $y=x^2$. If we take $x-y^2 \in \mathbb{R}[x,y]$, we shall get a parabola rotated 90 degree's (or $\pi/2$ radians) clockwise. If we take the polynomial $(y-x^2)(x-y^2) \in \mathbb{R}[x,y]$, then the zero set of this new polynomial shall be the zero-set of the two multiplied polynomials:



3. Take $(x^2+y^2)^2-(x^2-y^2) \in \mathbb{R}[x,y]$. This shape is called the *Bernoulli Lemniscate*:

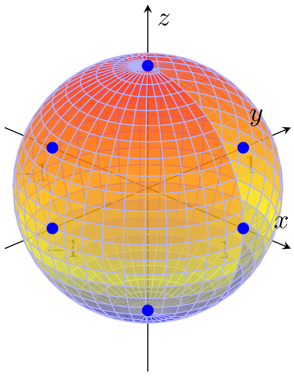


Notice that the shape crosses over itself. This shows that zero-sets of polynomials differ from graphs, and also differ from the usual smooth manifolds from differential geometry.

4. Take $p(x) \in k[x]$ over any field k. Then the shape associated to $p(x)$ are the *roots* of the polynomials. For example, taking $x^2-2 \in \mathbb{Q}(\sqrt{2})[x]$ shall give $\{\sqrt{2}, -\sqrt{2}\} \subseteq \mathbb{A}^1_{\mathbb{Q}(\sqrt{2})}$ as these are the solution to $x^2-2=0$. More generally, the shape given by a polynomial in one variable is always the collection of roots that is present in the underlying field. This means that $x^2-2 \in \mathbb{Q}[x]$ would give the empty set, as there are no rational roots. By the fundamental theorem of algebra, any polynomial $p(x) \in \mathbb{C}[x]$ of degree d shall have d roots, and hence the shape associated to $p(x)$ shall have d points.

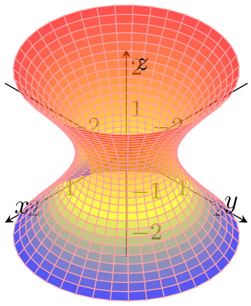
5. Take $x^2+y^2+z^2-1 \in \mathbb{R}[x,y,z]$. Then this is the classical unit sphere centered at the origin:

$$x^2 + y^2 + z^2 = 1$$

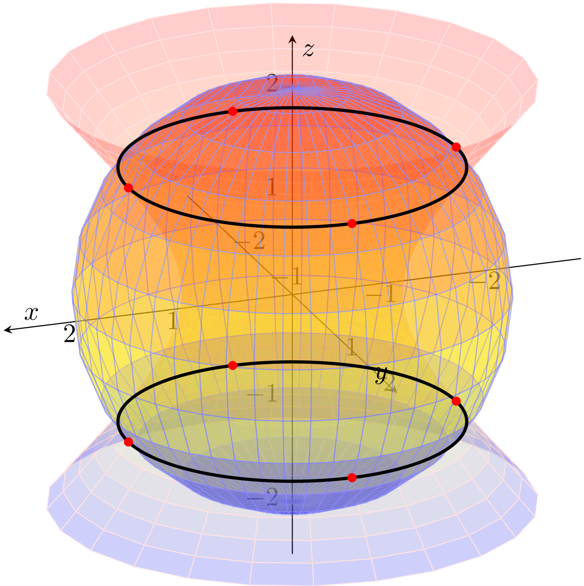


What polynomial would you choose to center the unit sphere at different points of $\mathbb{A}^3_{\mathbb{R}}$? How would you change the radius of the sphere?

6. Let us now consider taking two shapes: the sphere given by $x^2 + y^2 + z^2 - 4$ and the hyperboloid given by $x^2 + y^2 - z^2 - 1$. The hyperboloid looks like so:

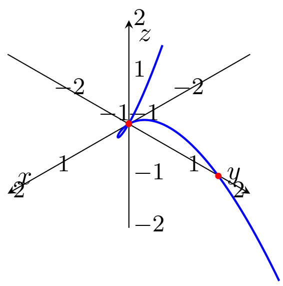


Then the intersection of these two shapes shall produce two circles, visualized like so:



This produce *two disconnected components* (in the usual euclidean topology). We shall show later that no single polynomial can create these two circles, hence we shall often have the case where we get interesting shapes by interesting or taking the union of two zero-sets.

7. The following is an infamous example of a shape that looks like it could be the zero-set of a single polynomial, but can't be: consider the following shape given by $t \mapsto (t, t^2, t^3)$:



It can be proven that this shape is *not* the zero-set of a single polynomial $p(x, y, z) \in k[x, y, z]$. On the other hand, this shape, is the intersection of two zero-sets of the surfaces $y = x^2$ and $z = xy$. This shape is called the *twisted cubic.*

More generally, given any polynomial in $k[x_1, x_2, ..., x_n]$, we can associate with it a geometric shape based on its zero set!

Definition 31.2.3: [Affine] Algebraic Set

Let $\mathbb{A}^n$ be an affine n-space over a field k, and let $S \subseteq \Gamma(\mathbb{A}^n)$. Then:

$$\mathcal{Z}(S) \subseteq \mathbb{A}^n \quad \mathcal{Z}(S) := \{(a_1, a_2, ..., a_n) \mid f(a_1, a_2, ..., a_n) = 0, \text{ for all } f \in S\}$$

If for $V \subseteq \mathbb{A}^n$, there exists an $S \subseteq \Gamma(\mathbb{A}^n)$ such that $V = \mathcal{Z}(S)$, then V is called an *affine algebraic set*, *locus*, or *zero set*. If it is unambiguous, the set may be called an *algebraic set*[a].

[a] In some textbooks, this set is called a *variety*. The term variety shall be reserved for definition 32.3.1

From now on, when taking a subset of $\mathbb{A}^n$, $A \subseteq \mathbb{A}^n$, it will be assumed that A is an algebraic set unless specified otherwise (i.e. it would be stated “for some subset $A \subseteq \mathbb{A}^n$)

Example 31.2.4: Affine Algebraic Sets

All the above are algebraic sets. Let's go over a few more examples:

1. If $n = 1$, then the zeros of a polynomial are always points, that is, the roots of the polynomial. When k is infinite the only polynomial with infinitely many zeros is 0 (more precisely, the regular function associated to 0), which has all of k as its vanishing locus. Infiniteness is the right hypothesis rather than characteristic 0: item (5) below exhibits the failure over $\mathbb{F}_2$, while $\overline{\mathbb{F}_p}$ has characteristic p and the claim still holds there. Furthermore, the polynomial 1 vanishes nowhere, and hence the corresponding algebraic set is $\emptyset$. Therefore, in $\mathbb{A}^1$, the affine sets are

$$\emptyset \qquad \text{finite sets} \qquad k$$

   This also shows that not all sets are algebraic sets (for example, if $k = \mathbb{R}$, then $[0, 1]$ is not an algebraic set in $\mathbb{A}^1_{\mathbb{R}}$)

2. If $n = 2$, Then take $f \in \Gamma(\mathbb{A}^2)$ such that $f(x, y) = x^2 + y^2 - 1$. Then

$$\mathcal{Z}(f) = \left\{(x, y) \in \mathbb{A}^2 \;\middle|\; x^2 + y^2 = 1\right\}$$

   If $k = \mathbb{R}$, then $\mathcal{Z}(f)$ is infinite, so it is not a product of two algebraic subsets of $\mathbb{A}^1$: those are finite or all of $\mathbb{A}^1$, and neither product is a circle.

   Furthermore, this examples shows that there are lot's more zero sets in $\mathbb{A}^2$ than there are in $\mathbb{A}^1 \times \mathbb{A}^1$. This is in stark contrast to how every element in the vector space $\mathbb{R}^2$ can be written as an element in $\mathbb{R}$ and an element in $\mathbb{R}$, i.e. $\mathbb{R}^2 \cong \mathbb{R} \times \mathbb{R}$ as vector spaces.

3. For any $\mathbb{A}^n$, can you always find a set of functions $F \subseteq \Gamma(\mathbb{A}^n)$ such that $|V(F)| = 1$ (i.e. is every singleton an algebraic set for every $\mathbb{A}^n$ over any field?) This shall be answered in section 32.4.

4. What is the vanishing set of linear polynomials?

5. In the first example, we produced the entire space using the zero polynomial. Is it necessary that we use the zero-polynomial to make the zero set the entire space? The answer is no: simply take $k = \mathbb{Z}/2\mathbb{Z}$ and $p(x) = x^2 + x$. However, this is a problem exclusive to finite fields. Can you prove that if k is an infinite field, $p \in k[x_1, x_2, ..., x_n]$ and $p(a_1, a_2, ..., a_n) = 0$ for all $a_i \in k$ then $p \equiv 0$? Freely use that a nonzero one-variable polynomial has finitely many roots, and induct on the number of variables.

6. Let k be a finite field and take any subset $S \subseteq \mathbb{A}_k^n$. Show that S is always an algebraic set. Hence, being algebraic gives no additional information in the finite case.

7. Let $f \in k[x_1, x_2, ..., x_n]$. Then $\mathcal{Z}(f)$ is called a *hyper-surface*. For example $S^1 = \mathcal{Z}(x^2 + y^2 - r^2)$ represents a circle of radius r. Another example would be $\mathcal{Z}(xy - 1)$ which represents the hyperbola $y = 1/x$. More generally, any conic section is a hyper-surface. In higher dimensions, $\mathcal{Z}(x^2 + y^2/4 + z^2/9 - 1)$ represents an ellipsoid in $\mathbb{R}^3$. The twisted cubic is *not* a hyper-surface.

8. For any polynomial function $f : k \to k$, we can define $F : k^2 \to k$ where $F(x, y) = f(x) - y$. Then $\mathcal{Z}(F)$ consists of all points where $f(x) - y = 0$, i.e. $f(x) = y$, which is the pair of points $\{(a, b) \mid f(a) = b\}$, i.e. the graph of f! More generally, if $f : k^n \to k$ is a polynomial, the polynomial $F : k^{2n} \to k$ gives rise to the polynomial $F : (x, y) = f(x) - y$ whose zero set is the graph of f (recall the convention that x, y represent multiple variables when it is clear from context).

Proposition 31.2.5: Properties of Affine Algebraic Sets

Let $S, T \subseteq \Gamma(\mathbb{A}^n)$. Then

1. If $S \subseteq T$ then $\mathcal{Z}(T) \subseteq \mathcal{Z}(S)$ (i.e. $\mathcal{Z}$ is *contravariant* in respect to inclusion)

2. If $(S) = I \subseteq \Gamma(\mathbb{A}^n)$ is the ideal of S, then $\mathcal{Z}(I) = \mathcal{Z}(S)$.

3. For any arbitrary collection of algebraic sets $\{S_i\}_{i\in I}$,
$$\bigcap_{i\in I} \mathcal{Z}(S_i) = \mathcal{Z}\left(\bigcup_{i\in I} S_i\right)$$
that is, the arbitrary intersection of algebraic sets is an algebraic sets, and is equal to the algebraic set of the intersections of the $\{S_i\}_{i\in I}$

4. For any finite collection of algebraic sets $\{S_i\}_{i=1}^n$,
$$\bigcup_{i=1}^{n} \mathcal{Z}(S_i) = \mathcal{Z}\left(\prod_{i=1}^{n} S_i\right)$$
that is, the finite union of algebraic sets is an algebraic set, and is equal to the product of the S_i as ideals (from part 2, we can assume $(S_i) = S_i$ without loss of generality).

5. If $0, 1 \in \Gamma(\mathbb{A}^n)$ denote the zero and constant function, then
$$\mathcal{Z}(0) = \mathbb{A}^n \qquad \mathbb{Z}(1) = \emptyset$$

6. If I is an ideal of $\Gamma(\mathbb{A}^n)$, then
$$\mathcal{Z}(I) = \mathcal{Z}(I^m)\ \forall m \in \mathbb{N}_{>0}$$
that is, $\mathcal{Z}$ is invariant to taking higher powers of the ideals

These are all straight-forwards proofs, and so should all be done before reading these proofs for the best learning experience.

***Proof*:**

1. Let $S \subseteq T$, and consider $x \in \mathcal{Z}(T)$. Then $f(x) = 0$ for every $f \in T$. Since $S \subseteq T$, in particular $g(x) = 0$ for every $g \in S$. Thus $x \in \mathcal{Z}(S)$, establishing $\mathcal{Z}(T) \subseteq \mathcal{Z}(S)$.

2. Let $S \subseteq \Gamma(\mathbb{A}^n)$ be any set and let $I = (S)$. We want to show that $\mathcal{Z}(I) = \mathcal{Z}(S)$. Since $S \subseteq I$, the $\mathcal{Z}(I) \subseteq \mathcal{Z}(S)$ conclusion comes from the first part. For the reverse, consider $x\mathcal{Z}(S)$. Then for all $t \in S$, $t(x) = 0$. If we pick any two $f, g \in S$, then $(f+g)(x) = f(x) + g(x) = 0$. If we pick any $c(x) \in \Gamma(\mathbb{A}^n)$ and any $f \in S$, then $(cf)(x) = c(x)f(x) = c(x)0 = 0$. Thus, if we enlarge S to be closed under addition and multiplication by elements of $k^[\mathbb{A}^n]$, those polynomial will also be zero on x, and so $\mathcal{Z}(S) \subseteq \mathcal{Z}(I)$, establishing $\mathcal{Z}(S) = \mathcal{Z}(I)$

3. We want to show that $\bigcap_{i \in I} \mathcal{Z}(S_i) = \mathcal{Z}\left(\bigcup_{i \in I} S_i\right)$ for an arbitrary indexing set I. This is just some set theory: by definition:

$$x \in \mathcal{Z}(\cup_{i \in I} S_i) = \{y \in \mathbb{A}^n \mid f(y) = 0,\ \forall f \in \cup_{i \in I} S_i\} = \mathcal{Z}\left(\sum_\alpha I_\alpha\right)$$

   which is true if and only if x is the solution for polynomials in every set S_i. The collection of such elements is:

$$\bigcap_{i \in I} \mathcal{Z}(S_i)$$

4. We want to show that $\bigcup_{i=1}^n \mathcal{Z}(S_i) = \mathcal{Z}\left(\prod_{i=1}^n S_i\right)$. By definition:

$$x \in \mathcal{Z}\left(\prod_{i=1}^n S_i\right) = \left\{ y \in \mathbb{A}^n \;\middle|\; f(y) = 0\ \forall f \in \prod_{i=1}^n S_i \right\}$$

   where by definition $f(x) = \sum_{j=1}^m (f_{1_j} f_{2_j} \cdots f_{n_j})(x) = \sum_{j=1}^m f_{1_j}(x) f_{2_j}(x) \cdots f_{n_j}(x) = 0$. Notice that for a particular term in the sum to be zero, we only need on of the f_{i_j} to be zero. Therefore, the sum is zero if and only if one polynomial in every term of the sum is zero. Since this also applies to sums with only one term in it, then if x is the solution to one polynomial in S_i, then it will be part of the zero's of $\prod_{i=1}^n S_i$. But this is just another way of saying:

$$x \in \bigcup_{i=1}^n \mathcal{Z}(S_i)$$

5. Notice that $0(x) = 0$ for all $x \in \mathbb{A}^n$ and $1(x) = 1 \neq 0$ for all $x \in \mathbb{A}^n$, and so

$$\mathcal{Z}(0) = \mathbb{A}^n \qquad \mathcal{Z}(1) = \emptyset$$

6. Since $I^m \subseteq I$, the first part gives $\mathcal{Z}(I) \subseteq \mathcal{Z}(I^m)$. For the reverse inclusion, let $x \in \mathcal{Z}(I^m)$ and let $f \in I$ be arbitrary. Then f^m is a product of m elements of I, so $f^m \in I^m$, and therefore

$$f(x)^m = f^m(x) = 0$$

   As k is a field it has no nonzero nilpotents, so $f(x) = 0$. Since $f \in I$ was arbitrary, $x \in \mathcal{Z}(I)$, giving $\mathcal{Z}(I^m) \subseteq \mathcal{Z}(I)$ and hence $\mathcal{Z}(I) = \mathcal{Z}(I^m)$, as we sought to show.

A couple of remarks are in order. From (2), we can without loss of generality restrict $\mathcal{Z}$ be a function from the ideals of $k[x_1, ..., x_n]$ to the algebraic sets in $\mathbb{A}^n$:

$$\mathcal{Z} : \{\text{ideals in } k[x_1, ..., x_n]\} \to \{\text{affine algebraic sets in } \mathbb{A}^n\}$$

Furthermore, $\mathcal{Z}$ is a surjection from the ideals of $k[x_1, x_2, ..., x_n]$ and the algebraic sets (the ideals I^m for each $m \geq 1$ map to the same algebraic set). Next, the finiteness condition on the product of ideals is a necessary condition for closure of algebraic sets:

Example 31.2.6: Not Closed Under Arbitrary Unions

Take $\mathbb{A}^1_{\mathbb{R}}$ and the sets $V(x-a)$ for $a \in \mathbb{Z}$. Then prove that the union of these sets is *not* an algebraic set (you may freely use the fact that polynomials have at most finite roots, and recall that $\mathbb{R}[x]$ is Noetherian).

Next, we took the product of ideal $\prod_i^n I_i$ instead of the intersection. Since it always the case that $IJ \subseteq I \cap J$ then in the cases where $IJ \subsetneq I \cap J$, $\mathcal{Z}(I \cap J) \subsetneq \mathcal{Z}(I) \cup \mathcal{Z}(J)$[8]. However, since $\mathcal{Z}(I^2) = \mathcal{Z}(I)$, the distinction is invisible to $\mathcal{Z}$, and $\mathcal{Z}(IJ) = \mathcal{Z}(I \cap J)$ always

Perhaps most importantly for this chapter, notice that these properties are the properties of a topology (see appendix C):

Definition 31.2.7: Zariski Topology

Let $\mathbb{A}^n$ be an n-affine space over k. Then the set

$$\mathcal{T}_{\mathcal{Z}} = \{\mathcal{Z}(I) \mid \text{I is an ideal of } \Gamma(\mathbb{A}^n)\}$$

from the set of closed sets in the *Zariski topology* $(\mathbb{A}^n, \mathcal{T}_{\mathcal{Z}})$

We can therefore try and study this topological space! This is essentially the foundation for studying geometrical concepts in algebra, and vice-versa, it is the foundation for studying algebraic concepts in geometry, and so we will spend a lot of time establishing the link between the ideals of $\Gamma(\mathbb{A}^n)$ and the Zariski topology.

Before such topological considerations, we shall first see if we can find some function that is the inverse of $\mathcal{Z}$, that is we start from an algebraic set in $\mathbb{A}^n$ (or more generally any subset of $\mathbb{A}^n$) and associate it to an ideal in $\Gamma(\mathbb{A}^n)$, letting us strive towards some way of corresponding the two in a manner similar to Galois Theory[9]. Towards the goal of finding an inverse for $\mathcal{Z}$, notice that we already have that $\mathcal{Z}$ is a surjection of ideals of $\Gamma(\mathbb{A}^n)$ to the algebraic sets. Thus, it is meaningful to ask about having a function from the set of algebraic sets to the set of ideals of $k[x_1, x_2, ..., x_n]$. To understand this question, we start off with a slightly more general question (just like we started with subsets of $k[x_1, ..., x_n]$ instead of ideals):

[8]The condition $IJ = I \cap J$ is more delicate than it looks: it holds exactly when $\mathrm{Tor}_1^R(R/I, R/J) = 0$, for which see [15].

[9]In fact,the order reversing nature of this correspondence will end up making this correspondence a *Galois correspondence*, which name is inspired by how the Galois correspondence between intermediate fields and subgroups was one of the first well-known order-reversing correspondences

Definition 31.2.8: Vanishing Ideal

Let $V \subseteq \mathbb{A}^n$ be a subset of the affine n-space. Then

$$\mathcal{I}(V) := \{f \in \Gamma(\mathbb{A}^n) \mid f(v) = 0, \ \forall v \in V\}$$

is the *vanishing ideal* of V.

Notice that $\mathcal{I}(V)$ was not defined as an ideal, however it is indeed an ideal; it is important for the sake of intuition that the reader should prove this at least once. Even better, $\mathcal{I}(V)$ is the *largest* ideal of $\Gamma(\mathbb{A}^n)$ that corresponds to the set V. Just like $\mathcal{Z}$, $\mathcal{I}$ can be interpreted as a function

$$\mathcal{I} : \{V \subseteq \mathbb{A}^n_k\} \to \{\text{ideals of } \Gamma(\mathbb{A}^n)\}$$

Example 31.2.9: Vanishing Ideal

1. Let $\mathbb{A}^2$ be an affine space over the field $\mathbb{R}$ and let $X \subseteq \mathbb{A}^2$ be the x-axis. Then $\mathcal{I}(X) = (y) \subseteq \mathbb{R}[x, y]$
2. Let k be infinite. Then $\mathcal{I}(\mathbb{A}^n) = 0$.
3. Find the vanishing ideals if of subsets $\mathbb{A}^n_k$ if k is finite.

Just like $\mathcal{Z}$, $\mathcal{I}$ shares similar properties:

Proposition 31.2.10: Properties of Vanishing Ideals

let $A, B \subseteq \mathbb{A}^n$ be two algebraic sets. Then

1. If $A \subseteq B$, then $\mathcal{I}(B) \subseteq \mathcal{I}(A)$ (i.e. $\mathcal{I}$ is *contravariant* with respect to inclusion)
2. $\mathcal{I}(A \cup B) = \mathcal{I}(A) \cap \mathcal{I}(B)$
3. $\mathcal{I}(\emptyset) = \Gamma(\mathbb{A}^n)$. If k is infinite, $\mathcal{I}(\mathbb{A}^n) = 0$

***Proof*:**

1. Let $A \subseteq B$ and take $f \in \mathcal{I}(B)$, so $f(b) = 0$ for every $b \in B$. Every $a \in A$ lies in B, so $f(a) = 0$, giving $f \in \mathcal{I}(A)$.
2. A polynomial vanishes on $A \cup B$ exactly when it vanishes on A and vanishes on B, which is the assertion $\mathcal{I}(A \cup B) = \mathcal{I}(A) \cap \mathcal{I}(B)$.
3. The condition defining $\mathcal{I}(\emptyset)$ is vacuous, so every polynomial belongs to it and $\mathcal{I}(\emptyset) = \Gamma(\mathbb{A}^n)$. For the second claim, suppose k is infinite and f vanishes at every point of $\mathbb{A}^n$. Induct on n. For $n = 1$ a nonzero polynomial has at most $\deg f$ roots, while k is infinite, so $f = 0$. For $n > 1$ write $f = \sum_i g_i(x_1, \ldots, x_{n-1})x_n^i$. Fixing any $a \in k^{n-1}$ makes $f(a, x_n)$ a one-variable polynomial vanishing on all of k, so each $g_i(a) = 0$ by the base case. As a was arbitrary, each g_i vanishes on $\mathbb{A}^{n-1}$, and by induction $g_i = 0$. Hence $f = 0$, so $\mathcal{I}(\mathbb{A}^n) = 0$, as we sought to show.

The hypothesis that k be infinite in (3) is not removable: over $\mathbb{F}_q$ the polynomial $x^q - x$ vanishes at every point of $\mathbb{A}^1$, so $\mathcal{I}(\mathbb{A}^1_{\mathbb{F}_q}) \neq 0$.

Notice that we have omitted showing what $\mathcal{I}(A \cap B)$ is. One problem is that $\mathcal{I}(A) \cup \mathcal{I}(B)$ is not necessarily an ideal (since the union of two ideals is not necessarily an ideal). It might be tempting to say that since

$$\langle \mathcal{I}(A) \cup \mathcal{I}(B) \rangle = \mathcal{I}(A) + \mathcal{I}(B)$$

we can conclude that:

$$\mathcal{I}(A \cap B) = \mathcal{I}(A) + \mathcal{I}(B)$$

However, this is not generally the case (consider the algebraic sets given by the ideals $(x^2 - y)$ and (x)). Proving the reverse inclusion needs the Nullstellensatz, but it can already be shown from the definitions that $\mathcal{I}(A \cap B) \supseteq \mathcal{I}(A) + \mathcal{I}(B)$, since a function vanishing on A or on B vanishes on $A \cap B$. With the properties of $\mathcal{I}$ established, we can start getting an idea of what ideals of $\Gamma(\mathbb{A}^n)$ are necessary to restrict $\mathcal{Z}$ to make it a bijection:

Proposition 31.2.11: Zero Sets and Coordinate Ideals

Let $\Gamma(\mathbb{A}^n)$ be the set of polynomial functions from $\mathbb{A}^n$ to k. Then

1. If $V \subseteq \mathbb{A}^n$, then $V \subseteq \mathcal{Z}(\mathcal{I}(V))$. If $I \subseteq \Gamma(\mathbb{A}^n)$ is an ideal of $\Gamma(\mathbb{A}^n)$, then $I \subseteq \mathcal{I}(\mathcal{Z}(I))$.
2. If $V = \mathcal{Z}(I)$ is an algebraic set, then $V = \mathcal{Z}(\mathcal{I}(V))$. Similarly, if $I = \mathcal{I}(V)$ is a vanishing ideal, then $I = \mathcal{I}(\mathcal{Z}(I))$. In other words, for every subset $V \subseteq \mathbb{A}^n$ and every ideal $I \subseteq \Gamma(\mathbb{A}^n)$,
$$\mathcal{I}(\mathcal{Z}(\mathcal{I}(V))) = \mathcal{I}(V) \qquad \mathcal{Z}(\mathcal{I}(\mathcal{Z}(I))) = \mathcal{Z}(I)$$

***Proof*:**

1. For $V \subseteq \mathcal{Z}(\mathcal{I}(V))$, since $\mathcal{I}(V)$ is the set of all functions such that $f(V) \equiv 0$ (including at least the zero polynomial), then V is certainly part of its zero set.

   Conversely, for $I \subseteq \mathcal{I}(\mathcal{Z}(I))$, the coordinate ideal of $\mathcal{Z}(I)$ certainly contains I since for any $f \in I$ and $x \in \mathcal{Z}(I)$, $f(x) = 0$. Thus, $I \subseteq \mathcal{I}(\mathcal{Z}(I))$
2. Let $V = \mathcal{Z}(I)$. By part 1 it suffices to prove $V \supseteq \mathcal{Z}(\mathcal{I}(V))$. Take $x \in \mathcal{Z}(\mathcal{I}(V))$, so that $f(x) = 0$ for every $f \in \mathcal{I}(V)$. Every $f \in I$ vanishes on $\mathcal{Z}(I) = V$ and so lies in $\mathcal{I}(V)$, giving $I \subseteq \mathcal{I}(V)$; hence $f(x) = 0$ for every $f \in I$, which says exactly that $x \in \mathcal{Z}(I) = V$. Therefore $V = \mathcal{Z}(\mathcal{I}(V))$.

   The second claim is the same argument with the roles exchanged. If $I = \mathcal{I}(V)$ then part 1 gives $I \subseteq \mathcal{I}(\mathcal{Z}(I))$; conversely if $g \in \mathcal{I}(\mathcal{Z}(I))$ then g vanishes on $\mathcal{Z}(\mathcal{I}(V))$, which we have just shown equals V, so $g \in \mathcal{I}(V) = I$. Applying $\mathcal{I}$ and $\mathcal{Z}$ to these two identities gives the displayed equations, completing the proof.

What the 2nd part of proposition 31.2.11 shows is that if we restrict to just the algebraic sets and vanishing ideals of $\mathbb{A}^n$ and $\Gamma(\mathbb{A}^n)$ respectively, then $\mathcal{Z}$ and $\mathcal{I}$ are indeed inverses of each other. The goal then would be to be able to characterize vanishing ideals, that is ideals that are of the form $I = \mathcal{I}(V)$ for some algebraic set V. It is in fact a rather involved process to find the nature of the ideal $\mathcal{I}(V)$; a lot of section 32.2 will be building up to get to the theorem which will tell us the answer: *Hilbert's Nullstellensatz*. In the process of building up the theory to answer this question, there are a few other loose ends that we will need to tie up. For example, what properties must the Zariski topology have, and what does that imply for the corresponding ring $\Gamma(\mathbb{A}^n)$? Another important point to address is that as $k[x_1, ..., x_n]$ is Noetherian, hence every ideal is finitely generated: $I = (f_1, ..., f_m) = (f_1) \cup (f_2) \cup \cdots \cup (f_m)$. By the properties of zero sets:

$$\mathcal{Z}(I) = \mathcal{Z}(f_1) \cap \mathcal{Z}(f_2) \cap \cdots \cap (f_m)$$

In other words, there seem to be a natural theory of decomposition of algebraic sets. Furthermore, we have been shown theoretically what properties algebraic sets have, but how is one computed in practice? These questions will receive answers in the following section.

Exercise 31.2.1

1. Show that $z \mapsto \overline{z}$ is not a complex polynomial.
2. Show that $V = \left\{(z, w) \in \mathbb{A}^2_{\mathbb{C}} \;\middle|\; |z|^2 + |w|^2 = 1\right\}$ is not an algebraic subset of $\mathbb{A}^2_{\mathbb{C}}$, but that the same set, viewed in $\mathbb{A}^4_{\mathbb{R}}$, is algebraic.
3. Let k be a perfect field with algebraic closure $\overline{k}$ and Galois group $\mathrm{Gal}_k(\overline{k})$, acting on $\mathbb{A}^n_{\overline{k}}$ coordinatewise. Show that
$$\mathbb{A}^n_k \cong \left\{p \in \mathbb{A}^n_{\overline{k}} \;\middle|\; p^\sigma = p \text{ for all } \sigma \in \mathrm{Gal}_k(\overline{k})\right\}$$
and say where perfectness is used.
4. Let $V = \mathcal{Z}(x^2 + y^2) \subseteq \mathbb{A}^2$. Show that V is irreducible over $\mathbb{Q}$ but reducible over $\mathbb{Q}(i)$, so that irreducibility depends on the field of definition. Why does this phenomenon disappear once the field is algebraically closed?
5. Here is a way of recovering $A = k[x_1, \ldots, x_n]$ from $V = k^n$. Write $V^* = \mathrm{Hom}_k(V, k)$ and recall the symmetric algebra (definition 16.3.5):
$$\mathrm{Sym}^\bullet(V^*) = k \oplus V^* \oplus \mathrm{Sym}^2(V^*) \oplus \mathrm{Sym}^3(V^*) \oplus \cdots$$
Show that $\mathrm{Sym}^\bullet(V^*) \cong A$. Then let $\mathfrak{m} \subseteq A$ be the maximal ideal of a point and show $\mathfrak{m}/\mathfrak{m}^2 \cong V^*$, so that the linear structure is recovered at each point. This is the *Zariski tangent space* of chapter 35.

31.3 The Zariski Topology

In this section, we will be assuming basic topological knowledge from the reader (see appendix C)

As the reader (ought to have) showed in in example 31.2.4, if $k = \mathbb{F}_q$ is finite, then every subset of $\mathbb{A}^n_{\mathbb{F}_q}$ is algebraic, hence the Zariski topology is isomorphic to the discrete topology, showing us that there is no "interesting" behaviour in the finite case. Thus, we shall usually focus on the case where k is not-finite. This doesn't mean that finite fields don't play an important role in algebraic geometry, however their importance shall not be visible until the development of schemes[10] or Class

[10] In particular, for any Scheme X, there is always a scheme morphism $X \to \mathrm{Spec}(\mathbb{Z})$ a there is always a ring homomorphism $\mathbb{Z} \to \mathcal{O}_X(X)$; the fibers of this scheme X_p are $\mathbb{F}_p$-schemes. Furthermore, $\mathbb{F}_q$-schemes shall be important in number theory

Field Theory[11] and so they shall have negligible importance this chapter.

As the topology was defined using closed sets (sets for which a collection of polynomials is zero on that set), a moment should be given to give a geometric interpretation to open sets. Open sets are those for which a collection of polynomials are *not all zero* at once on those points. If $S = \{f\} \in \Gamma(\mathbb{A}_k^n)$ is a singleton, then it will be precisely the set of points where the function f does not vanish. This makes all open sets of $\mathbb{A}_k^1$ (where k is not finite) the *cofinite sets* and hence it has the cofinite topology. If $n > 1$, the topology is certainly no longer cofinite. Open sets shall become importance when we look to define *rational polynomials* and *rational functions* for they give us the domain on which a function is non-zero. (see definition 31.3.5).

Let us now look at the separatedness of the Zariski topology. Notice that $\mathcal{T}_{\mathcal{Z}}$ is rarely Hausdorff (also known as T_2): if $\mathbb{A}^1 = k$ is any infinite field, as we've established that the only algebraic sets (and hence closed sets) are the empty set, finite sets, and $\mathbb{A}_k^1$ and so the only non-trivial open sets in $\mathcal{T}_{\mathcal{Z}}$ would be co-finite sets (i.e. $\mathcal{T}_{\mathcal{Z}}$ is the co-finite topology). Then as we can see, if we pick any two points $a, b \in \mathbb{A}^1$, we cannot separate them by two open disjoint sets. However, over any $\mathbb{A}^1 = k$, the singleton's are always algebraic sets (giving a hint to those who were working on example 31.2.4), and so it is always a Fréchet space (or T_1)[12].

This result generalizes for any k^n

Proposition 31.3.1: Zariski Topology Always T_1

Let k be any field and give $\mathbb{A}_k^n$ the Zariski topology. Then:

1. $\mathbb{A}_k^n$ is T_1, that is, every singleton is closed.
2. If k is infinite, $\mathbb{A}_k^n$ is not Hausdorff.

The two halves need different hypotheses, and the second genuinely fails without its one: over a finite field every subset is algebraic (example 31.2.4), so the topology is discrete and therefore Hausdorff.

***Proof*:**

1. For any $a = (a_1, \ldots, a_n) \in k^n$ let $I = (x_1 - a_1, \ldots, x_n - a_n)$. A point b lies in $\mathcal{Z}(I)$ exactly when $b_i - a_i = 0$ for every i, so $\mathcal{Z}(I) = \{a\}$ and singletons are closed. No hypothesis on k is used.
2. Let k be infinite and suppose U, V are nonempty open sets. Write $U = \mathbb{A}^n \setminus \mathcal{Z}(I)$ and $V = \mathbb{A}^n \setminus \mathcal{Z}(J)$ with $\mathcal{Z}(I), \mathcal{Z}(J) \neq \mathbb{A}^n$, so neither I nor J lies in $\mathcal{I}(\mathbb{A}^n) = 0$ (proposition 31.2.10); choose $f \in I$ and $g \in J$ nonzero. Then fg is nonzero, since $\Gamma(\mathbb{A}^n) \cong k[x_1, \ldots, x_n]$ is an integral domain, so again by proposition 31.2.10 the product fg does not vanish identically on $\mathbb{A}^n$. Any point where fg is nonzero has both f and g nonzero, hence lies in $U \cap V$. So any two nonempty open sets meet, and $\mathbb{A}_k^n$ is not Hausdorff, as we sought to show.

Two topological concepts which should be immediately introduced to be explored as the chapter develops are the following:

[11] In particular, the behaviour of unramified field extensions between local fields will be captured via the automorphisms of finite fields

[12] For those familiar with algebraic topology, schemes are almost never T_1, as prime ideals that are not maximal are not closed points

Definition 31.3.2: Zariski Dense And Closure

Let $A \subseteq \mathbb{A}^n$ be any subset of the affine space $\mathbb{A}^n$. Then the *zariski closure* of A is the smallest algebraic set containing A, denoted $\overline{A}$. Geometrically, it is the smallest set $\mathcal{A}$ for which every point in A is the zero set of a collection of polynomials.

If $\overline{A} = \mathbb{A}^n$, then A is said to be *zariski dense*. More generally if $A \subseteq V \subseteq \mathbb{A}^n$ such that $\overline{A} = V$, then A is said to be zariski dense in V.

As an example, if we give $\mathbb{R}$ the Zariski topology, the closure of any finite set is itself, while the closure of any infinite set is all of $\mathbb{R}$. The Zariski closure of a set is in fact quite easy to characterize using $\mathcal{Z}$ and $\mathcal{I}$ and follows quickly using proposition 31.2.11:

Corollary 31.3.3: Zariski Closure

Let $A \subseteq \mathbb{A}^n$. Then:
$$\overline{A} = \mathcal{Z}(\mathcal{I}(A))$$

***Proof*:**
The set $\mathcal{Z}(\mathcal{I}(A))$ is algebraic and contains A by proposition 31.2.11(1), so it is one of the algebraic sets whose intersection defines $\overline{A}$, giving $\overline{A} \subseteq \mathcal{Z}(\mathcal{I}(A))$.

Conversely, let W be any algebraic set with $A \subseteq W$. Applying $\mathcal{I}$ reverses the inclusion, so $\mathcal{I}(W) \subseteq \mathcal{I}(A)$, and applying $\mathcal{Z}$ reverses it again:
$$\mathcal{Z}(\mathcal{I}(A)) \subseteq \mathcal{Z}(\mathcal{I}(W)) = W$$
the last equality because W is algebraic (proposition 31.2.11(2)). So $\mathcal{Z}(\mathcal{I}(A))$ is contained in every algebraic set containing A, hence in $\overline{A}$, as we sought to show.

Sticking to $k = \mathbb{R}$ or $k = \mathbb{C}$ for a moment, we can compare the euclidean topology on $\mathbb{R}^n$ with the Zariski topology on $\mathbb{A}^n_{\mathbb{R}}$. (Coarser, and I think is the corsest topology on which all polynomial functions are continuous)

Another important topological consideration would be to find a topological basis for the Zariski topology. Recall a subset of the topology on a space X is a basis B if any open set of X is the union of a family of sets from B.

Proposition 31.3.4: Basis For Zariski Topology

For $f \in \Gamma(\mathbb{A}^n)$ define
$$D(f) = \mathbb{A}^n_k \setminus \mathcal{Z}(f) = \{a \in \mathbb{A}^n_k \mid f(a) \neq 0\}$$
Then the collection $\{D(f) \mid f \in \Gamma(\mathbb{A}^n)\}$ forms a [topological] basis for the Zariski topology on $\mathbb{A}^n$.

The letter D can be thought of as a mnemonic for *doesn't* vanish.

***Proof*:**
It suffices to show that for any open U and any $a \in U$ there is an f with $a \in D(f) \subseteq U$, since then U is the union of those $D(f)$. As U is open, $U = \mathbb{A}_k^n \setminus \mathcal{Z}(I)$ for some ideal $I \subseteq \Gamma(\mathbb{A}^n)$. Now $a \notin \mathcal{Z}(I)$ says precisely that $f(a) \neq 0$ for *some* $f \in I$; fix such an f, so that $a \in D(f)$. Since $(f) \subseteq I$,

$$\mathcal{Z}(I) \subseteq \mathcal{Z}(f)$$

and taking complements gives:

$$a \in D(f) \subseteq U$$

and since a was arbitrary, we see that U is the union of sets $D(f)$, as we sought to show.

The collection of $D(f)$ for each $f \in k[x_1, ..., x_n]$ forms the coarsest basis:

Definition 31.3.5: Distinguished Open Sets

Let $f \in k[x_1, ..., x_n]$. Then the set

$$D(f) = \mathbb{A}_k^n \setminus \mathcal{Z}(f) = \{a \in \mathbb{A}_k^n \mid f(a) \neq 0\}$$

is called he distinguished open set.

Example 31.3.6: Distinguished Open Sets

1. In $\mathbb{A}_k^1$ take $f = x$. Then $D(x) = \mathbb{A}_k^1 \setminus \{0\}$, the punctured line. It is not closed, but it is itself an algebraic set in disguise: the map

$$D(x) \to \mathcal{Z}(xy - 1) \subseteq \mathbb{A}_k^2 \qquad a \mapsto (a, 1/a)$$

   is a bijection with inverse $(a, b) \mapsto a$, and both are given by polynomials on their domains. So the punctured line is the hyperbola.

2. The same works in general. For $f \in k[x_1, \ldots, x_n]$,

$$D(f) \;\cong\; \mathcal{Z}\big(y\, f(x_1, \ldots, x_n) - 1\big) \;\subseteq\; \mathbb{A}_k^{n+1}$$

   by $a \mapsto (a, 1/f(a))$. Every distinguished open set is therefore an algebraic set in one more variable, which is why they are the right basic open sets: the topology has a basis of sets that are themselves affine.

3. The distinguished opens do form a basis. Any open set is $\mathbb{A}_k^n \setminus \mathcal{Z}(I)$, and

$$\mathbb{A}_k^n \setminus \mathcal{Z}(I) = \mathbb{A}_k^n \setminus \bigcap_{f \in I} \mathcal{Z}(f) = \bigcup_{f \in I} D(f)$$

4. Not every open set is distinguished. In $\mathbb{A}_k^2$ the set $\mathbb{A}_k^2 \setminus \{(0, 0)\}$ is open, but $D(f)$ misses the whole curve $\mathcal{Z}(f)$, which is infinite for nonconstant f, and equals $\mathbb{A}_k^2$ for constant $f \neq 0$. Neither omits exactly one point.

The next property we get about the Zariski topology is that it's always Noetherian, that is, if there is an ascending chain of open sets, it must stabilize:

Proposition 31.3.7: Zariski Topology Is Noetherian

Let $\mathbb{A}_k^n$ have the Zariski topology. Then $\mathbb{A}_k^n$ is Noetherian.

***Proof*:**
Let $U_1 \subsetneq U_2 \subsetneq \cdots$ be an ascending chain of open sets, so there is a corresponding

$$X_1 \supsetneq X_2 \supsetneq \cdots$$

descending chain of closed sets. Then there is a corresponding

$$I(X_1) \subsetneq I(X_2) \subsetneq \cdots$$

ascending chain of ideals. Then we know that $\Gamma(\mathbb{A}^n)$ is *noetherian*, and so this chain must stabilize at some n:

$$I(X_n) = I(X_{n+1}) = \cdots$$

meaning the respective closed chain, and hence open chain, must stabilize, as we sought to show.

Noetherianity already forces compactness, and by the same argument every subspace of $\mathbb{A}_k^n$ is compact too: given an open cover of a subspace, the closed sets complementary to finite subcovers form a descending chain, which must stabilize. Proposition 32.5.1 nonetheless gives a second proof, via the Nullstellensatz, because that argument produces the explicit partition of unity $1 = \sum g_i f_i$ rather than the bare existence of a finite subcover, and that identity is what later arguments use[13].

31.4 Regular Maps and Continuity

The next thing we should consider the continuous functions. As the topology is the weakest in which the zero-sets is closed, it may not surprise the reader that it is the coarsest topology in which polynomials are continuous

Definition 31.4.1: Regular Map on Affine Space

A map $\varphi : \mathbb{A}_k^n \to \mathbb{A}_k^m$ is called a *regular map* if there exists polynomials $\varphi_1, \varphi_2, ..., \varphi_m \subseteq k[x_1, x_2, ..., x_n]$ such that

$$\varphi(a_1, a_2, ..., a_n) = (\varphi_1(a_1, a_2, ..., a_n), \varphi_2(a_1, a_2, ..., a_n)..., \varphi_m(a_1, a_2, ...a_n))$$

If $m = 1$, a regular map is often called a *regular function*.

[13] Compactness is cheap here and correspondingly weak: almost every scheme is compact, so the useful strengthening is *properness*, which chapter 40 develops for projective varieties.

Lemma 31.4.2: Coordinate Ring and Regular Map

The map $\varphi : \mathbb{A}_k^n \to \mathbb{A}_k^m$ is regular if and only if the induced map $\varphi^\# : \Gamma(\mathbb{A}_k^m) \to \Gamma(\mathbb{A}_k^n)$ given by $\varphi^\#(f) = f \circ \varphi$ is a k-algebra homomorphism

***Proof*:**
Let $\varphi : \mathbb{A}_k^n \to \mathbb{A}_k^m$ be a regular map so that each component is given by a polynomial. Then $\varphi^\#$ maps a function $f \in \Gamma(\mathbb{A}_k^m)$ to $f \circ \varphi \in \Gamma(\mathbb{A}_k^n)$, namely $f \circ \varphi$ is a polynomial map. If $f, g \in \Gamma(\mathbb{A}_k^m)$, then:

$$(f+g)\circ\varphi = f\circ\varphi + g\circ\varphi$$
$$(f\cdot g)\circ\varphi = f\circ\varphi\cdot g\circ\varphi$$
$$(k\cdot f)\circ\varphi = k\cdot(f\circ\varphi)$$

thus it is a k-algebra homomorphism.

Conversely, let $\varphi^\# : \Gamma(\mathbb{A}_k^m) \to \Gamma(\mathbb{A}_k^n)$ is a k-algebra homomorphism that maps:

$$f \mapsto \varphi^\#(f) = f\circ\varphi \in \Gamma(\mathbb{A}_k^n)$$

Let $y_1, ..., y_n : \mathbb{A}_k^m \to k$ be the coordinate functions in $\Gamma(\mathbb{A}_k^m)$. If one of the components of φ where not a polynomial, then take $f = x_i$, so that the composition $x_i \circ \varphi = \varphi_i$ is not a polynomial, giving a contradiction. Hence φ must be a regular map, completing the proof.

Lemma 31.4.3: Ring homomorphism Induces Regular map

Let $f : \Gamma(\mathbb{A}_k^m) \to \Gamma(\mathbb{A}_k^n)$ be a k-algebra homomorphism. Then it induces a map $\varphi : \mathbb{A}_k^n \to \mathbb{A}_k^m$ such that $\varphi^\# = f$.

***Proof*:**
Let $k[y_1, ..., y_m] \cong \Gamma(\mathbb{A}_k^m)$ and $k[x_1, ..., x_n] \cong \Gamma(\mathbb{A}_k^n)$. Then as f is a k-algebra homomorphism, it is enough to map each y_i to some polynomial $f(y_i) = p(x_1, ..., x_m)$ and extend to form a map on all of $\Gamma(\mathbb{A}_k^m)$. Let φ_i be the function determine by $f(y_i)$. Then it is a matter of course to check that $\varphi^\# = f$, completing the proof.

Note that the maps must be k-algebra homomorphism, not just ring homomorphisms. For example, if $n = m = 1$, then $f : \mathbb{C}[\mathbb{A}_k^1] \to \mathbb{C}[\mathbb{A}_k^1]$ sending $p(x) \mapsto \overline{p(x)}$ (i.e. the complex conjugate) is not a $\mathbb{C}$-algebra homomorphism, and the reader could check there can't be a corresponding φ such that $\varphi^\# = f$.

Lemma 31.4.4: Regular Map is Continuous

A regular map $\varphi : \mathbb{A}_k^n \to \mathbb{A}_k^m$ is continuous.

***Proof*:**
It suffices to check that the pre-image of every closed set is closed. If $V = \mathcal{Z}(I) \subseteq \mathbb{A}_k^m$ is an algebraic set, we need to show there exists an ideal J such that

$$\mathcal{Z}(J) = \varphi^{-1}(V)$$

To that end:

$$\begin{aligned}
\varphi^{-1}(V) &= \{a \in \mathbb{A}_k^n \mid \varphi(a) \in V\} \\
&= \{a \in \mathbb{A}_k^n \mid f(\varphi(a)) = 0 \ \forall f \in I\} \\
&= \left\{a \in \mathbb{A}_k^n \;\middle|\; \varphi^{\#}(f)(a) = 0 \ \forall f \in I\right\}
\end{aligned}$$

Consider the set $\varphi^{\#}(I) = \{g \in \Gamma(\mathbb{A}_k^n) \mid g = f \circ \varphi\}$. This set would be the desired pre-image ideal, except it is in general not an ideal as it need not be closed under multiplication (recall the image of an ideal need not be an ideal). Thus, take $J = \langle \varphi^{\#}(I) \rangle$. Then it is clear that

$$\mathcal{Z}(J) = \varphi^{-1}(V)$$

and as V was an arbitrary closed set, φ is continuous, as we sought to show.

Note that *not all* continuous maps arise from a ring homomorphism:

Example 31.4.5: Continuous, No Associated Ring Homomorphism
Take $f : \mathbb{A}_{\mathbb{R}}^1 \to \mathbb{A}_{\mathbb{R}}^1$ given by:

$$f(a) = \begin{cases} 2 & a = 1 \\ 1 & a = 2 \\ a & \text{otherwise} \end{cases}$$

The closed sets of $\mathbb{A}_{\mathbb{R}}^1$ are the finite sets and the whole space, and f carries each of these to a set of the same size, so the pre-image of every closed set is closed and f is continuous. But f is not regular. If it were given by a polynomial p, then $p(a) = a$ for every $a \notin \{1, 2\}$, so the polynomial $p(x) - x$ would have infinitely many roots and hence be zero. That forces $p(x) = x$, which does not transpose 1 and 2.

Another such example is $k = \mathbb{C}$ with the conjugation map presented earlier.

There needs to be more information for the full and faithful correspondence between regular maps and ring homomorphisms. This extra information is a *sheaf* and a *locally ringed morphism*. We shall not define these in this book, instead the reader may refer to [5].

Example 31.4.6: Regular Maps

1. Take $V = \mathcal{Z}(y - x^2, z - x^3)$. Show that the map $f : \mathbb{A}_k^1 \to V$ given by $t \mapsto (t, t^2, t^3)$ is a regular map. Show it is not an isomorphism[a].

2. Any straight line $\mathbb{A}_k^n$ is isomorphic to any other straight-line. Similarly for any k-dimensional linear subspace.

3. The map $\mathbb{A}_k^1 \to \mathcal{Z}(y - x^2)$ given by $t \mapsto (t, t^2)$ is a regular map with inverse $(x, y) \mapsto x$, and hence is an isomorphism. Note that it was important which coordinate we project to.

4. Here is another version of the above map. Consider the global sections of $\mathbb{A}^1_k \to \mathbb{A}^1_k$ given by

$$k[y] \to k[x] \qquad y \mapsto x^2$$

(note that the k-homomorphism is the contravariant direction of the regular morphism). As a map between varieties, this gives the map $a \mapsto a^2$ (the reader should verify this!).

5. Take $f : \mathbb{A}^2_k \to \mathbb{A}^2_k$ given by $(x, y) \mapsto (x, xy)$. Show that $\mathrm{im}(f)$ is *not* an algebraic set. The image of a regular map is always a *constructible set*, a finite union of locally closed sets, which is theorem 41.3.4.

6. The reader should be careful with their geometric intuitions coming from the real numbers. Consider the map:

$$\mathcal{Z}(x^2 + y^2 - 1) \to \mathbb{A}^1_{\mathbb{C}} \qquad (x, y) \mapsto x$$

Show that this map is *surjective* (in contrast to the map certainly being *injective* when over $\mathbb{R}$). In fact, by taking different cross sessions of the resulting shape interpreted as a 2-real dimensional shape living in 4-real dimensional space, you will see that $\mathcal{Z}(x^2 + y^2 - 1)$ will have both the parabola and the hyperbolic curve as sections. The hyperbolic sections demonstrate why the map is surjective and 2-to-1.

[a] It shall later be shown to be a *birational equivalence*

Let us now take a moment to look at isomorphism of algebraic sets:

Definition 31.4.7: Isomorphism of Varieties

let X, Y be two algebraic sets. Then if there exists a regular map $f : X \to Y$ with regular inverse, then the two varieties are said to be *isomorphic*

Note that this was not called a homeomorphism between two varieties. All isomorphisms are homeomorphisms, but not all homeomorphisms are isomorphisms

Example 31.4.8: Isomorphism of Varieties

1. Consider $X = \mathcal{Z}(y - x^n) \subseteq \mathbb{A}^2_k$. Then $X \cong \mathbb{A}^1_k$ with $\varphi(x, y) = x$, which has inverse $\psi(t) = (t, t^n)$

2. Take $X = \mathcal{Z}(x^3 - y^2) \subseteq \mathbb{A}^2_k$. Then X can be parameterized by the regular map $f : \mathbb{A}^1_k \to X$ by $f(t) = (t^2, t^3)$. However, this is not an isomorphism: the inverse map is:

$$g(x, y) = \frac{y}{x}$$

however, there is no polynomial associated to g (can the reader see/prove why?), and hence it is not an isomorphism.

3. The reader may have recalled that $\mathcal{Z}(x^3 - y^2)$ has a cusp at 0, and believe this is the obstruction to the inverse. It is in fact a bit more subtle: a map can be bijective, with no singularity anywhere, and still fail to be an isomorphism. Let $\mathrm{char} k = p > 0$ and consider the Frobenius $\varphi : \mathbb{A}^1_k \to \mathbb{A}^1_k$ given by $\varphi(t) = t^p$. Over $k = \overline{k}$ this is a bijection, since $t \mapsto t^p$ is injective ($t^p = s^p$ gives $(t - s)^p = 0$) and surjective (k is algebraically closed), and it is

regular. Yet its inverse $t \mapsto t^{1/p}$ is not regular: the induced map on coordinate rings is $k[x] \to k[x]$, $x \mapsto x^p$, whose image is $k[x^p]$, and x does not lie in it. So φ is a bijective regular map that is not an isomorphism.

The hypothesis on the characteristic matters. In characteristic 0, or more generally whenever $p \nmid n$, the map $t \mapsto t^n$ is n-to-1 away from the origin over an algebraically closed field, so it is not even bijective.

On the other hand, the map given in the previous example had a rational polynomial inverse. Rational functions appear as localization of the coordinate ring, and so they offer a different class of functions and a different classification problem that turns out to be much easier, as we shall demonstrate in chapter 33.

It is in general difficult to ascertain isomorphic classes of algebraic sets or varieties. Some isomorphism classes that we shall state here but not prove are:

1. Smooth genus 0 curves are isomorphic to conic curves in $\mathbb{P}^2_k$
2. classes of elliptic curves can be classified by their j-invariant
3. Algebraic surfaces are birationally equivalent (defined in chapter 33), but have different isomorphism classes given their Kodaira dimension.

Exercise 31.4.1

1. Show that the Zariski topology on $\mathbb{A}^1_k$ is the cofinite topology, hence the coarsest topology in which points are closed. Then show that for $n \geq 2$ the Zariski topology on $\mathbb{A}^n_k$ is strictly finer than the cofinite topology, so the characterization fails in higher dimension.
2. Prove that $(I \cap J)^2 \subseteq IJ \subseteq I \cap J$, and conclude that $\mathcal{Z}(I \cap J) = \mathcal{Z}(IJ)$.
3. Let $k = \mathbb{F}_q$ be a finite field. Show that every set function $k^n \to k$ is given by a polynomial. Hint: build a characteristic function $\chi_{\overline{a}}$ with $\chi_{\overline{a}}(\overline{a}) = 1$ and 0 elsewhere, and show these span. Conclude that the Zariski topology on $\mathbb{A}^n_{\mathbb{F}_q}$ is discrete.
4. Show that the Zariski topology on $\mathbb{A}^n_k$ is Hausdorff if and only if k is finite.
5. Let $V \subseteq \mathbb{A}^n_k$ and $W \subseteq \mathbb{A}^m_k$ be algebraic sets. Show that $V \times W$ is an algebraic set in $\mathbb{A}^{n+m}_k$, and that $\mathbb{A}^n_k \times \mathbb{A}^m_k = \mathbb{A}^{n+m}_k$ as algebraic sets[14].
6. Let $f, g \in k[x, y]$ have no common *factor*. Show that $\mathcal{Z}(f, g)$ is finite. Hint: they remain coprime in $k(x)[y]$, a principal ideal domain, by a Gauss-lemma argument.
7. Show that if $V \subseteq \mathbb{A}^n_k$ and $W \subseteq \mathbb{A}^m_k$ are varieties, not merely algebraic sets, then $V \times W \subseteq \mathbb{A}^{n+m}_k$ is a variety.

[14]This easy statement becomes markedly harder for projective algebraic sets; see section 40.1.

32

The Algebra-Geometry Dictionary

Chapter 31 left $\mathcal{Z}$ and $\mathcal{I}$ almost inverse to one another: an algebraic set is recovered from its vanishing ideal, but an ideal need not be recovered from its zero set. This chapter identifies exactly which ideals are recovered. The answer, Hilbert's Nullstellensatz, is that they are the radical ideals, and it holds precisely when the ground field is algebraically closed.

From here to the end of the book, k is algebraically closed unless a result says otherwise. The hypothesis is not decorative: over $\mathbb{R}$ the ideal (x^2+1) is its own radical and has empty zero set, so the correspondence fails at once. With the Nullstellensatz in hand, the geometric side and the algebraic side can be tabulated against each other, and the rest of the book consists of extending that table.

32.1 Coordinate Rings

In this section, we explore more properties of affine sets. As affine sets correspond to ideals, we shall see that there is a correspondence between the two objects. In particular it shall will show that properties of algebraic sets will often have corresponding properties in their coordinate rings, and vice-versa. This theme shall play out often in this chapter, where a property proven in a geometric or algebraic setting shall have a corresponding result in the respective dual.

By lemma 31.4.2, the collection of regular function $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{A}^n_k, \mathbb{A}^1_k)$ can be thought of as the generalization of the dual vector-space, where polynomial functions are taken instead of linear functions. We saw that for each vector subspace $W \subseteq V$, there is a dual space $W^\vee = \mathrm{Hom}_k(W, k)$ which it is isomorphic to. It is thus natural to ask what is the appropriate dual space for an algebraic set $V \subseteq \mathbb{A}^n_k$ corresponding to the *quotient* of $\Gamma(\mathbb{A}^n_k)$[1].

[1] For the categorically inclined, since the arrows in the dual space are reversed, sub-objects correspond to quotient-objects

In order to find the dual, we must consider more the subspace topology put on $V \subseteq \mathbb{A}_k^n$. Note that all of the properties of the Zariski topology apply to A since $\mathbb{A})k^n$ is T1 (proposition 31.3.1), from which we can conclude that closed sets are preserved in the subspace topology. We will always limit ourselves to taking A to be an algebraic set, since algebraic set are the object of interest. The dual space we wish to establish is a corresponding "polynomial ring" which will generate all of the closed sets of A, just like how $k[x_1, x_2, ..., x_n]$ is needed to generate the closed sets of $\mathbb{A}^n$. Without looking at the next definition, can you see what the definition of such a ring may be?

To elucidate the coming definition, let us come back to the algebraic set V defined given by the vanishing set of $x^2 + y^2 - 1$. Then on V, the function $X^2 + Y^2 - 1$ on V will evaluate to 0, hence these two polynomials are equivalent as functions:

$$X^2 + Y^2 - 1 \equiv 0 \qquad \text{on } V$$

If g is any other polynomial corresponding to the function G, then $(X^2 + Y^2 - 1)G$ evaluates to 0 everywhere as well, showing the set of regular functions taking inputs on V is closed under multiplication by regular functions $\Gamma(\mathbb{A}_k^n)$. Furthermore, if two regular functions f, g which evaluate to zero everywhere are added, the function $f + g$ will also evaluate to zero, showing it is closed under addition. In other words, the collection of functions which evaluates to 0 forms an ideal of $\Gamma(\mathbb{A}_k^n)$. What is this ideal? If we let F be the function

$$F : k[x, y] \to \mathrm{Hom}_{\mathbf{Reg}}(V, k) \qquad f \mapsto ((a, b) \to f(a, b)) \tag{32.1}$$

where $\mathrm{Hom}_{\mathbf{Reg}}(V, k)$ is the set of regular functions which evaluate only on the points V, then we get that this map is surjective and that:

$$\frac{k[x, y]}{\ker(F)} \cong_k \mathrm{Hom}_{\mathbf{Reg}}(V, k)$$

The reader should clue in that $\ker(F)$ is by definition $\mathcal{I}(V)$ as defined in definition 31.2.8! This leads to the following definition:

Definition 32.1.1: [Affine] Coordinate Ring

Let $k[x_1, ..., x_n]$ be a polynomial ring over n variables, V an algebraic set, and $\mathcal{I}(V)$ the corresponding vanishing ideal. Then:

$$\Gamma(V) = k[V] = \frac{k[x_1, ..., x_n]}{\mathcal{I}(V)}$$

is called the *coordinate ring* of V. The corresponding regular functions shall be denoted $k[V]$ or $\Gamma(V)$.

Notice how this notation is the same as for regular functions: the coordinate ring of $V = \mathbb{A}_k^n$ is isomorphic to $k[X_1, ..., X_n]$ since $I(\mathbb{A}^n) = (0)$. In $\Gamma(V)$, we have that $\mathcal{I}(V) = \overline{(0)}$, showing the notation is consistent.

We can naturally bring the notion of regular function to algebraic sets:

Definition 32.1.2: Regular Maps on Algebraic Sets

Let $V \subseteq \mathbb{A}_k^n$, $W \subseteq \mathbb{A}_k^m$ be algebraic sets. Then a map $\varphi : V \to W$ is called a *regular map*, or *regular morphism*, if there exists polynomials $\varphi_1, \varphi_2, ..., \varphi_m \subseteq k[x_1, x_2, ..., x_m]$ such that

$$\varphi(a_1, a_2, ..., a_n) = (\varphi_1(a_1, a_2, ..., a_n), \varphi_2(a_1, a_2, ..., a_n)..., \varphi_m(a_1, a_2, ...a_n))$$

If $m = 1$, then φ is often called a *regular function*.

This definition also allows us to upgrade definition 31.1.2 and definition 31.4.1. To check that $\varphi : V \to W$ is well-defined, it suffices to check that $\varphi_1, ..., \varphi_m$ as elements of $k[V]$ satisfy the equations of W.

Proposition 32.1.3: Regular Maps Are Continuous

Let $\varphi : V \to W$ be a regular map where V, W are equipped with the Zariski topology. Then φ is continuous.

***Proof*:**
Let $S \subseteq W$ be a closed subset. It suffices to show that $\varphi^{-1}(S)$ is closed. if $\varphi^{-1}(S) = \emptyset$, it is closed by definition, so assume $\varphi^{-1}(S) \neq \emptyset$. As S is closed, there exists polynomials $f_1, ..., f_n$ such that for each $x \in S$, $g_1(x) = \cdots = g_m(x) = 0$. If $a \in \varphi^{-1}(S)$, then $\varphi(a) \in S$, so

$$g_1(\varphi(a)) = \cdots = g_m(\varphi(a)) = 0 \tag{32.2}$$

As $\varphi = (\varphi_1, ..., \varphi_n)$ is a tuple of polynomials, notice that (32.2) is a collection of polynomials in $k[V]$ where a vanishes. As this is true for all points in $\varphi^{-1}(S)$, we see that:

$$\varphi^{-1}(S) = \mathcal{Z}(g_1 \circ \varphi, ..., g_m \circ \varphi)$$

showing it is closed, as we sought to show.

As before, this is not an iff as not all continuous functions are regular functions (simply take $V = W = \mathbb{A}_{\mathbb{C}}^1$ and the conjugation map). That is because continuity in the Zariski topology is not enough to preserve the algebraic relations. In particular, any point $a \in V \subseteq \mathbb{A}_k^n$ satisfying

$$f_1(a) = \cdots f_n(a) = 0$$

must have an image that satisfies:

$$g_1(w) = \cdots = g_m(w) = 0 \qquad \text{i.e.} \qquad g_1(\varphi(a)) = \cdots g_1(\varphi(a)) = 0$$

Example 32.1.4: Coordinate Ring and Regular Mapping

1. Let $V = \mathcal{Z}(xy - 1)$, which represents the hyperbola $y = 1/x$ in $\mathbb{R}^2$. Then the coordinate ring $\mathbb{R}[V] = \mathbb{R}[x, y]/(xy - 1)$. In $\mathbb{R}[V]$, $f(x, y) = x$ and $g(x, y) = x + xy - 1$ are the same function since $f - g \in \mathcal{I}(V)$. In $\mathbb{R}[V]$, $\overline{xy} = \overline{1}$, giving us that $\mathbb{R}[V] \cong \mathbb{R}[x, 1/x]$. Thus, for any $f \in \mathbb{R}[x, y]$ and $(a, b) \in V$, $\overline{f}(a, b) = f(a, 1/a)$ for any f that maps to $\overline{f}$.

Take the regular map $\varphi : V \to \mathbb{A}^1_k$ mapping $(x, y) \mapsto x$. The image of this map is $\mathbb{A}^1_k \setminus \{0\}$, which is certainly *not* a closed set (can the reader see why). It is an open set, being the complement of the closed set $\{0\}$. However, if we take the map to be $\varphi' : V \to \mathbb{A}^2_k$ mapping $(x, y) \mapsto (x, 0)$, then the image is no longer an open set, and hence it is possible for the images of regular maps to be neither open or closed. Further exploration the properties of the image of regular maps shall be done section 39.4.

2. Take $k = \mathbb{F}_p$ and consider $\mathbb{A}^n_{\mathbb{F}_p}$. Then the map:

$$\varphi(a_1, ..., a_n) = (a_1^p, ..., a_n^p)$$

is a regular function. If $V \subseteq \mathbb{A}^n_{\mathbb{F}_p}$ is an algebraic set, notice that φ will always take V to itself, since if f is one of the polynomials that define V so that $f(a) \equiv 0 \bmod p$, then:

$$f(a_1^p, ..., a_n^p) = (f(a_1, ..., a_n))^p \equiv (0)^p \equiv 0 \bmod p$$

The regular function φ is called the *Frobenius mapping*

3. Take $t \mapsto (t^3, t^2)$. This is a regular function and maps $\mathbb{A}^1_{\mathbb{R}}$ to the curve given by $x^3 = y^2$ in $\mathbb{A}^2_{\mathbb{R}}$.

4. Take $V = \mathcal{Z}(xy - 1)$ and $W = \mathcal{Z}(v - u^2)$. We can define a map between global sections:

$$\varphi : \frac{k[u, v]}{(v - u^2)} \to \frac{k[x, y]}{(xy - 1)} \qquad u \mapsto \frac{x + y}{2}$$

and extend k-linearly (note that $v \mapsto \left(\frac{x+y}{2}\right)^2$). As the left hand side is a free k-algebra up to the quotient relation, let's insure the relation is preserved, and indeed:

$$\varphi(0) = \varphi(v - u^2) = \frac{(x + y)^2}{2} - \frac{(x + y)^2}{2} = 0$$

showing that the relation is preserved, and hence φ is well-defined. The associated map on the varieties is given by:

$$(a, 1/a) \mapsto \left(\frac{a + 1/a}{2}, \left(\frac{a + 1/a}{2}\right)^2\right)$$

Note the image is 2-to-1. If $k = \mathbb{R}$, the image is *not* surjective (ex. nothing maps to 0). However if $i \in k$ (where $i^2 = -1$), then $i + 1/i = i - i = 0$, which shows the map is surjective and 2-to-1. This demonstrates part of the importance of working over an algebraically closed field.

Theorem 32.1.5: Regular Map Algebraic Correspondence

Let $V \subseteq \mathbb{A}^n$ and $W \subseteq \mathbb{A}^m$. then there is a bijective correpspondence between the morphisms between V and W and the associated k-algebra homomorphisms, more precisely

$$\{\text{regular functions from } V \text{ to } W\} \leftrightarrow \{k\text{-algebra homomorphisms from } k[W] \text{ to } k[V]\}$$

$$\left\{\begin{matrix}\text{regular functions} \\ \varphi : V \to W\end{matrix}\right\} \underset{\psi^a}{\overset{f\circ\varphi}{\rightleftarrows}} \left\{\begin{matrix}k\text{-algebra homomorphism} \\ \varphi^\# : k[W] \to k[V]\end{matrix}\right\}$$

More generally, if k-**Aff** is the category whose objects are algebraic sets and morphism are regular functions and k-$\mathbf{Alg}_0$ is the category whose objects are coordinate rings (reduced, commutative, finite-type k-algebras) and morphisms are k-homomorphisms, then $k\text{-}\mathbf{Aff}^{\mathrm{op}} \cong k\text{-}\mathbf{Alg}_0$ (the equivalence of categories requires k algebraically closed, so that every such algebra is realized as a coordinate ring by proposition 32.5.5).

***Proof*:**
The two constructions are already in hand: lemma 31.4.2 sends a regular map φ to the k-algebra homomorphism $\varphi^\#(f) = f \circ \varphi$, and lemma 31.4.3 sends a k-algebra homomorphism back to a regular map. It remains to see they are mutually inverse.

Given $\varphi\colon V \to W$, write ψ for the regular map induced by $\varphi^\#$. Let $y_1, \ldots, y_m$ be the coordinate functions on W. By construction the ith component of ψ is $\varphi^\#(y_i) = y_i \circ \varphi = \varphi_i$, the ith component of φ; as the components agree, $\psi = \varphi$.

Conversely let $\theta\colon k[W] \to k[V]$ be a k-algebra homomorphism, φ the regular map it induces, and $\varphi^\#$ the homomorphism φ induces in turn. Both θ and $\varphi^\#$ are k-algebra maps out of $k[W]$, which is generated over k by the $\overline{y_i}$, and both send $\overline{y_i}$ to $\theta(\overline{y_i})$; a k-algebra homomorphism is determined by its values on generators, so $\varphi^\# = \theta$.

For the categorical statement, $\varphi \mapsto \varphi^\#$ is contravariant and functorial, since $(\varphi \circ \psi)^\# = \psi^\# \circ \varphi^\#$ and $\mathrm{id}^\# = \mathrm{id}$. The bijection just established makes it fully faithful, and proposition 32.5.5 makes it essentially surjective onto k-$\mathbf{Alg}_0$ when k is algebraically closed, completing the proof.

Thus, if $f : X \to Y$, then $(f^\#)^a = f$ and if $\varphi : k[Y] \to k[X]$, then $(\varphi^a)^\# = \varphi$. Similarly to the dual theory provided in section 13.3, the dual map gives information about our original map:

Proposition 32.1.6: Regular Map Properties

Let $\varphi : X \to Y$ be a regular map with $\varphi^{\#} : k[Y] \to k[X]$ the associated k-algebra homomorphism. Then:

1. The kernel of $\tilde{\varphi}$ is $\mathcal{I}(\varphi(X))$: $\ker \tilde{\varphi} = \mathcal{I}(\varphi(X))$. Furthermore, the Zariski closure of $\varphi(X)$ is $\mathcal{Z}(\ker(\tilde{\varphi}))$: $\overline{\varphi(X)} = \mathcal{Z}(\ker(\tilde{\varphi}))$.

2. As a consequence, the homomorphism $\tilde{\varphi}$ is injective if and only if $\varphi(X)$ is Zariski dense in Y, or equivalently if $\overline{f(X)} = Y$

3. $\varphi(v) = w$ if and only if $(\varphi^{\#})^{-1}(\mathcal{I}(v)) = \mathcal{I}(w)$, where $\mathcal{I}(v) \subseteq k[X]$ and $\mathcal{I}(w) \subseteq k[Y]$ are the maximal ideals of the two points

***Proof*:**

1. A function $g \in k[Y]$ satisfies $\varphi^{\#}(g) = g \circ \varphi = 0$ exactly when g vanishes at every point of $\varphi(X)$, which is to say $g \in \mathcal{I}(\varphi(X))$. Hence $\ker \varphi^{\#} = \mathcal{I}(\varphi(X))$, and applying $\mathcal{Z}$ gives $\mathcal{Z}(\ker \varphi^{\#}) = \mathcal{Z}(\mathcal{I}(\varphi(X))) = \overline{\varphi(X)}$ by corollary 31.3.3.

2. By part 1, $\varphi^{\#}$ is injective if and only if $\mathcal{I}(\varphi(X)) = 0$ in $k[Y]$, and $\mathcal{Z}(0) = Y$, so this says $\overline{\varphi(X)} = Y$: the image is dense.

3. Suppose $\varphi(v) = w$. For $g \in k[Y]$, $\varphi^{\#}(g)(v) = g(\varphi(v)) = g(w)$, so $\varphi^{\#}(g) \in \mathcal{I}(v)$ if and only if $g \in \mathcal{I}(w)$, which is exactly $(\varphi^{\#})^{-1}(\mathcal{I}(v)) = \mathcal{I}(w)$. Conversely, suppose that identity holds. Both $\mathcal{I}(v)$ and $\mathcal{I}(w)$ are maximal (theorem 32.4.3), and writing $w' = \varphi(v)$ the forward direction gives $(\varphi^{\#})^{-1}(\mathcal{I}(v)) = \mathcal{I}(w')$. Hence $\mathcal{I}(w) = \mathcal{I}(w')$, and since $\mathcal{I}$ is injective on points, $w = w' = \varphi(v)$, completing the proof.

Exercise 32.1.1

1. Show that $k[X \times Y] \cong k[X] \otimes_k k[Y]$ for algebraic sets X, Y, and deduce another proof that $\mathbb{A}_k^n \times \mathbb{A}_k^m \cong \mathbb{A}_k^{n+m}$ as objects of **Reg**.

2. Show that the product is unique up to isomorphism: if $\varphi\colon X \to X'$ and $\psi\colon Y \to Y'$ are isomorphisms, there is a unique isomorphism $X \times Y \to X' \times Y'$ commuting with the projections.

3. Let $T\colon \mathbb{A}_k^n \to \mathbb{A}_k^n$ be an affine isomorphism with $T(p) = q$. Show that $T^{\#}\colon \mathcal{O}_q(\mathbb{A}_k^n) \to \mathcal{O}_p(\mathbb{A}_k^n)$ is an isomorphism, and that for a variety V it induces $\mathcal{O}_q(V) \to \mathcal{O}_p(V^T)$. This is the precise sense in which affine space has no preferred origin.

4. Sharpen theorem 32.1.5: show that a regular map $\varphi\colon X \to Y$ is dominant if and only if $\varphi^{\#}$ is injective, and that φ is a closed immersion, meaning an isomorphism onto a closed subset, if and only if $\varphi^{\#}$ is surjective.

32.2 Radical Ideals

As we've seen in proposition 31.2.5, given some polynomial f or collection of polynomials $S \subseteq k[x_1, ..., x_n]$, the set of zero's of these polynomials does not change if we take higher powers of the polynomials (ex. $f, f^2, f^3, ...$ all produce the same zero set). Thus, studying the set $\mathcal{Z}(I^n)$ is equivalent to studying $\mathcal{Z}(I)$. This property inspires the following definition:

Definition 32.2.1: Radical Ideal

Let $I \subseteq R$ be an ideal of a commutative ring R. Then:

1. The *radical of* I in R is the collection elements for which some power of them lie in I, that is:
$$\sqrt{I} = \text{rad}(I) := \left\{a \in R \;\middle|\; a^k \in I \text{ for some } k \in \mathbb{N}\right\}$$
here $\text{rad}(I)$ stands for the radical of I. It is often written as $\sqrt{I}$.
2. The radical of the zero ideal ($\text{rad}(0) = \sqrt{(0)}$) is called the *nilradical* of R
3. An ideal I is called a *radical ideal* if $I = \text{rad}(I)$ ($I = \sqrt{I}$)

Note that the nilradical by definition contains all the nilpotent elements of R, and that $\text{rad}(\text{rad}(I)) = \text{rad}(I)$.

Proposition 32.2.2: $\text{rad}(I)$ Is An Ideal

Let $I \subseteq R$ be an ideal of a commutative ring. Then $\text{rad}(I)$ is indeed an ideal (containing I). Furthermore, $\text{rad}(I)/I$ is the nilradical of R/I.

The last statement shows us that R/I has no nilpotent elements if and only if $I = \text{rad}(I)$.

***Proof*:**
See [10].

A type of ideal in which we've seen a similar property is the prime ideal, in which $ab \in I$ if and only if $a \in I$ or $b \in I$. One important way of looking at radical is in how they correspond to prime ideals. The prime ideals in a sense "generate" the radical ideals:

Proposition 32.2.3: Radical Through Prime Ideals

Let $I \subsetneq R$ be a proper ideal of a commutative ring and $\text{rad}(I)$ the radical ideal of I. Then $\text{rad}(I)$ is the intersection of all prime ideals containing I. In particular, the nilradical is the intersection of all prime ideals of R.

***Proof*:**
This is the description of the radical as an intersection of primes; see [10].

Corollary 32.2.4: Prime Or Maximal Then Radical

Let $I \subseteq R$ be a prime ideal. Then I is a radical ideal

***Proof*:**
A prime ideal P satisfies $P = \sqrt{P}$; see [10].

Example 32.2.5: Radical Ideals

1. Let R be a UFD. Given an ideal, finds its radical.
2. The ideal $(x^3 - y^2)$ is prime in $k[x, y]$, and hence radical
3. If $l_1, l_2, ..., l_m$ is a collection of linear polynomials in $k[x_1, ..., x_n]$, then $I = (l_1, l_2, ..., l_m)$ is either $k[x_1, x_2, ..., x_n]$ or a prime ideal, and hence radical.

In the context of this chapter, since we are working over polynomials rings, we are working over Noetherian rings. Due to this, the elements of a radical ideal $\text{rad}(I)$ can be related back to elements of I quite naturally:

Proposition 32.2.6: Radical Ideals In Noetherian Rings

Let R be a noetherian ring and $I \subseteq R$ an ideal of R. Then there exists a $k \in \mathbb{N}$ such that $I^k \subseteq \text{rad}(I)$. In particular, if N is the nilradical ideal of R, then $N^k = 0$ for some $k \in \mathbb{N}$ (i.e. N is a nilpotent ideal)

***Proof*:**
See [10].

Now, returning to the fact that $\mathcal{Z}(I) = \mathcal{Z}(I^k)$, we now have that $\mathcal{Z}(I) = \mathcal{Z}(\sqrt{I})$. Remember how we were trying to characterize the ideals for which $\mathcal{Z}$ and $\mathcal{I}$ are inverses, i.e. what are the ideals $\mathcal{I}(\mathcal{Z}(I))$? We can now state one direction of this:

Proposition 32.2.7: Radical and Algebraic Sets

Let $I \subseteq R$ be an ideal where R is a polynomial ring. Then

$$\sqrt{I} \subseteq \mathcal{I}(\mathcal{Z}(I))$$

***Proof*:**
Let $f \in \sqrt{I}$, so $f^m \in I$ for some $m \geq 1$, and let $x \in \mathcal{Z}(I)$ be arbitrary. Every element of I vanishes at x, so in particular

$$f(x)^m = f^m(x) = 0$$

Since k is a field it has no nonzero nilpotents, so $f(x) = 0$. As $x \in \mathcal{Z}(I)$ was arbitrary, f vanishes on $\mathcal{Z}(I)$, which is to say $f \in \mathcal{I}(\mathcal{Z}(I))$, as we sought to show.

It would be great if we could get $\sqrt{I} = \mathcal{I}(\mathcal{Z}(I))$, however this is not true in general: consider $I = (x^2+1) \subseteq \mathbb{R}[x]$. Since $x^2 = 1$ is irreducible, it is a maximal ideal, and so $I = \sqrt{I}$. Then as we are over the reals, $\mathcal{Z}(I) = \emptyset$, so $\mathcal{I}(\mathcal{Z}(I)) = \mathbb{R}[x]$ But $I \not\supseteq \mathbb{R}[x]$, showing equality doesn't hold. The blocker here was that x^2+1 doesn't factor in $\mathbb{R}[x]$: if we were working over $\mathbb{C}$, then we would get that $(x^2+1) = ((x+i)(x-i))$, telling us that $\mathcal{Z}(I) = \{i, -i\}$, which by the basic properties of $\mathcal{I}$ we have that $\mathcal{I}(\mathcal{Z}(I)) = ((x-i)(x+i)) = (x^2+1) = I$, showing us in this case that $I = \sqrt{I}$. In fact, the underlying field k being algebraically closed is the *only* other condition we need for equality to hold; this will be theorem 32.4.4 (Hilbert's Nullstellensatz). It is tricky to show this, since it is in a sense a very simple condition: All we need to characterize the zero sets of the polynomials (over a closed field) $\mathcal{Z}(I)$ in terms of an ideal is to take the radical of I.

32.3 Irreducibility and the Decomposition Theorem

We now return to the earlier fact that $\mathcal{Z}(I) = \mathcal{Z}(f_1, ..., f_n) = \mathcal{Z}(f_1) \cap \cdots \cap \mathcal{Z}(f_n)$. This shows that we can decompose algebraic sets into smaller components. We will therefore take a moment to see if we can find "decomposition" properties of algebraic sets, and see if there is a corresponding property the coordinate ideals will poses

Definition 32.3.1: [Affine] Variety

let $V \subseteq \mathbb{A}^n$ be an algebraic set. The set V is reducible if for $V_1, V_2 \subseteq V$ where $V_1, V_2 \neq V$

$$V = V_1 \cup V_2$$

If there does not exist such sets, we say that V is *irreducible*, or more commonly an *algebraic variety*

32.3.2 Remark Note that this notion of irreducibility is in fact a topological notion, we simply choose the Zariski topology. In particular, X is irreducible if $X = X_1 \cup X_2$ for some closed subsets X_1 and X_2, then either $X = X_1$ or $X = X_2$. For those who are curious, it may be shown that irreducibility implies connected. Furthermore, the condition translates to open sets to say that if

$$\emptyset = U_1 \cap U_2$$

where U_1, U_2 open, then either $U_1 = \emptyset$ or $U_2 = \emptyset$. It follows that it is equivalent to say that every open set is *dense* in an irreducible space. This contrasts heavily with any Hausdorff space, since by definition a Hausdorff space *must* have disjoint open subsets if the space is not empty or a singleton.

The name *algebraic variety* comes from HERE. Note that this condition automatically implies that V_1 and V_2 are non-empty (do you see why?). If V is an irreducible algebraic set, then the corresponding ideal has a very nice property:

Proposition 32.3.3: Coordinate Ideal of Algebraic Variety

A set $V \subseteq \mathbb{A}^n$ is an algebraic variety if and only if $I(V)$ is a prime ideal

***Proof*:**

(⇒) Taking the contrapositive, let's assume $I(V)$ is not prime. Then there exists $a, b \in k[x_1, .., x_n]$ such that $ab \in I(V)$ but $a \notin I(V)$ and $b \notin I(V)$. But then:

$$V = (V \cap \mathcal{Z}(a)) \cup (V \cap \mathcal{Z}(b))$$

with $V \cap V(a) \subsetneq V$, $V \cap V(b) \subsetneq V$, showing that V is in fact reducible

(⇐) Doing the contrapositive again, let's assume V is reducible, so $V = V_1 \cup V_2$, where both $V_i \subsetneq V$. Then by the contra-positive correspondence of inclusion between algebraic sets and ideals, $I(V) \subsetneq I(V_i)$, $i \in \{1, 2\}$. Since the inclusion is proper, choose $a \in I(V_1)$ and $b \in I(V_b)$ such that $a, b \notin I(V)$. Then since a and b are polynomials which are zero on their respective algebraic sets and $V = V_1 \cup V_2$, $ab \in I(V)$. However, $a, b \notin I(V)$, showing that $I(V)$ is not prime

Corollary 32.3.4: Equivalent characterization

Let $V \subseteq \mathbb{A}^n$ be an algebraic set. Then V is an algebraic variety if and only if $k[V]$ is an integral domain

***Proof*:**
By definition 32.1.1, $k[V] = \Gamma(\mathbb{A}^n)/\mathcal{I}(V)$, and a quotient of a commutative ring is an integral domain exactly when the ideal quotiented out is prime. So $k[V]$ is a domain if and only if $\mathcal{I}(V)$ is prime, which by proposition 32.3.3 holds if and only if V is irreducible, as we sought to show.

This means there is a certain correspondence between being a prime and being irreducible as a variety. To deepen the conection, let's prove that every algebraic set can be decomposed into algebraic varieties:

Theorem 32.3.5: Irreducible Decomposition

Let $V \subseteq \mathbb{A}^n$ be an algebraic set. Then there exist algebraic varieties $V_1, ..., V_r$, unique up to reordering, such that

$$V = \bigcup_{i=1}^{r} V_i \qquad V_i \not\subseteq V_j \quad i \neq j$$

***Proof*:**
Existence. Since $\Gamma(\mathbb{A}^n)$ is Noetherian, every nonempty collection of ideals has a maximal element, and $\mathcal{I}$ reverses inclusion, so every nonempty collection of algebraic sets has a *minimal* element. Let

$$S = \{W \subseteq \mathbb{A}^n \text{ algebraic} \mid W \text{ is not a finite union of algebraic varieties}\}$$

and suppose for contradiction that $S \neq \emptyset$. Choose $W \in S$ minimal. Then W is not itself a variety, so $W = W_a \cup W_b$ with both $W_a, W_b \subsetneq W$. By minimality neither lies in S, so each is a finite union of varieties, say

$$W_a = V_{1,1} \cup \cdots \cup V_{1,n_1} \qquad W_b = V_{2,1} \cup \cdots \cup V_{2,n_2}$$

and then $W = \bigcup_{i,j} V_{i,j}$ is one too, contradicting $W \in S$. Hence $S = \emptyset$.

Given any finite decomposition, discard every $V_{i,j}$ contained in another; what remains still has union V and now satisfies $V_i \not\subseteq V_j$ for $i \neq j$.

Uniqueness. Suppose $V = V_1 \cup \cdots \cup V_r = W_1 \cup \cdots \cup W_m$ are two such decompositions. Fix i. Then

$$V_i = V_i \cap V = \bigcup_j (W_j \cap V_i)$$

expresses the irreducible set V_i as a finite union of closed subsets, so by irreducibility $V_i = W_j \cap V_i$ for some j, that is $V_i \subseteq W_j$. Running the same argument on W_j against the first decomposition gives $W_j \subseteq V_k$ for some k, whence $V_i \subseteq V_k$. The decomposition has no containments among distinct members, so $i = k$, and therefore $V_i = W_j$. This assigns to each i a j with $V_i = W_j$, and symmetrically to each j an i; the two assignments are mutually inverse, so $r = m$ and the two families agree up to reordering, completing the proof.

Definition 32.3.6: Irreducible Decomposition

Let V be an algebraic set. Then the *irreducible decomposition of* V is

$$V = V_1 \cup \cdots V_n \quad V_i \not\subseteq V_j i \neq j$$

for appropriate algebraic varieties V_i, $1 \leq i \leq n$

32.3.7 Remark In a more general topological setting, it can be shown that if X is a Noetherian space (i.e. satisfies A.C.C. on open sets, so D.C.C. on closed sets), X can be decomposed into irreducible sets just liked was done in theorem 32.3.5. It then follows easily that any closed subset of X has this property too.

Example 32.3.8: Affine Varieties

1. All linear polynomials produce affine varieties. Thus, the study of linear algebra can be thought as the study of varieties with multiplicity 1.
2. $\mathcal{Z}(xy-1) \subseteq \mathbb{A}^2_{\mathbb{R}}$ is an affine variety, as $\mathbb{R}[x,y]/(xy-1) \cong \mathbb{R}[x, 1/x]$. Note that $xy-1$ has two branches, however the variety is still irreducible and connected in the Zariski topology. Show that there is no variety that is only one branch of $xy-1$ (show that if two affine varieties agree on an open subset, they agree everywhere).

The decomposition of a Noetherian variety into irreducible components has an algebraic mirror: the *primary decomposition* of ideals. The minimal primes over $I(X)$ are precisely the ideals of the irreducible components of X, while embedded primes record finer, scheme-theoretic information carried by the coordinate ring but invisible to the underlying set. The full theory (primary ideals, the Lasker-Noether existence and uniqueness theorems, and the associated primes of a module) is developed in [10]; we use it freely when passing between a variety and its coordinate ring.

Exercise 32.3.1

1. Show that an algebraic set is irreducible if and only if any two nonempty open subsets of it meet, and use this to give a second proof that $\mathbb{A}_k^n$ is irreducible.
2. Show that the intersection of two irreducible algebraic sets need not be irreducible. Hint: take $\mathcal{Z}(z)$ and $\mathcal{Z}(xy-z)$ in $\mathbb{A}_k^3$.
3. Show that the closure of an irreducible subset is irreducible, and that a nonempty open subset of an irreducible set is irreducible and dense.
4. Show that a Noetherian topological space is quasicompact, and that every subspace of one is Noetherian.
5. Let X be an algebraic set with irreducible decomposition $X = X_1 \cup \cdots \cup X_r$ as in theorem 32.3.5. Show that the X_i are exactly the maximal irreducible closed subsets of X, which is why the decomposition is unique.

32.4 Hilbert's Nullstellensatz

In this section, we shall make precise the correspondence between which ideals of the coordinate ring of an affine set correspond to closed subsets of the affine set. In this exploration, we shall also produce a new tower condition on ring extensions via Noether's Normalization theorem which builds upon the theme of separating an extension to "property" and "not property" (ex. separable and inseparable, algebraic and transcendental[2]) Recall if $a_1, a_2, ..., a_n \in S$ for a k-algebra S, these elements are called *algebraically independent* if

$$k[x_1, x_2, ..., x_n] \to k[a_1, a_2, ..., a_n] \qquad x_i \mapsto a_i$$

is an isomorphism. Noether's Normalization theorem is the generalization of the idea that any field extension can be split into a transcendental extension, followed by an algebraic extension:

Theorem 32.4.1: Noether's Normalization Theorem

Let k be a field and suppose that $A = k[r_1, ..., r_n]$ is a finitely generated k-algebra. Then for some q, $0 \le q \le n$, there are algebraically independent elements $y_1, y_2, ..., y_q \in A$ such that A is integral over $k[y_1, y_2, ..., y_q]$

***Proof*:**
Induct on the number n of generators. If $n = 0$ then $A = k$ and there is nothing to prove, so let $n \ge 1$ and assume the theorem for k-algebras on fewer than n generators.

Step 1: the independent case. If $r_1, \ldots, r_n$ are algebraically independent then A is integral over itself and we may take $q = n$ and $y_i = r_i$. So assume they are algebraically dependent: there is a nonzero $f \in k[x_1, \ldots, x_n]$ with $f(r_1, \ldots, r_n) = 0$. Write d for the total degree of f, where a monomial $ax_1^{m_1} \cdots x_n^{m_n}$ has degree $m_1 + \cdots + m_n$ and $\deg f$ is the largest degree occurring.

Step 2: a change of variables making f monic in x_n. Set $\alpha_i = (1+d)^i$ for $1 \le i \le n-1$, introduce new variables $X_i = x_i - x_n^{\alpha_i}$, and define

$$g(X_1, \ldots, X_{n-1}, x_n) = f(X_1 + x_n^{\alpha_1}, \ldots, X_{n-1} + x_n^{\alpha_{n-1}}, x_n)$$

[2]Another such example will appear in the next chapter, and shall be ramified and unramified

so $g \in k[X_1, \ldots, X_{n-1}, x_n]$. A monomial $ax_1^{m_1} \cdots x_n^{m_n}$ of f contributes to g a single term in which the X_i do not appear, namely $a\, x_n^e$ with

$$e = m_n + m_1\alpha_1 + \cdots + m_{n-1}\alpha_{n-1} = m_n + m_1(1+d) + \cdots + m_{n-1}(1+d)^{n-1}$$

every other term carries at least one X_i. Since each $m_i \leq d < 1+d$, the tuple $(m_n, m_1, \ldots, m_{n-1})$ is the base-$(1+d)$ expansion of e, so distinct monomials of f give distinct e. Hence the largest such e, call it N, is attained exactly once, and

$$g = cx_n^N + \sum_{i=0}^{N-1} h_i(X_1, \ldots, X_{n-1})x_n^i$$

for some nonzero $c \in k$: after dividing by c, g is monic in x_n over $k[X_1, \ldots, X_{n-1}]$.

Step 3: descending one generator. Put $s_i = r_i - r_n^{\alpha_i}$ and $B = k[s_1, \ldots, s_{n-1}] \subseteq A$. Substituting $X_i \mapsto s_i$ and $x_n \mapsto r_n$ in g recovers $f(r_1, \ldots, r_n) = 0$, so

$$\frac{1}{c} g(s_1, \ldots, s_{n-1}, r_n) = 0$$

exhibits r_n as a root of a monic polynomial over B; thus r_n is integral over B. Each remaining $r_i = s_i + r_n^{\alpha_i}$ lies in $B[r_n]$, so $A = B[r_n]$, and A is integral over B because it is generated over B by the single integral element r_n.

Step 4: induction. B is a k-algebra generated by the $n-1$ elements $s_1, \ldots, s_{n-1}$, so by the inductive hypothesis there are algebraically independent $y_1, \ldots, y_q \in B$ with B integral over $k[y_1, \ldots, y_q]$. Integrality is transitive, so A is integral over $k[y_1, \ldots, y_q]$, and $q \leq n-1 \leq n$, as we sought to show.

Noether's Normalization can be thought of as a very geometric result: we shall see that any finitely generated k-algebra shall be an n-dimensional affine set along with some extra important information given by the integral extension, more on this in chapter 34. One very important is that if we have an extension F/k that is a finite-type k-algebra, is finitely generated if we allow for both addition and multiplication, it is finitely gendered by *just* allowing addition!!

Theorem 32.4.2: Zariski's Lemma

Let F/k be a field extension, and assume F is a finite-type k-algebra. Then F/k is a finite (and hence algebraic) extension.

***Proof*:**
Since F is a finite-type k-algebra, $F = k[r_1, r_2, ..., r_n]$. By Noether's Normalization Theorem, there exists a $q \in \mathbb{N}$ (possibly 0) enumerating variables $y_1, ..., y_q \in F$ such that F is integral over $k[y_1, y_2, ..., y_q]$, i.e. F is a finitely generated $k[y_1, ..., y_q]$-module. We can re-phrase this by saying we have a finite integral extension $F/k[y_1, y_2, ..., y_q]$. By proposition 26.1.8, since F is an integral domain, F is a field if and only if $k[y_1, y_2, ..., y_q]$ is a field. But then, $k[y_1, y_2, ..., y_q]$ is a field if and only if there are no indeterminate variables, i.e. $q = 0$. Thus, we get the finite integral extension F/k, which is equivalent to saying we get a finite field extension, as we sought to show.

The last two theorem's are true no matter what field we are working over. The following theorem requires k to be algebraically closed.

Theorem 32.4.3: Hilbert's Nullstellensatz - Weak Version

Let k be an algebraically closed field. Then M is a maximal ideal of the polynomial ring $k[x_1, ..., x_n]$ if and only if

$$M = (x_1 - a_1, x_2 - a_2, ..., x_n - a_n)$$

for any $a_1, a_2, ..., a_n \in k$. As a result, the maps:

$$\{\text{Points in } \mathbb{A}^n\} \underset{\mathcal{Z}}{\overset{\mathcal{I}}{\rightleftarrows}} \{\text{Maximal ideals in } \Gamma(\mathbb{A}^n)\}$$

are in bijective correspondence, and if $I \subseteq \Gamma(\mathbb{A}^n)$ is a proper ideal, then $\mathcal{Z}(I) \neq \emptyset$

***Proof*:**
Certainly, $(x_1 - a_1, ..., x_n - a_n)$ is a maximal ideal in $k[x_1, x_2, ..., x_n]$ since its quotient is k. Conversely, suppose M is a maximal ideal in $k[x_1, x_2, ..., x_n]$. Consider $F = k[x_1, x_2, ..., x_n]/M$. Then since $k \subseteq F$, F/k is a field extension that is also a finitely generated k-algebra (generated by $\overline{x_1}, ...\overline{x_n}$). By Zariski's lemma, F/k is a finite field extension, and hence is algebraic over k.

Now, we take advantage of the fact that k is algebraically closed, meaning there does not exist a non-trivial algebraic extension of k (lemma 19.5.2), implying that $F \cong_k k$, in particular we $\overline{x_i} \mapsto a_i$ for some $a_i \in k$. Thus, this is a k-algebra homomorphism, and $\overline{a_i} \in F$, $\overline{x_i - a_i} \mapsto a_i - a_i = 0$, which since the to fields are isomorphic, they are in bijective correspondence, implying $\overline{x_i - a_i} = \overline{0}$, i.e. $x_i - a_i \in M$. Thus, we must have $x_i - a_i \in M$ for every x_i, implying that $(x_1 - a_1, ..., x_n - a_n) \subseteq M$, which by maximality shows that $(x_1 - a_1, ..., x_n - a_n) = M$.

As a consequence, if I is any ideal of $k[x_1, x_2, ..., x_n]$, then $I \subseteq M$ for some maximal ideal M. By what we've just shown, for some $a_1, ..., a_n$, $M = (x_1 - a_1, ..., x_n - a_n)$. Thus, $(a_1, ..., a_n) \in \mathcal{Z}(I)$, showing that $\mathcal{Z}(I)$ is non-empty.

Theorem 32.4.4: Hilbert's Nullstellensatz

Let k be an algebraically closed field. Then for any ideal $I \subseteq k[x_1, x_2, ..., x_n]$,

$$\mathcal{I}(\mathcal{Z}(I)) = \sqrt{I} = \text{rad}(I)$$

Furthermore, the maps $\mathcal{I}$ and $\mathcal{Z}$ are order-reversing bijections:

$$\left\{\begin{matrix}\text{Algebraic Sets} \\ (= \text{closed sets})\end{matrix}\right\} \underset{\mathcal{Z}}{\overset{\mathcal{I}}{\rightleftarrows}} \{\text{Radical Ideals}\}$$

Under this bijection the *irreducible* algebraic sets, that is the affine varieties, correspond to the *prime* ideals, and the points to the maximal ideals.

Example 32.4.5: The Nullstellensatz in Practice

1. *Radicals are unavoidable.* In $k[x]$ take $I = (x^2)$. Then $\mathcal{Z}(I) = \{0\}$ and $\mathcal{I}(\{0\}) = (x)$, so
$$\mathcal{I}(\mathcal{Z}(I)) = (x) = \sqrt{(x^2)} \neq (x^2)$$
The theorem recovers $\sqrt{I}$ and nothing finer: passing to zero sets forgets multiplicity, which is the observation chapter 42 has to work around.

2. *A two-variable case.* Let $I = (x^2, xy) \subseteq k[x, y]$. Then $\mathcal{Z}(I) = \mathcal{Z}(x)$, the y-axis, so $\mathcal{I}(\mathcal{Z}(I)) = (x)$. Directly, $\sqrt{I} = (x)$ as well: $x^2 \in I$ gives $x \in \sqrt{I}$, and conversely every element of I is divisible by x.

3. *Algebraic closure is essential.* Over $\mathbb{R}$ take $I = (x^2 + 1) \subseteq \mathbb{R}[x]$. Then $\mathcal{Z}(I) = \emptyset$, so $\mathcal{I}(\mathcal{Z}(I)) = \mathbb{R}[x] = (1)$, while $\sqrt{I} = (x^2 + 1)$ because $(x^2 + 1)$ is maximal. The two differ, and the theorem fails. Over $\mathbb{C}$ the zero set is $\{\pm i\}$ and $\mathcal{I}(\{\pm i\}) = (x^2 + 1) = \sqrt{I}$ as promised.

4. *The bijection at work.* Under theorem 32.4.4 the maximal ideal $(x - a, y - b)$ corresponds to the point (a, b), the prime $(y - x^2)$ to the parabola, and the ideal $(y^2 - x^4) = \big((y - x^2)(y + x^2)\big)$ to the union of two parabolas. That ideal is already radical, being an intersection of the two primes $(y - x^2)$ and $(y + x^2)$, and reducibility of the zero set corresponds to the ideal failing to be prime rather than failing to be radical.

The refinement matters, and mixing the three levels up is the standard way to misread the theorem. An algebraic set is closed and corresponds to a radical ideal; it is a variety exactly when that radical ideal is prime (proposition 32.3.3); and it is a point exactly when the ideal is maximal (theorem 32.4.3). Every prime is radical, so the varieties sit inside the algebraic sets on one side just as the primes sit inside the radicals on the other, and the bijection restricts.

***Proof*:**
First, we've already shown that $\mathrm{rad}(I) \subseteq \mathcal{I}(\mathcal{Z}(I))$ (proposition 32.2.7), so it remains to show that $\mathrm{rad}(I) \supseteq \mathcal{I}(\mathcal{Z}(I))$. By Hilbert's basis theorem, we have that $I = (f_1, f_2, ..., f_n)$. Let $g \in \mathcal{I}(\mathcal{Z}(I))$. If we show that $g^N \in I$ for some $N \in \mathbb{N}_{>0}$, this would imply $g \in \mathrm{rad}(I)$. To that end, we employ the following trick known as the Rabinowitsch trick: introduce a new variable x_{n+1} and consider the ideal:
$$(f_1, ..., f_n, x_{n+1}g - 1) = I' \subseteq k[x_1, ..., x_n, x_{n+1}]$$
By definition of g, at any point where each $f_1, f_2, ..., f_n$ vanish, g also vanishes (since $g \in \mathcal{I}(\mathcal{Z}(I))$). But then, $x_{n+1}g - 1$ is nonzero! Thus, $\mathcal{Z}(I') = \emptyset$ in $\mathbb{A}^{n+1}$, and by Hilbert's weak Nullstellensatz, I' cannot be a proper ideal, and so $1 \in I'$. Since $1 \in I'$, we can write it as:
$$1 = a_1 f_1 + \cdots + a_n f_n + a_{n+1}(x_{n+1}g - 1) \qquad a_i \in k[x_1, ..., x_{n+1}]$$
For the following steps, it is insightful to expand the equation:
$$1 = \sum_i^n a_i(x_1, ..., x_{n+1}) f_1(x_1, ..., x_n) + a_{n+1}(x_1, ..., x_{n+1})(x_{n+1}g(x_1, ..., x_n) - 1)$$
Now, since x_{n+1} is a free variable, this equation still holds true if we substitute x_{n+1} for another expression (it will simply limit the equation to solution which also satisfy the substituted expression). We wil choose $x_{n+1} = 1/g(x_1, ..., x_n)$ so we get the following expression in

$k(x_1, ..., x_n)$:

$$1 = \sum_i^n a_i \left(x_1, ..., x_n, \frac{1}{g(x_1, ...x_n)} \right) f_i(x_1, ..., x_n)$$

Importantly for us, the only terms in the denominator would be some powers of $g(x_1, ..., x_n)$. Thus, for suitably large $N \in \mathbb{N}$, we may re-write the right hand side as:

$$1 = \sum_i^n \frac{b_i\,(x_1, ..., x_n)\, f_i(x_1, ..., x_n)}{g(x_1, ..., x_n)^N}$$

for suitable $b_1, ..., b_n \in k[x_1, ..., x_n]$. Multiplying both sides by the denominator gives

$$g(x_1, ..., x_n)^N = \sum_i^n b_i(x_1, ..., x_n) f_i(x_1, ..., x_n)$$

an identity between polynomials, so it holds in $k[x_1, \dots, x_n]$ and not just in the fraction field. The right hand side lies in I, so $g^N \in I$ and therefore $g \in \mathrm{rad}(I)$. As g was arbitrary, $\mathcal{I}(\mathcal{Z}(I)) \subseteq \mathrm{rad}(I)$, and with the reverse inclusion already in hand, $\mathcal{I}(\mathcal{Z}(I)) = \mathrm{rad}(I)$.

It remains to see that the two maps are mutually inverse bijections between algebraic sets and radical ideals. If I is radical then $\mathcal{I}(\mathcal{Z}(I)) = \mathrm{rad}(I) = I$, which is one composite. For the other, let A be an algebraic set, say $A = \mathcal{Z}(J)$. Then $\mathcal{Z}(\mathcal{I}(A)) = A$ by proposition 31.2.11(2). Finally $\mathcal{I}(A)$ really is radical: if $f^m \in \mathcal{I}(A)$ then $f(a)^m = 0$ for every $a \in A$, and k is a field, so $f(a) = 0$ and $f \in \mathcal{I}(A)$. Hence the maps are inverse to each other, and both reverse inclusion by proposition 31.2.5 and proposition 31.2.10.

For the refinement, $\mathcal{I}(A)$ is prime if and only if A is irreducible (proposition 32.3.3), and maximal if and only if A is a point (theorem 32.4.3), so the bijection restricts to varieties against primes and to points against maximal ideals, as we sought to show.

Corollary 32.4.6: Nullstellensatz in Algebraic Closure

Let k be any field with algebraic closure $\overline{k}$, and $I \subseteq k[x_1, ..., x_n]$ an ideal. Then:

$$\mathcal{I}_k(\mathcal{Z}_{\overline{k}}(I)) = \sqrt{I}$$

As a particular result, $I = (1)$ if and only if the polynomials in I have no common zero in $\overline{k}^n$.

***Proof*:**
Let $I^e = I\overline{k}[x_1, \dots, x_n]$ be the extension of I to the algebraic closure. Since $\overline{k}$ is algebraically closed, theorem 32.4.4 applies there and gives $\mathcal{I}_{\overline{k}}(\mathcal{Z}_{\overline{k}}(I)) = \sqrt{I^e}$. Intersecting both sides with $k[x_1, \dots, x_n]$, the left hand side becomes $\mathcal{I}_k(\mathcal{Z}_{\overline{k}}(I))$ by definition. For the right hand side, $\sqrt{I^e} \cap k[x_1, \dots, x_n] = \sqrt{I}$: the inclusion $\supseteq$ is immediate, and for $\subseteq$, if $f \in k[x_1, \dots, x_n]$ has $f^m \in I^e$ then writing f^m as an $\overline{k}$-combination of generators of I and comparing coefficients against a k-basis of $\overline{k}$ exhibits f^m as a k-combination of them, so $f^m \in I$.

For the last claim, $\mathcal{Z}_{\overline{k}}(I) = \emptyset$ gives $\mathcal{I}_k(\emptyset) = k[x_1, \dots, x_n]$, so $\sqrt{I} = (1)$ and hence $I = (1)$; the converse is immediate, as we sought to show.

32.5 The Dictionary

With these results established, let us recap all the algebraic/geometric correspondences and prove some more. There are some immediate consequence of these result. An immediate easy result is that it can finally be concluded that:

$$\mathcal{I}(A \cap B) = \sqrt{\mathcal{I}(A) + \mathcal{I}(B)}$$

Next, we now have made precise the relation between radical ideals and prime ideals, as we have fully geometrically classified radical and prime ideals. Next, we get the following dictionary between the language of geometry and the language of algebra:

Geometry	Algebra
Affine sets V	coordinate rings $k[V]$
points of V	maximal ideals of $k[V]$
closed subsets of V	radical ideals of $k[V]$
sub-varieties of V	prime ideals of $k[V]$
regular function: $\varphi : V \to W$	k-algebra homomorphism $\tilde{\varphi} : k[W] \to k[V]$

This dictionary is expanded throughout the rest of the book. As a teaser, we shall show that all PID's correspond to smooth curves (see section 50.7).

Now that we have established this definition between algebraic sets and it's algebraic counter-part, we can expand some more on the Zariski Topology:

Proposition 32.5.1: Zariski Topology is Compact

Let $\mathbb{A}^n_k$ have the Zariski topology. Then $\mathbb{A}^n_k$ is compact

***Proof*:**
Let $\mathcal{O}$ index an open cover for $\mathbb{A}^n_k$

$$\mathbb{A}^n_k = \bigcup_{\alpha\ \in \mathcal{O}} U_\alpha$$

By proposition 31.3.4, any open set is the union of sets of the form $D(f)$, so we may re-write this as:

$$\mathbb{A}^n_k = \bigcup_{\alpha \in \mathcal{O}'} D(f_\alpha)$$

appropriately re-indexing. Then taking the complement, we get that it's equivalent that:

$$\emptyset = \bigcap_{\alpha \in \mathcal{O}'} \mathcal{Z}(f_\alpha) = \mathcal{Z}\left(\sum_{\alpha \in \mathcal{O}'} (f_\alpha)\right)$$

By the Nullstellensatz, we get that it's equivalent that

$$1 \in \sum_{\alpha \in \mathcal{O}'} (f_\alpha)$$

Thus, for appropriate coefficients $g_i \in \Gamma(\mathbb{A}^n)$, not necessarily constants, it is equivalent that:

$$1 = g_1 f_1 + \cdots + g_n f_n \in (f_1, ..., f_n) = \sum_{i=1}^{n} (f_i)$$

But then

$$\emptyset = \bigcap_{i=1}^{n} \mathcal{Z}(f_i) \quad \Leftrightarrow \quad \mathbb{A}_k^n = \bigcup_{i=1}^{n} D(f_i)$$

so finitely many of the $D(f_\alpha)$ already cover $\mathbb{A}_k^n$, as we sought to show.

Recall that for any algebraic subset $V \subseteq \mathbb{A}_k^n$, the corresponding coordinate ring $k[V]$ is used to define the subspace topology. Using the Nullstellensatz, we may deduce that it cannot have nilpotent elements:

Corollary 32.5.2: Coordinate Ring Always Reduced

Let $V \subseteq \mathbb{A}_k^n$. be an algebraic subset and $k[V]$ the associated coordinate ring. Then $k[V]$ is has no nilpotent elements

***Proof*:**
Since $k[V] = k[x_1, x_2, ..., x_n]/I(V)$, and $I(V)$ is a radical ideal by the Nullstellensatz, the quotient cannot contain any nilpotent elements, as we sought to show.

Corollary 32.5.3: Nullstellensatz For Subspaces

Let $V \subseteq \mathbb{A}_k^n$ be an algebraic subset (i.e. a closed subset) with corresponding coordinate ring $k[V]$. Then we can define $\mathcal{Z}$ and $\mathcal{I}$ as:

$$\left\{ \begin{matrix} \text{affine algebraic subsets} \\ \text{of } V \end{matrix} \right\} \underset{\mathcal{Z}}{\overset{\mathcal{I}}{\rightleftarrows}} \left\{ \begin{matrix} \text{Radical Ideals} \\ \text{of } k[V] \end{matrix} \right\}$$

***Proof*:**
Write $\pi \colon \Gamma(\mathbb{A}_k^n) \to k[V]$ for the quotient by $\mathcal{I}(V)$. The correspondence theorem for rings makes $J \mapsto \pi^{-1}(J)$ a bijection between the ideals of $k[V]$ and the ideals of $\Gamma(\mathbb{A}_k^n)$ containing $\mathcal{I}(V)$, and it preserves radicals in both directions: $\pi^{-1}(\sqrt{J}) = \sqrt{\pi^{-1}(J)}$, since $f^m \in \pi^{-1}(J)$ says exactly $\pi(f)^m \in J$. So the radical ideals of $k[V]$ correspond to the radical ideals of $\Gamma(\mathbb{A}_k^n)$ containing $\mathcal{I}(V)$.

On the geometric side, the algebraic subsets of V are precisely the algebraic subsets of $\mathbb{A}_k^n$ contained in V, and $\mathcal{Z}$ reverses inclusion, so those correspond to the ideals containing $\mathcal{I}(V)$. Composing with theorem 32.4.4, which matches algebraic subsets of $\mathbb{A}_k^n$ against radical ideals of

$\Gamma(\mathbb{A}^n_k)$, gives the stated bijection, as we sought to show.

Next, sticking to the case where $k = \overline{k}$ is algebraically closed, from this section we can deduce that any coordinate ring is finitely generated, nilpotent-free (i.e. reduced) and is a k-algebra over an algebraically closed field. We can show that all such rings appear as coordinate rings for an affine set.

We first have the following:

Definition 32.5.4: Reduced Ring

Let R be a ring. Then R is said to be *reduced* if $x^n = 0$ implies $x = 0$

(finish here)

Proposition 32.5.5: Coordinate Ring Correspondence

Let R be a ring. Then if R is:

1. Finitely generated
2. Reduced
3. over an algebraically closed field

then R is isomorphic to a coordinate ring for an appropriate dimension n of $\mathbb{A}^n_{\overline{k}}$ and $\mathcal{Z}(S) \subseteq \mathbb{A}^n_{\overline{k}}$.

***Proof*:**
Write $R = \overline{k}[t_1, \ldots, t_n]$ for a choice of finitely many generators, and let

$$\pi\colon \overline{k}[x_1, \ldots, x_n] \to R \qquad x_i \mapsto t_i$$

be the resulting surjection of $\overline{k}$-algebras, with $I = \ker \pi$, so that $R \cong \overline{k}[x_1, \ldots, x_n]/I$. Since R is reduced, I is a radical ideal: if $f^m \in I$ then $\pi(f)^m = 0$ in R, so $\pi(f) = 0$ and $f \in I$.

Set $V = \mathcal{Z}(I) \subseteq \mathbb{A}^n_{\overline{k}}$. By theorem 32.4.4 the ground field being algebraically closed gives $\mathcal{I}(V) = \mathcal{I}(\mathcal{Z}(I)) = \sqrt{I} = I$. Therefore

$$\Gamma(V) = \frac{\overline{k}[x_1, \ldots, x_n]}{\mathcal{I}(V)} = \frac{\overline{k}[x_1, \ldots, x_n]}{I} \cong R$$

so R is the coordinate ring of the algebraic set V, as we sought to show.

Notice that through this result, we can define an affine set without the reference of an ambient space, similar to how we may define a manifold without the need an ambient embedding space. This idea is greatly generalized by scheme theory, which chapter 49 points the reader toward.

Exercise 32.5.1

1. Deduce the strong Nullstellensatz from the weak one by the Rabinowitsch trick: given f vanishing on $\mathcal{Z}(I)$, apply the weak form to the ideal generated by I and $1 - yf$ in one extra variable y.

2. Show that every maximal ideal of $k[x_1, \ldots, x_n]$ is $(x_1 - a_1, \ldots, x_n - a_n)$ for a unique point $(a_1, \ldots, a_n)$, and explain why this fails over $\mathbb{R}$.
3. Show that the Nullstellensatz fails over a field that is not algebraically closed, by computing $\mathcal{I}(\mathcal{Z}(x^2 + 1))$ in $\mathbb{R}[x]$ and comparing with $\sqrt{(x^2 + 1)}$.
4. Show that $\mathcal{Z}$ and $\mathcal{I}$ are mutually inverse inclusion-reversing bijections between the radical ideals of $k[x_1, \ldots, x_n]$ and the algebraic subsets of $\mathbb{A}^n_k$, and that under this correspondence prime ideals match irreducible sets.
5. Use corollary 32.4.6 to show that a system of polynomials over $\mathbb{Q}$ with no common zero in $\overline{\mathbb{Q}}$ generates the unit ideal, and contrast this with $x^2 + 1$ over $\mathbb{R}$, which has no real zero yet generates a proper ideal. What exactly does the closure give?

33

Rational Maps and Birational Classification

Isomorphism is a demanding relation between varieties, and the classification problem it poses is largely intractable. Weakening it produces a relation that can be classified: two varieties are birationally equivalent when they agree on a dense open set. Algebraically this replaces the coordinate ring by its field of fractions, and fields of transcendence degree d are far simpler objects than finitely generated reduced algebras.

The price is that the maps involved are no longer defined everywhere. This chapter pays that price carefully: it locates the domain of definition of a rational function, shows the domain is always dense, and then proves that every variety is birationally equivalent to a hypersurface.

33.1 Rational Functions and the Function Field

Let V be a variety and $k = \overline{k}$ be an algebraically closed field. In this section, we take advantage of the fact that we may localize $k[x_1, ..., x_n]/\mathcal{I}(V)$. By Noether's Normalization Theorem (theorem 32.4.1) $k[V]/k$ is a finite transcendental extension followed by an integral extension. As $k[V]$ is an integral domain we may take its field of fractions $k(V)$, and passing to fraction fields in Noether normalization exhibits $k(V)$ as a *finite* extension of the purely transcendental field $k(y_1, \dots, y_q)$. The extension is genuinely finite and not an equality: for the cuspidal cubic $V = \mathcal{Z}(y^2 - x^3)$ we have $k[V] \cong k[t^2, t^3]$, integral over $k[x]$, while $k(V) = k(t)$ is a degree-two extension of $k(x) = k(t^2)$. Were $k(V)$ always purely transcendental every variety would be rational, which item (4) of example 33.3.8 disproves. What *is* intrinsic is q, the transcendence degree, which chapter 34 identifies with $\dim V$. Geometrically $k(V)$ shall represent all *rational polynomial functions*, or all rational polynomials functions defined on V. Note that we must be a bit more careful in interpreting elements of $k(V)$ as functions: if

$f/g \in k(V)$, then if $g(p) = 0$ for some $p \in V$ then we get the undefined $f(p)/g(p) = f(p)/0$. We shall address this soon.

Rational functions supply a weaker relation than isomorphism for classifying varieties. We shall see that being *birationally equivalent* is weaker than being a (regular) isomorphism, giving coarser isomorphism classes of varieties that shall give us more information about algebraic sets. As an example, elliptic curves[1] shall require three curve invariants to be classified (the genus, the j-invariant, and the Mordell-Weil group of the curve). However, up to birational map it shall only require the genus and we can without loss of generality work with smooth elliptic curves. Though coarser, it is nonetheless a powerful tool in gathering information about varieties.

Definition 33.1.1: Rational Functions

Let V be an affine variety. Then the fraction field of $k[V]$ is called the field of *rational function on* V, and is denoted $k(V)$. An element of $k(V)$ is called a *rational function*.

The *evaluation* of a rational function at p is defined whenever it admits a representative f/g with $g(p) \neq 0$. Two rational functions are equal if they agree at every point where both are defined. The points at which *no* representative has nonvanishing denominator form the *pole set*; being a pole is a property of the function, not of a chosen representative.

If $\varphi \in k(V)$, then $\varphi = \frac{f}{g}$ where $g \notin I(V)$ (or else the denominator would be the zero function, contradicting the construction of the field of fractions). We shall say that two rational polynomial f/g and f'/g' represent the same rational function if and only if $fg' - f'g \in I(V)$. Note that if $k[V]$ is not a UFD, then there can be representatives of $k(V)$ which are not equivalent up to a unit:

Example 33.1.2: Not UFD, Different Polynomial Representatives

Let $V = \mathcal{Z}(xw - yz) \subseteq \mathbb{A}^4_k$. Show that:

$$\frac{\overline{x}}{\overline{y}} = \frac{\overline{z}}{\overline{w}} = f \in k(V)$$

if $y \neq 0$ or $w \neq 0$.

Another way of constructing $k(V)$ is the following: take the collection

$$\mathcal{O}_V = \{\varphi = f/g \in k(x_1, ..., x_n) \mid g \notin I(V)\}$$

then take the subset $\mathfrak{m}_V = \{\varphi = f/g \in \mathcal{O}_V \mid f \in I(V)\}$. This is the unique maximal ideal of the local ring $\mathcal{O}_V$, and

$$k(V) \cong \mathcal{O}_V/\mathfrak{m}_V$$

since a rational function on V is a ratio f/g of polynomials with $g \notin I(V)$, taken up to the relation that identifies two such ratios agreeing on V, and that relation is exactly congruence modulo $\mathfrak{m}_V$. This shall become the dominant way of interpreting the set of rational functions when working with quasi-projective varieties (see section 39.4)[2].

[1] for those familiar with complex geometry, genus 1 curves

[2] In Scheme theory, this shall be the rational functions at the point (closed or non-closed) associated to X

33.2 Domains of Definition and Local Rings

A key difference between regular and rational functions is that a rational function need not be defined at every point. In fact, it *has* to be the case that a rational function is not defined on a finite set of points for it to not be equivalent to a regular function (when working over an algebraically closed field). To see this, consider the following definition:

Definition 33.2.1: Regular Point

Let $\varphi \in k(X)$ be a rational function. Then a *regular point* at $x \in X$ is a point where we can represent φ as f/g, $\varphi(x) = f(x)/g(x)$, and $g(x) \neq 0$. In this case, the element $f(x)/g(x)$ in k is called the *value* of φ at x and is denoted $\varphi(x)$

For example, take $\varphi = 1/x$ on $\mathbb{A}^1_k$. Then all points except 0 are regular points. If $\varphi = f/g$ is regular at a point x, then it is regular in an open neighborhood of X, namely the neighborhood $D(g) \cap X$. Some authors put that a rational function is regular at a point if it is regular in an open neighborhood.

Proposition 33.2.2: Regular at All Points, then Regular

Let $\varphi \in k(X)$ be a rational function that is regular at all points. Then φ is a regular function

***Proof*:**
Let $\varphi \in k(X)$ be a rational function that is regular at every point. Then for each $x \in X$, we can represent φ as f_x/g_x. Take $\mathfrak{a} = (g_x)_{x\in X}$. Then as $k[X]$ is Noetherian, this is a finitely generated ideal:

$$\mathfrak{a} = (g_{x_1}, \dots, g_{x_n})$$

Note that the g_{x_i} have no common zero in X: at any $x \in X$ the chosen g_x satisfies $g_x(x) \neq 0$, and $g_x \in \mathfrak{a}$. So $\mathcal{Z}(\mathfrak{a}) = \emptyset$ in X, and the weak Nullstellensatz (theorem 32.4.3) applied in $k[X]$ forces

$$\mathfrak{a} = (1)$$

In particular, there exist $u_i \in k[X]$ such that

$$\sum_{i=1}^{n} u_i g_i = 1$$

The key point is that $\varphi = f_i/g_i$ is an identity in the field $k(X)$, so $\varphi g_i = f_i$ holds globally, not just on the neighbourhood where g_i is nonzero. Multiplying the displayed identity by φ therefore gives

$$\varphi = \varphi \cdot 1 = \sum_{i=1}^{n} u_i(\varphi g_i) = \sum_{i=1}^{n} u_i f_i$$

whose right hand side lies in $k[X]$, so φ is regular, completing the proof.

The Nullstellensatz is essential for the proof, i.e. that k is an algebraically closed field, or else this result is false!

Example 33.2.3: Rational Function That is Regular

the function
$$\frac{x}{x+100}$$
is regular on $\mathcal{Z}(x^2+y^2-1) \subseteq \mathbb{A}^2_{\mathbb{R}}$ even though it is not a polynomial: there does not exist a point (x, y) satisfying x^2+y^2-1 such that $x+100=0$ namely since all points x where $x^2+y^2-1=0$ must be within $[-1, 1]$[a]

[a] This failure is *not* present when working with the scheme $\operatorname{Spec} \mathbb{R}[x,y]/(x^2+y^2-1)$ as $x+100$ has a zero at the prime ideal $(x-100, y^2+9999)$, and so this "anomaly" is present if we don't work in the right context

Hence we always have points on which a rational function is not defined. This set of points will always be dense:

Lemma 33.2.4: Domain of Definition

Let $\varphi \in k(V)$ be a rational function. Then set of regular points is non-empty, open and dense.

***Proof*:**
Let $\varphi = f/g$ and take $U = \{p \in V \mid g(p) \neq 0\} = D(g) \cap V$. Then in V, this set is certainly open, and as g is not the zero function there is certainly at least one point $p \in V$ such that $g(p) \neq 0$.

To show U is dense, let $O \subseteq V$ be any nonempty open set; it suffices to show $U \cap O \neq \emptyset$. Suppose instead $U \cap O = \emptyset$. Then
$$V = (U \cap O)^c = U^c \cup O^c$$
writes V as a union of two closed sets, and both are *proper*: $U^c \neq V$ because $U \neq \emptyset$, and $O^c \neq V$ because $O \neq \emptyset$. That contradicts the irreducibility of V. Hence U meets every nonempty open set, which is density, completing the proof.

Definition 33.2.5: Domain of Definition

Let $\varphi \in k(V)$ a rational function. Then the set of regular point is called the *domain of definition*.

Corollary 33.2.6: Collection of Rational Points

Let $\varphi_1, ..., \varphi_n \in k(X)$ be rational functions on a variety X. Then their common domain of definition is open, non-empty, and dense.

***Proof*:**
Let U_i be the domain of definition of φ_i, which by lemma 33.2.4 is open, nonempty and dense. A finite intersection of open sets is open, so $\bigcap_i U_i$ is open.

For nonemptiness and density it is enough to show that $\bigcap_i U_i$ meets every nonempty open $O \subseteq X$, and by induction it suffices to treat $n = 2$. Given nonempty open O, density of U_1 gives $U_1 \cap O \neq \emptyset$, and $U_1 \cap O$ is open, so density of U_2 gives $U_2 \cap (U_1 \cap O) \neq \emptyset$. Hence $U_1 \cap U_2$ meets O. Taking $O = X$ gives nonemptiness, as we sought to show.

In fact, as the open sets in the Zariski topology are "huge", it suffices to define a rational mapping on any open subset:

Proposition 33.2.7: Suffice To Define On Open Set

Let $\varphi \in k(X)$ be a rational function. Then if φ is specified on some non-empty open subset $U \subseteq X$, then there is a unique extension of φ to all of X.

***Proof*:**
Take $\varphi \in k(X)$. If $\varphi = 0$, there is nothing to prove, so assume $\varphi \neq 0$. Say we specify what φ is on an open non-empty subset $U \subseteq X$, call this function $\varphi|_U$. Then let's say that φ' is a rational function where φ' on U is equal to $\varphi|_U$ (where a-priori it is unknown where there is a unique extension, and hence it may be another function). Consider $\varphi - \varphi' = \varphi''$. On U, this function is identically 0. Take the representative $\varphi'' = f/g$ on U so that $f = 0$. Then take $X_1 \subseteq X$ given by $f = 0$. This is not all of X as $\varphi \neq 0$, however we then have $X_1 \cup (X \setminus U) = X$ where both are proper subsets, contradicting irreducibility of X, completing the proof.

We are often interested in all the functions that are defined at a particular point, namely since geometrically much of the information of an object is given by collections of functions at every point (the reader familiar with differential geometry should be thinking of germs). To that end, we box the following

Definition 33.2.8: Stalk At A Point

Let V be an affine variety and $p \in V$. Then $\mathcal{O}_p(V) \subseteq k(V)$ is the collection of rational functions:

$$\mathcal{O}_p(V) = \{f/g \in k(V) \mid g(p) \neq 0\}$$

Proposition 33.2.9: Regular Functions and Stalk

$$k[V] = \bigcap_{p \in V} \mathcal{O}_p(V)$$

***Proof*:**
Certainly $k[V] \subseteq \mathcal{O}_p(V)$ for all $p \in V$ so $k[V] \subseteq \bigcap_{p \in V} \mathcal{O}_p(V)$.

For the converse, fix $\varphi \in \bigcap_{p \in V} \mathcal{O}_p(V)$ and consider its *ideal of denominators*

$$\mathfrak{d}_\varphi = \{h \in k[V] \mid h\varphi \in k[V]\}$$

This is an ideal: it is closed under addition, and if $h\varphi \in k[V]$ then $(ah)\varphi = a(h\varphi) \in k[V]$ for any $a \in k[V]$. Its zero set is exactly the pole set of φ. Indeed, if $p \notin \mathcal{Z}(\mathfrak{d}_\varphi)$ then some $h \in \mathfrak{d}_\varphi$ has $h(p) \neq 0$, and writing $\varphi = (h\varphi)/h$ exhibits a representative with nonvanishing denominator at p, so φ is regular at p; conversely a representative u/v with $v(p) \neq 0$ puts v in $\mathfrak{d}_\varphi$ with $v(p) \neq 0$, so $p \notin \mathcal{Z}(\mathfrak{d}_\varphi)$. In particular the pole set is closed.

Now φ lies in every $\mathcal{O}_p(V)$, so it is regular at every point and its pole set is empty, that is $\mathcal{Z}(\mathfrak{d}_\varphi) = \emptyset$. Lifting $\mathfrak{d}_\varphi$ to $k[x_1, \ldots, x_n]$ and applying the Nullstellensatz (theorem 32.4.3) gives

$\mathfrak{d}_\varphi = k[V]$, so $1 \in \mathfrak{d}_\varphi$ and therefore
$$\varphi = 1 \cdot \varphi \in k[V]$$
as we sought to show.

Proposition 33.2.10: Stalks Are Local Noetherian Domains

let V be a variety and $p \in V$. Then $\mathcal{O}_p(V)$ is a local Noetherian domain

***Proof*:**
Domain. $\mathcal{O}_p(V)$ is by construction a subring of the field $k(V)$, and a subring of a field has no zero divisors.

Local. Put
$$\mathfrak{m}_p = \{f/g \in \mathcal{O}_p(V) \mid f(p) = 0\}$$
This is the kernel of the evaluation map $\mathrm{ev}_p \colon \mathcal{O}_p(V) \to k$, $f/g \mapsto f(p)/g(p)$, which is well defined precisely because $g(p) \neq 0$ and is a surjective ring homomorphism; so $\mathfrak{m}_p$ is an ideal with $\mathcal{O}_p(V)/\mathfrak{m}_p \cong k$, hence maximal. Every element outside $\mathfrak{m}_p$ is a unit: if $f/g \in \mathcal{O}_p(V)$ has $f(p) \neq 0$ then g/f again has nonvanishing denominator at p, so it lies in $\mathcal{O}_p(V)$ and inverts f/g. A proper ideal contains no unit, so it is contained in $\mathfrak{m}_p$; thus $\mathfrak{m}_p$ is the unique maximal ideal and $\mathcal{O}_p(V)$ is local.

Noetherian. $\mathcal{O}_p(V)$ is the localization of $k[V]$ at the prime $\mathcal{I}(p)$, and $k[V]$ is Noetherian as a quotient of the Noetherian ring $\Gamma(\mathbb{A}^n)$. A localization of a Noetherian ring is Noetherian, since every ideal of $S^{-1}R$ is the extension of its contraction to R, and extension carries a finite generating set to a finite generating set. Hence $\mathcal{O}_p(V)$ is Noetherian, completing the proof.

In section 35.1, we shall see that when V is a curve and $\mathcal{O}_p(V)$ is a *discrete valuation ring*, then V is *smooth* at p. This requires a lot of build-up, and so we shall leave stalks alone for now.

33.3 Rational and Birational Maps

Let us now generalize regular maps:

Definition 33.3.1: Rational Map

Let X be a variety and $Y \subseteq \mathbb{A}^m_k$ a variety. A *rational mapping* $\varphi \colon X \dashrightarrow Y$ is a tuple
$$\varphi = (\varphi_1, ..., \varphi_m) \qquad \varphi_i \in k(X)$$
of rational functions such that $(\varphi_1(x), \dots, \varphi_m(x)) \in Y$ for every x in the common domain of definition of the φ_i, which by corollary 33.2.6 is a dense open subset of X. A rational mapping all of whose components happen to be regular is exactly a regular map.

Example 33.3.2: Rational Maps

1. *The circle, parameterized.* Let $C = \mathcal{Z}(x^2 + y^2 - 1) \subseteq \mathbb{A}_k^2$ and consider
$$\varphi\colon C \dashrightarrow \mathbb{A}_k^1 \qquad \varphi(x,y) = \frac{y}{1-x}$$
This is a rational map, its single component lying in $k(C)$. It is undefined where $1-x$ vanishes on C, that is at the point $(1,0)$, and defined on the dense open complement. Its inverse is the regular map
$$t \mapsto \left(\frac{t^2-1}{t^2+1}, \frac{2t}{t^2+1}\right)$$
so C and $\mathbb{A}_k^1$ are birational, though not isomorphic: the map misses $(1,0)$ in one direction and the two points with $t^2 = -1$ in the other.

2. *A rational map with no regular representative.* On $\mathbb{A}_k^2$ the assignment $(x,y) \mapsto x/y$ is a rational map $\mathbb{A}_k^2 \dashrightarrow \mathbb{A}_k^1$ whose domain of definition is $D(y)$. It cannot be extended to the origin: along the line $y = cx$ it is constantly $1/c$, so every value of k is taken arbitrarily close to the origin and no single value can be assigned there.

3. *Regular maps are the special case.* The map $(x,y) \mapsto (x^2, xy)$ has polynomial components, so its domain of definition is all of $\mathbb{A}_k^2$ and it is regular. Its image, computed in example 41.3.5, is not closed, which is a separate matter from being defined everywhere.

The image of the rational map shall be denoted $\varphi(X)$, even though not every point may be regular. Note that a rational map shall necessarily map an open subset $U \subseteq X$ into Y, and hence it is well-defined by proposition 33.2.7. By proposition 33.2.7, an equivalent definition of a rational map is that it is the collection of equivalence relations $[(\varphi, U)]$ with $U \subseteq X$ open and $\varphi : U \to Y$ where $[(\varphi, U)] \sim [(\psi, V)]$ if and only if
$$\varphi|_{U \cap V} = \psi|_{U \cap V}$$
This equivalent to definition 33.3.1, and is more prominent in the context of algebraic geometry. Its upside is that each representative is a well-defined map and hence can be seen as the appropriate quotient of some hom-sets, while its downside is that a rational mapping is now an equivalence relationship.

The following is the equivalent of being surjective:

Definition 33.3.3: Dominating Rational Map

Let $f : X \dashrightarrow Y$ be a rational map. Then f is said to be *dominating* if $f(U)$ is dense in Y.

Recall that if A, B are local rings where $A \subseteq B$ is a subring, then B dominates A if $\mathfrak{m}_A \subseteq \mathfrak{m}_B$. This vocabulary shall be made clear from the following

Proposition 33.3.4: Properties of Rational Maps

Let $F : X \dashrightarrow Y$ be a dominating rational map, $U \subseteq X$ and $V \subseteq Y$ affine open subsets where $f : U \to V$ represents F. Then:

1. If $\varphi : X \dashrightarrow Y$ and $\psi : Y \dashrightarrow Z$ are dominating rational maps, then $\psi \circ \varphi$ is dominating and $(\psi \circ \varphi)^{\#} = \varphi^{\#} \circ \psi^{\#}$.
2. $f^{\#} : k[V] \to k[U]$ is injective, hence extends to an injective map $k(V) \to k(U)$, and so gives $F^{\#} : k(Y) \hookrightarrow k(X)$, i.e. a field extension $k(X)/k(Y)$. It is an *embedding*, not an isomorphism; $F^{\#}$ is an isomorphism exactly when F is birational (proposition 33.3.6).
3. If p is in the domain of F and $F(p) = q$, then $\mathcal{O}_p(X)$ dominates $F^{\#}(\mathcal{O}_q(Y))$. Conversely, if $p \in X$ and $q \in Y$ are such that $\mathcal{O}_p(X)$ dominates $F^{\#}(\mathcal{O}_q(Y))$, then p belongs to the domain of F and $F(p) = q$.
4. Any k-homomorphism $k(Y) \to k(X)$ induces a unique dominating rational map $X \dashrightarrow Y$.

***Proof*:**

1. Let $U' \subseteq X$ be a dense open set on which φ is defined. Then $\psi\circ\varphi$ is defined on $U' \cap \varphi^{-1}(V')$ for V' a dense open set on which ψ is defined, and this is nonempty because $\varphi(U')$ is dense in Y and so meets V'. Its image contains $\psi(\varphi(U') \cap V')$, which is dense in Z since ψ is dominating and $\varphi(U') \cap V'$ is a nonempty open subset of V'. So $\psi \circ \varphi$ is dominating. Functoriality is then the computation $(\psi \circ \varphi)^{\#}(h) = h \circ \psi \circ \varphi = \varphi^{\#}(\psi^{\#}(h))$, so $(\psi \circ \varphi)^{\#} = \varphi^{\#} \circ \psi^{\#}$: pullback reverses composition.
2. Recall $f^{\#}(\varphi) = \varphi \circ f$. Suppose $f^{\#}(\varphi) = f^{\#}(\psi)$, that is $\varphi \circ f = \psi \circ f$. Then φ and ψ agree on $f(U)$, which is dense in V because F is dominating; two regular functions agreeing on a dense subset of a variety are equal (their difference vanishes on a dense set, hence on its closure). So $\varphi = \psi$ and $f^{\#}$ is injective. An injective map of integral domains extends to their fraction fields, giving $k(V) \hookrightarrow k(U)$, and since $U \subseteq X$ and $V \subseteq Y$ are nonempty open subsets of varieties we have $k(U) = k(X)$ and $k(V) = k(Y)$ by proposition 33.2.7. Hence $F^{\#}\colon k(Y) \hookrightarrow k(X)$ is a field embedding. It need not be surjective: $F^{\#}$ is onto exactly when F admits a rational inverse, which is proposition 33.3.6.
3. If $f(p) = q$, then it is a matter of pushing around the definition to see that $\mathcal{O}_p(X)$ dominates $F^{\#}(\mathcal{O}_q(Y))$. Conversely, suppose $\mathcal{O}_p(X)$ dominates $F^{\#}(\mathcal{O}_q(Y))$. Take an affine neighbourhood V of p and W of q where
$$k[W] = k[y_1, ..., y_n]$$
and $F^{\#}(y_i) = \frac{a_i}{b_i}$ for $a_i, b_i \in k[V]$ with $b_i(p) \neq 0$. Take $b = b_1 \cdots b_n$, and take the localization V_b. Then
$$F^{\#}(k[W]) \subseteq k[V_b]$$
Hence the map $F^{\#} : k[W] \to k[V_b]$ induces a unique morphism $f : V_b \to W$. Then if $g \in k[W]$ vanishes at q, $F^{\#}(g)$ vanishes at p, but then it must be that $f(p) = q$
4. If $\varphi : k(Y) \to k(X)$ wit h$\varphi(k[Y]) \subseteq k[X_b]$, for some $b \in k[X]$, φ induces a morphism $f : X_b \to Y$. Hence $f(X_b)$ is dense in Y as $f^{\#}$ is injective, giving us the desired result.

Definition 33.3.5: Birational Map

Let $\varphi : X \dashrightarrow Y$ be a rational map. Then φ is said to be *birational* if the image of φ is dense and there exists a rational map $\psi : Y \dashrightarrow X$ with dense image such that $\varphi \circ \psi = \psi \circ \varphi = \mathrm{id}$.

Proposition 33.3.6: Birational Maps and Isomorphisms

Let $\varphi\colon X \dashrightarrow Y$ be a dominating rational map of varieties. Then φ is birational if and only if $\varphi^{\#}\colon k(Y) \to k(X)$ is an isomorphism of fields over k.

***Proof*:**
Suppose φ is birational, with rational inverse ψ. Both composites are the identity, so applying proposition 33.3.4(1) gives $\varphi^{\#} \circ \psi^{\#} = (\psi \circ \varphi)^{\#} = \mathrm{id}$ and likewise $\psi^{\#} \circ \varphi^{\#} = \mathrm{id}$. Hence $\varphi^{\#}$ is an isomorphism with inverse $\psi^{\#}$.

Conversely, suppose $\varphi^{\#}$ is an isomorphism. Then $(\varphi^{\#})^{-1}\colon k(X) \to k(Y)$ is a k-homomorphism of function fields, so by proposition 33.3.4(4) it induces a dominating rational map $\psi\colon Y \dashrightarrow X$ with $\psi^{\#} = (\varphi^{\#})^{-1}$. Then $(\psi \circ \varphi)^{\#} = \varphi^{\#} \circ \psi^{\#} = \mathrm{id}$, and the uniqueness clause of proposition 33.3.4(4) forces $\psi \circ \varphi = \mathrm{id}$ as rational maps; symmetrically $\varphi \circ \psi = \mathrm{id}$. So φ is birational, as we sought to show.

The next definition uses dimension, which chapter 34 develops formally; for now read $\dim V$ as the number of independent parameters a general point of V carries.

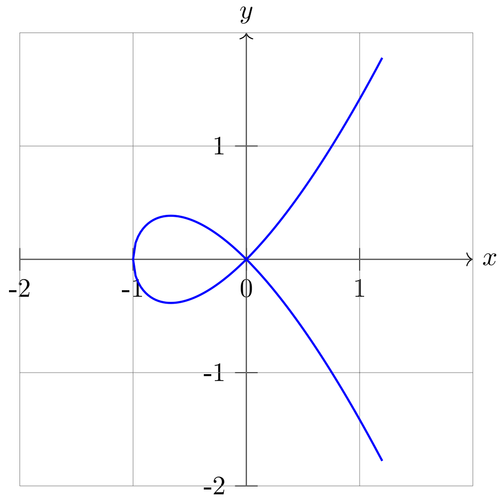
Definition 33.3.7: Rational Closed Set

Let V be a variety. Then if V is birational to $\mathbb{A}^n_k$ or $\mathbb{P}^n_k$, then V is called *affine rational* or *projective rational* respectively.

If V satisfies one of the above two conditions and has dimension $1, 2$ or codimension 1, then it is a *rational curve*, *rational surface*, or *rational hypersurface* respectively.

Example 33.3.8: Rational Mapping and Birational Maps

1. Naturally, all curves of order 1 (i.e., straight lines) are tautologically rational. More generally any linear subspace is rational.
2. Consider the curve given by
$$y^2 = x^2 + x^3$$
which looks like:



Label this curve C. Then this is a rational curve. To see this, consider that the line given by $y = tx$ passing through the origin intersects the curve at a single point (not counting the origin). Then substituting $y = tx$ into our equation, we get:

$$x^2(t^2 - x - 1) = 0$$

The root $x = 0$ corresponds to the origin, and the other roots $x = t^2 - 1$ corresponds to non-trivial solution. Hence, we get $x = t^2 - 1, y = t(t^2 - 1)$, and the rational map:

$$\varphi(t) = (t^2 - 1, t(t^2 - 1))$$

The inverse recovers the slope from the point: given $p = (x_0, y_0) \in C$ other than the origin, the line through p and the origin has slope y_0/x_0, so

$$\psi\colon C \dashrightarrow \mathbb{A}^1_k \qquad \psi(x, y) = \frac{y}{x}$$

is a rational map, regular away from $x = 0$. It inverts φ: substituting gives $\psi(\varphi(t)) = t(t^2 - 1)/(t^2 - 1) = t$ whenever $t^2 \neq 1$, and the two composites agree with the identity on dense open sets, which is equality of rational maps. So φ is birational. It is not an isomorphism: φ sends both $t = 1$ and $t = -1$ to the origin, the node of C, so it is not even injective.

If we take $k = \mathbb{Q}$, then this gives all rational solutions to the equation $y^2 = x^3 + x^2$. The case is a little more subtle if we were looking for integer solutions to the equation, which is explored in chapter 50.

3. Let us show that all irreducible curves C of order 2 are rational (note that the above example is an order 3 curve, the maximal degree being 3). Let C be given by the equation $f(x, y)$. Take any point $(x_0, y_0) \in C$, and equation of the line through (x_0, y_0) with slope t

$$y - y_0 = t(x - x_0)$$

Label this line L_t. Let us find the points of intersection of the curve C with line L_t. To do so, we substitute:

$$f(x, y_0 + t(x - x_0)) = 0$$

which is equivalent to the mapping $\mathbb{A}^1_k$ to the curve. This mapping is well-defined (notice it is still of degree 2). Then one of the roots is certainly x_0. Then let a denote the coefficient of x after dividing the equation $f(x, y_0 + t(x - x_0))$ by the coefficient of x^2. Then we can see that the remaining roots must be:

$$x + x_0 = -a \qquad \Rightarrow \qquad x = -x_0 - a$$

Then x is a rational function of t, and substituting the expression for x into L_t, we obtain an expression for y as a rational function of t.

Note that if the coordinates x_0, y_0 of $(x_0, y_0) \in C$ and the coefficients of $f(x, y)$ belong to some subfield $k_0 \subseteq k$, then so do the coefficients of the function that gives the parameterization. In this case, we can find the general form of the solution in rational numbers of a Diophantine equation of degree 2 by knowing *at least* one solution! However, it turns out that knowing there is at least one solution can sometimes be tricky[a]

4. More generally, an irreducible hypersurface $X \subseteq \mathbb{A}^n_k$ given by a polynomial of degree 2 $f(x_1, ..., x_n) = 0$ is rational. The proof generalizes the above and is left as an exercise. The geometric picture is projection the hypersurface to a hyper-plane via a projection that does not pass through some point x. The point x can be any point that is not a "vertex" on X, namely that for at least one variable:

$$\frac{\partial f}{\partial x_i}(x) \neq 0$$

5. The curve order 3 given by $x^3 + y^3 = 1$ is *not* rational. More generally, $x^n + y^n = 1$ is not rational for $n \geq 3$, provided $\mathrm{char} k \nmid n$. To see this, let C_n be the curve given by $x^n + y^n = 1$ and suppose it is rational so that there exists rational functions φ, ψ such that $x = \varphi(t), y = \psi(t)$. Then we may find polynomials p, q, r relatively prime such that

$$\varphi(t) = \frac{p(t)}{r(t)} \qquad \psi(t) = \frac{q(t)}{r(t)}$$

where the denominator is the same for simplicity (the same argument follows with more steps by taking p/r and q/s). Then plugging into our equation we get:

$$p(t)^n + q(t)^n - r(t)^n = 0$$

for all $t \in k$. Differentiating is legitimate and does not annihilate the exponent, since $\mathrm{char} k \nmid n$, and so we have:

$$p(t)^{n-1}p'(t) + q(t)^{n-1}q'(t) - r(t)^{n-1}r'(t) = 0$$

We now have two systems equations. Treating $p^{n-1}, q^{n-1}, -r^{n-1}$ as the unknowns, we can consider the above two equations as being a system of linear equations which has has the matrix:

$$\begin{pmatrix} p & q & r \\ p' & q' & r' \end{pmatrix}$$

Solving this system of linear equations, we get that $p^{n-1}, q^{n-1}, -r^{n-1}$ are proportional to

$$qr' - rq' \qquad rp' - pr' \qquad pq' - qp'$$

As p, q, r are relatively prime, we get that:

$$p^{n-1} \big| (qr' - rq') \qquad q^{n-1} \big| (rp' - pr') \qquad r^{n-1} \big| (pq' - qp')$$

Finally, if a, b, c are the degrees of p, q, r . If $a \geq b \geq c$, then

$$(n-1)a \leq b + c - 1$$

But $a \geq b \geq c$ gives $b + c - 1 \leq 2a - 1$, so $(n-1)a \leq 2a - 1$, forcing $(n-3)a \leq -1$, which is impossible for $n \geq 3$ and $a \geq 0$. The other orderings of a, b, c give the same contradiction by symmetry.

[a] see Legendre theorem in cite:HERE

33.4 Classification up to Birational Equivalence

Birational mappings are weaker than isomorphisms (of varieties). This problem can be translated algebraically to the difference between having $k[X]$ and $k[Y]$ be isomorphic and $k(X)$ and $k(Y)$ be isomorphic. The reader may recall from section 32.4 that $k[X]$ and $k[Y]$ must be finitely generated reduced k-algebras, $k(X)$ and $k(Y)$ finite field extensions. As the structure of field extensions is much simpler, we expect birational mappings to be much simpler. In fact, we may even classify all affine variety up to birational isomorphism:

Theorem 33.4.1: Classification of Varieties Up To Birational Map

Let X be a variety of dimension d over an algebraically closed field k. Then X is birationally isomorphic to a hypersurface in $\mathbb{A}_k^{d+1}$.

Thus, birationality of varieties reduces to the classification of hypersurfaces. Note that being birationally isomorphic to a hypersurface does not imply a curve or plane is rational. For example, the curve given by $x^3 + y^3 = 1$ is already a hypersurface in $\mathbb{A}^2$ as it is given by $\mathcal{Z}(x^3 + y^3 - 1)$, however it is not a rational curve. Its projective closure is the Fermat cubic $\mathcal{Z}(x^3 + y^3 - z^3)$, which is nonsingular, and corollary 44.4.3 shows no nonsingular plane cubic is birational to $\mathbb{A}_k^1$; the invariant responsible is the genus, which chapter 44 constructs.

That claim deserves more than a forward reference, because the curve looks as though it ought to yield. Every technique available at this point can be tried on it, and watching each one fail is the most economical argument for building the machinery of part IX.

Example 33.4.2: Why $x^3 + y^3 = 1$ Resists Parameterization

Assume $\operatorname{char} k \neq 3$, so that the projective closure $\mathcal{Z}(x^3 + y^3 - z^3)$ is nonsingular; the excluded case is degenerate and treated at the end. Write $C = \mathcal{Z}(x^3 + y^3 - 1) \subseteq \mathbb{A}_k^2$.

Attempt 1: the chord construction. A conic is parameterized by fixing a point on it and sweeping the lines through that point, as in example 39.4.4(3). Run the identical computation on three curves, substituting the line through the chosen point and factoring out the known root.

- The conic $x^2 + y^2 = 1$ at $(1,0)$, with $y = t(x-1)$:

$$(x-1)\left[\, x + 1 + t^2(x-1) \,\right] = 0$$

  leaving a factor *linear* in x.

- The nodal cubic $y^2 = x^2 + x^3$ at the node $(0,0)$, with $y = tx$:

$$x^2\left[\, t^2 - 1 - x \,\right] = 0$$

  again leaving a factor *linear* in x.

- The Fermat cubic $x^3 + y^3 = 1$ at $(1,0)$, with $y = t(x-1)$:

$$(x-1)\left[\, x^2 + x + 1 + t^3(x-1)^2 \,\right] = 0$$

  leaving a factor *quadratic* in x.

In the first two cases the leftover factor is linear, so x is a rational function of t and the construction succeeds: the conic gives $x = (t^2-1)/(t^2+1)$, and the nodal cubic gives $x = t^2 - 1$, recovering the parameterization of example 33.3.8.

In the third it is quadratic, and solving it introduces a square root. The reason is visible in the factorizations: the method needs the marked point to absorb all but one of the intersections. A line meets a conic twice and the marked point takes one; a line through the node of $y^2 = x^2 + x^3$ meets the cubic three times and the node, being a double point, takes two. A smooth cubic has no double point, so the marked point takes only one of three and two are left over. *The construction does not fail by accident; it fails because the curve is smooth*, which is exactly the hypothesis under which the conclusion is true.

A warning about what this does and does not show. Given *two* points of a cubic the chord still produces a third, and over $\mathbb{Q}$ that is the classical method for generating new solutions from old. That is a statement about individual points, not about parameterizing the whole curve by one variable, and the two are easy to conflate.

Attempt 2: symmetric functions. The equation is symmetric in x and y, so set $u = x + y$ and $v = xy$. Then $x^3 + y^3 = u^3 - 3uv$, and the curve becomes

$$u^3 - 3uv = 1 \qquad \text{that is} \qquad v = \frac{u^3 - 1}{3u}$$

which parameterizes the pair $\{x, y\}$ rationally by u alone. But recovering x and y individually means solving $T^2 - uT + v = 0$, whose discriminant is

$$u^2 - 4v = u^2 - \frac{4(u^3-1)}{3u} = \frac{4 - u^3}{3u}$$

So a square root of $(4 - u^3)/3u$ is needed. Setting $W = 3uw$ where w is that square root gives

$$W^2 = 3u\,(4 - u^3) = 12u - 3u^4$$

a square root of a quartic with four distinct roots, namely $u = 0$ and the three cube roots of 4. That is another curve of the same kind: section 44.4 will assign it genus 1, exactly as for C. The attempt is circular, and it is circular in a way one can see before having any theory: it trades the problem for an equal one.

Attempt 3: look for a parameterization directly. Suppose C were rational, so that $x = p(t)/r(t)$ and $y = q(t)/r(t)$ for polynomials p, q, r with no common factor, not all constant. Substituting and clearing denominators,

$$p(t)^3 + q(t)^3 = r(t)^3$$

This is Fermat's Last Theorem for polynomials in the exponent 3, and unlike its arithmetic namesake it has a short proof. The Mason–Stothers theorem states that for coprime polynomials $a + b = c$ in $k[t]$, not all constant and with $\operatorname{char} k = 0$,

$$\max(\deg a, \deg b, \deg c) \;\leq\; n_0(abc) - 1$$

where n_0 counts *distinct* roots. Apply it to $a = p^3$, $b = q^3$, $c = r^3$ and set $d = \max(\deg p, \deg q, \deg r)$. The left side is $3d$. On the right, $p^3q^3r^3$ has the same distinct roots as pqr, so $n_0 \leq \deg(pqr) \leq 3d$, giving

$$3d \;\leq\; 3d - 1$$

which is absurd. So no such p, q, r exist and C is not rational.

What the third attempt costs. It is a complete proof, but only in characteristic zero: the Mason–Stothers argument differentiates, and in characteristic $\rho > 0$ all three of p, q, r may be polynomials in t^ρ, with vanishing derivatives, and the argument collapses. And in the excluded characteristic 3 the curve is not what it appears: $x^3 + y^3 = (x + y)^3$, so $C = \mathcal{Z}((x + y)^3 - 1)$ is a union of lines and is rational after all.

So one attempt fails structurally, one is circular, and one succeeds in a single characteristic by an argument owing nothing to geometry. What is missing is an invariant of the curve that decides the question uniformly, is computable, and explains why the conic and the nodal cubic behave differently from this one. That invariant is the genus. Theorem 44.4.2 shows a plane curve is rational exactly when its genus vanishes, definition 44.4.1 computes the genus of a smooth plane curve of degree d as $\binom{d-1}{2}$, giving 1 here and 0 for a conic, and section 44.4 shows a node drops the genus by exactly 1, which is why the nodal cubic is rational and this one is not. The argument is characteristic-free.

***Proof*:**
Write $K = k(X)$, the fraction field of $k[X] = \Gamma(\mathbb{A}^n)/\mathcal{I}(X)$. It is generated over k by the images $t_1, \ldots, t_n$ of the coordinate functions, a *finite* set, so from it we may extract a maximal algebraically independent subset; after renumbering call it $t_1, \ldots, t_d$, so that $d = \operatorname{trdeg}_k K$ and every remaining t_j is algebraic over $k(t_1, \ldots, t_d)$.

Step 1: each algebraic generator can be taken separable. Fix $j > d$. Then $t_1, \ldots, t_d, t_j$ are algebraically dependent, so some irreducible $f \in k[x_1, \ldots, x_{d+1}]$ has $f(t_1, \ldots, t_d, t_j) = 0$. We claim $\partial f/\partial x_i \neq 0$ for some i. In characteristic 0 this is immediate, as f is nonconstant. In characteristic p, suppose every $\partial f/\partial x_i$ vanished. Then each variable occurs in f only in exponents divisible by p, so

$$f = \sum a_{i_1,\ldots,i_{d+1}}\, x_1^{pi_1} \cdots x_{d+1}^{pi_{d+1}}$$

Since k is algebraically closed it is perfect, so each coefficient has a p-th root: pick $b_{i_1,\ldots,i_{d+1}}$ with

$b^p_{i_1,\dots,i_{d+1}} = a_{i_1,\dots,i_{d+1}}$. Then $g = \sum b_{i_1,\dots,i_{d+1}} x_1^{i_1} \cdots x_{d+1}^{i_{d+1}}$ satisfies $f = g^p$, since the Frobenius is a ring homomorphism in characteristic p. That contradicts irreducibility of f.

Step 2: putting the separable variable last. Say $\partial f/\partial x_i \neq 0$, so x_i genuinely occurs in f and hence t_i is algebraic over the field generated by the other d elements of $\{t_1,\dots,t_d,t_j\}$. Those d elements are still algebraically independent: if they were not, the transcendence degree of $k(t_1,\dots,t_d,t_j)$ would fall below d, contradicting the independence of $t_1,\dots,t_d$. Renaming so that the independent ones are $t_1,\dots,t_d$ and the algebraic one is t_{d+1}, we have $\partial f/\partial x_{d+1} \neq 0$, which says precisely that t_{d+1} is separable over $k(t_1,\dots,t_d)$.

Step 3: collapsing to one generator. K is generated over $k(t_1,\dots,t_d)$ by the finitely many elements $t_{d+1},\dots,t_n$, each separable by Step 1 applied in turn, so $K/k(t_1,\dots,t_d)$ is a finite separable extension. The primitive element theorem then supplies a single z_{d+1} with

$$K = k(t_1,\dots,t_d)(z_{d+1})$$

Writing $z_i = t_i$ for $i \leq d$, let f be an irreducible polynomial with $f(z_1,\dots,z_{d+1}) = 0$, and set $Y = \mathcal{Z}(f) \subseteq \mathbb{A}^{d+1}_k$, a hypersurface. By construction $k(Y) \cong K = k(X)$.

Step 4: an isomorphism of function fields is a birational map. By proposition 33.3.6, a dominating rational map is birational exactly when the induced map of function fields is an isomorphism, and proposition 33.3.4(4) produces such a dominating rational map $X \dashrightarrow Y$ from the isomorphism $k(Y) \to k(X)$. Hence X and Y are birationally isomorphic, as we sought to show.

Note that $k(X)/k(z_1,...,z_d)$ is a finite separable extension, and that the primitive elements $z_1,...,z_{d+1}$ can be chosen as linear combinations of the $x_1,...,x_n$ for appropriate c_{ij}:

$$z_i = \sum_j^n c_{ij} x_j$$

Then the mapping $(x_1,...,x_n) \to (z_1,...,z_{d+1})$ is a projection from $\mathbb{A}^n_k$ that is parallel to the linear subspace given by:

$$\sum_j^n c_{ij} x_j = 0 \qquad 1 \leq i \leq d+1$$

Thus, the birational mapping theorem says that there is an appropriate hypersurface (not necessarily a hyperplane) on which we may project in a rational manner the variety! From this perspective, linear algebra results which are birationally invariant can be translated over to varieties, which we shall soon see gives us some interesting results!

One direction of the classification is easy to get wrong. A variety dominated by $\mathbb{A}^n_k$, meaning one admitting a dominant rational map from affine space, is called *unirational*; a variety birational to $\mathbb{A}^n_k$ is *rational*. Rational implies unirational trivially. In dimension one the converse also holds, and that is Lüroth's theorem. In higher dimensions it fails, which is one of the deepest facts in the subject and well outside this book.

Theorem 33.4.3: Lüroth's Theorem

Let L be a field with $k \subsetneq L \subseteq k(t)$, where t is transcendental over k. Then $L = k(u)$ for some $u \in L$.

***Proof*:**
Choose $u_0 \in L \setminus k$. Then t is algebraic over $k(u_0)$: writing $u_0 = a(t)/b(t)$ with $a, b \in k[t]$ not both constant, t is a root of $a(X) - u_0 b(X) \in k(u_0)[X]$, which is nonzero because a and b are not proportional. So t is algebraic over L as well; put $n = [k(t) : L]$ and let

$$f(X) = X^n + c_{n-1}X^{n-1} + \cdots + c_0 \ \in L[X]$$

be the minimal polynomial of t over L.

Step 1: some coefficient is not in k. If every c_j lay in k then t would be algebraic over k, contradicting transcendence. Fix j with $u = c_j \notin k$ and write $u = a(t)/b(t)$ in lowest terms, with $m = \max(\deg a, \deg b) \geq 1$.

Step 2: $[k(t) : k(u)] = m$. The polynomial $P(X) = a(X) - u\, b(X) \in k(u)[X]$ has degree m and kills t. It is irreducible over $k(u)$: regard it in $k[X][u]$, where it is linear in u and primitive, since a and b are coprime; Gauss's lemma then makes it irreducible in $k(u)[X]$. Hence it is the minimal polynomial of t over $k(u)$ and $[k(t) : k(u)] = m$.

Step 3: $n \leq m$. We have $k(u) \subseteq L \subseteq k(t)$ because $u = c_j \in L$, so $n = [k(t) : L]$ divides $[k(t) : k(u)] = m$; in particular $n \leq m$.

Step 4: $m \leq n$. Clear denominators: let $d(t) \in k[t]$ be a common denominator for $c_0, \ldots, c_{n-1}$, chosen so that $F(t, X) = d(t)f(X)$ lies in $k[t][X]$ and is primitive as a polynomial in X over $k[t]$. Its degree in X is n. Since f is the minimal polynomial of t over L and $P(X) = a(X) - ub(X)$ also kills t, we get $f \big| P$ in $L[X]$; clearing denominators and applying Gauss's lemma in $k[t][X]$,

$$F(t, X) \ \Big| \ a(X)b(t) - a(t)b(X)$$

The right side has degree at most m in t. On the other hand $u = a(t)/b(t)$ appears among the coefficients of f, so after clearing denominators F has degree at least m in t. Hence $\deg_t F = m$ and the quotient is a constant, so

$$F(t, X) = c\,\big(a(X)b(t) - a(t)b(X)\big) \qquad c \in k^*$$

Comparing degrees in X gives $n = \deg_X F = m$.

Conclusion. Steps 3 and 4 give $n = m$, so $[k(t) : L] = [k(t) : k(u)]$; since $k(u) \subseteq L$, the two fields coincide and $L = k(u)$, as we sought to show.

Corollary 33.4.4: Unirational Curves Are Rational

Let C be a curve admitting a dominant rational map $\mathbb{P}^1_k \dashrightarrow C$. Then C is rational, that is birational to $\mathbb{P}^1_k$.

***Proof*:**
A dominant rational map induces an inclusion of function fields $k(C) \hookrightarrow k(\mathbb{P}^1_k) = k(t)$ by proposition 33.3.4. Its image is a subfield of $k(t)$ containing k, and it properly contains k because C is a curve, so $k(C)$ has transcendence degree 1. Theorem 33.4.3 makes that image $k(u)$ for some u, hence $k(C) \cong k(u) \cong k(t)$, and isomorphic function fields mean birational varieties by theorem 33.4.1 and its proof.

The failure in higher dimension is worth naming, since it is easy to assume the pattern continues. There are unirational surfaces over fields of positive characteristic that are not rational, and unirational threefolds over $\mathbb{C}$ that are not rational; the first examples over $\mathbb{C}$ are due to Clemens and Griffiths, Iskovskikh and Manin, and Artin and Mumford, all in 1971–72. Deciding rationality is a live problem, and nothing in this book bears on it.

Exercise 33.4.1

1. In the proof of proposition 33.2.2, verify the identity $\varphi g_i = f_i$ in $k(X)$, and explain why it holds on all of X even though the representation $\varphi = f_i/g_i$ was chosen only near x_i.
2. Let X be irreducible. Show that any finite collection of rational functions on X has a non-empty common domain of definition
3. Show that the collection of poles of a rational function $f \in k(V)$ is an algebraic set
4. Show that for each $a \in k$, the stalk $\mathcal{O}_a(\mathbb{A}^1_k)$ at a is a DVR with uniforming parameter $x - a$.
5. Define $\mathcal{O}_\infty = \left\{ \frac{f}{g} \;\middle|\; \deg(f) \leq \deg(g) \right\}$. Show that $\mathcal{O}_\infty$ is a DVR with uniforming parameter $1/x$. (Note: This is foreshadowing that it is natural consider curves in *projective space* rather than affine space; see chapter 38).

Part VII

Local Properties

Everything in Part VI is an invariant of a whole variety. This Part changes the question: fix a point p of a variety X and ask what can be said about X near p. The answer throughout is that the local ring $\mathcal{O}_{X,p}$ carries it. The dimension of X at p is the Krull dimension of that ring, smoothness at p is the equality of that dimension with the dimension of the cotangent space $\mathfrak{m}_p/\mathfrak{m}_p^2$, the multiplicity of X at p is read from the associated graded ring, and normality is the condition that every $\mathcal{O}_{X,p}$ is integrally closed.

The passage runs both ways: A global statement is repeatedly proved by checking a condition at every point. The regular functions on a variety are the intersection of its local rings, a rational function regular everywhere is regular, and a variety is normal exactly when each of its local rings is.

Dimension theory, regular local rings, completion and the Cohen structure theorem are the commutative algebra the Part runs on, and they come from *Commutative Algebra* [10].

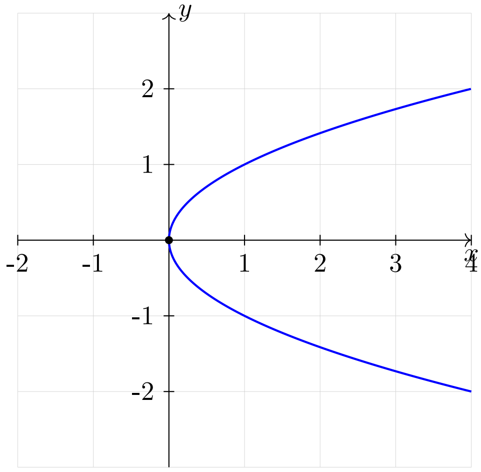
34

Dimension

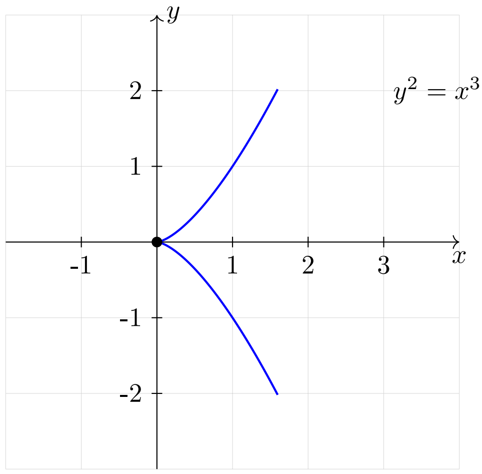
Every notion of dimension that works in analysis or topology fails on the Zariski topology, whose open sets are too large for covering arguments and whose only irreducible subsets in the Euclidean sense are points. What survives is a definition built from chains of irreducible closed subsets, and its algebraic mirror, chains of prime ideals. This chapter establishes that the two agree, and that for a variety both agree with the transcendence degree of its function field.

34.1 What Dimension Should Mean

When looking at $\mathbb{A}_k^n$, we may naturally think of this space as being n-dimensional, and in this special case this matches with our notion of a 3-dimensional vector-space. We may think that varieties also have a notion of dimension, for example the curve with coordinate ring $\frac{k[x,y]}{(y^2-x)}$ gives the impression that it should be thought of as a 1-dimensional variety:



This variety should even be thought of as being smooth, as compared to the variety with coordinate ring $\frac{k[x,y]}{(y^2-x^3)}$ which has a cusp at $(x, y) = (0, 0)$.



We may hope that the notion of dimension is as simple as it was for vector spaces, however this turns out to be a more subtle problem. For example, continuous maps do not preserve dimension (there is a continuous map from $\mathbb{R}$ onto $\mathbb{R}^2$ given by the Peano space-filling curve). Homeomorphisms between open sets of $\mathbb{R}^n$ and $\mathbb{R}^m$ do force the condition that $n = m$[1], however we still need to define the notion of dimension so that it can be preserved.

One of the most general definition of dimension can be defined in the topological level and is called the *Lebesgue covering dimension* where a space X is dimension at most n if every open cover can be refined to an open cover in which each point lies in at most $n + 1$ sets. However, this definition will fail spectacularly in the Zariski topology as most open sets are huge (in fact, most Zariski topologies will have infinite Lebesgue covering dimension).

[1]see [38]

There are a few other notion of dimension (to name some notable example: the Brouwer-Menger-Urysohn boundary dimension, the Hausdorff Dimension, Deviation of Poset). One that the Nullstellensatz has already put within reach is the transcendence degree of a field extension. For example, if we take $k[V]$ to be some coordinate ring for a variety (so that $k[V]$ is an integral domain), we may take the field of fractions $k(V)$. Then taking the transcendental degree of $k(V)/k$, we may define this to be the *transcendental dimension* of $k[V]$. This works well on smooth shapes, and theorem 40.4.4 and theorem 40.4.3 will show that every affine or projective variety admits a finite surjection onto $\mathbb{A}^n_k$ or $\mathbb{P}^m_k$ respectively, so the transcendence degree is always attained. It is also invariant under isomorphism, being defined from the function field. However this definition fails when there the coordinate ring is not an integral domain[2]. Furthermore, it does not generalize to the spectrum of an arbitrary ring: the geometric object attached to $\mathbb{Z}$ has transcendence degree 0 over no field at all, while the definition settled on below gives it dimension 1.

One limitation is that these notions of dimension are global; the entire space has some dimension. This turns out to be a misnomer, as the example of the curve $y^2 = x^3$ mentioned earlier demonstrates (it *drops* a dimension at $(x, y) = (0, 0)$). To anyone who has done differential geometry, they may already be comfortable with the fact that the dimension of a smooth manifold is given by the vector space dimension of the tangent space at a point (which for a smooth-manifold should be invariant to the choice of point, and hence a well-defined global notion). Then the reader well-versed in the equivalent definition's of tangent spaces of a manifold may recall that the tangent space can be defined as the dual of $\mathfrak{m}/\mathfrak{m}^2$ where $\mathfrak{m}$ is the maximal ideal of C^∞_a (the set of germs of C^∞ on a manifold at the point a). This definition is agnostic of the differential structure, and so can be used on varieties. It shall also capture the local subtleties; to reiterate the same example the tangent space at $(x, y) = (0, 0)$ of $y^2 = x^3$ will be dimension 2, representing the fact that it should be treated differently than the other points. Section 35.1 takes up this notion.

34.2 Krull Dimension and Transcendence Degree

What has been settled on as the most useful notion of global dimension that translates well between algebra and geometry is the following:[3]

Definition 34.2.1: Topological Krull Dimension

Let X be a topological space. Then the *Krull dimension* of X is the supremum of the length of all chains:

$$Z_0 \subsetneq Z_1 \subsetneq \cdots \subsetneq Z_n$$

of distinct irreducible closed subsets of X. The Krull dimension of a topological space will be denoted kdim

This definition is not interesting in euclidean topology, for example for $\mathbb{R}^n$ as only points are irreducible we have $\text{kdim}(\mathbb{R}^n) = 0$. If the dimension is finite, then it is equal to the length of the longest chain of irreducible closed subsets. The Krull dimension of $\mathbb{A}^1_k$ is always 1, $\text{kdim}(\mathbb{A}^1_k) = 1$, as the only irreducible closed subsets of $\mathbb{A}^1_k$ are the single point and whole space. As irreducible closed subsets

[2]It also fails as an adequate definition when localizing a ring or taking its completion, which are two important tools that we shall often use on shapes

[3]The Krull dimension turns out to be equivalent to the Brouwer-Menger-Urysohn definition of dimension, which is useful for cohomological intuitions

correspond to prime ideals, we have the equivalent notion for primes:

Definition 34.2.2: Height of Prime

Let $\mathfrak{p} \subseteq R$ be a prime ideal. Then the *height* of a prime ideal is the supremum of all integers n for which there is a chain of distinct prime ideals:

$$\mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_n = \mathfrak{p}$$

The *dimension* of R is the supremum of the heights of all prime ideals.

A field has exactly one prime, (0), of height 0, so its Krull dimension is 0. A principal ideal domain that is not a field has Krull dimension 1: its nonzero primes are maximal, so the longest chain is $(0) \subsetneq \mathfrak{p}$.

Proposition 34.2.3: Dimension of Affine Algebraic Set

Let $Y \subseteq \mathbb{A}^n_k$ be an affine algebraic set. Then $\mathrm{kdim}(Y)$ is equal to the dimension of the affine coordinate ring $k[Y]$

***Proof*:**
By proposition 32.3.3 the irreducible closed subsets of Y correspond to the prime ideals of $\Gamma(\mathbb{A}^n)$ containing $\mathcal{I}(Y)$, which by the correspondence theorem are the prime ideals of $k[Y] = \Gamma(\mathbb{A}^n)/\mathcal{I}(Y)$. The correspondence *reverses* inclusion, so a strictly ascending chain of length d of irreducible closed subsets of Y is the same thing as a strictly descending chain of length d of primes of $k[Y]$, and conversely. Taking suprema, $\mathrm{kdim}(Y) = \mathrm{kdim}(k[Y])$, as we sought to show.

When covering Noether's Normalization (theorem 32.4.1), it was observed that this can be used to define the dimension of a ring. The following definition captures this idea:

Definition 34.2.4: Transcendental Dimension

Let X be a variety. Then the *transcendence dimension* of X over k is the transcendence degree of its function field $k(X)$, and is denoted $\dim X$. (Proposition 34.2.5 shows this agrees with $\mathrm{kdim}X$, after which the two notations are used interchangeably.) The transcendence degree of a field extension, and the fact that it is well-defined, are established in *Core Algebra* [25].

Proposition 34.2.5: Transcendental and Krull Dimension

Let k be a field and R a finitely generated k-algebra which is an integral domain. Then

$$\mathrm{kdim}(R) = \mathrm{trdeg}_k \mathrm{Frac}(R)$$

Furthermore, for every prime $\mathfrak{p} \subseteq R$,

$$\mathrm{height}(\mathfrak{p}) + \mathrm{kdim}(R/\mathfrak{p}) = \mathrm{kdim}(R)$$

Neither hypothesis can be dropped. Transcendence degree is an invariant of a field extension, so R must be a domain for $\mathrm{Frac}(R)$ to exist; and finite generation cannot be dropped, as example 34.2.6

shows. The second identity is the statement that finitely generated domains over a field are catenary and equidimensional, which is what makes codimension behave additively.

***Proof*:**
This is the equality $\text{kdim}R = \text{trdeg}_k R$ for a finitely generated k-algebra, together with the dimension formula $\text{height}(\mathfrak{p}) + \text{kdim}(R/\mathfrak{p}) = \text{kdim}R$; both are proved via Noether normalization in [10].

The conditions are necessary for the equality of both equations:

Example 34.2.6: Different Krull and Transcendental Dimension
Take $R = k(x)$, the field of rational functions in one variable. As a field it has exactly one prime, so $\text{kdim}R = 0$, while $\text{trdeg}_k R = 1$. There is no contradiction with proposition 34.2.5: $k(x)$ is *not* a finitely generated k-algebra. It is finitely generated as a *field* extension, which is a strictly weaker condition, and the proposition needs the algebra version.

Geometrically the collapse is familiar to a reader who has met schemes: $k(x)$ is the local ring at the generic point of $\mathbb{A}^1_k$, a single non-closed point, and a one-point space has Krull dimension 0 however large the field attached to it.

Corollary 34.2.7: Dimension of Affine Space

The Krull dimension of affine space $\mathbb{A}^n_k$ is n.

***Proof*:**
$\Gamma(\mathbb{A}^n) \cong k[x_1, \ldots, x_n]$ is a finitely generated k-algebra and an integral domain, so proposition 34.2.5 applies and gives $\text{kdim}\mathbb{A}^n = \text{trdeg}_k k(x_1, \ldots, x_n)$. The x_i are algebraically independent over k and generate the field, so they form a transcendence basis and that degree is n, as we sought to show.

34.3 Codimension, Curves, and Surfaces

Definition 34.3.1: Codimension

Let $Y \subseteq X$ be a closed subvariety of a variety X. The *codimension* of Y in X, written $\text{codim}_X Y$, is the supremum of the lengths of chains

$$Y = Z_0 \subsetneq Z_1 \subsetneq \cdots \subsetneq Z_c \subseteq X$$

of irreducible closed subsets of X starting at Y. The ambient is part of the data and is dropped from the notation only when it is fixed by context.

Proposition 34.3.2: Codimension Is a Difference of Dimensions

Let $Y \subseteq X$ be a closed subvariety of a variety X over a field. Then

$$\operatorname{codim}_X Y = \dim X - \dim Y$$

***Proof*:**
Passing to an affine open subset changes neither side, so assume X affine with coordinate ring $k[X]$, a finitely generated domain over k. Chains of irreducible closed subsets of X starting at Y correspond, reversing inclusion, to chains of primes of $k[X]$ descending from $\mathcal{I}(Y)$, so $\operatorname{codim}_X Y = \operatorname{height}(\mathcal{I}(Y))$. Likewise $\dim Y = \operatorname{kdim}(k[X]/\mathcal{I}(Y))$ by proposition 34.2.3. The dimension formula of proposition 34.2.5 applied to $\mathfrak{p} = \mathcal{I}(Y)$ then reads $\operatorname{codim}_X Y + \dim Y = \dim X$, as we sought to show.

The identity fails without the hypotheses of proposition 34.2.5: it is exactly the statement that the ring is catenary and equidimensional, which is why codimension is *defined* by chains and only *computed* as a difference.

One consequence is used constantly and deserves a name: dimension cannot be detected locally, in the sense that shrinking to a smaller open set does not shrink the dimension.

Corollary 34.3.3: Dimension Is Determined by Any Open Subset

Let X be an irreducible variety and $U \subseteq X$ a nonempty open subset. Then $\dim U = \dim X$.

***Proof*:**
U is dense in X by irreducibility, so restriction identifies the two function fields, $k(U) = k(X)$. Both dimensions equal the transcendence degree of that common field by proposition 34.2.5, completing the proof.

Verify as a check on the definitions that planar curves have dimension 1, that finite sets have dimension 0, and that $\mathbb{A}^n_k$ and $\mathbb{P}^n_k$ have dimension n.

Definition 34.3.4: Curves and Surfaces

Let X be an algebraic variety. Then:

1. If X is 1-dimensional, it is called a *curve*
2. If X is 2-dimensional, it is called a *surface*
3. If X is 1-codimensional, it is called a *hypersurface*.

Proposition 34.3.5: Dimension Between Irreducible Varieties

Let $Y \subseteq X$ be a closed subvariety of a variety X. Then $\dim Y \leq \dim X$, with equality if and only if $Y = X$.

***Proof*:**
Every chain of irreducible closed subsets of Y is a chain of irreducible closed subsets of X, since Y is closed in X; taking suprema gives $\dim Y \leq \dim X$.

Suppose $\dim Y = \dim X = d$ and $Y \subsetneq X$. Take a chain $Z_0 \subsetneq \cdots \subsetneq Z_d = Y$ of irreducible closed subsets of Y realizing its dimension. As Y is irreducible, closed and properly contained in X, appending X extends this to

$$Z_0 \subsetneq \cdots \subsetneq Z_d = Y \subsetneq X$$

a chain of length $d + 1$ in X, so $\dim X \geq d + 1$, contradicting $\dim X = d$. Hence $Y = X$; the converse is trivial, completing the proof.

34.4 Hypersurface Sections and Codimension One

Cutting a variety by one equation ought to drop its dimension by exactly one. That is the geometric content of Krull's principal ideal theorem, and it is the fact that makes dimension usable: it lets a variety be built up, or cut down, one equation at a time. This section records it, and then proves the converse in affine space, where codimension one turns out to be the same thing as being cut out by a single polynomial.

Theorem 34.4.1: Hypersurface Sections Drop Dimension by One

Let X be a variety and $f \in k[X]$ neither zero nor a unit. Then every irreducible component of $\mathcal{Z}_X(f) = \{p \in X \mid f(p) = 0\}$ has dimension $\dim X - 1$.

***Proof*:**
The irreducible components of $\mathcal{Z}_X(f)$ correspond to the primes of $k[X]$ minimal over (f). Let $\mathfrak{p}$ be such a prime. Krull's principal ideal theorem (theorem 29.5.2) gives $\operatorname{height}(\mathfrak{p}) \leq 1$.

For the reverse bound, $k[X]$ is a domain because X is a variety (corollary 32.3.4), so (0) is prime; and $f \neq 0$ forces $\mathfrak{p} \neq (0)$. Hence $(0) \subsetneq \mathfrak{p}$ is a chain of length 1 and $\operatorname{height}(\mathfrak{p}) \geq 1$, so $\operatorname{height}(\mathfrak{p}) = 1$.

The component attached to $\mathfrak{p}$ has coordinate ring $k[X]/\mathfrak{p}$, so by proposition 34.2.5,

$$\dim \mathcal{Z}_X(\mathfrak{p}) = \operatorname{kdim}(k[X]/\mathfrak{p}) = \operatorname{kdim} k[X] - \operatorname{height}(\mathfrak{p}) = \dim X - 1$$

as we sought to show.

The theorem says nothing about $\mathcal{Z}_X(f)$ being irreducible, and it need not be: $\mathcal{Z}(xy) \subseteq \mathbb{A}^2$ is the union of the two axes, two components each of dimension 1. What the theorem guarantees is that no component is smaller than expected. The hypothesis that f be a nonunit is what keeps $\mathcal{Z}_X(f)$ nonempty in the first place, and $f \neq 0$ is what stops it from being all of X.

In affine space the converse holds, and it is a genuine dictionary entry: codimension one on the geometric side is principality on the algebraic side.

Theorem 34.4.2: Codimension One in Affine Space Means Hypersurface

Let $Y \subsetneq \mathbb{A}^n_k$ be an irreducible closed subset with $\operatorname{codim}_{\mathbb{A}^n} Y = 1$. Then there is an irreducible polynomial f, unique up to a nonzero scalar, with

$$\mathcal{I}(Y) = (f) \qquad Y = \mathcal{Z}(f)$$

Conversely $\mathcal{Z}(f)$ is irreducible of codimension 1 for every irreducible f.

***Proof*:**
$\mathcal{I}(Y)$ is prime because Y is irreducible (proposition 32.3.3), and $\operatorname{height}(\mathcal{I}(Y)) = \operatorname{codim}_{\mathbb{A}^n} Y = 1$ by proposition 34.3.2. So it suffices to show that a height-one prime $\mathfrak{p}$ in a unique factorization domain is principal, generated by an irreducible element.

The ring $\Gamma(\mathbb{A}^n) \cong k[x_1, \ldots, x_n]$ is a UFD, being a polynomial ring in finitely many variables over the field k (corollary 11.2.4). Choose $0 \neq g \in \mathfrak{p}$ and factor it into irreducibles, $g = f_1 \cdots f_r$. As $\mathfrak{p}$ is prime, some $f_i \in \mathfrak{p}$; write $f = f_i$. In a UFD an irreducible element is prime (proposition 10.1.29), so (f) is a nonzero prime ideal with

$$(0) \subsetneq (f) \subseteq \mathfrak{p}$$

If the second inclusion were strict, that chain would have length 2 and give $\operatorname{height}(\mathfrak{p}) \geq 2$. Hence $(f) = \mathfrak{p}$. Uniqueness up to a scalar is uniqueness of the generator of a principal ideal in a domain, and $Y = \mathcal{Z}(\mathcal{I}(Y)) = \mathcal{Z}(f)$ by proposition 31.2.11.

Conversely let f be irreducible. Then (f) is prime, so $\mathcal{Z}(f)$ is irreducible, and theorem 34.4.1 applied to $X = \mathbb{A}^n$ gives $\dim \mathcal{Z}(f) = n - 1$, that is codimension 1, as we sought to show.

Example 34.4.3: Hypersurfaces and Their Ideals

1. The cuspidal cubic $\mathcal{Z}(y^2 - x^3) \subseteq \mathbb{A}^2$ has $y^2 - x^3$ irreducible, so its vanishing ideal is $(y^2 - x^3)$ and it is a curve: codimension 1 in $\mathbb{A}^2$.

2. $\mathcal{Z}(xy) \subseteq \mathbb{A}^2$ is not irreducible, and correspondingly (xy) is not prime. Its two components $\mathcal{Z}(x)$ and $\mathcal{Z}(y)$ each have codimension 1, as theorem 34.4.1 predicts.

3. The twisted cubic $\mathcal{Z}(y - x^2, z - x^3) \subseteq \mathbb{A}^3$ has dimension 1, hence codimension 2, and so by theorem 34.4.2 it cannot be cut out by a single equation. This is the promise made when the twisted cubic first appeared in example 31.2.2 that it is not a hypersurface.

Exercise 34.4.1

1. Let X, Y be irreducible affine varieties. Show that $\dim(X \times Y) = \dim(X) + \dim(Y)$ directly from the transcendence-degree definition. Corollary 40.5.4 proves this a different way, by reading the projection as a family of fibres, so the two arguments are worth comparing.

2. Define the *coheight* of a prime $\mathfrak{p} \subseteq R$ to be the supremum of the lengths of chains of primes $\mathfrak{p} = \mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_d$. Show that $\operatorname{coht}(\mathfrak{p}) = \operatorname{kdim}(R/\mathfrak{p})$ for any ring, give an example where it is infinite, and show it is finite whenever R is a finitely generated k-algebra.

3. Let R be a Noetherian ring. Show that $\mathrm{kdim} R[x] = \mathrm{kdim} R + 1$.
4. Compute the dimension of $\mathcal{Z}(xy, xz) \subseteq \mathbb{A}^3_k$, identify its irreducible components, and observe that they do not all have the same dimension. Which hypothesis of proposition 34.3.2 does this violate?
5. Show that $\dim \mathcal{Z}(f) = n - 1$ for any nonconstant $f \in k[x_1, \ldots, x_n]$, and deduce that a proper closed subset of $\mathbb{A}^n_k$ has dimension at most $n - 1$.
6. Let $X \subseteq \mathbb{A}^n_k$ be an irreducible variety of dimension d. Show that X is contained in no linear subspace of dimension less than d, and give an example where it is contained in one of dimension exactly d.
7. Verify from the definitions that a plane curve has dimension 1, that a finite set has dimension 0, and that $\mathbb{A}^n_k$ has dimension n.

35

Smooth Points and Regular Local Rings

The dimension theory the previous chapter used, and which this one uses again, rests on the Hilbert-Samuel function of an $\mathfrak{m}$-primary ideal and the Dimension Theorem $\delta(R) = d(R) = \mathrm{kdim} R$ it yields, together with systems of parameters. Those are in *Commutative Algebra* [10].

This chapter takes the one consequence that carries geometric content, the tangent-space inequality $\mathrm{kdim} R \leq \dim_k(\mathfrak{m}/\mathfrak{m}^2)$, and turns it into a criterion. A point is *smooth* when the inequality is an equality, which says the tangent space has no more directions than the variety has dimensions. The Jacobian gives a computable test for this, regular local rings give an intrinsic one free of any embedding, and the two agree. The chapter closes with the case that matters most for Part IX: in dimension one, regular is the same as being a discrete valuation ring.

35.1 The Tangent Space Bound

For a Noetherian local ring $(R, \mathfrak{m})$ the Dimension Theorem ([10]) identifies the Krull dimension with the degree of the Hilbert-Samuel polynomial and with the least number of generators of an $\mathfrak{m}$-primary ideal. The one consequence we need geometrically bounds the dimension by the embedding dimension.

Corollary 35.1.1: Dimension and Tangent Space

Let $(R, \mathfrak{m})$ be a Noetherian local ring with residue field $k = R/\mathfrak{m}$. Then

$$\mathrm{kdim}(R) \leq \dim_k(\mathfrak{m}/\mathfrak{m}^2)$$

***Proof*:**
Choose $r_1, \ldots, r_s \in \mathfrak{m}$ whose images form a basis of $\mathfrak{m}/\mathfrak{m}^2$; by Nakayama they generate $\mathfrak{m}$, hence an $\mathfrak{m}$-primary ideal on s generators, so the Dimension Theorem ([10]) gives $\mathrm{kdim} R \leq s = \dim_k(\mathfrak{m}/\mathfrak{m}^2)$.

35.2 The Jacobian Criterion and Regular Local Rings

One of the properties most geometric objects carry is *smoothness*, or nonsingularity. In this section, we shall introduce an intuitive way of defining smoothness given an embedding into an affine/projective space. We shall then show a more intrinsic definition that will not require any embedding.

Definition 35.2.1: Nonsingular Variety - Embedding Variant

Let $X \subseteq \mathbb{A}^n_k$ be an affine variety of dimension r, and let $f_1, \ldots, f_t$ generate its vanishing ideal $\mathcal{I}(X) \subseteq \Gamma(\mathbb{A}^n)$. Then X is *nonsingular* at $p \in X$ if the Jacobian matrix evaluated at p,

$$J(p) = \left(\frac{\partial f_i}{\partial x_j}(p)\right)_{\substack{1 \leq i \leq t \\ 1 \leq j \leq n}}$$

has rank $J(p) = n - r$. We say X is *nonsingular* if it is nonsingular at every point.

If the reader knows differential geometry, this is saying that the tangent space must be "full rank" at every point. The matrix is called the *Jacobian matrix*. Its rank at p does not depend on the chosen generators, even though the matrix itself does: the proof of proposition 35.2.2 below identifies rank $J(p)$ with $n - \dim_k \mathfrak{m}_p/\mathfrak{m}_p^2$, an invariant of the local ring alone. This definition is geometrically well-motivated, but is not intrinsic to the variety: it is dependent on the "global" information of the embedding space and generators. We shall immediately work towards the intrinsic definition of nonsingular variety. The key is that at each point p the local ring $\mathcal{O}_{X,p}$ has a single maximal ideal $\mathfrak{m}_p$ representing where functions evaluate to 0, and $\mathfrak{m}_p/\mathfrak{m}_p^2$ "remembers" only linear terms, making it the best analogy to the cotangent space at a point. Recall that $\dim_k \mathfrak{m}_p/\mathfrak{m}_p^2 \geq \mathrm{kdim} k[X]$ by corollary 35.1.1. The inequality is strict exactly at a singular point, where the tangent space picks up extra dimensions. We thus seek conditions where the local ring at each point shall have the same dimension everywhere:

A local Noetherian ring of dimension d with maximal ideal $\mathfrak{m}$ and residue field k is *regular* when $\dim_k(\mathfrak{m}/\mathfrak{m}^2) = d$, equivalently when $\mathfrak{m}$ can be generated by d elements, equivalently when the associated graded ring $G_{\mathfrak{m}}(R)$ is the polynomial ring $k[t_1, \ldots, t_d]$ on independent degree-one indeterminates. The definition, the equivalence of the three conditions, and the consequences used below are commutative algebra and are developed in *Commutative Algebra*: see definition 29.7.2 and theorem 29.7.3.

Proposition 35.2.2: Jacobian Criterion and Regular Local Rings

Let $X \subseteq \mathbb{A}^n_k$ be a variety. Then X is nonsingular at p iff the local ring at p is regular.

***Proof*:**
Let $p = (a_1, \dots, a_n) \in \mathbb{A}^n$ and let $\mathfrak{a}_p = (x_1 - a_1, \dots, x_n - a_n)$ be the corresponding maximal ideal of $A = \Gamma(\mathbb{A}^n) \cong k[x_1, \dots, x_n]$. Define a k-linear map $\theta_p \colon A \to k^n$ by

$$\theta_p(f) = \left\langle \frac{\partial f}{\partial x_1}(p), \dots, \frac{\partial f}{\partial x_n}(p) \right\rangle$$

The images $\theta_p(x_i - a_i)$ are the standard basis vectors, so θ_p is surjective and its restriction to $\mathfrak{a}_p$ is still surjective. That restriction has kernel exactly $\mathfrak{a}_p^2$: the product rule gives $\theta_p(fg) = f(p)\theta_p(g) + g(p)\theta_p(f)$, which vanishes when $f, g \in \mathfrak{a}_p$, and conversely a Taylor expansion of $f \in \mathfrak{a}_p$ at p has linear part determined by $\theta_p(f)$. Note the restriction is essential: θ_p kills every constant, so $\ker \theta_p \neq \mathfrak{a}_p^2$ on all of A. Thus θ_p induces an isomorphism $\theta_p' \colon \mathfrak{a}_p/\mathfrak{a}_p^2 \to k^n$.

Now let $\mathfrak{b} = \mathcal{I}(X)$ be the ideal of X in A, and let $f_1, \dots, f_t$ be a set of generators of $\mathfrak{b}$. Then the rank of the Jacobian matrix $J = (\partial f_i/\partial x_j)(p)$ is just the dimension of $\theta_p(\mathfrak{b})$ as a subspace of k^n. Using the isomorphism θ_p', this is the same as the dimension of the subspace $(\mathfrak{b} + \mathfrak{a}_p^2)/\mathfrak{a}_p^2$ of $\mathfrak{a}_p/\mathfrak{a}_p^2$. On the other hand, the local ring $\mathcal{O}_p$ of p on X is obtained from A by dividing by $\mathfrak{b}$ and localizing at the maximal ideal $\mathfrak{a}_p$. Thus if $\mathfrak{m}$ is the maximal ideal of $\mathcal{O}_p$, we have

$$\mathfrak{m}/\mathfrak{m}^2 \cong \mathfrak{a}_p/(\mathfrak{b} + \mathfrak{a}_p^2)$$

Counting dimensions of vector spaces, we have $\dim \mathfrak{m}/\mathfrak{m}^2 + \operatorname{rank}(J) = n$.

But this gives what we want. If $\dim X = r$ then $\mathcal{O}_p$ has Krull dimension r, since localizing $k[X]$ at the maximal ideal of p leaves the dimension of the irreducible X unchanged by proposition 34.3.2. So $\mathcal{O}_p$ is regular if and only if $\dim_k \mathfrak{m}/\mathfrak{m}^2 = r$. But this is equivalent to $\operatorname{rank}(J) = n - r$, which says that p is a nonsingular point of X, completing the proof.

Example 35.2.3: The Jacobian Criterion on Three Curves
Each of the following is a curve in $\mathbb{A}_k^2$, and the criterion is applied at the origin, which lies on all three. Assume $\operatorname{char} k \neq 2, 3$.

1. *The parabola* $f = y - x^2$. The Jacobian is $(-2x,\ 1)$, of rank 1 everywhere. So every point is nonsingular, and $\dim_k \mathfrak{m}_p/\mathfrak{m}_p^2 = 1 = \dim C$ at each.
2. *The node* $f = y^2 - x^2 - x^3$. The Jacobian is $\left(-2x - 3x^2,\ 2y\right)$, which vanishes at $(0,0)$ and at $(-2/3, 0)$; only the first is on the curve. So the origin is the unique singular point, and there $\dim_k \mathfrak{m}/\mathfrak{m}^2 = 2 > 1$.
3. *The cusp* $f = y^2 - x^3$. The Jacobian is $\left(-3x^2,\ 2y\right)$, vanishing only at the origin, which is on the curve. Again the origin is the unique singular point with $\dim_k \mathfrak{m}/\mathfrak{m}^2 = 2$.

The criterion separates the parabola from the other two but says nothing distinguishing the node from the cusp: both are singular points of multiplicity 2. Telling them apart needs the tangent cone of definition 36.1.2, taken up in the next chapter, which sees two tangent lines at the node and one doubled at the cusp.

From this, we can extend the definition naturally to any quasiprojective variety.

Definition 35.2.4: Nonsingular Variety

Let X be a quasi-projective variety. Then X is *nonsingular* or *regular* if the local ring at every point is regular.

35.3 The Singular Locus

The set of points that are singular are usually "measure 0". We shall not go so far to prove this statement, but the following simpler result that a variety cannot *only* consist of singular points:

Proposition 35.3.1: Singular Points of Variety

Let X be a variety. Then the set of singular points of X forms a proper closed subset of X

The fact that it is closed should be unsurprising as it is essentially the pre-image of the closed set 0 for the right continuous function, the key take-away is that it must be proper.

***Proof*:**
Let $\mathrm{Sing}(X)$ denote the set of singular points of X.

Closed. Being closed is local, so covering X by affine open sets reduces us to X affine, say of dimension r in $\mathbb{A}^n$ with $\mathcal{I}(X) = (f_1, \ldots, f_t)$. Combining corollary 35.1.1 with the dimension count in the proof of proposition 35.2.2 gives rank $J(p) \leq n - r$ at every p, with equality exactly at the nonsingular points. So the singular points are those where the rank is *strictly* less than $n - r$. Thus $\mathrm{Sing}(X)$ is the algebraic set defined by the ideal generated by $I(X)$ together with all determinants of $(n-r) \times (n-r)$ sub-matrices of the matrix $\|\partial f_i/\partial x_j\|$. From these, we can see that $\mathrm{Sing}\, X$ is closed.

Proper. By theorem 33.4.1, X is birationally isomorphic to a hypersurface $Y \subseteq \mathbb{A}^{d+1}$, where $d = \dim X$; note the theorem produces an *affine* hypersurface, not a projective one. By proposition 39.5.2 a birational isomorphism identifies a dense open subset of X with one of Y, and nonsingularity is a local condition, so it is enough to exhibit a single nonsingular point on Y. Thus we may assume X is a hypersurface in $\mathbb{A}^n$ cut out by one irreducible polynomial $f(x_1, \ldots, x_n)$.

Now, $\mathrm{Sing}(X)$ is the set of points $p \in X$ such that $(\partial f/\partial x_i)(p) = 0$ for $i = 1, \ldots, n$. If $\mathrm{Sing}\, X = X$, then the functions $\partial f/\partial x_i$ are zero on X, and hence $\partial f/\partial x_i \in I(X)$ for each i. But $I(X)$ is the principal ideal generated by f, and $\deg(\partial f/\partial x_i) \leq \deg f - 1$ for each i, so we must have $\partial f/\partial x_i = 0$ for each i.

In characteristic 0 this is already impossible, because if x_i occurs in f, then $\partial f/\partial x_i \neq 0$. So we must have char $k = p > 0$, and then the fact that $\partial f/\partial x_i = 0$ implies that f is a polynomial in x_i^p. This is true for each i, so by taking pth roots of the coefficients (which is possible since k is algebraically closed), we get a polynomial $g(x_1, \ldots, x_n)$ such that $f = g^p$. But this contradicts the hypothesis that f was irreducible, and so $\mathrm{Sing}\, X \subsetneq X$, as we sought to show.

35.4 Homological Characterization: Serre's Theorem

Before stating the main theorem on regular local rings, we need a homological invariant[1]:

Definition 35.4.1: Projective and Global Dimension

Let R be a ring and M an R-module. The *projective dimension* of M, denoted $\mathrm{pd}_R(M)$, is the minimal length n of a projective resolution of M:

$$0 \to P_n \to \cdots \to P_0 \to M \to 0$$

If no finite resolution exists, $\mathrm{pd}_R(M) = \infty$.

The *global dimension* of R, denoted $\mathrm{gldim}(R)$, is the supremum of the projective dimensions of all R-modules:

$$\mathrm{gldim}(R) = \sup\{\mathrm{pd}_R(M) \big| M \in \mathrm{Mod}_R\}$$

Example 35.4.2: Infinite Global Dimension When There is A Singularity

Take $R = k[x, y]/(x^2 - y^3)$. This corresponds to the cusp singularity at the origin. Let us compute the global dimension by finding the projective dimension of the residue field $k \cong R/(x, y)$ (where $\mathfrak{m} = (\overline{x}, \overline{y})$). We begin a free resolution of k by killing $\mathfrak{m} = (\overline{x}, \overline{y})$:

$$R^2 \xrightarrow{d_1} R \to k \to 0$$

where $d_1 = \begin{pmatrix} x & y \end{pmatrix}$. The kernel of this map consists of relations between x and y. In the polynomial ring, the only relation is trivial ($yx - xy = 0$). However, in our quotient ring R, we have the relation defining the ring: $x^2 - y^3 = 0$. Thus, the kernel is generated by two elements:

1. The "Koszul" relation: $y \cdot (x) - x \cdot (y) = 0$
2. The "Curve" relation: $x \cdot (x) - y^2 \cdot (y) = 0$

So we have a map $R^2 \xrightarrow{d_2} R$ given by the matrix $\begin{pmatrix} y & x \\ -x & -y^2 \end{pmatrix}$. (Check: $\begin{pmatrix} x & y \end{pmatrix} \begin{pmatrix} y & x \\ -x & -y^2 \end{pmatrix} = \begin{pmatrix} xy - yx & x^2 - y^3 \end{pmatrix} = \begin{pmatrix} 0 & 0 \end{pmatrix}$).

Now we need the kernel of d_2. Calculating the determinant of the matrix, we find $\det(d_2) = -y^3 + x^2 = 0$. Because the determinant vanishes, the columns are linearly dependent, and the kernel is non-trivial. In fact, the resolution becomes *periodic*. The resolution continues forever with alternating matrices:

$$\cdots \xrightarrow{d_3} R^2 \xrightarrow{d_2} R^2 \xrightarrow{d_1} R \to k \to 0$$

where $d_{\text{odd}} = \begin{pmatrix} y & x \\ -x & -y^2 \end{pmatrix}$ and $d_{\text{even}} = \begin{pmatrix} y^2 & x \\ -x & -y \end{pmatrix}$. Since the resolution never terminates (it never reaches a 0 module), the projective dimension of k is infinite. Therefore, the global dimension of R is infinite.

[1] These terms will be central in section 57.2 and will be reintroduced there

For a local ring $(R, \mathfrak{m})$ with residue field k, a fundamental result of Auslander and Buchsbaum states that $\mathrm{gldim}(R) = \mathrm{pd}_R(k)$. Thus, the global dimension is determined entirely by the resolution of the residue field.

Theorem 35.4.3: Auslander-Buchsbaum-Serre Theorem

A local Noetherian ring $(R, \mathfrak{m})$ has finite global dimension if and only if it is a regular local ring.

The proof is homological rather than geometric, and belongs with the machinery that produces it: it runs through the Auslander-Buchsbaum identity $\mathrm{gldim}\, R = \mathrm{pd}_R\, k$ and the Koszul resolution of the residue field, neither of which this book develops. *Homological Algebra* [15, Auslander-Buchsbaum-Serre Theorem] gives it in full; the two books are co-requisites for exactly this reason.

***Proof Key ideas*:**
One direction is the Koszul resolution. If R is regular of dimension d, then $\mathfrak{m}$ is generated by a regular sequence $x_1, \dots, x_d$, and the Koszul complex on that sequence is a free resolution of $k = R/\mathfrak{m}$ of length d. Hence $\mathrm{pd}_R\, k \leq d < \infty$, and by the Auslander-Buchsbaum identity $\mathrm{gldim}\, R = \mathrm{pd}_R\, k$ is finite.

The converse is the substantive half. Finiteness of $\mathrm{pd}_R\, k$ forces the minimal free resolution of k to terminate, and one shows by induction on $\dim_k \mathfrak{m}/\mathfrak{m}^2$ that this can happen only when a minimal generating set of $\mathfrak{m}$ is a regular sequence, which is regularity. See [15, Auslander-Buchsbaum-Serre Theorem] for the details.

35.5 Regular Local Rings in Dimension One

Let us now take a closer look at the properties regular local rings must have, especially in low dimension. In one dimension, this shall produce a very restrictive result that will be very powerful, and in higher dimensions we shall find an algebraic condition that eventually lets the rings of integers of *Algebraic Number Theory* [7] be read as nonsingular $\mathbb{Z}$-curves. For curves this is the decisive case, and section 37.3 uses it to show that each birational class of curves contains a unique nonsingular projective model, so that a field extension K/k of transcendence degree one determines *the* curve attached to it.

One consequence is needed before the dimension-one case, and it is not visible from the numerical definition: a regular local ring has no zero-divisors. The mechanism is that regularity makes the associated graded ring a polynomial ring, hence a domain, and a domain downstairs lifts to a domain upstairs whenever $\bigcap_n \mathfrak{m}^n = 0$, which Krull's theorem supplies in any Noetherian local ring. Both steps are commutative algebra and are carried out in corollary 29.7.5.

Corollary 35.5.1: Regular Local Rings of Dimension 1

Let R be a local Noetherian ring of dimension 1. Then R is a regular local ring if and only if R is a DVR.

***Proof*:**
Suppose $(R, \mathfrak{m})$ is regular of dimension 1, so $\dim_{R/\mathfrak{m}} \mathfrak{m}/\mathfrak{m}^2 = \mathrm{kdim} R = 1$. Choose $m \in \mathfrak{m}$ whose class spans $\mathfrak{m}/\mathfrak{m}^2$. Nakayama's lemma (theorem 23.4.30) then gives $\mathfrak{m} = (m)$: the single element m generates. By the discussion above R is a domain, and a Noetherian local domain of dimension 1 with principal maximal ideal is a discrete valuation ring (theorem 27.2.2).

Conversely let R be a discrete valuation ring with uniformizer m. It is local: its unique maximal ideal is (m), the elements of positive valuation. Note it is *not* true that (m) is its only prime, as (0) is prime too; indeed the chain $(0) \subsetneq (m)$ is what makes $\mathrm{kdim} R = 1$, and no longer chain exists because every nonzero ideal is $(m)^n$. Finally $(m)/(m)^2$ is spanned by the class of m over $R/(m)$ and is nonzero, so $\dim_{R/(m)}(m)/(m)^2 = 1 = \mathrm{kdim} R$ and R is regular, as we sought to show.

This gives a nice condition for 1-dimensional regular local rings. It will sometimes be useful to identify regular local rings in different context:

Proposition 35.5.2: Equivalences of 1 Dimensional Regular Local Rings

Let $(R, \mathfrak{m})$ be a Noetherian local domain of dimension 1. Then the following are equivalent:

1. R is a regular local ring
2. R is a DVR
3. R is normal (integrally closed)
4. $\mathfrak{m}$ is principal
5. every nonzero ideal of R is a power of $\mathfrak{m}$

***Proof*:**
This is a statement about Noetherian local domains with no geometric content, and it is proved in full upstream: see theorem 27.2.2, which lists exactly these five conditions.

The equivalence of (1) and (3) is the one chapter 37 consumes. It says that for a curve, being smooth at a point and being normal at that point are the same condition, which is why normalization resolves the singularities of a curve completely while leaving higher-dimensional singularities behind.

For higher-dimensions, the situation is more subtle, and the full account belongs with divisors on a scheme; this book records only the following:

Corollary 35.5.3: Regular Local Ring, then Normal

Let R be a regular local Noetherian ring. Then R is normal.

***Proof*:**
This is corollary 29.8.7, where it is obtained from factoriality: a regular local ring is a unique factorization domain by the theorem of Auslander and Buchsbaum, and a unique factorization domain is integrally closed. In dimension one the statement is already contained in proposition 35.5.2, which is the case this book uses.

The converse does not hold in general in dimension > 1, a normal domain need not be regular, so normality alone does not detect nonsingular varieties. Chapter 37 takes up exactly this gap.

Proposition 35.5.4: Completion and Regularity

Let $(R, \mathfrak{m})$ be a Noetherian local ring and $\hat{R}$ its $\mathfrak{m}$-adic completion. Then R is regular if and only if $\hat{R}$ is regular.

***Proof*:**
This is proposition 29.7.6. The mechanism is that completion leaves the associated graded ring alone, $G_{\mathfrak{m}}(R) \cong G_{\hat{\mathfrak{m}}}(\hat{R})$, and leaves the dimension alone; the graded criterion for regularity depends on nothing else, so it holds for one exactly when it holds for the other, as we sought to show.

In this case $\hat{R}$ is again an integral domain.

Exercise 35.5.1

1. Compute the singular locus of $\mathcal{Z}(y^2 - x^3)$, of $\mathcal{Z}(y^2 - x^2 - x^3)$, and of $\mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$, using proposition 35.2.2 in each case.
2. Show that the singular locus of a variety is a proper closed subset, so that the nonsingular points are dense. Where does the argument use irreducibility?
3. Let $X = \mathcal{Z}(f) \subseteq \mathbb{A}^n_k$ be a hypersurface. Show that $p \in X$ is nonsingular if and only if some $\partial f / \partial x_i$ fails to vanish at p, and give an example in characteristic $p > 0$ where every partial derivative vanishes identically on a nonconstant f.
4. Show that $\dim_k \mathfrak{m}_p / \mathfrak{m}_p^2 \geq \dim X$ at every point of a variety, with equality exactly at the nonsingular points, and identify which inequality of corollary 35.1.1 is being used.
5. Show that a regular local ring is a domain, and give an example of a Noetherian local domain that is not regular.
6. Show that the local ring of the node $\mathcal{Z}(y^2 - x^2 - x^3)$ at the origin is not a domain after completion, although it is a domain before. (This is why $\mathcal{O}_p$ alone cannot distinguish a node from a cusp, and why proposition 35.5.4 is stated for completions.)
7. Use theorem 35.4.3 to show that a regular local ring is a unique factorization domain in dimension one, and explain why the same argument does not immediately give the general case.

36

Tangent Cones and Completions

The Jacobian criterion of chapter 35 decides whether a point is smooth and stops there. It cannot tell the node $y^2 = x^2 + x^3$ from the cusp $y^2 = x^3$: both are singular at the origin, both have a one-dimensional variety with a two-dimensional cotangent space, and no invariant built from $\mathfrak{m}_p/\mathfrak{m}_p^2$ alone separates them. Yet they are visibly different curves, the node crossing itself and the cusp not.

This chapter builds the invariants that see the difference. The first keeps more of the filtration than $\mathfrak{m}_p/\mathfrak{m}_p^2$ does: the associated graded ring of $\mathcal{O}_{X,p}$, whose zero set is the cone of tangent directions and whose Hilbert polynomial is the multiplicity. The second is finer still. Passing to the completion $\hat{\mathcal{O}}_{X,p}$ makes available power series that converge in no algebraic sense, and in that larger ring the node's local equation factors while the cusp's does not; the factors are the branches of the curve through the point. The chapter closes by using regularity to show that on a smooth variety every codimension-one subvariety is locally cut out by one equation, which is the fact section 37.5 needs and could not prove.

36.1 The Tangent Cone and Multiplicity

Throughout, $X \subseteq \mathbb{A}^n_k$ is an affine variety and $p \in X$ a point, and after a translation p is the origin. Write $A = \Gamma(\mathbb{A}^n_k) = k[x_1, \ldots, x_n]$ and $\mathfrak{n} = (x_1, \ldots, x_n)$ for the maximal ideal at the origin.

Definition 36.1.1: Initial Form

For $0 \neq f \in A$ write $f = f_m + f_{m+1} + \cdots$ with each f_j homogeneous of degree j and $f_m \neq 0$. The *initial form* of f is $f_* = f_m$, and m is the *order* of f at the origin. For an ideal $I \subseteq A$, the *initial ideal* is $I_* = (f_* : 0 \neq f \in I)$, the ideal generated by all initial forms.

The initial form records the lowest-order behaviour of f at the origin, so it is the first place a curve's shape shows up: for the node $f = y^2 - x^2 - x^3$ it is $y^2 - x^2$, which factors into two distinct lines when $\operatorname{char} k \neq 2$, while for the cusp $f = y^2 - x^3$ it is y^2, a single line doubled. In characteristic 2 the node's initial form is $(y+x)^2$ and the distinction collapses, so that hypothesis is carried explicitly wherever the node is used. That the initial ideal is generated by initial forms and not merely by the initial forms of a generating set is a real distinction, and the next proposition is what makes the definition intrinsic in spite of it.

Definition 36.1.2: Tangent Cone

The *tangent cone algebra* of X at p is the associated graded ring

$$\operatorname{gr}_{\mathfrak{m}_p} \mathcal{O}_{X,p} = \bigoplus_{j \geq 0} \mathfrak{m}_p^j / \mathfrak{m}_p^{j+1}$$

a graded k-algebra. The *tangent cone* $TC_p(X) \subseteq \mathbb{A}_k^n$ is the affine algebraic set $\mathcal{Z}(I_*)$, where $I = \mathcal{I}(X)$.

Proposition 36.1.3: The Tangent Cone Algebra Is Intrinsic

With the notation above, there is an isomorphism of graded k-algebras

$$\operatorname{gr}_{\mathfrak{m}_p} \mathcal{O}_{X,p} \cong A/I_*$$

In particular the tangent cone algebra does not depend on the embedding $X \subseteq \mathbb{A}_k^n$, and $TC_p(X) = \mathcal{Z}(I_*)$ is the zero set of the tangent cone algebra.

***Proof*:**
Step 1: the local ring may be replaced by the coordinate ring. Put $R = \Gamma(X) = A/I$ with maximal ideal $\mathfrak{m} = \mathfrak{n}/I$ at the origin. Each $\mathfrak{m}^j/\mathfrak{m}^{j+1}$ is annihilated by $\mathfrak{m}$, hence is a vector space over $R/\mathfrak{m} = k$, and localizing at $\mathfrak{m}$ acts as the identity on such a module. So $\operatorname{gr}_{\mathfrak{m}_p} \mathcal{O}_{X,p} \cong \operatorname{gr}_{\mathfrak{m}} R$.

Step 2: the surjection and its kernel. The quotient $A \twoheadrightarrow R$ carries $\mathfrak{n}^j$ onto $\mathfrak{m}^j$, hence induces a surjection of graded rings $\operatorname{gr}_{\mathfrak{n}} A \twoheadrightarrow \operatorname{gr}_{\mathfrak{m}} R$, and $\operatorname{gr}_{\mathfrak{n}} A \cong A$ as graded rings since $\mathfrak{n}^j/\mathfrak{n}^{j+1}$ is the space of forms of degree j. In degree j the kernel is

$$\big((I \cap \mathfrak{n}^j) + \mathfrak{n}^{j+1}\big)/\mathfrak{n}^{j+1}$$

and it remains to identify this with the degree-j part of I_*.

Step 3: the kernel is I_*. For one inclusion, let $f \in I$ have initial form f_* of degree m and let g be homogeneous of degree $j - m$. Then $gf \in I$, and since A is a domain the initial form of gf is gf_*, of degree j; so $gf \in I \cap \mathfrak{n}^j$ and $gf \equiv gf_* \pmod{\mathfrak{n}^{j+1}}$. Hence every degree-$j$ element of I_* lies in the kernel. Conversely let $a \in I \cap \mathfrak{n}^j$. Its initial form a_* has degree at least j. If the degree exceeds j then $a \in \mathfrak{n}^{j+1}$ and a contributes 0; if it equals j then $a \equiv a_* \pmod{\mathfrak{n}^{j+1}}$ with $a_* \in I_*$. So the kernel is exactly the degree-j part of I_*, completing the proof.

The proposition is what licenses the name: the left-hand side is built from $\mathcal{O}_{X,p}$ alone and knows nothing of the embedding, so the right-hand side cannot depend on it either, even though I_* is written in the coordinates of $\mathbb{A}_k^n$.

One caution follows immediately, and it is the first place this book runs into the limitation that chapter 49 takes up. The tangent cone algebra A/I_* and the tangent cone $TC_p(X) = \mathcal{Z}(I_*)$ are not equivalent data: passing from the ideal to its zero set discards nilpotents, so the coordinate ring of $TC_p(X)$ is $A/\sqrt{I_*}$ rather than A/I_*. For the cusp $I_* = (y^2)$, so the tangent cone algebra is $k[x,y]/(y^2)$ while the tangent cone is the line $\mathcal{Z}(y)$, and the doubling is visible only in the algebra. The algebra is therefore the finer invariant, and it is the one the multiplicity is defined from.

Definition 36.1.4: Multiplicity

Let $d = \mathrm{kdim}\mathcal{O}_{X,p}$. The function $j \mapsto \ell(\mathcal{O}_{X,p}/\mathfrak{m}_p^j)$ agrees for $j \gg 0$ with a polynomial in j (proposition 29.3.2) whose degree is d (theorem 29.4.1), and whose leading coefficient may be written $e/d!$ for a positive integer e. This e is the *multiplicity* of X at p, written $m_p(X)$.

Two things in that definition need saying. First, the leading coefficient is $e/d!$ with e a positive integer because a polynomial taking integer values at all large integers is an integer combination $\sum_i c_i\binom{j}{i}$ of binomial coefficients, so its degree-d coefficient is $c_d/d!$ with $c_d \in \mathbb{Z}$; here the values $\ell(\mathcal{O}_{X,p}/\mathfrak{m}_p^j)$ are lengths, hence non-negative integers, and $c_d > 0$ since the polynomial has degree exactly d and is eventually increasing. Second, the first difference of $j \mapsto \ell(\mathcal{O}_{X,p}/\mathfrak{m}_p^j)$ is $\dim_k \mathfrak{m}_p^j/\mathfrak{m}_p^{j+1}$, the Hilbert function of the tangent cone algebra, so $m_p(X)$ is determined by that algebra, and by proposition 36.1.3 by the point alone.

Proposition 36.1.5: Multiplicity of a Hypersurface

Let $n \geq 2$ and let $X = \mathcal{Z}(f) \subseteq \mathbb{A}_k^n$ be a hypersurface with f irreducible, and let $p \in X$. Then $I_* = (f_*)$ and

$$m_p(X) = \deg f_* = \text{the order of } f \text{ at } p$$

***Proof*:**
Since f is irreducible, $\mathcal{I}(X) = (f)$ by the Nullstellensatz (theorem 32.4.4), (f) being prime hence radical. Every element of (f) is gf, and A being a domain gives $(gf)_* = g_*f_*$, so every initial form of an element of (f) is a multiple of f_*; hence $I_* = (f_*)$. Write $m = \deg f_*$.

By proposition 36.1.3 the tangent cone algebra is $A/(f_*)$, whose degree-j piece has dimension $\binom{j+n-1}{n-1} - \binom{j-m+n-1}{n-1}$ for $j \geq m$, multiplication by the form f_* being injective on a domain. This is a polynomial in j of degree $n-2$ with leading coefficient $m/(n-2)!$; the identity holds for $j \geq m$, and the finitely many earlier terms shift the sum below by a constant without affecting its degree or leading coefficient. Summing over j raises the degree by one, so $\ell(\mathcal{O}_{X,p}/\mathfrak{m}_p^j)$ has degree $n-1$ and leading coefficient $m/(n-1)!$. By the dimension theorem that degree is $\mathrm{kdim}\mathcal{O}_{X,p}$, so $d = n-1$, and definition 36.1.4 gives $m_p(X) = m$, as we sought to show.

Proposition 36.1.6: Smooth Points Have Multiplicity One

If p is a smooth point of X then $m_p(X) = 1$. For a hypersurface the converse holds: an irreducible hypersurface with $m_p(X) = 1$ is smooth at p.

***Proof*:**
If p is smooth then $\mathcal{O}_{X,p}$ is regular of dimension d (proposition 35.2.2), so its tangent cone algebra is the polynomial ring $k[t_1, \ldots, t_d]$ by theorem 29.7.3. Then $\dim_k \mathfrak{m}_p^j/\mathfrak{m}_p^{j+1} = \binom{j+d-1}{d-1}$, a polynomial of degree $d-1$ with leading coefficient $1/(d-1)!$, and summing gives leading coefficient $1/d!$; so $m_p(X) = 1$.

For the converse on a hypersurface $X = \mathcal{Z}(f)$, proposition 36.1.5 makes $m_p(X) = 1$ say that f_* is a nonzero linear form. That linear form is $\sum_i (\partial f/\partial x_i)(p)\, x_i$ up to translation, so some partial derivative of f is nonzero at p and the Jacobian has rank one there, which is smoothness by definition 35.2.1, completing the proof.

The converse in fact holds for every variety, not only for hypersurfaces, but its proof needs an unmixedness theorem of Nagata that this book does not develop; see [37]. What the general statement does require is irreducibility. On a reducible algebraic set multiplicity one can fail to force regularity: for $\mathcal{Z}(xz, yz) \subseteq \mathbb{A}^3_k$, a plane meeting a line, the local ring at the origin has $\dim_k \mathfrak{m}^j/\mathfrak{m}^{j+1} = j+2$ for $j \geq 1$, so $\ell(R/\mathfrak{m}^j) = j^2/2 + 3j/2 - 1$ and $m = 1$ at a point where the ring is not even a domain.

Example 36.1.7: Tangent Cones of the Node, the Cusp, and the Quadric Cone

1. *The node* $C = \mathcal{Z}(y^2 - x^2 - x^3)$ at the origin. The initial form is $y^2 - x^2 = (y-x)(y+x)$, so the tangent cone is the pair of lines $\mathcal{Z}(y-x) \cup \mathcal{Z}(y+x)$ and $m_0(C) = 2$. The two lines are the two directions in which the curve leaves the origin.

2. *The cusp* $C = \mathcal{Z}(y^2 - x^3)$ at the origin. The initial form is y^2, so $m_0(C) = 2$ as well, but the tangent cone algebra is $k[x,y]/(y^2)$ and the tangent cone is the single line $\mathcal{Z}(y)$, doubled. So the multiplicity does not separate the node from the cusp, while the tangent cone does: two distinct lines against one line with multiplicity two. This is the distinction example 35.2.3 promised.

3. *The quadric cone* $X = \mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$ at the origin. Here f is already homogeneous, so $f_* = f$ and the tangent cone is X itself: a cone is its own tangent cone at its vertex. By proposition 36.1.5, $m_0(X) = 2$, and by proposition 36.1.6 the vertex is singular, which exercise set 35.5.1 found by computing the Jacobian.

4. *A smooth point.* For the parabola $\mathcal{Z}(y - x^2)$ at the origin the initial form is y, the tangent cone is the tangent line $\mathcal{Z}(y)$, and $m_0 = 1$. At a smooth point the tangent cone is always the tangent space: theorem 29.7.3 makes the tangent cone algebra a polynomial ring on d degree-one generators, so I_* is generated by linear forms.

For a plane curve the tangent cone is a form in two variables, hence a product of linear factors over the algebraically closed k; its factors are the *tangent lines* at the point and their exponents are the tangent multiplicities. That is the description chapter 42 works with, where the multiplicity of a plane curve at a point is defined directly as the order of its defining polynomial. For an *irreducible* f the two definitions agree, by proposition 36.1.5. They part company otherwise, and deliberately so: that chapter takes a plane curve to be a polynomial up to scalar rather than a zero set, so $\mathcal{Z}(y^2)$ carries multiplicity two there while as a variety it is the line $\mathcal{Z}(y)$, of multiplicity one.

36.2 Completion and Local Parameters

The tangent cone keeps more of the local ring than $\mathfrak{m}_p/\mathfrak{m}_p^2$ does, but it is still a linearization: it records the graded pieces $\mathfrak{m}_p^j/\mathfrak{m}_p^{j+1}$ and forgets how they are glued. The completion forgets nothing. It is the inverse limit of the quotients $\mathcal{O}_{X,p}/\mathfrak{m}_p^j$, so an element of it is a compatible system of Taylor approximations to arbitrary order, and the ring it lives in is large enough to contain power series that no polynomial fraction represents.

The construction of the $\mathfrak{m}$-adic completion, its Noetherianity, and the Cohen structure theorem are in *Commutative Algebra* [10, Completion Of A Ring] and are used here without redevelopment. Write $\hat{\mathcal{O}}_{X,p} = \varprojlim_j \mathcal{O}_{X,p}/\mathfrak{m}_p^j$ and $\hat{\mathfrak{m}}_p$ for its maximal ideal. The natural map $\mathcal{O}_{X,p} \to \hat{\mathcal{O}}_{X,p}$ is injective, since its kernel is $\bigcap_j \mathfrak{m}_p^j$, which vanishes in a Noetherian local ring by corollary 25.4.12. So completing loses no functions and adds many.

Theorem 36.2.1: The Completion at a Smooth Point

Let X be a variety over the algebraically closed field k and let $p \in X$ be a smooth point with $\dim_p X = d$. Then

$$\hat{\mathcal{O}}_{X,p} \cong k[[t_1, \ldots, t_d]]$$

as k-algebras, and the t_i may be taken to be the images of any regular system of parameters of $\mathcal{O}_{X,p}$.

***Proof*:**
Write $(R, \mathfrak{m}) = (\mathcal{O}_{X,p}, \mathfrak{m}_p)$, a Noetherian local ring of dimension d. Its residue field is k: it equals $k[X]/\mathcal{I}(p)$ for an affine neighbourhood, and Zariski's lemma (theorem 32.4.2) makes that a finite extension of the algebraically closed k, hence k itself. Since p is smooth, R is regular (proposition 35.2.2).

Step 1: the completion is complete regular local of dimension d. The ring $\hat{R}$ is Noetherian local with maximal ideal $\hat{\mathfrak{m}}$ and the same residue field k, by theorem 25.5.7, and $\mathrm{kdim}\hat{R} = \mathrm{kdim}R = d$ by corollary 25.5.9. It is regular by proposition 35.5.4.

Step 2: Cohen's theorem gives a presentation. The ring $\hat{R}$ is complete Noetherian local, contains k, and has residue field k, so theorem 25.6.1 presents it as

$$\hat{R} \cong k[[x_1, \ldots, x_n]]/I, \qquad n = \dim_k \hat{\mathfrak{m}}/\hat{\mathfrak{m}}^2$$

Regularity of $\hat{R}$ makes $n = \mathrm{kdim}\hat{R} = d$, so the presentation is $k[[x_1, \ldots, x_d]]/I$, and Cohen's theorem takes the x_i to any lift of a basis of $\hat{\mathfrak{m}}/\hat{\mathfrak{m}}^2$, which a regular system of parameters of R provides.

Step 3: the ideal vanishes. This is lemma 36.2.2 below, applied to $\hat{R}$, completing the proof.

The last step is worth isolating, since it is used again in section 36.3 and its argument is independent of the geometry.

Lemma 36.2.2: A Complete Regular Local Ring Is a Power Series Ring

Let $(T, \mathfrak{n})$ be a complete Noetherian regular local ring of dimension d containing a field k with $T/\mathfrak{n} = k$. Then $T \cong k[[x_1, \ldots, x_d]]$, the variables mapping to any regular system of parameters.

***Proof*:**
theorem 25.6.1 presents $T \cong S/I$ with $S = k[[x_1, \ldots, x_n]]$ and $n = \dim_k \mathfrak{n}/\mathfrak{n}^2$, which regularity makes d; its proof sends the variables to any lift of a basis of $\mathfrak{n}/\mathfrak{n}^2$, that is to any regular system of parameters. It remains to show $I = 0$.

First, S is a domain. A nonzero element of S has a well-defined initial form, its lowest-degree homogeneous part, and the initial form of a product is the product of the initial forms because the polynomial ring $k[x_1, \ldots, x_d]$ is a domain; so a product of nonzero elements has a nonzero initial form and is nonzero. (Completion does not preserve domains in general, so this needs the argument rather than a citation.)

Second, $\mathrm{kdim} S = d$: it is the completion of $k[x_1, \ldots, x_d]_{(x_1, \ldots, x_d)}$, whose dimension is d by corollary 34.2.7 and proposition 34.3.2, and corollary 25.5.9 applies.

Now suppose $I \neq 0$ and pick $0 \neq f \in I$; it is a nonunit, I being proper. Any chain of primes $\mathfrak{q}_0 \subsetneq \cdots \subsetneq \mathfrak{q}_e$ in S/I lifts to a chain of primes of S all containing f, hence all nonzero, so prepending the zero ideal, legitimate as S is a domain, gives a chain of length $e+1$ in S. Therefore $e + 1 \leq \mathrm{kdim} S = d$, so $\mathrm{kdim} S/I \leq d - 1$. But $S/I \cong T$ has dimension d, a contradiction. So $I = 0$, as we sought to show.

Definition 36.2.3: Local Parameters

A *system of local parameters* at a smooth point p of a d-dimensional variety is a regular system of parameters $t_1, \ldots, t_d$ of $\mathcal{O}_{X,p}$, that is, d elements of $\mathfrak{m}_p$ generating it. For a curve, $d = 1$ and a single generator t of $\mathfrak{m}_p$ is a *local parameter* or *uniformizer* at p.

Corollary 36.2.4: Power Series Expansion

Let p be a smooth point of X with local parameters $t_1, \ldots, t_d$. Every $f \in \mathcal{O}_{X,p}$ has a unique expansion as a formal power series in $t_1, \ldots, t_d$ with coefficients in k, and $f \in \mathfrak{m}_p^j$ if and only if that series has no terms of degree less than j.

***Proof*:**
The composite $\mathcal{O}_{X,p} \hookrightarrow \hat{\mathcal{O}}_{X,p} \cong k[[t_1, \ldots, t_d]]$ is injective by the remark before theorem 36.2.1, which gives existence and uniqueness of the expansion. Under the isomorphism $\hat{\mathfrak{m}}_p^j$ corresponds to the series of order at least j, so it remains to see that $\mathcal{O}_{X,p} \cap \hat{\mathfrak{m}}_p^j = \mathfrak{m}_p^j$. For a Noetherian local ring, corollary 25.1.5 identifies $\hat{\mathcal{O}}/\hat{\mathfrak{m}}_p^j$ with $\mathcal{O}_{X,p}/\mathfrak{m}_p^j$ compatibly with the map from $\mathcal{O}_{X,p}$, so that map composed with the projection is the projection $\mathcal{O}_{X,p} \to \mathcal{O}_{X,p}/\mathfrak{m}_p^j$, whose kernel is $\mathfrak{m}_p^j$, completing the proof.

For a curve the corollary is the statement that a regular function near a smooth point is a power series in the uniformizer, and the order of that series is the order of vanishing; definition 42.2.4 will take it as the definition. In higher dimension it is the algebraic substitute for a coordinate chart: a smooth point has no neighbourhood isomorphic to an open set of $\mathbb{A}^d_k$ in the Zariski topology, but it always has a formal one.

Example 36.2.5: Completions at Smooth and Singular Points

1. *Affine space.* At the origin of $\mathbb{A}^d_k$ the coordinates $x_1, \ldots, x_d$ are local parameters and $\hat{\mathcal{O}} \cong k[[x_1, \ldots, x_d]]$, which is example 25.1.2 read geometrically.
2. *A smooth plane curve.* On $C = \mathcal{Z}(y - x^2)$ the function x generates $\mathfrak{m}_0$, since $y = x^2$ in $\Gamma(C)$, so x is a uniformizer and $\hat{\mathcal{O}}_{C,0} \cong k[[x]]$. Every regular function near the origin is a power series in x alone, the variable y contributing nothing new.
3. *The parabola meets its axis.* On the same curve the function y has expansion x^2, so $\mathrm{ord}_0(y) = 2$: the axis $\mathcal{Z}(y)$ meets C doubly at the origin. That doubling is the intersection multiplicity chapter 42 will count.
4. *A singular point is not a power series ring.* At the origin of the cusp $\mathcal{Z}(y^2 - x^3)$ the ring $\hat{\mathcal{O}}$ is $k[[x, y]]/(y^2 - x^3)$, computed in proposition 36.3.1 below. It is not isomorphic to $k[[t]]$, since $\dim_k \hat{\mathfrak{m}}/\hat{\mathfrak{m}}^2 = 2$ there while $k[[t]]$ has $\dim_k (t)/(t^2) = 1$; theorem 36.2.1 of course forbids it, the origin being singular.

36.3 Formal Branches

The completion separates the node from the cusp, and it does so in the most direct way available: at the node the local equation factors, and at the cusp it does not. Neither factorization exists in $\mathcal{O}_{X,p}$, because the factors involve a square root that is a power series and not a rational function. This section makes that precise and attaches to each singular point of a curve a number, the count of branches through it.

Proposition 36.3.1: The Completion of a Plane Curve

Let $C = \mathcal{Z}(f) \subseteq \mathbb{A}^2_k$ be a plane curve with f irreducible and $p = (0, 0) \in C$. Then

$$\hat{\mathcal{O}}_{C,p} \cong k[[x, y]]/(f)$$

***Proof*:**
Write $A = k[x, y]$, $\mathfrak{n} = (x, y)$ and $R = \Gamma(C) = A/(f)$, with $\mathfrak{m}$ the image of $\mathfrak{n}$.

Step 1: the local ring may be replaced by the coordinate ring. For every j the ideal $\mathfrak{m}^j$ is $\mathfrak{m}$-primary, so $R/\mathfrak{m}^j$ is already local with maximal ideal $\mathfrak{m}/\mathfrak{m}^j$ and localizing at $\mathfrak{m}$ does nothing: $R/\mathfrak{m}^j \cong R_\mathfrak{m}/(\mathfrak{m}R_\mathfrak{m})^j$. Taking inverse limits, the $\mathfrak{m}$-adic completion of R agrees with the $\mathfrak{m}_p$-adic completion of $\mathcal{O}_{C,p} = R_\mathfrak{m}$. The same argument identifies the $\mathfrak{n}$-adic completion of A with that of $A_\mathfrak{n}$, and the former is $k[[x, y]]$ by example 25.1.2.

Step 2: complete the presentation. Completion is exact on finitely generated modules over a Noetherian ring (corollary 25.4.4), so applying it to $0 \to (f) \to A \to R \to 0$ gives $\hat{R} \cong k[[x,y]]/(f)k[[x,y]]$, and $(f)k[[x,y]]$ is the ideal generated by f there. Combining with Step 1 gives the claim, as we sought to show.

Definition 36.3.2: Formal Branch

Let p be a point of a variety X. A *formal branch* of X at p is a minimal prime of $\hat{\mathcal{O}}_{X,p}$. The number of formal branches is the number of such primes, which is finite because $\hat{\mathcal{O}}_{X,p}$ is Noetherian.

A smooth point has one branch, since $\hat{\mathcal{O}}_{X,p}$ is then a power series ring and hence a domain, whose unique minimal prime is 0. The content of the definition is at singular points, where a curve may pass through p more than once.

Proposition 36.3.3: The Node Has Two Branches, the Cusp One

At the origin,

1. if $\operatorname{char} k \neq 2$, the node $N = \mathcal{Z}(y^2 - x^2 - x^3)$ has exactly two formal branches, and $\hat{\mathcal{O}}_{N,0} \cong k[[u,v]]/(uv)$;
2. in every characteristic, the cusp $C = \mathcal{Z}(y^2 - x^3)$ has exactly one formal branch, and $\hat{\mathcal{O}}_{C,0}$ is a domain that is not a power series ring.

***Proof*:**
The node. In $k[[x]]$ the series $1+x$ has a square root when $\operatorname{char} k \neq 2$. Seek $w = 1 + \sum_{n\geq 1} a_n x^n$ with $w^2 = 1+x$; comparing coefficients gives $2a_1 = 1$ and, for $n \geq 2$,

$$2a_n = -\sum_{0<i<n} a_i a_{n-i}$$

Each equation determines a_n from its predecessors, division by 2 being the only division performed, so w exists, and it is a unit since $w(0) = 1$. Then in $k[[x,y]]$

$$y^2 - x^2 - x^3 = y^2 - x^2(1+x) = (y - xw)(y + xw)$$

Put $u = y - xw$ and $v = y + xw$. Both have order 1 with linear parts $y - x$ and $y + x$, which are linearly independent as $\operatorname{char} k \neq 2$, so their classes span $\mathfrak{n}/\mathfrak{n}^2$ for $\mathfrak{n}$ the maximal ideal of $k[[x,y]]$, and Nakayama's lemma (lemma 23.4.27) makes u, v generate $\mathfrak{n}$. Thus u, v is a regular system of parameters of the complete regular local ring $k[[x,y]]$, and lemma 36.2.2 gives $k[[x,y]] = k[[u,v]]$. By proposition 36.3.1, $\hat{\mathcal{O}}_{N,0} \cong k[[u,v]]/(uv)$, whose minimal primes are (u) and (v): these are prime because the quotients $k[[v]]$ and $k[[u]]$ are domains, they are minimal because $(uv) \subseteq \mathfrak{p}$ forces $u \in \mathfrak{p}$ or $v \in \mathfrak{p}$, and they are distinct. So there are exactly two branches.

The cusp. By proposition 36.3.1, $\hat{\mathcal{O}}_{C,0} \cong k[[x,y]]/(y^2 - x^3)$, so it suffices to show $y^2 - x^3$ is irreducible in $k[[x,y]]$; then $(y^2 - x^3)$ is prime, it is the unique minimal prime of the quotient, and the quotient is a domain. Suppose $y^2 - x^3 = gh$ with g, h nonunits. Setting $x = 0$ gives $y^2 = g(0,y)h(0,y)$ in $k[[y]]$, so the orders of $g(0,y)$ and $h(0,y)$ in y sum to 2; neither can be 0, since a factor with $g(0,y)$ a unit would be a unit in $k[[x,y]]$, so both orders are 1. The

Weierstrass preparation theorem (theorem 25.7.3) then writes each as a unit times a monic degree-one polynomial in y over $k[[x]]$, so

$$y^2 - x^3 = \varepsilon\,(y - a(x))(y - b(x)), \qquad a, b \in (x) \subseteq k[[x]]$$

with ε a unit. Here $(y-a)(y-b)$ is a Weierstrass polynomial of degree two, its lower coefficients lying in (x), and so is $y^2 - x^3$ itself; the uniqueness clause of the same theorem therefore forces $\varepsilon = 1$. Comparing coefficients gives $a + b = 0$ and $ab = -x^3$, so $b = -a$ and $a^2 = x^3$. Taking orders in $k[[x]]$ gives $2\,\mathrm{ord}(a) = 3$, impossible. So $y^2 - x^3$ is irreducible.

Finally $\hat{\mathcal{O}}_{C,0}$ is not a power series ring, since $\dim_k \hat{\mathfrak{m}}/\hat{\mathfrak{m}}^2 = 2$ while $\mathrm{kdim} = 1$, completing the proof.

Definition 36.3.4: Analytically Isomorphic Singularities

Two pointed varieties (X, p) and (Y, q) are *analytically isomorphic* if $\hat{\mathcal{O}}_{X,p} \cong \hat{\mathcal{O}}_{Y,q}$ as k-algebras.

The computation says more than that the node has two branches: it says the node is analytically isomorphic to the crossing of the two coordinate axes $\mathcal{Z}(xy)$ at the origin, since both completions are $k[[u,v]]/(uv)$, while the cusp belongs to a different class. This is a genuinely finer relation than isomorphism of neighbourhoods: the node and the pair of axes are not isomorphic as varieties near the origin, one being irreducible and the other not, and it is exactly the passage to the completion that makes them agree. The same argument applies to any plane curve whose tangent cone at p is two distinct lines, which definition 42.1.6 will call an ordinary double point.

The characteristic hypothesis in the first case is not a technicality. In characteristic two, $y^2 - x^2 - x^3 = (y+x)^2 - x^3$, so substituting $u = y + x$ turns the node's equation into $u^2 - x^3$: the curve is analytically a cusp there, with one branch rather than two. The tangent cone sees the same collapse, its initial form being the doubled line $(y+x)^2$.

The count of branches is a local invariant that a global construction also computes: the normalization of a curve separates its branches, so the points lying over p should correspond to them. Making that precise needs the normalization, which is chapter 37, and the comparison is carried out there as proposition 37.2.4.

36.4 Local Factoriality and Weil Divisors

The last local property of this chapter is the one section 37.5 depends on. A Weil divisor on a normal variety is a formal sum of codimension-one subvarieties, and the class group measures how far such a sum is from being the divisor of a function. That measurement is only meaningful once one knows when a codimension-one subvariety is cut out by a single equation near each point, and the answer is that smoothness suffices.

Corollary 36.4.1: A Smooth Variety Is Locally Factorial

Let X be a variety and $p \in X$ a smooth point. Then $\mathcal{O}_{X,p}$ is a unique factorization domain.

***Proof*:**
By proposition 35.2.2 the ring $\mathcal{O}_{X,p}$ is regular local, and a regular local ring is factorial by theorem 29.8.5, as we sought to show.

Theorem 36.4.2: Codimension One Is Locally Principal at a Smooth Point

Let X be a variety, $Y \subseteq X$ an irreducible closed subvariety of codimension one, and $p \in Y$ a point at which X is smooth. Then the ideal of Y in $\mathcal{O}_{X,p}$ is principal: there is $f \in \mathcal{O}_{X,p}$ generating it.

***Proof*:**
Step 1: reduce to the affine case. Choose an affine open $U \subseteq X$ containing p. Passing to U changes neither $\mathcal{O}_{X,p}$ nor the codimension, so $Y \cap U$ is an irreducible closed subvariety of U of codimension one, and its ideal $\mathcal{I}(Y \cap U) \subseteq k[U]$ is prime and contained in the maximal ideal at p, the point p lying on Y.

Step 2: the ideal has height one. By definition 34.3.1 the codimension of $Y \cap U$ in U is the supremum of lengths of chains of irreducible closed subsets ascending from $Y \cap U$, and the correspondence between irreducible closed subsets and prime ideals reverses inclusions (theorem 32.4.4), so such chains correspond to chains of primes descending from $\mathcal{I}(Y \cap U)$. Hence $\operatorname{ht} \mathcal{I}(Y \cap U) = \operatorname{codim}_U(Y \cap U) = 1$. Localizing at p preserves both primality and height, since the primes contained in $\mathcal{I}(Y \cap U)$ are exactly those surviving in the localization.

Step 3: apply factoriality. The ring $R = \mathcal{O}_{X,p}$ is a Noetherian local domain by proposition 33.2.10 and factorial by corollary 36.4.1, p being a smooth point. A height-one prime of a Noetherian factorial domain is principal, by lemma 29.8.1, which gives the generator f, completing the proof.

The theorem is what makes the class group of section 37.5 a global invariant on a smooth variety: every prime divisor is locally the zero set of one function, so a nonzero class records an obstruction to patching those local equations into a single global one, not a failure at any individual point. On a singular normal variety the obstruction is already local, and the quadric cone is the standard example.

Proposition 36.4.3: The Quadric Cone Is Not Locally Factorial at Its Vertex

Let $X = \mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$ with vertex v the origin. Then $\mathcal{O}_{X,v}$ is not a unique factorization domain, and the ideal of the ruling $L = \mathcal{Z}(x, z) \subseteq X$ is a height-one prime of $\mathcal{O}_{X,v}$ that is not principal.

***Proof*:**
Write $R = \mathcal{O}_{X,v}$ with maximal ideal $\mathfrak{m}$, and let $\overline{x}, \overline{y}, \overline{z}$ be the images of the coordinates. Each lies in $\mathfrak{m} \setminus \mathfrak{m}^2$: the images of x, y, z form a basis of $\mathfrak{m}/\mathfrak{m}^2$, because the defining equation $xy - z^2$ lies in $(x, y, z)^2$ and so imposes no linear condition on $\mathfrak{m}/\mathfrak{m}^2$. An element of $\mathfrak{m} \setminus \mathfrak{m}^2$ is irreducible in R: a factorization into two nonunits would place it in $\mathfrak{m}^2$. So $\overline{x}, \overline{y}, \overline{z}$ are irreducible, and no two are associates, their classes in $\mathfrak{m}/\mathfrak{m}^2$ being linearly independent while an associate would differ by a unit and hence have proportional class.

The relation $\overline{x}\,\overline{y} = \overline{z}^{\,2}$ therefore exhibits two factorizations of one element into irreducibles that do not match up to associates and reordering, so R is not factorial. Here R is a Noetherian local domain by proposition 33.2.10, the cone being a variety, so lemma 29.8.1 applies and some height-one prime of R fails to be principal.

That prime may be named. The ideal $\mathfrak{p} = (\overline{x}, \overline{z})$ is the ideal of L in R, and it has height one, L having codimension one in X. Suppose $\mathfrak{p} = (f)$. Then f divides $\overline{x}$ and is a nonunit, and $\overline{x}$ is irreducible, so $(f) = (\overline{x})$. From $\overline{z} \in (\overline{x})$ write $\overline{z} = \overline{x}h$; then

$$\overline{x}\,\overline{y} = \overline{z}^{\,2} = \overline{x}^{\,2}h^2$$

and cancelling $\overline{x}$, legitimate in a domain, gives $\overline{y} = \overline{x}h^2$. As $\overline{y}$ is irreducible and $\overline{x}$ is not a unit, h^2 must be a unit, making $\overline{y}$ and $\overline{x}$ associates and contradicting what was shown above. So $\mathfrak{p}$ is not principal, as we sought to show.

The failure is concentrated at the vertex alone: away from v the cone is smooth, so theorem 36.4.2 applies at every other point of L and makes the ideal of L principal there. Note that L is nonetheless the zero set of a single function, since $\mathcal{Z}(x) \cap X = \mathcal{Z}(x, z^2) \cap X = L$ as a set; what fails is that no one function generates the ideal near v, and $\operatorname{div}(x) = 2L$ in section 37.5 is the quantitative form of that failure, the function that does vanish exactly on L vanishing to order two.

Exercise 36.4.1

1. Compute the tangent cone and the multiplicity at the origin of $C = \mathcal{Z}(y^2 - x^5) \subseteq \mathbb{A}^2_k$, and show that C is irreducible. How do the answers compare with the cusp $\mathcal{Z}(y^2 - x^3)$, and what does the comparison say about whether the tangent cone alone classifies plane singularities?
2. Let $\operatorname{char} k \neq 3$ and let $F = \mathcal{Z}(x^3 + y^3 - 3xy) \subseteq \mathbb{A}^2_k$ be the folium. Compute its tangent cone and multiplicity at the origin, and decide whether the origin is an ordinary double point.
3. Show that if $f \in k[x_1, \dots, x_n]$ is homogeneous and irreducible, then the tangent cone of $\mathcal{Z}(f)$ at the origin is $\mathcal{Z}(f)$ itself. Why is this what the word *cone* is meant to record?
4. Let p be a smooth point of a variety X with $\dim_p X = d$. Show that $TC_p(X)$ is a linear subspace of $\mathbb{A}^n_k$ of dimension d, and identify it with the tangent space.
5. The node $N = \mathcal{Z}(y^2 - x^2 - x^3)$ passes through $(-1, 0)$ as well as the origin. Show that N is smooth at $(-1, 0)$ and compute $m_{(-1,0)}(N)$ and the tangent cone there.
6. Let $\operatorname{char} k \neq 2$ and let $C = \mathcal{Z}(x^2 + y^2 - 1)$. Show that y is a local parameter at $(1, 0)$ and that $\hat{\mathcal{O}}_{C,(1,0)} \cong k[[y]]$. Write the expansion of $x - 1$ as a power series in y to order three.
7. Let C be a curve and $p \in C$. Show that if $\hat{\mathcal{O}}_{C,p} \cong k[[t]]$ then p is a smooth point of C, so the converse of theorem 36.2.1 holds in dimension one.
8. Show that $k[[x, y]]/(xy)$ has exactly two minimal primes, and conclude that the union of the two coordinate axes has two formal branches at the origin.
9. Show that analytically isomorphic pointed varieties have the same multiplicity and the same number of formal branches. Deduce that the node and the cusp are not analytically isomorphic when $\operatorname{char} k \neq 2$, and explain what happens to this deduction in characteristic two.

10. Show that every irreducible closed subvariety of $\mathbb{A}_k^n$ of codimension one is the zero set of a single irreducible polynomial, and that its ideal is principal in every local ring of $\mathbb{A}_k^n$. Which is the stronger statement, and why does theorem 36.4.2 not already give it?

11. Let p be a smooth point of X. Show that $\mathcal{O}_{X,p}$ is integrally closed in its fraction field, so that X is normal at every smooth point.

12. For the quadric cone $X = \mathcal{Z}(xy - z^2)$ and the ruling $L = \mathcal{Z}(x, z)$, show directly that $\mathcal{I}(L)$ is a prime of height one in $k[X]$, and that $\mathcal{Z}(x) \cap X = L$ as sets.

13. Show that the tangent cone algebra of the cusp at the origin is $k[x, y]/(y^2)$, and compute $\dim_k \mathfrak{m}^j/\mathfrak{m}^{j+1}$ for every j. Confirm that the multiplicity read from this Hilbert function is 2.

14. Let R be the local ring of $\mathcal{Z}(xz, yz) \subseteq \mathbb{A}_k^3$ at the origin, a plane meeting a line. Show $\dim_k \mathfrak{m}^j/\mathfrak{m}^{j+1} = j + 2$ for $j \geq 1$, deduce $m = 1$, and explain why this does not contradict proposition 36.1.6.

37

Normal Varieties and Normalization

A variety can fail to be smooth in two quite different ways, and only one of them is repairable by an isomorphism of the function field. Normality is the condition that isolates the repairable case: a variety is normal when its coordinate ring is integrally closed in its function field, and every variety admits a normalization, a finite birational map onto it from a normal one.

For curves normality and smoothness coincide, and the normalization is the smooth model. That gives this chapter's structural result: a field of transcendence degree one over k determines a unique nonsingular projective curve, so a curve and its function field are the same information.

37.1 Integrally Closed Domains and Normal Varieties

The map $\varphi\colon \mathbb{A}^1_k \to \mathcal{Z}(x^3 - y^2)$ given by $t \mapsto (t^2, t^3)$ of example 31.4.8 is a bijective birational morphism that is not an isomorphism. Its inverse is y/x, a rational function that is not regular at the origin. That failure has a purely algebraic signature. The coordinate ring is $k[t^2, t^3]$, its function field is $k(t)$, and the missing element $t = t^3/t^2$ satisfies

$$T^2 - t^2 = 0$$

a monic equation over $k[t^2, t^3]$. So t is integral over the coordinate ring without belonging to it: the ring is not integrally closed in its own fraction field. Normality is the condition that this cannot happen, and it will turn out to be exactly the condition under which the pathology above is absent.

Integral dependence, integral closure, and the term *normal domain* are developed in *Commutative Algebra* [10, Integral Elements] and are used here without redevelopment.

Definition 37.1.1: Normal Variety

Let X be an affine variety, so that $k[X]$ is an integral domain with fraction field $k(X)$. Then X is *normal* if $k[X]$ is integrally closed in $k(X)$.

More locally, X is *normal at* $p \in X$ if the stalk $\mathcal{O}_p(X)$ is integrally closed in $k(X)$.

The two notions agree, which is what makes normality a usable local condition rather than a global accident.

Proposition 37.1.2: Normality Is Local

An affine variety X is normal if and only if it is normal at every point.

***Proof*:**
By proposition 33.2.9, $k[X] = \bigcap_{p \in X} \mathcal{O}_p(X)$, and each $\mathcal{O}_p(X)$ is the localization of $k[X]$ at the maximal ideal $\mathcal{I}(p)$. Integral closure commutes with localization (corollary 26.1.10), which gives exactly the statement that a domain is normal precisely when all of its localizations at maximal ideals are, as we sought to show.

The first supply of normal varieties comes from a purely algebraic observation.

Proposition 37.1.3: Unique Factorization Implies Normal

Every unique factorization domain is integrally closed in its fraction field.

***Proof*:**
Let R be a UFD with fraction field K and let $x = a/b \in K$ be integral over R, written in lowest terms so that a and b share no irreducible factor. An integral relation

$$\left(\frac{a}{b}\right)^n + r_{n-1}\left(\frac{a}{b}\right)^{n-1} + \cdots + r_0 = 0 \qquad r_i \in R$$

becomes, after multiplying through by b^n,

$$a^n = -b\left(r_{n-1}a^{n-1} + r_{n-2}a^{n-2}b + \cdots + r_0 b^{n-1}\right)$$

So every irreducible factor of b divides a^n, and being prime in a UFD, divides a. As a and b are coprime, b has no irreducible factors at all, so b is a unit and $x \in R$, as we sought to show.

Example 37.1.4: Normal and Non-Normal Varieties

1. Affine space $\mathbb{A}^n_k$ is normal. Its coordinate ring is the polynomial ring $k[x_1, \ldots, x_n]$, a UFD (corollary 11.2.4), hence normal by proposition 37.1.3.
2. The cuspidal cubic $C = \mathcal{Z}(x^3 - y^2) \subseteq \mathbb{A}^2_k$ is not normal, by the computation opening this section: $t = y/x$ lies in $k(C)$ and is integral over $k[C]$ but not in it. The failure is concentrated at one point, the cusp: away from the origin x is invertible, so y/x is already

regular there and C is normal at every other point.

3. The nodal cubic $N = \mathcal{Z}(y^2 - x^2 - x^3)$ is not normal either. Its parameterization $t \mapsto (t^2-1, t(t^2-1))$ from example 33.3.8 identifies $k(N)$ with $k(t)$, and $t = y/x$ is again integral over $k[N]$ without lying in it. Here the failure sits at the node, where two branches of the curve cross.

4. The quadric cone $Q = \mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$ *is* normal, and it is singular at the origin. Section 37.4 returns to this: in dimension one normality and smoothness coincide, but from dimension two onward normality is strictly weaker.

Items (2) and (3) share a shape. In both, the curve is the image of a map from a smooth curve that is injective away from a small set, and the element of the function field that fails to be regular is the one that undoes the map. Item (4) shows the shape is special to curves.

37.2 The Normalization of an Affine Variety

Given a variety that is not normal, one can ask for the closest normal variety above it. The construction is forced: take the integral closure of the coordinate ring, and read it back as a variety. The only thing that needs proof is that the result is again the coordinate ring of a variety, and that is exactly the finiteness theorem for integral closures.

Theorem 37.2.1: Existence of the Normalization

Let X be an affine variety and let $\widetilde{k[X]}$ be the integral closure of $k[X]$ in $k(X)$. Then there is an affine variety $\tilde{X}$, the *normalization* of X, with

$$k[\tilde{X}] = \widetilde{k[X]}$$

together with a morphism $\nu\colon \tilde{X} \to X$ induced by the inclusion $k[X] \hookrightarrow \widetilde{k[X]}$. Moreover:

1. $\tilde{X}$ is normal;
2. $k[\tilde{X}]$ is a finite $k[X]$-module;
3. ν is surjective with finite fibres, and induces an isomorphism $k(\tilde{X}) \cong k(X)$, so ν is birational;
4. ν restricts to an isomorphism over the set of points at which X is already normal.

***Proof*:**
Step 1: the ring is a coordinate ring. $k[X]$ is a domain, finitely generated as a k-algebra, so theorem 26.1.11 applies with $L = \mathrm{Frac}(k[X]) = k(X)$: the integral closure $\widetilde{k[X]}$ is a finite $k[X]$-module, and in particular is itself a finitely generated k-algebra. This gives (2). Being a subring of the field $k(X)$ it is a domain, hence reduced, so proposition 32.5.5 realizes it as the coordinate ring of an affine algebraic set $\tilde{X}$, which is a variety by corollary 32.3.4. The inclusion of k-algebras corresponds under theorem 32.1.5 to a morphism $\nu\colon \tilde{X} \to X$.

Step 2: normality. An element of $k(\tilde{X})$ integral over $\widetilde{k[X]}$ is integral over $k[X]$ by transitivity of integral dependence, hence already lies in $\widetilde{k[X]}$. So $\widetilde{k[X]}$ is integrally closed and $\tilde{X}$ is normal, giving (1).

Step 3: birational and surjective. Every element of $\widetilde{k[X]}$ lies in $k(X)$, so $k(\tilde{X}) = \mathrm{Frac}(\widetilde{k[X]}) = k(X)$ and ν is birational. Since $k[\tilde{X}]$ is integral over $k[X]$, the going-up property gives a prime of $k[\tilde{X}]$ over every prime of $k[X]$, and in particular a point of $\tilde{X}$ over every point of X; finiteness of the fibres follows because $k[\tilde{X}]$ is a finite $k[X]$-module. This is (3), and it is the first instance of what section 40.3 will call a *finite morphism*.

Step 4: isomorphism over the normal locus. Suppose X is normal at p, so $\mathcal{O}_p(X)$ is integrally closed. Localizing the inclusion $k[X] \subseteq \widetilde{k[X]}$ at $\mathcal{I}(p)$ and using that integral closure commutes with localization (corollary 26.1.10) gives $\mathcal{O}_p(X) = \widetilde{\mathcal{O}_p(X)}$, so ν is an isomorphism of local rings there and hence an isomorphism on a neighbourhood, which is (4), completing the proof.

Part (4) says the normalization only does work where the variety was not already normal, and part (3) says it never changes the function field. Together these make ν the minimal repair: it is birational, so it preserves everything visible to rational functions, and it is an isomorphism wherever no repair was needed. The universal property makes "minimal" precise.

Proposition 37.2.2: Universal Property of Normalization

Let X be an affine variety with normalization $\nu\colon \tilde{X} \to X$. If Y is a normal affine variety and $f\colon Y \to X$ is a dominating morphism, then f factors uniquely through ν:

$$f = \nu \circ g \qquad \text{for a unique morphism } g\colon Y \to \tilde{X}$$

***Proof*:**
Since f is dominating, $f^{\#}\colon k[X] \to k[Y]$ is injective (proposition 33.3.4(2)) and extends to an embedding $k(X) \hookrightarrow k(Y)$. Any $u \in \widetilde{k[X]}$ satisfies a monic equation over $k[X]$; applying $f^{\#}$ to that equation shows $f^{\#}(u)$ is integral over $k[Y]$, and $k[Y]$ is integrally closed because Y is normal, so $f^{\#}(u) \in k[Y]$. Hence $f^{\#}$ extends to $\widetilde{k[X]} = k[\tilde{X}] \to k[Y]$, and this extension is unique because $\widetilde{k[X]}$ sits inside $k(X)$, on which $f^{\#}$ is already determined. Applying theorem 32.1.5 converts this into the asserted unique factorization $f = \nu \circ g$, as we sought to show.

Example 37.2.3: Normalizing the Cuspidal and Nodal Cubics

1. For the cuspidal cubic $C = \mathcal{Z}(x^3 - y^2)$ with $k[C] = k[t^2, t^3]$, the integral closure in $k(t)$ is all of $k[t]$: it contains t by the opening computation, and $k[t]$ is normal by proposition 37.1.3, so nothing larger is needed. Hence $\tilde{C} = \mathbb{A}^1_k$ and ν is the parameterization $t \mapsto (t^2, t^3)$. It is bijective, and an isomorphism away from the cusp.

2. For the nodal cubic N, the same computation gives $\tilde{N} = \mathbb{A}^1_k$ with $\nu(t) = (t^2 - 1, t(t^2 - 1))$. Here ν is *not* injective: both $t = 1$ and $t = -1$ map to the origin. The normalization has pulled the two branches of the node apart, which is what separating a self-crossing requires.

3. Both examples end at $\mathbb{A}^1$: by corollary 37.4.2 below, normalizing a curve always produces a

smooth one.

The contrast between (1) and (2) is worth holding on to. A cusp is repaired without changing the underlying set, since ν is a bijection; a node is repaired by separating points that had been glued. Both are invisible to the function field, which is why birational geometry cannot see them and why a normal model is the right thing to ask for.

What the normalization separates is exactly what the completion sees, which is the comparison section 36.3 deferred to here.

Proposition 37.2.4: Branches and the Normalization of a Curve

Let C be an affine curve, $p \in C$ a point, and $\nu\colon \tilde{C} \to C$ the normalization of theorem 37.2.1. Then the number of formal branches of C at p, in the sense of definition 36.3.2, equals the number of points of $\tilde{C}$ lying over p.

***Proof Key ideas*:**
Both counts are computed by the same ring. The points of $\tilde{C}$ over p correspond to the maximal ideals of the integral closure $\tilde{\mathcal{O}}$ of $\mathcal{O}_{C,p}$ in its fraction field, which is finite over $\mathcal{O}_{C,p}$ by theorem 37.2.1 together with corollary 26.1.10, hence semilocal; and the minimal primes of $\hat{\mathcal{O}}_{C,p}$ correspond to the factors in the decomposition of $\hat{\tilde{\mathcal{O}}}$ into complete local rings, one for each maximal ideal of $\tilde{\mathcal{O}}$. Matching the two requires knowing that completion commutes with integral closure for a curve over a field, which is the statement that $\mathcal{O}_{C,p}$ is analytically unramified; that is a theorem about excellent rings and is not developed in this series. See [37].

The two cases this book uses are checked directly instead. Proposition 36.3.3 gives two branches at the node and one at the cusp, and the fifth and first exercises of exercise set 37.5.1 compute the normalizations: two points lie over the node, at $t = \pm 1$, and one over the cusp, at $t = 0$. So the counts agree in both cases, completing the argument in the cases used.

37.3 Curves, Function Fields, and Discrete Valuation Rings

Definition 37.3.1: Local Ring of Field

Let K/k be a field extension. Then A is a *local ring of* K if $\mathrm{Frac}(A) = K$ and $k \subseteq A$. If A is a DVR, we shall say that A is a *discrete valuation ring of* K.

The prototypical example of local fields over a ring are the stalks $\mathcal{O}_p(V)$ of $\kappa(V)$ for a variety V.

Theorem 37.3.2: Dominating DVR

Let C be a projective curve, $K = \kappa(C)$, and let L/K be a field extension. Let R be a DVR of L containing k. Assume $K \not\subseteq R$. Then there is a unique point $p \in C$ such that R dominates $\mathcal{O}_p(C)$.

***Proof*:**
First, such a point is unique; if R dominates $\mathcal{O}_p(C)$ and $\mathcal{O}_q(C)$, then choose $f \in \mathfrak{m}_p(C)$ so $1/f \in \mathcal{O}_q(C)$. Then $\operatorname{ord}(f) > 0$ and $\operatorname{ord}(1/f) \geq 0$, a contradiction.

Thus, let's show it exists. Let $C \subseteq \mathbb{P}^n_k$ be a projective curve (a closed one-dimensional subvariety. Without loss of generality, we may take C to not be strictly contained in any x_i-hyperplane so that $C \cap U_i \neq \emptyset$. Then in each $k_{\mathbb{P}}[C] = k[x_1, ..., x_n + 1]/I(C) \cong k[u_1, ..., u_{n+1}]$. Let

$$N = \max_{i,j}(x_i/x_j)$$

As the max is achieve, without loss of generality assume $\operatorname{ord}(x_j/x_{n+1}) = N$ for some j. Then for all i:

$$\operatorname{ord}\left(\frac{u_i}{u_{n+1}}\right) = \operatorname{ord}\left(\frac{(u_j/u_{n+1})}{(u_i/u_j)}\right) = N - \operatorname{ord}(u_j/u_i) \geq 0$$

If C_* is the affine curve corresponding to $C \cap U_{n+1}$, then $\Gamma(C_*)$ can be defined with

$$k\left[\frac{u_1}{u_{n+1}}, ..., \frac{u_n}{u_{n+1}}\right]$$

hence, $\Gamma(C_*) \subseteq R$.

Now, if $\mathfrak{m}$ is the maximal ideal of R, let $J = \mathfrak{m} \cap \Gamma(C_*)$. Then J is a prime ideal, so J corresponds to a closed subvariety $W \subseteq C_*$. IF $W = C_*$, $J = 0$, and every nonzero element of $\Gamma(C_*)$ is a unit of R. But then $K \subseteq R$, contradiction our assumption. So $W = \{p\}$ must be a point. Then R certainly dominates $\mathcal{O}_p(C_*)$, and hence dominates $\mathcal{O}_p(C)$, completing the proof.

Corollary 37.3.3: Rational Map of Curves

Let f be a rational map from C' to a projective curve C. Then the domain of f must include every simple point of C'. If C' is nonsingular, f is a morphism.

***Proof*:**
If F is not dominating, it is constant (as shown in corollary 40.2.4), hence its domain must be all of C. Thus, assume $F^{\#}$ embeds $K = \kappa(C)$ as subfield of $L = \kappa(C')$. Let P be a simple point of C', $R = \mathcal{O}_p(C')$. Then it is enough to show that $K \not\subseteq R$. Suppose that $K \subseteq R \subseteq L$ The L is a finite algebraic extension of K, so R is in fact a field. But DVR's are by definition *not* a field.

Corollary 37.3.4: Function Field and Morphism Correspondence

Let C be a projective curve, C' a nonsingular curve. Then there is a natural one-to-one correspondence between dominant morphisms $f : C' \to C$ and homomorphism $f^{\#} : \kappa(C) \to \kappa(C')$.

***Proof*:**
immediate

Corollary 37.3.5: Characterizing Nonsingular Projective Curves

Two nonsingular projective curves are isomorphic if and only if their function fields are isomorphic if and only if they are birationally equivalent.

***Proof*:**
immediate

Corollary 37.3.6: Function Field associated to Curve

Let C be a nonsingular projective curve over k, $K = \kappa(C)$. Then there is a natural one-to-one correspondence between the points of C and the discrete valuation rings of K, namely

$$p \in C \text{ correspond to } k \subseteq \mathcal{O}_p(C) \subseteq K$$

***Proof*:**
Certainly $\mathcal{O}_p(C)$ is a DVR in K. On the other hand if R is any such DVR, then we saw that R dominates a unique $\mathcal{O}_p(C)$, and as these are both DVR's of K, $R = \mathcal{O}_p(C)$, as we sought to show.

From this, notice that we can create the Zariski topology on the collection of DVRs: Let X be the set of all DVRS of $\kappa(C)/k$. Give the cofinite topology on X. Then the correspondence $p \mapsto \mathcal{O}_p(C)$ is a homeomorphism! We shall use this observation when looking at "smooth $\mathbb{Z}$-curves" in section 50.7 which shall how how to interpret Dedekind domains as smooth curves!

37.4 Normality and the Serre Conditions

Regularity implies normality (corollary 35.5.3), and in dimension one the implication reverses (proposition 35.5.2). The question is how far the reverse implication reaches. The answer is: exactly one codimension. A normal variety is smooth in codimension one, and no further.

Proposition 37.4.1: Normal Implies Regular in Codimension One

Let X be a normal variety and $p \in X$ a point whose closure has codimension 1 in X. Then $\mathcal{O}_p(X)$ is a discrete valuation ring, and in particular X is nonsingular at p.

***Proof*:**
The ring $\mathcal{O}_p(X)$ is a Noetherian local domain (proposition 33.2.10) of Krull dimension 1, since its dimension is the codimension of p in X by proposition 34.3.2. It is integrally closed, because X is normal and normality is local (proposition 37.1.2). A Noetherian local domain of dimension one that is integrally closed is a discrete valuation ring, and hence regular, by proposition 35.5.2. Regularity of the local ring is nonsingularity of the point by proposition 35.2.2, as we sought to show.

Corollary 37.4.2: A Normal Curve Is Smooth

A normal curve is nonsingular at every point. Consequently the normalization $\nu\colon \tilde{C} \to C$ of any curve is a smooth curve, and ν resolves every singularity of C.

***Proof*:**
Every point of a curve has codimension 1 in it, so proposition 37.4.1 applies at every point. The normalization $\tilde{C}$ is normal and is a curve, being birational to C (theorem 37.2.1(3)) and hence of the same dimension, completing the proof.

This is the structural payoff of the chapter, and it is what makes curves so much better behaved than surfaces. For a curve, "normal" and "smooth" are the same word, so a single algebraic operation, taking an integral closure, removes every singularity at once. Section 37.3 converts this into the statement that each birational class of curves contains exactly one smooth projective model.

In dimension two the two conditions come apart.

Example 37.4.3: A Normal Singular Surface

Let $\operatorname{char} k \neq 2$ and let $Q = \mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$, the quadric cone. It is singular at the origin: the Jacobian of $xy - z^2$ is $(y,\ x,\ -2z)$, which vanishes at $(0,0,0)$, so by definition 35.2.1 the rank there is 0 rather than the required $3 - 2 = 1$.

Nonetheless Q is normal. Its coordinate ring is isomorphic to the subring $k[u^2, uv, v^2] \subseteq k[u,v]$ under $x \mapsto u^2$, $y \mapsto v^2$, $z \mapsto uv$, which is the ring of invariants of $k[u,v]$ under $(u,v) \mapsto (-u,-v)$. A ring of invariants of a normal domain under a finite group is normal: if w in the fraction field is integral over the invariants, it is integral over $k[u,v]$, hence lies in $k[u,v]$ by proposition 37.1.3, and it is invariant, so it lies in the invariant subring.

So Q is normal and singular, and its singular locus is a single point, of codimension 2. That is the smallest codimension proposition 37.4.1 permits.

The example is sharp, and it explains the shape of the general criterion. Normality controls codimension one and says nothing beyond it, so a full characterization needs a second condition governing the deeper codimensions. That condition is a statement about depth, and it is what Serre's criterion supplies.

A Noetherian domain is integrally closed exactly when it satisfies two conditions, one asking regularity in codimension one and one asking a lower bound on depth. Write (R_1) for "$R_{\mathfrak{p}}$ is regular for every prime $\mathfrak{p}$ of height at most one" and (S_2) for "$\operatorname{depth} R_{\mathfrak{p}} \geq \min(2, \operatorname{height} \mathfrak{p})$ for every prime $\mathfrak{p}$". The statement that normality is their conjunction is *Serre's Criterion for Normality*, theorem 57.3.2; it runs on the theory of depth and regular sequences, which is developed there and not here.

The geometric content of the two halves is worth separating. Condition (R_1) is proposition 37.4.1 read backwards: it requires smoothness exactly in codimension one. Condition (S_2) says a function defined outside a closed set of codimension two extends across it, which is why a normal variety cannot be repaired by deleting a small set and gluing differently. The quadric cone of example 37.4.3 satisfies both: it is smooth away from a codimension-two point, and it is a hypersurface, which forces (S_2).

Read geometrically, the criterion says normality is precisely "smooth in codimension one, plus no missing codimension-two information". For curves the second condition is vacuous and the first is everything, which recovers corollary 37.4.2. From dimension two onward both are needed, and normality becomes a genuinely weaker and more flexible condition than smoothness, which is why it is normality rather than smoothness that appears as a hypothesis throughout the theory of divisors in chapter 44.

37.5 Weil Divisors and the Class Group

Proposition 37.4.1 says that a normal variety is regular in codimension one, so at every codimension-one subvariety the local ring is a discrete valuation ring. That is exactly the hypothesis needed to make sense of the order of vanishing of a function along a subvariety, and with it the divisor theory of chapter 44 generalizes from curves to normal varieties of any dimension.

Definition 37.5.1: Prime Divisor and Weil Divisor

Let X be a normal variety. A *prime divisor* on X is an irreducible closed subvariety $Y \subseteq X$ of codimension one. A *Weil divisor* is a formal sum

$$D = \sum_Y n_Y Y \qquad n_Y \in \mathbb{Z}$$

over the prime divisors, with all but finitely many n_Y zero. They form a group $\mathrm{Div}(X)$.

For a curve a prime divisor is a point, and definition 44.1.1 is the case $\dim X = 1$.

Proposition 37.5.2: The Order Along a Prime Divisor

Let X be a normal variety and $Y \subseteq X$ a prime divisor. Then the local ring $\mathcal{O}_Y(X)$ of X along Y, that is the localization of $k[U]$ at the prime $\mathcal{I}(Y \cap U)$ for any affine open U meeting Y, is a discrete valuation ring with fraction field $k(X)$. Writing ord_Y for its valuation, every nonzero $f \in k(X)$ has $\mathrm{ord}_Y(f) = 0$ for all but finitely many Y.

***Proof*:**
The ring $\mathcal{O}_Y(X)$ is Noetherian and local, and it is a domain with fraction field $k(X)$, being a localization of a coordinate ring of X. Its dimension is $\mathrm{codim}_X Y = 1$ by proposition 34.3.2. It is normal, being a localization of a normal domain, as the sixth exercise of exercise set 37.5.1 shows. So proposition 35.5.2 applies through its equivalence of normality with being a discrete valuation ring.

For the finiteness, fix an affine open U and write $f = g/h$ with $g, h \in k[U]$. Then $\mathrm{ord}_Y(f) \neq 0$ forces $Y \cap U$ to lie in $\mathcal{Z}(g) \cup \mathcal{Z}(h)$, a proper closed subset of U, which has finitely many irreducible components of codimension one. Covering X by finitely many affine opens gives the claim, completing the proof.

Definition 37.5.3: Principal Divisor and the Class Group

For $f \in k(X)^*$ the *principal divisor* is $\operatorname{div}(f) = \sum_Y \operatorname{ord}_Y(f)\, Y$. The principal divisors form a subgroup $\operatorname{Prin}(X) \subseteq \operatorname{Div}(X)$, and the *class group* is

$$\operatorname{Cl}(X) = \operatorname{Div}(X)/\operatorname{Prin}(X)$$

Two divisors with the same class are *linearly equivalent.*

For a nonsingular projective curve this is $\operatorname{Pic}(C)$ of definition 44.3.1; the two names coexist because on a general variety the divisor class group and the group of line bundles are different objects, agreeing exactly when X is nonsingular. The distinction is developed in [5].

Example 37.5.4: Class Groups

1. *Affine space.* $\operatorname{Cl}(\mathbb{A}^n_k) = 0$. A prime divisor is a hypersurface $\mathcal{Z}(f)$ with f irreducible, by theorem 34.4.2, and $\operatorname{div}(f) = \mathcal{Z}(f)$; so every prime divisor is principal, and hence so is every divisor.
2. *Projective space.* $\operatorname{Cl}(\mathbb{P}^n_k) \cong \mathbb{Z}$, by degree. A prime divisor is $\mathcal{Z}(F)$ for an irreducible form F, and assigning it $\deg F$ gives a surjection $\operatorname{Div}(\mathbb{P}^n_k) \to \mathbb{Z}$. Its kernel is exactly the principal divisors: a rational function on $\mathbb{P}^n_k$ is a ratio F/G of forms of equal degree, so $\operatorname{div}(F/G) = \mathcal{Z}(F) - \mathcal{Z}(G)$ has degree zero, and conversely a degree-zero divisor $\sum n_i \mathcal{Z}(F_i)$ is $\operatorname{div}\left(\prod F_i^{n_i}\right)$.
3. *The quadric cone.* Let $X = \mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$, which is normal by the fourth exercise of exercise set 37.5.1 although singular at the origin. Let $L = \mathcal{Z}(x, z) \subseteq X$ be the line through the vertex. Then L is a prime divisor, and

$$\operatorname{div}(x) = 2L$$

To see this, note $y \notin (x, z)$, so y is a unit in the local ring $\mathcal{O}_L(X)$ along L. The relation $xy = z^2$ then gives $x = z^2/y$, so the maximal ideal $(x, z)\mathcal{O}_L(X)$ is generated by z alone and $\operatorname{ord}_L(z) = 1$; hence $\operatorname{ord}_L(x) = 2\operatorname{ord}_L(z) - \operatorname{ord}_L(y) = 2$. No other prime divisor occurs, since $\mathcal{Z}(x) \cap X = L$ as a set. So $2L$ is principal but L is not, by proposition 36.4.3, and $\operatorname{Cl}(X) \cong \mathbb{Z}/2\mathbb{Z}$ generated by the class of L.

The last example is the point of the section. On a nonsingular variety every codimension-one subvariety is locally cut out by a single equation, which is theorem 36.4.2, so the class group there measures a global obstruction to patching those local equations together. On a singular normal variety the obstruction is already local, and Cl detects the singularity: the line L on the quadric cone is not the zero set of any single function near the vertex, by proposition 36.4.3, which is what $\operatorname{div}(x) = 2L$ records.

Exercise 37.5.1

1. Let $A = k[x, y]/(y^2 - x^3)$ be the coordinate ring of the cuspidal cubic and put $t = y/x$ in $\operatorname{Frac}(A)$. Show that t is integral over A but does not lie in A, so A is not normal, and show that $A[t] = k[t]$. Conclude that the normalization of the cuspidal cubic is $\mathbb{A}^1_k$.

2. Show that $\mathbb{Z}[\sqrt{-3}]$ is not integrally closed in its fraction field by exhibiting an element of $\mathbb{Q}(\sqrt{-3})$ that is integral over it but not in it. Which ring is its integral closure?

3. Let $A \subseteq B$ be an integral extension of domains with $\mathrm{Frac}(A) = \mathrm{Frac}(B)$. Show that if A is normal then $A = B$. Deduce that the normalization map of theorem 37.2.1 is an isomorphism exactly when the variety is already normal.

4. Show that the quadric cone $\mathcal{Z}(xy - z^2) \subseteq \mathbb{A}^3_k$ is normal but singular at the origin, and explain why this does not contradict corollary 37.4.2. Which of Serre's two conditions in theorem 57.3.2 is doing the work?

5. Let $C = \mathcal{Z}(y^2 - x^2 - x^3) \subseteq \mathbb{A}^2_k$ be the nodal cubic. Using the parameterization $t \mapsto (t^2 - 1,\, t(t^2 - 1))$ of example 33.3.8, show that $k[C]$ is not normal and that its normalization is $k[t]$. How many points of the normalization lie over the node, and why is that different from the cuspidal case?

6. Show that a localization of a normal domain is normal, and use this together with proposition 37.1.2 to show that normality of a variety may be checked on any affine open cover.

7. Give an example of a birational morphism of affine varieties that is bijective on points but not an isomorphism. (Chapter 47 will give a systematic supply.)

8. Let C be an irreducible curve with function field $K = k(C)$. Show that a discrete valuation ring R with $\mathrm{Frac}(R) = K$ and $k \subseteq R$ determines at most one point of any nonsingular projective model of C, and identify the valuation ring attached to the point at infinity of $\mathbb{P}^1_k$.

Part VIII

Projective Varieties

The affine theory of Part VI is incomplete in two ways that turn out to be the same way. A rational function need not be defined everywhere, and two curves of degrees m and n need not meet in mn points. Both failures are failures of points to exist, and both are repaired by the same construction: adjoin a point for every direction in which something can run off to infinity.

The resulting space is projective space, and the varieties inside it are the subject of this Part. The affine dictionary carries over almost unchanged once polynomials are replaced by homogeneous ones, but the geometry is genuinely better behaved: projective varieties are complete, so the image of a regular map out of one is closed, and the only regular functions on one are the constants. Those two facts drive everything in Part IX.

38

Projective Space and Homogeneous Ideals

This chapter builds projective space and transplants the dictionary of chapter 32 onto it. The transplant is not free: a polynomial is not a function on projective space, and the zero set of one is well defined only when the polynomial is homogeneous. Working out what replaces the coordinate ring, and which ideals the Nullstellensatz now describes, occupies the chapter.

38.1 Points at Infinity

So far, all of the algebraic sets were called *affine* algebraic sets, as they were all a subset of $\mathbb{A}_k^n$. These offer great geometrical intuition, however they are lacking in certain algebraic qualities, namely rational functions need not be defined at all points, and not all algebraic curves intersect. As an example of the former point, it is simplest to resort to an analogy from calculus. The reader may recall that the function $f : \mathbb{R} \to \mathbb{R}$ defined as $f(x) = 1/x$ is famously undefined at $x = 0$, as we cannot divide by 0.

However, we can enlarge $\mathbb{R}$ to make this function well-defined by adding a *point at infinity.* Namely, we may take $\mathbb{R}_\infty = \mathbb{R} \cup \{\infty\}$ where (for the sake of limits)[1] we extend the arithmetic of $\mathbb{R}$ to $\mathbb{R}_\infty$ by doing:

$$a + \infty = \infty + a = \infty \qquad b \cdot \infty = \infty \cdot b = \infty$$

where $a \in \mathbb{R}$ and $0 \neq b \in \mathbb{R}_\infty$. We then say that if (x_n) diverges, then

$$\lim_{n\to\infty} x_n = \infty$$

[1]The arithmetic defined here certainly does not satisfy the axioms of a ring; instead it is a structure called a *wheel*; we shall not study these in this textbook

In this case we now have that the function $1/x$ has a well-defined value of ∞ at 0, and even better under the right frame-work (provided in differential geometry), the function $f(x) = 1/x$ can be shown to be smooth on $\mathbb{R}_\infty$. In this way, we have ensured that we cannot have an undefined rational polynomials on $\mathbb{R}_\infty$! The space $\mathbb{R}_\infty$ is called the *projective line.* This "closure" on the set of definable rational polynomials makes the projective line an algebraically nicer space to work with, in a similar way that $\mathbb{C}$ is the better space to work in as all polynomials have roots.

For the latter interpretation (the one about there always being an intersection), consider a polynomial $f(z)$ defined over $\mathbb{C}$ so that there is no worry about roots not existing. Let us regard $\mathbb{C}$ as $\mathbb{R}^2$ with coordinates x, y so that $f(z) = f(x, y)$. Consider the line $L_{(a,b)}$ which has angle α given by (a, b):

$$L_{(a,b)} : t \mapsto (at, bt)$$

Then either $f = L$, in which case their intersection is an entire line, or f and $L_{(a,b)}$ intersect where these two equations agree:

$$f(at, bt) = f_n(a, b)t^n + \cdots + f_1(a, b)t + f_0(a, b)$$

where $f_n(a, b)$ represents the constant in front of the t-term. if $f_n(a, b) \neq 0$ then there are n roots, and hence n points of intersections. However, if $f_n(a, b) = 0$, then there must be a smallest m where

$$f_n(a, b) = 0,\ f_{n-1}(a, b) = 0,\ \cdots f_{m+1}(a, b) = 0,\ f_m(a, b) \neq 0$$

or else $f = L_{(a,b)}$, which we are taking to not be the case. But then we would have a number of intersections lower than the number of roots. There is a remedy to this, which is to consider the remaining $(n-m)$ points to be the intersection of L with f at a point at infinity. To see this, consider the substitution $s = 1/t$. Then:

$$f_n(a, b) + f_{n-1}(a, b)s + \cdots + f_0(a, b)s^n = 0$$

Notice that if $f_n(a, b) \neq 0$, then at $s = 0$ (conceptually can be thought of as $1/t = 0$) there is no root. But if there are $n - m$ leading terms that are zero, then this polynomial has a root of order $n - m$ at $s = 0$. Thus, we recover the intersection of L with f as an invariance! In particular, for each line $L_{(a,b)}$ we can think of there being an extra point at infinity. Notice that by combining the coordinates s, t we get a function:

$$f_n(a, b)t^n + f_{n-1}t^{n-1}s + \cdots + f_0(a, b)s^n = 0$$

which allows us to find all points of intersections at once. This motivates the use of homogeneous functions and the linear equivalence construction that shall be at the start of this section.

Why is the space called projective? This is understood from the following construction of projective space that extends to higher dimensions. Let us start in one dimension. We may define $\mathbb{R}_\infty$ as the

$$\mathbb{R}\mathrm{P}^1 := \frac{\mathbb{R}^2 \setminus \{(0, 0)\}}{\{(x, y) \sim (\lambda x, \lambda y), \forall \lambda \in \mathbb{R} \setminus \{0\}\}}$$

by taking the representative of each equivalence class to have norm 1, notice that we may associate all the points of $\mathbb{R}\mathrm{P}^1$ to S^1, and we can associate points of $\mathbb{R}$ with the equivalence class where $y \neq 0$. The equivalence class $[(\lambda x, 0)]$ can be thought of as the "point at infinity" that we've added, hence we may think of $\mathbb{R}\mathrm{P}^1$ as

$$\mathbb{R}\mathrm{P}^1 = \mathbb{R}^1 \sqcup \mathbb{R}^0 \tag{38.1}$$

The term "projective" comes from the idea that parallel lines will meet at the "point at infinity". In terms of "closure" that we talked about earlier, the reader may recall that in classical geometry, two non-parallel lines will always have a solution. In $\mathbb{R}\mathrm{P}^1$, we have added the extra property that there is one point at which parallel lines meet; they also have a solution. In terms of linear algebra, every system of linear equations has a solution.

We may extend this further, and take $\mathbb{R}^2$ and add "points at infinity". In this case, there are many possible pairs of parallel lines. We may consider that up to scaling, we have many new points that we may add. Formally, let:

$$\mathbb{R}\mathrm{P}^2 := \frac{\mathbb{R}^3 \setminus \{(0,0,0)\}}{\{(x,y,z) \sim (\lambda x, \lambda y, \lambda z), \forall \lambda \in \mathbb{R} \setminus \{0\}\}}$$

We may imagine that this insures that any rational function in two variables always has a solution. Adding multiple points at infinity insures that the function $1/y$, $1/x$, $1/xy$ and so forth are all considered distinct when evaluating ($1/y$ is zero when evaluated at one infinity but not another). In terms of parallel lines, we may think that parallel lines in any angle will have a unique solution (note that the distance between the lines does not matter, they still "meet" at the same point at infinity). The shape $\mathbb{R}\mathrm{P}^2$ can be thought of as $\mathbb{R}^2$ with a circle of points at infinity added where opposites are glued. Can the reader use this intuition to generalize (38.1) to:

$$\mathbb{R}\mathrm{P}^2 = \mathbb{R}^2 \sqcup \mathbb{R}^1 \sqcup \mathbb{R}^0$$

The reader familiar with differential geometry will know that $\mathbb{R}\mathrm{P}^2$ is a two dimensional smooth manifold, and is one of the simplest example of a shape that is 2-dimensional but cannot be embedded in 3-dimensions without self-intersection. The following image from Wikipedia may help in trying to visualize (note that this is an *immersion*, meaning it is an approximation of the shape by embedding it in a space in which there is not enough dimensions to visualize it without intersection)

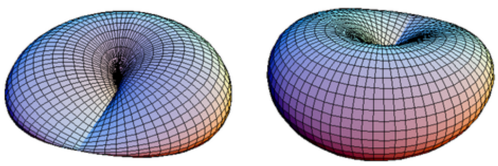


Figure 38.1: Wikipedia: Immersion of $\mathbb{R}\mathrm{P}^2$

We may continue this process and define $\mathbb{R}\mathrm{P}^n$, or more generally $\mathbb{P}^n_k$ for some field k. These shall have a larger class of functions that we may define on them (we shall eventually say that there are an "ample" amount of function[2]). Thus, we shall treat $\mathbb{P}^n_k$ as an extension of $\mathbb{A}^n_k$, and consider the equivalence classes of $\mathbb{P}^n_k$ as *points*.

An important technicality that we may encounter is that we must convert a function that is defined on $\mathbb{A}^n_k$ to a function defined on $\mathbb{P}^n_k$, namely the points of $\mathbb{P}^n_k$ are now equivalence relations and hence a function whose domain is $\mathbb{P}^n_k$ must be independent of representative. This shall form an important class of rings that are "good representatives" to extend polynomials to $\mathbb{P}^n_k$. As we are extending results from $\mathbb{A}^n_k$, this class of rings shall have a similar dictionary as that provided between affine varieties and radical ideals of coordinate rings, namely we shall show that polynomials solutions over $\mathbb{P}^n_k$ shall correspond to *graded ideals* of *graded rings*.

[2] More technically speaking, we shall say that $\mathbb{P}^n_k$ has *ample line bundles*, a notion belonging to scheme theory

38.2 Projective Space and Homogeneous Polynomials

Let us first formally define projective space

Definition 38.2.1: Projective Space

Let k be a field. Then *projective space* over k of dimension n is:

$$\mathbb{P}_k^n = \frac{k^{n+1} \setminus \{0\}}{x \sim \lambda x \text{ for all } \lambda \in k^\times}$$

The points of $\mathbb{P}_k^n$ are often denoted $[x_1 : x_2 : \cdots : x_{n+1}]$.

The first thing we must do is define the topology on this space which parallels the Zariski topology on $\mathbb{A}_k^n$. Polynomial functions need not give well-defined zero sets on projective space, for example $f(x, y) = x^2 + y$ does not map two elements in the same equivalence class to zero. We must limit to polynomials that maps the representatives of an equivalence class to the same point. These are precisely the homogeneous polynomials:

Definition 38.2.2: Homogeneous Polynomial (Algebraic Form)

Let $f \in k[x_1, \ldots, x_n]$ be a polynomial. Then f is a *homogeneous polynomial* of degree d, or an *algebraic d-form*, if every monomial occurring in f has total degree d. Equivalently, as a formal identity in $k[x_1, \ldots, x_n, \lambda]$,

$$f(\lambda x_1, \ldots, \lambda x_n) = \lambda^d f(x_1, \ldots, x_n)$$

The identity is the useful form, and it is the reason homogeneous polynomials have well defined zero sets in projective space. It characterizes homogeneity only when read formally, or when k is infinite: over $\mathbb{F}_2$ the only scalar available is $\lambda = 1$, so the identity holds vacuously for every f.

The term *algebraic form* is a bit out-dated, but is often still used for the degree two case, where such algebraic forms are called *quadratic forms*. This condition extends to a more general class of functions. The reader comfortable with some analysis will see in exercise set 38.5.1 that any (at least) d-times differential degree d homogeneous function is in fact a homogeneous polynomial[3].

Example 38.2.3: Homogeneous Polynomials

For example:

1. $f(x, y, z) = x^3 + xy^2 - 2y^3$ is homogeneous
2. $f(x, y) = x^2 + y^3$ is not homogeneous

Notice that if $f_1, \ldots, f_n$ are all homogeneous polynomial of the same degree k, then $(f_1 + \ldots + f_n)^m$ is a homogeneous polynomial of degree mk. Hence, homogeneous polynomials behave well under addition and multiplication.

[3] homogeneity does not imply differentiability or continuity, can you think of a counter-example?

If $(a_1, ..., a_n) \in k^n$ is a solution to a homogeneous polynomials, then all points on the line passing through this point and the origin is also a solution, hence homogeneous polynomials are the "natural" polynomials for the zero set of projective space, as projective space is an equivalence relation on lines. It is tempting conclude the collection of homogeneous polynomials form the set $k[\mathbb{P}^n_k]$ where the set is either equal to $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{P}^n_k, \mathbb{A}^1_k)$ or $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{P}^n_k, \mathbb{P}^1_k)$ and we get the same theory as with affine spaces. However, neither of these sets is the collection of homogeneous polynomials. If we consider $\mathrm{Hom}_{\mathbf{Reg}}(\mathbb{P}^n_k, \mathbb{P}^1_k)$, we have the problem that $[0:0] \notin \mathbb{P}^1_k$ and so we lose the fundamental property that the topology is defined by the zero-sets. The reader can further check that if $f : \mathbb{P}^n_k \to \mathbb{A}^1_k$ is homogeneous, then extending to $\mathbb{P}^1_k$ by mapping to $[f(x_1, ..., x_n) : 1]$ is not well-defined[4] (we shall see that $\mathbb{A}^1_k$ is dense in $\mathbb{P}^1_k$ and the given extension is the *only* continuous extension, and it does not work).

For the first option; even when $n = 1$ there is a problem of well-definedness. Consider $f : \mathbb{P}^1_k \to \mathbb{A}^1_k$ given by $f([x:y]) = f\left(\left[\frac{x}{y} : 1\right]\right) = \frac{x}{y}$, i.e. the closest we can do to define the identity. The reader may immediately see the problem: when $y = 0$, x/y is not defined (the codomain is $\mathbb{A}^1_k$). Even if we "ignore" this problem by simply not considering where $y = 0$, we have that f is no well-defined:

$$\frac{x}{y} = f\left(\left[\frac{x}{y} : 1\right]\right) = f([x:y]) = f\left(\left[1 : \frac{y}{x}\right]\right) = 1$$

But then f is not well-defined as it is not the case that for all $x, y \in k$, $x/y = 1$. If we instead try $f([x:y]) = xy$ then

$$xy = f([x:y]) = f\left(\left[\frac{x}{y} : 1\right]\right) = \left(\frac{x}{y}\right) \cdot 1 = \frac{x}{y}$$

but it is not always the case that $xy = \frac{x}{y}$ (ex. let $x = y = 2$), and hence it is once again not well-defined. The reader shall find that any such attempt to define a (non-constant) polynomial shall not be well-defined, namely since $f(\lambda x, \lambda y) \neq f(x, y)$.

This may unsettle the reader, as a "regular function" can't be well-defined unless the polynomial is constant. As it turns out, we can't extend (non-constant) polynomials from affine space to projective in a well-defined manner (see section 39.1) unless it is a constant, which the above exploration is a first demonstration on why this is the case.

However, we will be able to treat homogeneous polynomials as regular functions whenever we limit to one of the variables x_i to be nonzero. In particular, if $f \in k[x_1, ..., x_{n+1}]$ is homogeneous, and $x_i \neq 0$, then we can interpret f to be a regular function on $U_i = \{x \in \mathbb{P}^n_k \mid x_i \neq 0\}$:

$$f([x_1 : ... : x_i : ... : x_{n+1}]) = f\left(\left[\frac{x_1}{x_i} : ... : 1 : ... : \frac{x_{n+1}}{x_i}\right]\right) = f(x'_1, ..., x'_{n+1})$$

where we write $x'_j = \frac{x_j}{x_i}$ as $x_i \neq 0$. Notice that since the ith position can be fixed to 1 by dividing by x_i, we have chosen a representative of this equivalence relation, which is why we dropped the square brackets in the above equation. For example, for the homogeneous polynomial $x \in k[x, y]$, when $y \neq 0$, we can think of it as defining the function:

$$f(x) = x$$

and when $x \neq 0$, we can think of it as defining the function:

$$f(y) = 1$$

[4]There shall be well-defined regular maps from $\mathbb{P}^n_k$ to $\mathbb{P}^1_k$, see section 39.4, but these are not extensions of affine regular maps

This mirrors how $f([x:y]) = f([x/y:1]) = f([x':1]) = x'$ and $f([x:y]) = f([1:y/x]) = f([1:y']) = 1$. Notice that it was important to define two functions and how each behaves when $y \neq 0$ and $x \neq 0$ respectively. If we want to recover the homogeneous polynomial that defined these functions but only defined it on $x \neq 0$, we see that the $y \neq 0$ case can be λx or simply λ for any nonzero λ, showing we require the function to be defined in both situations (we shall see that having the function defined for each $x_i \neq 0$ and is compatible via "transition mappings" is enough to recover the homogeneous polynomial).

This also means that homogeneous polynomials on $\mathbb{P}^n_k$ act less like functions and more like vector-fields which "locally" are given by functions (i.e. are "local trivializations"). For the reader familiar with Differential Geometry, they may recognize that this vocabulary is used to define *vector bundles*, and that homogeneous polynomials can be seen as the sections of this vector bundle. This is in fact exactly what is going on, but it is beyond the scope of this book to get into the details of this realization (see [5] for a full exploration).

For now, we shall use homogeneous polynomial to define the closed subsets of $\mathbb{P}^n_k$. To that end, let's examine ideals generate by homogeneous elements. For each $d \in \mathbb{N}$, we can take the collection of homogeneous polynomials $R_d \subseteq k[x_1, ..., x_{n+1}]$. Then these form a k-vector space (exercise set 38.5.1(1)). Furthermore, $R_d R_e \subseteq R_{d+e}$, and so these form an $\mathbb{N}$-graded algebra over $R_0 = k$ (recall section 25.3). By proposition 16.2.7 and a bit of work, we may consider $k[x_1, ..., x_{n+1}]$ as:

$$k[x_1, ..., x_{n+1}] = R_0 \oplus R_1 \oplus \cdots \oplus R_d \oplus \cdots$$

with the $\mathbb{N}$-graded structure given by homogeneity.

Definition 38.2.4: Projective Algebraic Set

Take $R \subseteq k[x_1, x_2 ..., x_{n+1}]$ with the homogeneous $\mathbb{N}$-graded structure. Let $I \subseteq R$ be a homogeneous ideal. Then a *projective algebraic set* is:

$$\mathcal{Z}_{\mathbb{P}}(I) = \{p \in \mathbb{P}^n_k \mid f(p) = 0, \ \forall f \in I\}$$

If it is clear from context, the $\mathbb{P}$ subscript will be omitted and it shall be written as $\mathcal{Z}(I)$.

Note that we could have taken an arbitrary homogeneous set $S \subseteq R$, and then taken the homogeneous closure ${}^h\langle S \rangle = I$. By proposition 16.2.9, we get that homogeneous ideals are closed under ideal addition, multiplication, intersection, and taking the radical:

$$I + J \qquad IJ \qquad I \cap J \qquad \sqrt{I}$$

Furthermore, to check that a homogeneous ideal I is prime, it suffices to check the condition $fg \in I$ iff $f \in I$ or $g \in I$ with homogeneous polynomials (see corollary 16.2.8). The addition can naturally be extended to arbitrary sums, allowing us to define the Zariski topology on $\mathbb{P}^n_k$ when focusing on the homogeneous ideals of a $k[x_1, ..., x_{n+1}]$:

Definition 38.2.5: Zariski Topology on Projective Space

Letting the projective algebraic sets to be the closed subsets of $\mathbb{P}^n_k$, we get the [projective] Zariski topology on $\mathbb{P}^n_k$.

The vanishing ideal transplants as well, once restricted to homogeneous elements.

Definition 38.2.6: Projective Vanishing Ideal

Let $V \subseteq \mathbb{P}^n_k$. Then $\mathcal{I}_{\mathbb{P}}(V)$ is the ideal generated by

$$\{f \in R \mid f \text{ homogeneous and } f(p) = 0 \text{ for all } p \in V\}$$

It is a homogeneous ideal by construction, and it is radical by the same argument as in the affine case.

Definition 38.2.7: Projective Coordinate Ring

Let $V \subseteq \mathbb{P}^n_k$ be a projective algebraic set. Then a *projective coordinate ring* is defined as:

$$\Gamma_{\mathbb{P}}(V) = k_{\mathbb{P}}[V] = \frac{R}{(\mathcal{I}_{\mathbb{P}}(V))}$$

where we drop the $\mathbb{P}$ subscript when unambiguous.

Calling these the coordinate ring is a little misleading as the elements are not functions on V, but the similar algebraic properties between affine and projective coordinate rings shall warrant this nomenclature.

With a topology, we may define all of the topological and geometric notion such as compactness, connectedness, dimension, irreducibility, and so forth. The irreducibility condition in projective space becomes a condition on homogeneous prime ideals, from which we define

Definition 38.2.8: Projective Variety

A *projective variety* is an irreducible projective algebraic set.

As mentioned in the introduction of this section, projective space and projective algebraic sets extend affine space. Let us now make this precise. Let us first consider an algebraic subset $V = \mathcal{Z}_{\mathbb{P}}(I) \subseteq \mathbb{P}^n_k$. Then as $\mathbb{P}^n_k = \mathbb{A}^{n+1}_k / \sim$, we see that we can consider $\mathcal{Z}_{\mathbb{A}}(I) \subseteq \mathbb{A}^{n+1}_k$:

Before turning to the cone, one family of projective varieties is worth classifying completely, because it can be done with linear algebra alone and because its members supply most of the small examples in this book.

Definition 38.2.9: Quadric and Its Rank

A *quadric* in $\mathbb{P}^n_k$ is $\mathcal{Z}(Q)$ for a nonzero quadratic form $Q \in k[x_0, \ldots, x_n]$. Assume $\operatorname{char} k \neq 2$ and write $Q(x) = x^\top A x$ for the unique symmetric matrix A. The *rank* of the quadric is the rank of A.

Proposition 38.2.10: Classification of Quadrics by Rank

Let $\operatorname{char} k \neq 2$. Every quadric of rank $r+1$ in $\mathbb{P}^n_k$ is carried by a linear change of coordinates to

$$\mathcal{Z}\big(x_0^2 + x_1^2 + \cdots + x_r^2\big)$$

and two quadrics are projectively equivalent if and only if they have the same rank. The singular locus of the quadric above is the linear subspace $\mathcal{Z}(x_0, \ldots, x_r)$, of dimension $n-r-1$, so the quadric is nonsingular exactly when $r = n$, that is when A is invertible.

***Proof*:**
A symmetric bilinear form over a field of characteristic $\neq 2$ admits an orthogonal basis, by the standard diagonalization; in that basis $Q = \sum_{i=0}^{r} \lambda_i x_i^2$ with all $\lambda_i \neq 0$ and $r+1$ the rank. Since k is algebraically closed each λ_i has a square root, and rescaling $x_i \mapsto x_i/\sqrt{\lambda_i}$ brings Q to $\sum_{i \le r} x_i^2$. Rank is unchanged by an invertible linear substitution, since $A \mapsto T^\top A T$, so it is a projective invariant and two quadrics of equal rank are equivalent to the same normal form, hence to each other.

For the singular locus, $\partial Q/\partial x_i = 2x_i$ for $i \le r$ and 0 otherwise, so by proposition 35.2.2 the singular points of $\mathcal{Z}(Q)$ are those with $x_0 = \cdots = x_r = 0$, which all lie on the quadric. That is the linear subspace $\mathcal{Z}(x_0, \ldots, x_r) \cong \mathbb{P}^{n-r-1}_k$, empty exactly when $r = n$, as we sought to show.

Example 38.2.11: Quadrics of Small Rank
Take $\operatorname{char} k \neq 2$ throughout.

1. *Rank* 1. $\mathcal{Z}(x_0^2)$ is a hyperplane doubled: the same point set as $\mathcal{Z}(x_0)$, but a different curve in the sense of definition 42.1.1, which is one reason that definition keeps the polynomial rather than its zero set.
2. *Rank* 2. $\mathcal{Z}(x_0^2 + x_1^2) = \mathcal{Z}\big((x_0 + ix_1)(x_0 - ix_1)\big)$ is a pair of distinct hyperplanes meeting in a $\mathbb{P}^{n-2}$, which is its singular locus.
3. *Rank* 3 *in* $\mathbb{P}^2_k$. A nonsingular conic. It is isomorphic to $\mathbb{P}^1_k$, by the projection computed in example 39.4.4(3), and this is the genus-zero case of theorem 44.4.2.
4. *Rank* 3 *in* $\mathbb{P}^3_k$. Singular along a point, namely $\mathcal{Z}(x_0, x_1, x_2) = [0:0:0:1]$. It is the cone over a nonsingular conic with that vertex, and it is the quadric cone of example 37.4.3 in projective form: normal, and singular at one point.
5. *Rank* 4 *in* $\mathbb{P}^3_k$. A nonsingular quadric surface. Example 40.1.2 identifies it with $\mathbb{P}^1_k \times \mathbb{P}^1_k$ under the Segre embedding, and its two rulings are the two families of lines on it.

So in $\mathbb{P}^3_k$ the quadrics come in exactly four projective equivalence classes, distinguished by a single integer.

38.3 The Affine Cone and Homogenization

Definition 38.3.1: Affine Cone

Let f be a homogeneous polynomial. Then its zero set in $\mathbb{A}^{n+1}$ is called an *affine cone*.

More generally, if $V \subseteq \mathbb{P}_k^n$ is a projective algebraic subset, then $C(V) \subseteq \mathbb{A}_k^{n+1}$ is the affine cone of V.

The cone translates the projective dictionary into the affine one, and the two directions are worth recording, since section 38.4 rests on them.

Proposition 38.3.2: Cone Identities

Let $\emptyset \neq V \subseteq \mathbb{P}_k^n$ be a projective algebraic set and let I be a homogeneous ideal with $\mathcal{Z}_{\mathbb{P}}(I) \neq \emptyset$. Then

$$\mathcal{I}_{\mathbb{A}}(C(V)) = \mathcal{I}_{\mathbb{P}}(V) \qquad C(\mathcal{Z}_{\mathbb{P}}(I)) = \mathcal{Z}_{\mathbb{A}}(I)$$

***Proof*:**
For the first, a point of $C(V) \subseteq \mathbb{A}^{n+1}$ is either the origin or a nonzero vector whose class lies in V. A homogeneous f vanishes on all of $C(V)$ exactly when it vanishes at every such vector, which is exactly when it vanishes at every point of V; and f automatically vanishes at the origin, since a homogeneous polynomial of positive degree has no constant term, while a nonzero constant vanishes nowhere on the nonempty V. Since both ideals are homogeneous, agreement on homogeneous elements gives equality.

For the second, $\mathcal{Z}_{\mathbb{A}}(I)$ is stable under scaling because I is homogeneous, so it is a union of lines through the origin together with the origin itself; the set of classes of its nonzero vectors is precisely $\mathcal{Z}_{\mathbb{P}}(I)$, and taking the cone recovers $\mathcal{Z}_{\mathbb{A}}(I)$. The hypothesis $\mathcal{Z}_{\mathbb{P}}(I) \neq \emptyset$ is what rules out the degenerate case where $\mathcal{Z}_{\mathbb{A}}(I)$ is the origin alone, as we sought to show.

Let us consider a concrete example. The affine cone of the (homogeneous) polynomial $x^2 + y^2 - z^2$ is the zero-set in $\mathbb{A}_k^{2+1}$ that looks like:

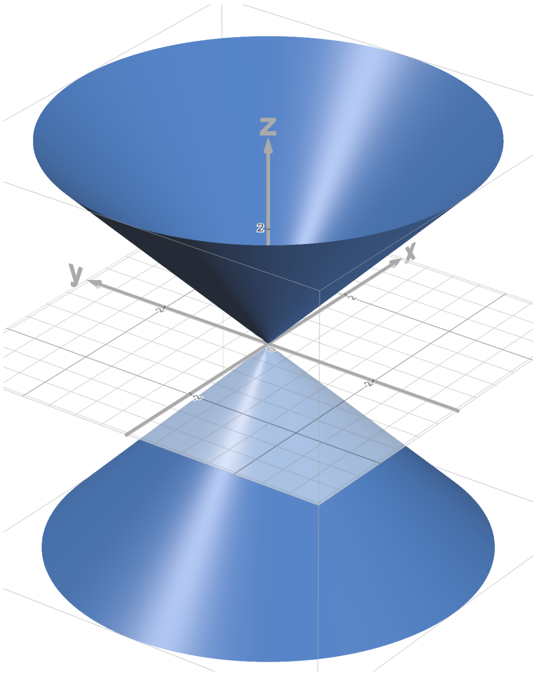

Figure 38.2: zero set of $x^2 + y^2 - z^2$

When $z \neq 0$, This equation in $\mathbb{P}^2_{\mathbb{R}}$ would resemble a circle, which we can see by intersecting the above zero-set with the plane $z = 1$, and hence the usual solution to $x^2 + y^2 = 1$ shall be in this zero set. By setting $z = 0$, we see that $x^2 + y^2 = 0$ if and only if $x = y = 0$, but $[0 : 0 : 0] \notin \mathbb{P}^2_k$, and so all the points of the zero-set $x^2 + y^2 - z^2 = 0$ are precisely the points given by lines passing through $x^2 + y^2 - 1 = 0$

Hence, we see that $x^2 + y^2 - z^2$ becomes the equation of a circle in projective space $\mathbb{P}^2_{\mathbb{R}}$. This matches how the circle has no points going "off to infinity", and so we should expect recovering the same set! However, if we instead consider $xy - z^2$, we see that when $z \neq 0$, we can take the plane where $z = 1$ and get the set $xy = 1$, which is the graph of $y = 1/x$. This has a point at infinity, and indeed if we let $z = 0$, we get the equation $xy = 0$ which is true if either x or y is zero (not that both x and y can both be zero as that would imply $[0 : 0 : 0] \in \mathbb{P}^2_{\mathbb{R}}$). Hence, we gained two additional points corresponding to the two direction the points go off to infinity (see example 38.3.4 for a visual).

The process by which we extend transform a polynomial to a homogeneous polynomial to extend the zero-set is given a name:

Definition 38.3.3: Homogenization

Let $f \in k[x_1, \dots, x_n]$ be a polynomial of degree d. Its *homogenization* is

$$f^*(x_1, \dots, x_{n+1}) = x_{n+1}^d\, f\left(\frac{x_1}{x_{n+1}}, \dots, \frac{x_n}{x_{n+1}}\right)$$

Clearing denominators shows f^* lies in $k[x_1, \dots, x_{n+1}]$ and is homogeneous of degree d. The exponent must be at least $\deg f$ for f^* to be a polynomial at all, and taking it equal to $\deg f$ is what makes f^* divisible by no power of x_{n+1}.

Conversely, a homogeneous $F \in k[x_1, \dots, x_{n+1}]$ is *dehomogenized* with respect to x_i by setting that variable to 1:

$$F_*(x_1, \dots, \widehat{x_i}, \dots, x_{n+1}) = F(x_1, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_{n+1})$$

the hat marking the omitted variable. Unless said otherwise $i = n+1$. These two operations are written $(-)^*$ and $(-)_*$ throughout; the alternative f^* for f^* is not used.

Example 38.3.4: Homogenizing Polynomials

1. Take $x^2 + y^2 - 1$. Homogenizing (with degree 2) and labelling $x_3 = z$, we get $x^2 + y^2 - z^2$. If we homogenizing in degree n, we would get:

   $$z^{n-2}x^2 + z^{n-2}y^2 = z^n$$

   Homogenizing in a degree larger than $\deg f$ multiplies the result by a power of z, which adds the whole line $z = 0$ to the zero set. Those points are an artifact of the padding, so the convention is always to homogenize in degree exactly $\deg f$.

   An affine solution (x_0, y_0) with $x_0^2 + y_0^2 = 1$ becomes the projective point $[x_0 : y_0 : 1]$. For points at infinity, set $z = 0$ and solve $x^2 + y^2 = 0$. Over $\mathbb{R}$ the only solution is $x = y = 0$, which is not a point of $\mathbb{P}^2_{\mathbb{R}}$, so the real circle acquires nothing at infinity. *Over an algebraically closed field of characteristic $\neq 2$ this fails*, and that is the standing hypothesis of this book. Choosing i with $i^2 = -1$,

   $$x^2 + y^2 = (x + iy)(x - iy)$$

   so the circle meets the line at infinity in the two points

   $$[1 : i : 0] \qquad [1 : -i : 0]$$

   These are the *circular points at infinity*, and every circle in $\mathbb{P}^2_{\overline{k}}$ passes through both of them, whatever its centre or radius. The intuition that a circle is bounded and so gains nothing at infinity is an artifact of working over $\mathbb{R}$; the projective conic is a conic like any other, and chapter 43 counts its intersections accordingly.

2. Take $xy - 1$. Its shape looks like:

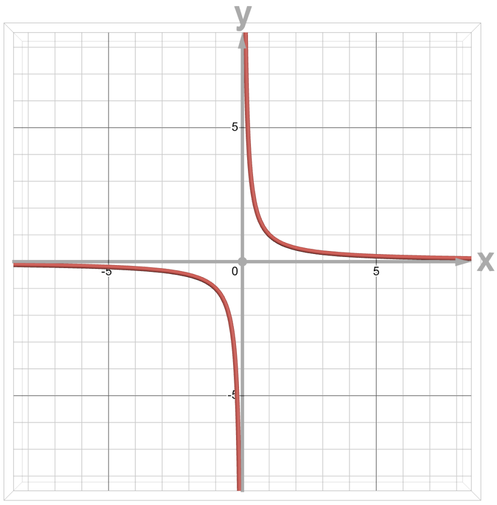

Figure 38.3: zero-set of $xy = 1$

Homogenizing, we get $xy - z^2$. A solution $x_0y_0 - 1 = 0$ in projective coordinates is of the form:

$$[x_0 : y_0 : 1]$$

setting $z = 0$, we can ask if there are any points where:

$$[x_0 : y_0 : 0]$$

is a solution. And indeed, if $x_0 = 0$ or $y_0 = 0$, we get a solution, since

$$0y_0 - 0 = 0 \qquad x_00 - 0 = 0$$

We can see by visualizing the zero set that there seems to be two extra point added at infinite, one for the y-axis and one for the x-axis (remember that opposite points are considered the same).

If we de-homogenize at x, we get $y - z^2 = 0$, equivalently $y = z^2$, and de-homogenizing at y we get $x - z^2 = 0$, equivalently $x = z^2$. In both of these cases, we see that $x = z = 0$ and $y = z = 0$ is a solution. Hence, by de-homogenizing at each variable, we can find the vanishing set of a homogeneous polynomial over projective space. This can be seen more clearly when looking at the affine cone of the homogenized polynomial:

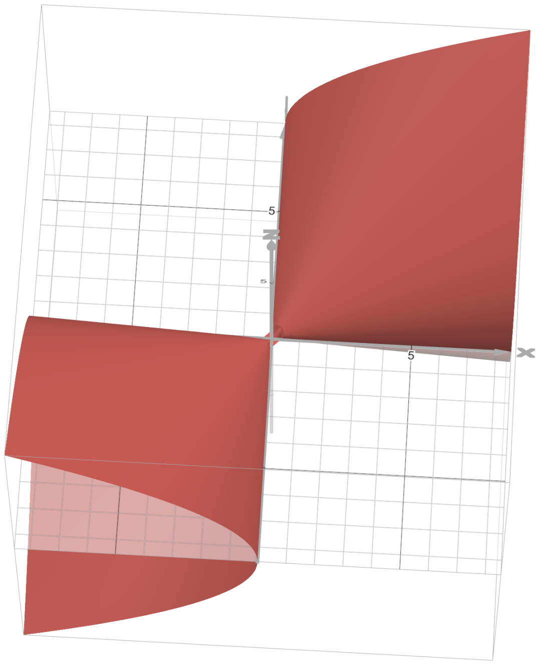

Figure 38.4: affine cone: $xy - z^2$

3. Take $x^3 + xy^2 - 2y^3 - 1$. Its shape looks like:

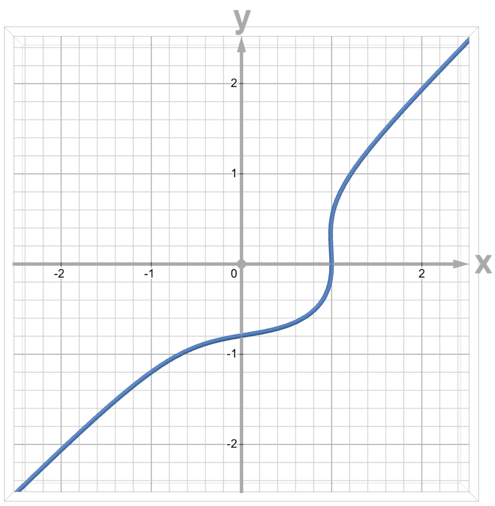

Figure 38.5: $x^3 + xy^2 - 2y^3 = 1$

When homogenizing, the affine cone gives:

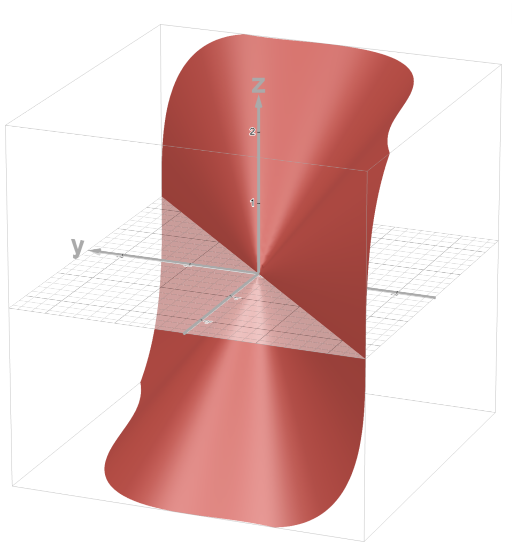

Figure 38.6: affine cone of $x^3 = xy^2 - 2y^3 = z^3$

are there any added points, and if so what are they?

4. Take $f(x) = x^2$. Its vanishing set is the single point 0. Then $f^*(x, x_\infty) = x^2$ is the degree 2 homogenization. Then this has a single zero, namely $[0 : 1]$, which correspond to the single root of x^2 in $\mathbb{A}^1_k$

5. Take $f(x, y) = x^2 - y$, whose zero set is the usual parabola. Its degree-2 homogenization in the variable z is $x^2 - zy$. Setting $z = 1$ recovers the affine points, which are

$$[x_0 : x_0^2 : 1] \qquad x_0 \in k$$

and setting $z = 0$ leaves $x^2 = 0$, so $x = 0$ and the only point at infinity is

$$[0 : 1 : 0]$$

in particular, we added a single point at infinity. This is the point where the parabola "meets". Notice that it wasn't that there was two points at infinite but just 1. The idea is that the "angle" with which the function approaches infinity tends towards $\pi/2$, and hence the edges of the graph shall meet at infinity. This shows that parabola's can be thought of as infinitely large ellipsoids[a].

Can the reader see different sorts of connections between circles, parabolas, ellipses, and hyperbolas through projective space?

[a]for those comfortable with some Riemann geometry, can the reader see why projective space can be thought of as having positive curvature?

Proposition 38.3.5: Properties of Homogenization

Let $F, G \in k[x_1, \ldots, x_{n+1}]$ be homogeneous and $f, g \in k[x_1, \ldots, x_n]$ arbitrary, with $(-)^*$ and $(-)_*$ taken at x_{n+1} as in definition 38.3.3. Then:

1. $(FG)_* = F_* G_*$ and $(fg)^* = f^* g^*$;
2. $(F+G)_* = F_* + G_*$; and writing $r = \deg f$, $s = \deg g$ and $u = \deg(f+g)$,
$$x_{n+1}^{r+s-u}\,(f+g)^* = x_{n+1}^{s} f^* + x_{n+1}^{r} g^*$$
3. if $F \neq 0$ and r is the largest power with $x_{n+1}^r \big| F$, then $x_{n+1}^r (F_*)^* = F$; in particular $(F_*)^* = F$ when $x_{n+1} \nmid F$.

***Proof*:**
Throughout write $z = x_{n+1}$ and use that dehomogenizing is the ring homomorphism $z \mapsto 1$.

1. Dehomogenization is a ring homomorphism, so $(FG)_* = F_* G_*$ is immediate. For the second, $\deg(fg) = \deg f + \deg g$ because k is a domain, and
$$(fg)^* = z^{\deg f + \deg g}(fg)\big(\tfrac{x_1}{z}, \ldots\big) = z^{\deg f} f\big(\tfrac{x_1}{z}, \ldots\big) \cdot z^{\deg g} g\big(\tfrac{x_1}{z}, \ldots\big) = f^* g^*$$
2. Additivity of $(-)_*$ is again the homomorphism property. For the second identity, all three of $f^*, g^*, (f+g)^*$ arise from the same substitution $x_i \mapsto x_i/z$ scaled by different powers of z, namely z^r, z^s and z^u. Multiplying each by the power of z that brings it to the common exponent $r+s$ gives
$$z^{\,s} f^* + z^{\,r} g^* = z^{\,r+s}\,(f+g)\big(\tfrac{x_1}{z}, \ldots\big) = z^{\,r+s-u}\,(f+g)^*$$
The correction $z^{\,r+s-u}$ is needed exactly when the top-degree terms of f and g cancel, so that $u < \max(r, s)$.
3. Write $F = z^r H$ with $z \nmid H$, so H is homogeneous of degree $\deg F - r$. Setting $z = 1$ gives $F_* = H_*$, and since $z \nmid H$ the polynomial H_* has degree exactly $\deg H$; homogenizing therefore returns $(H_*)^* = H$, whence $z^r (F_*)^* = z^r H = F$, as we sought to show.

Corollary 38.3.6: Factorization of Homogeneous Polynomials

Let $F \in k[x_1, \ldots, x_{n+1}]$ be a homogeneous polynomial. Then up to a power of x_{n+1}, factorizing F is the same as factoring F_*.

In particular, if $F \in k[x, y]$, then F factors into a product of linear factors.

***Proof*:**
The first result is immediate from proposition 38.3.5. For the second, as we are asuming k is

algebraically closed in this section we get that F_* must factor into a product of lienar terms,

$$F_* = c\prod(x - \lambda_i)$$

Then by homogenizing we get:

$$F = cy^r\prod(x - \lambda_i y)$$

as we sought to show.

From this, we are justified in decomposing projective algebraic sets by their behaviour when dehomogenizing elements of the generating ideal:

Example 38.3.7: Zero Sets of Projective Space

Example 38.3.4 contained multiple examples of zero sets. All of those examples were from a single homogeneous polynomial.

1. Every point $[a_1 : \cdots : a_{n+1}] \in \mathbb{P}^n_k$ is a projective algebraic set. A point $[x_1 : \cdots : x_{n+1}]$ equals it exactly when

   $$(x_1, \ldots, x_{n+1}) = \lambda(a_1, \ldots, a_{n+1}) \qquad \text{for some } \lambda \neq 0$$

   that is, exactly when the two vectors are proportional, which holds exactly when each 2×2 minor of the matrix

   $$\begin{pmatrix} x_1 & x_2 & \cdots & x_{n+1} \\ a_1 & a_2 & \cdots & a_{n+1} \end{pmatrix}$$

   vanish, namely that

   $$\begin{vmatrix} x_i & x_j \\ a_i & a_j \end{vmatrix} = a_j x_i - a_i x_j = 0$$

   These are $\binom{n+1}{2}$ equations, of which n already suffice (one for each variable beyond a fixed nonzero coordinate). In other words, we get a point via linear homogeneous polynomials with the appropriate coefficients. This shows how "linear" projective space is. These equations can be thought of as the intersection of all the hyper-planes passing through $[a_0 : \cdots : a_n]$. Equivalently, if you know some differential geometry, it shows that we can view $\mathbb{P}^n_k$ as the Grassmannian $G(1, n+1)$.

   The coordinate ring associated to a point would be:

   $$\frac{k[x_1, \ldots, x_{n+1}]}{\langle a_j x_i - a_i x_j \big| 1 \leq i, j \leq n+1\rangle} \cong k[x_{n+1}]$$

   That is, the coordinate ring is *not* just k at a single point! The reader may think of this as the grading condition for the coordinate rings.

2. In $\mathbb{P}^1_k$, the only closed sets are points, the empty set, and the entire space. We shall see why when we show that any closed subset of projective space can be restricted to a closed subset of affine space, in which these are the only possibilities

3. $\mathbb{P}^2_k$ has many more closed sets just like $\mathbb{A}^2_k$. Any line is given by $a_1x_1 + a_2x_2 + a_3x_3$ and any conic by $ax_1^2 + bx_1x_2 + cx_2^2 + dx_1x_3 + ex_2x_3 + fx_3^2$. A famous set of curves is the Fermat curves given by $x_1^n + x_2^n + x_3^n$. There are many more equations.

   To give one example of a coordinate ring, the coordinate ring for a line is isomorphic to $k[s, t]$ with $\deg(s) = \deg(t) = 1$.

4. In $\mathbb{P}^3_k$ the twisted cubic is cut out by three equations,

$$x_1x_3 - x_2^2, \quad x_1x_4 - x_2x_3, \quad x_2x_4 - x_3^2$$

and its homogeneous coordinate ring is

$$\frac{k[x_1, x_2, x_3, x_4]}{(x_1x_3 - x_2^2,\ x_1x_4 - x_2x_3,\ x_2x_4 - x_3^2)} \cong k[s^3, s^2t, st^2, t^3] \subseteq k[s,t]$$

the subring of $k[s,t]$ generated by the degree-three monomials. That isomorphism exhibits the parameterization $[s : t] \mapsto [s^3 : s^2t : st^2 : t^3]$, so the twisted cubic is a *rational* curve: it is the image of $\mathbb{P}^1$. What is notable about it is different: it needs three equations in $\mathbb{P}^3$ although its codimension is two, so it is not a complete intersection.

Another example in $\mathbb{P}^3_k$ are the quadratic surfaces given by $\sum_{i,j} a_{ij}x_ix_j$.

38.4 The Projective Nullstellensatz and Irrelevant Ideals

As we are considering the case where k is algebraically closed, we may naturally want the Nullstellensatz to apply between projective space and homogeneous polynomials. In particular, if $I \subseteq k[x_1, ..., x_n]$ then $Z(I) = \emptyset$ if and only if $I = (1)$. However, this is not the case:

Example 38.4.1: Nullstellensatz False in Projective Space

Let $\mathfrak{m} = (x_1, \ldots, x_{n+1})$, the ideal of all polynomials with zero constant term. Its affine zero set is the origin, and the origin is not a point of $\mathbb{P}^n_k$, so $\mathcal{Z}_{\mathbb{P}}(\mathfrak{m}) = \emptyset$ while $\mathfrak{m} \neq (1)$.

The same happens for every power: writing $\mathfrak{m}^s$ for the ideal generated by all monomials of degree s, its affine zero set is again just the origin, so $\mathcal{Z}_{\mathbb{P}}(\mathfrak{m}^s) = \emptyset$. So the projective Nullstellensatz cannot say "empty zero set implies the unit ideal"; the best it can say is "empty zero set implies the ideal contains some $\mathfrak{m}^s$", which is lemma 38.4.2.

Fortunately, the above ideals are the only ideals for which this could happen, namely because these ideals correspond to ideals that contain the origin in affine space:

Lemma 38.4.2: Characterizing Irrelevant Ideals

Let k be algebraically closed and let $I \subseteq k[x_1, \ldots, x_{n+1}]$ be a homogeneous ideal. Then $\mathcal{Z}_{\mathbb{P}}(I) = \emptyset$ if and only if $\mathfrak{m}^s \subseteq I$ for some $s > 0$, where $\mathfrak{m} = (x_1, \ldots, x_{n+1})$.

***Proof*:**

If $\mathfrak{m}^s \subseteq I$ then every x_i^s lies in I, so any point of $\mathcal{Z}_{\mathbb{P}}(I)$ has all coordinates zero, and $[0 : \cdots : 0]$ is not a point of $\mathbb{P}^n_k$. Hence $\mathcal{Z}_{\mathbb{P}}(I) = \emptyset$.

Conversely assume $\mathcal{Z}_{\mathbb{P}}(I) = \emptyset$. As $k[x_1, \ldots, x_{n+1}]$ is Noetherian, write $I = (f_1, \ldots, f_r)$ with each f_i homogeneous. Fix an index j and dehomogenize at x_j: the polynomials

$$(f_i)_* = f_i(x_1, \ldots, 1, \ldots, x_{n+1}) \qquad i = 1, \ldots, r$$

have no common root in $\mathbb{A}^n_k$, since a common root α would lift to the projective point obtained by inserting 1 in the jth slot, which would lie in $\mathcal{Z}_{\mathbb{P}}(I)$. By the weak Nullstellensatz (theorem 32.4.3) there are g_i with

$$\sum_{i=1}^{r} (f_i)_* \, g_i = 1$$

Homogenizing this identity and clearing denominators multiplies the right hand side by a power of x_j, giving $x_j^{m_j} \in I$ for some $m_j \geq 1$. Running the argument for each j produces exponents $m_1, \ldots, m_{n+1}$.

Put $m = \max_j m_j$ and $s = (n+1)(m-1)+1$. Any monomial $x_1^{a_1} \cdots x_{n+1}^{a_{n+1}}$ of total degree at least s must have some $a_j \geq m \geq m_j$, by the pigeonhole principle: were every $a_j \leq m-1$, the total degree would be at most $(n+1)(m-1) < s$. Such a monomial is therefore divisible by $x_j^{m_j} \in I$ and so lies in I. As $\mathfrak{m}^s$ is generated by the monomials of degree s, this gives $\mathfrak{m}^s \subseteq I$, as we sought to show.

Definition 38.4.3: Irrelevant Ideal

The ideal $\mathfrak{m} = (x_1, \ldots, x_{n+1}) \subseteq k[x_1, \ldots, x_{n+1}]$, consisting of the polynomials with zero constant term, is the *irrelevant ideal*. Its powers $\mathfrak{m}^s$ are the ideals generated by the monomials of degree s.

The name records the point of lemma 38.4.2: $\mathfrak{m}$ and its powers are precisely the homogeneous ideals invisible to projective space, so the projective correspondence must quotient them out. Note that $\mathfrak{m}^s$ and $(x_1^s, \ldots, x_{n+1}^s)$ are different ideals, though each contains a power of the other, which is all the lemma needs.

38.5 The Hilbert Function of a Projective Variety

An affine variety carries its coordinate ring, and dimension is read off from it as a Krull dimension. A projective variety carries a *graded* ring, and the grading holds more information than the dimension alone: counting how fast the graded pieces grow recovers the dimension, and the constant in front of that growth is a genuinely new invariant, the degree. This section extracts both, and the arithmetic genus that chapter 44 needs.

Throughout let $S = k[x_0, \ldots, x_n]$ with its grading by degree, $X \subseteq \mathbb{P}^n_k$ a projective variety, and $S(X) = S/\mathcal{I}_{\mathbb{P}}(X)$ its homogeneous coordinate ring, which inherits a grading because $\mathcal{I}_{\mathbb{P}}(X)$ is homogeneous.

Definition 38.5.1: Hilbert Function of a Projective Variety

The *Hilbert function* of X is

$$H_X \colon \mathbb{N} \to \mathbb{N} \qquad H_X(m) = \dim_k S(X)_m$$

the dimension over k of the degree-m graded piece of $S(X)$.

The definition is a count: $H_X(m)$ is the number of linearly independent forms of degree m on $\mathbb{P}^n$, modulo those vanishing on X. Equivalently it is the number of independent degree-m conditions X can impose. That it eventually behaves polynomially is Hilbert's theorem on graded modules.

Theorem 38.5.2: Hilbert Polynomial

There is a polynomial $h_X \in \mathbb{Q}[T]$, the *Hilbert polynomial* of X, and an integer m_0, such that

$$H_X(m) = h_X(m) \qquad \text{for all } m \geq m_0$$

Moreover $\deg h_X = \dim X$.

***Proof Key ideas*:**
Polynomiality is a statement about finitely generated graded modules over a polynomial ring and carries no geometric content, so it is cited rather than rebuilt: see *Commutative Algebra* [10], where it appears as the graded companion of the Hilbert-Samuel theory this book already cites in section 35.1. The argument is an induction on n, using the exact sequence obtained by multiplying by a variable.

That $\deg h_X = \dim X$ is the geometric half. Intersecting X with a general hyperplane drops the dimension by one (theorem 34.4.1) and drops the degree of the Hilbert polynomial by one, since $H_{X\cap H}(m) = H_X(m) - H_X(m-1)$ for large m and taking that difference lowers the degree of a polynomial by exactly one. Inducting until the dimension reaches zero, where the Hilbert polynomial is the constant counting points, matches the two numbers.

With polynomiality in hand, the leading coefficient is available to be named.

Definition 38.5.3: Degree and Arithmetic Genus

Let $X \subseteq \mathbb{P}^n_k$ be a projective variety of dimension d, so that h_X has degree d and its leading coefficient is c. The *degree* of X is

$$\deg X = d!\, c$$

and the *arithmetic genus* of X is

$$p_a(X) = (-1)^d\,(h_X(0) - 1)$$

The normalization by $d!$ is what makes $\deg X$ an integer and makes $\deg \mathbb{P}^d = 1$, as the first example below checks. Both invariants depend on the embedding $X \subseteq \mathbb{P}^n$ through the grading, not on X alone; a variety embedded two different ways can have two different degrees, which is why the degree of a curve is always quoted together with the projective space it sits in.

Example 38.5.4: Hilbert Polynomials

1. *Projective space.* $S(\mathbb{P}^n) = S$, and the monomials of degree m in $n+1$ variables number $\binom{m+n}{n}$, so
$$H_{\mathbb{P}^n}(m) = \binom{m+n}{n} = \frac{(m+n)(m+n-1)\cdots(m+1)}{n!}$$
This is already a polynomial in m of degree n with leading coefficient $1/n!$. So $\dim \mathbb{P}^n = n$

and $\deg \mathbb{P}^n = n! \cdot \frac{1}{n!} = 1$, and $h_{\mathbb{P}^n}(0) = \binom{n}{n} = 1$ gives $p_a(\mathbb{P}^n) = 0$.

2. *A hypersurface.* Let $X = \mathcal{Z}(F) \subseteq \mathbb{P}^n$ with F irreducible of degree e. Multiplying by F is injective on S and raises degree by e, so

$$H_X(m) = \binom{m+n}{n} - \binom{m-e+n}{n}$$

The two leading terms $m^n/n!$ cancel, leaving degree $n-1$ with leading coefficient $e/(n-1)!$. So $\dim X = n-1$ and $\deg X = e$: *the degree of a hypersurface is the degree of its equation.* This is the fact Bézout's theorem counts with, and it is the reason chapter 43 can speak of the degree of a plane curve without ambiguity.

3. *A plane curve.* Taking $n = 2$ in (2), a smooth plane curve of degree e has

$$h_X(T) = \binom{T+2}{2} - \binom{T-e+2}{2} = eT - \frac{e(e-3)}{2}$$

so $h_X(0) = -e(e-3)/2$ and

$$p_a(X) = (-1)^1\left(-\tfrac{e(e-3)}{2} - 1\right) = \frac{(e-1)(e-2)}{2}$$

This is the *genus-degree formula.* Section 44.4 takes it as the definition of the genus and puts it to work, showing that it vanishes exactly for the curves isomorphic to $\mathbb{P}^1_k$. A line and a conic have genus 0, a smooth cubic has genus 1, which is why smooth plane cubics are exactly the curves chapter 45 finds a group law on.

4. *The twisted cubic.* From example 38.3.7, $S(X) \cong k[s^3, s^2t, st^2, t^3]$, whose degree-$m$ piece is spanned by the monomials of degree $3m$ in s, t, of which there are $3m+1$. So $h_X(T) = 3T+1$: dimension 1, degree 3, and $p_a = -(1-1) = 0$. It is a rational curve of degree 3 in $\mathbb{P}^3$, matching example 38.3.7(4).

Items (1) and (4) both describe a curve of genus 0, but with different degrees, 1 and 3. That is the embedding-dependence made concrete: the twisted cubic is abstractly isomorphic to $\mathbb{P}^1$, and the two are told apart by their Hilbert polynomials only because they sit in projective space differently.

Exercise 38.5.1

1. Let $R_d \subseteq k[x_1, \ldots, x_n]$ be the space of homogeneous polynomials of degree d. Show that $\dim_k R_d = \binom{d+n-1}{n-1}$.

2. Let $T\colon \mathbb{A}^{n+1}_k \to \mathbb{A}^{n+1}_k$ be a linear isomorphism, inducing a map on $\mathbb{P}^n_k$, and let $V \subseteq \mathbb{P}^n_k$ be a subset with $V^T = T^{-1}(V)$.
   a) Show that V is a projective variety if and only if V^T is.
   b) Show that $V \cong V^T$, and that T induces an isomorphism of homogeneous coordinate rings $\Gamma_h(V) \cong \Gamma_h(V^T)$.

3. Let $V = \mathbb{P}^1_k$ with $\Gamma_h(V) = k[x, y]$ and set $t = x/y$. Show that $k(V) \cong k(t)$, and that the points of $\mathbb{P}^1_k$ correspond to the discrete valuation rings R with $\mathrm{Frac}(R) = k(V)$ and $k \subseteq R$. Which valuation ring belongs to the point at infinity?

4. Show that any two hyperplanes in $\mathbb{P}^n_k$ meet, for $n \geq 2$: if L_1, L_2 are nonzero linear forms then $\mathcal{Z}(L_1) \cap \mathcal{Z}(L_2) \neq \emptyset$. Then show the corresponding statement for two *lines* is true in $\mathbb{P}^2_k$ and false in $\mathbb{P}^3_k$, by exhibiting two disjoint lines there.

5. (Euler's relation) Let $\frac{\partial f}{\partial x_i}$ denote the formal partial derivative. Show that if $f \in k[x_0, \ldots, x_n]$ is homogeneous of degree d, then
$$df = \sum_{i=0}^{n} x_i \frac{\partial f}{\partial x_i}$$
It suffices to check both sides on a monomial, since both are k-linear.

6. Let $R = \bigoplus_{j \geq 0} R_j$ be a graded ring and write $1 = \sum_j r_j$ with $r_j \in R_j$. Show that r_0 is a multiplicative identity for R_0, and in fact that $1 = r_0$.

7. Show that $\mathcal{I}(\mathcal{Z}(I)) = \sqrt{I}$ fails for the irrelevant ideal of definition 38.4.3, and state the projective Nullstellensatz that repairs it.

8. Compute the Hilbert polynomial of the twisted cubic in $\mathbb{P}^3_k$ directly from definition 38.5.1, and check the degree and arithmetic genus against example 38.5.4(4).

9. Show that a homogeneous polynomial in two variables over an algebraically closed field factors into linear forms, and deduce corollary 38.3.6 for $n = 1$.

10. (Analysis aside, over $\mathbb{R}$.) Let $f\colon \mathbb{R}^n \to \mathbb{R}$ be d times continuously differentiable and homogeneous of degree d, meaning $f(\lambda v) = \lambda^d f(v)$ for all $\lambda > 0$. Show that f is a homogeneous polynomial of degree d. So for smooth enough functions, homogeneity in the scaling sense already forces homogeneity in the algebraic sense.

39

Quasi-Projective Varieties and Regular Maps

Projective space is covered by $n+1$ copies of affine space, and that single observation converts every local question about a projective variety into an affine one. This chapter develops the consequence: the class of varieties closed under both taking closed subsets and taking open subsets, the quasi-projective varieties, which contains the affine and the projective ones and is the setting in which the rest of the book works.

39.1 The Affine Cover of Projective Space

A common characterization of $\mathbb{P}^n_k$ is by showing that it can be constructed by gluing together $n+1$ copies of $\mathbb{A}^n_k$. Let $R = k[x_1, x_2, ..., x_{n+1}]$, and let H_i be the zero set of the (homogeneous) polynomial x_i for each i, giving us $H_1, H_2, ..., H_{n+1}$. These sets certainly cover $\mathbb{P}^n_k$ (their union is $\mathbb{P}^n_k$) and are closed as

$$H_i = \mathcal{Z}(x_i)$$

If we consider the map $\mathbb{A}^n_k \to \mathbb{P}^n_k$ mapping $(a_1, ..., a_n) \mapsto [1 : a_1 : \cdots : a_n]$, then the hyperplane H_{n+1} is called the *hyperplane at infinity*, being the hyperplane where $x_{n+1} = 0$ (it contains the points at infinity). For any hyperplane H_i, we have a map

$$H_i \to \mathbb{P}^{n-1}_k \qquad [a_1, ..., a_{i-1}, 0, a_{i+1}, ..., a_n] \to [a_1, ..., a_{i-1}, a_{i+1}, ..., a_n]$$

Once we define regular maps, the reader can verify that $H_i \cong \mathbb{P}^{n-1}_k$. Let

$$D(x_i) = U_i = \mathbb{P}^n_k - H_i$$

Then these sets are open and cover $\mathbb{P}^n_k$, as H_i is closed, and they contain all points where $x_i \neq 0$. Define a map:

$$\varphi_i : U_i \to \mathbb{A}^n_k \qquad [a_1 : \cdots : a_{n+1}] \mapsto \left(\frac{a_1}{a_i}, \ldots, \frac{a_{n+1}}{a_i}\right)$$

where we omit $\frac{a_i}{a_i}$. Notice how this is similar to de-homogenization. Verify that the map is well-defined, namely that it is independent of representative of points $U_i \subseteq \mathbb{P}^n_k$. Then:

Proposition 39.1.1: Projective Space Affine Cover

Let φ_i be defined as above. Then φ_i is a homeomorphism:

$$U_i \cong \mathbb{A}^n_k$$

***Proof*:**
First, φ_i is certainly a bijection: if

$$[x_1 : \cdots : 1_i : \cdots : x_n] = \varphi_i(x_1, ..., x_n) = \varphi(y_1, ..., y_n) = [y_1 : \cdots : 1_i : \cdots : y_n]$$

these two are equal if each $x_j = \lambda y_j$ for some $\lambda \in k$. Indeed, since $1_i = \lambda 1_i$, we must have $\lambda = 1$, which shows that $x_j = y_j$ for each coefficient, giving injectivity. For surjectivity, given any $[x_1, ..., x_i, ..., x_n]$ where $x_i \neq 0$, take:

$$[x_1 : \cdots : x_i : \cdots x_n] = \left[\frac{x_1}{x_i} : \cdots : 1_i : \cdots : \frac{x_n}{x_i}\right]$$

We now see that $(\frac{x_1}{x_i}, ..., \frac{x_n}{x_i})$ map to this point, giving surjectivity, and hence bijectivity.

For continuity, notice that $\varphi_i = \pi \circ \psi_i$ where $\psi_i : \mathbb{A}^n_k \to \mathbb{A}^{n+1}_k \setminus \{0\}$ is the natural embedding with ith-coordinate shifted by 1, and π is the projection. The map π is continuous as $\mathbb{P}^n_k$ is given the natural quotient from $\mathbb{A}^n_k$, and ψ_i is continuous as any pre-image of closed subsets of $\mathbb{A}^{n+1}_k \setminus \{0\}$ is given by the dehomogenization of the polynomials at the ith coordinate.

Furthermore, the map is open, since ψ_i is open (its image is a shifted-by-1 copy of $\mathbb{A}^n_k$, so any open set in $\mathbb{A}^n_k$ is open in $\mathcal{Z}(y_i - 1) \cap \mathbb{A}^{n+1}_k \setminus \{0\}$) and π is open since for any open subset $U \subseteq \mathbb{A}^{n+1}_k \setminus \{0\}$ the set

$$\bigcup_{\lambda \in k^*} \lambda U$$

is open, since the map $x \mapsto \lambda x$ is a homeomorphism (as is quickly verifiable). This is the pre-image of $\pi(U)$ and so since π is a quotient map we have that $\pi(U)$ is also open. Thus, the composition is open, making φ open.

Combining all the results, we get that φ_i is a homeomorphism, as we sought to show.

Given $H_i \cong \mathbb{P}^{n-1}_k$, this implies that we have a decomposition:

$$\mathbb{P}^n_k = \mathbb{A}^n_k \sqcup \mathbb{P}^{n-1}_k$$

For example, if $n = 2$, then:

$$\mathbb{P}^2_k = \mathbb{A}^2_k \sqcup \mathbb{P}^1_k$$

For this reason, we often think of $\mathbb{P}_k^2$ to be $\mathbb{A}_k^2$ along with a "line at infinity" (the reader should take the time to internalize this idea). This decomposition can be extended further, breaking down $\mathbb{P}_k^{n-1}$ into an affine and projective space. Repeating inductively, we get:

$$\mathbb{P}_k^n = \mathbb{A}_k^n \sqcup \mathbb{A}_k^{n-1} \sqcup \cdots \sqcup \mathbb{A}_k^1 \sqcup \mathbb{A}_k^0$$

Another "immediate" result from our above discussion is that projective space $\mathbb{P}_k^n$ can be covered with $n+1$ copies of $\mathbb{A}_k^n$. This shall become the dominant way of viewing projective space in modern algebraic geometry (similar to how smooth manifolds are viewed as patches of euclidean space glued together), making this result important enough to be a theorem:

Theorem 39.1.2: Projective Variety Affine Cover

Let $Y \subseteq \mathbb{P}_k^n$ be a projective algebraic set. Then the sets $Y \cap U_i$, $1 \leq i \leq n+1$, form an open cover of Y, and each one is isomorphic to an *affine* algebraic set in $\mathbb{A}_k^n$.

***Proof*:**
The U_i cover $\mathbb{P}_k^n$, since a point has some nonzero coordinate, so the $Y \cap U_i$ cover Y and are open in Y. Fix i and identify U_i with $\mathbb{A}_k^n$ by the homeomorphism φ_i of proposition 39.1.1.

Let $Y = \mathcal{Z}_{\mathbb{P}}(F_1, \ldots, F_r)$ with each F_j homogeneous. Under φ_i a point of U_i is the class of a vector whose ith coordinate is 1, and F_j vanishes there exactly when its dehomogenization $(F_j)_*$ at x_i vanishes at the corresponding point of $\mathbb{A}_k^n$. Hence

$$\varphi_i(Y \cap U_i) = \mathcal{Z}_{\mathbb{A}}\big((F_1)_*, \ldots, (F_r)_*\big)$$

an affine algebraic set. Conversely φ_i^{-1} carries that set back, so the two are isomorphic, as we sought to show.

The content is the second clause: it is not just that Y is covered by sets homeomorphic to open subsets of $\mathbb{A}^n$, but that each piece is a genuine affine algebraic set with its own coordinate ring. Every local question about a projective variety can therefore be answered affinely, which is the working method for the rest of the book.

For the reader's awareness, we box the following[1]:

[1] this shall be the transition maps to verify the gluing is well-defined

Corollary 39.1.3: Transition Between Affine Cover

For $i \neq j$ the two charts agree on the overlap: the composite

$$\varphi_{ij} = \varphi_j \circ \varphi_i^{-1} \colon \varphi_i(U_i \cap U_j) \to \varphi_j(U_i \cap U_j)$$

is an isomorphism of affine varieties, given in coordinates by:

$$\begin{aligned}(x_1, ..., \hat{x}_i, ..., x_{n+1}) &\mapsto [x_1, ..., x_{i-1}, 1, x_{i+1}, ..., x_{n+1}] \\ &\mapsto \left[\frac{x_1}{x_j}, ..., \frac{x_{i-1}}{x_j}, \frac{1}{x_j}, \frac{x_{i+1}}{x_j}, ..., \frac{x_j}{x_j}..., \frac{x_{n+1}}{x_j}\right] \\ &\mapsto \left(\frac{x_0}{x_j}, ..., \frac{x_{i-1}}{x_j}, \frac{1}{x_j}, \frac{x_{i+1}}{x_j}, ..., \hat{1}_j..., \frac{x_{n+1}}{x_j}\right)\end{aligned}$$

where the hats mark omitted variables, and $i < j$ is assumed without loss of generality.

***Proof*:**
On $U_i \cap U_j$ both x_i and x_j are nonzero, so each displayed coordinate is a ratio with nonvanishing denominator and the composite is regular. Reversing the roles of i and j gives φ_{ji}, and $\varphi_{ji} \circ \varphi_{ij} = \mathrm{id}$ because both sides come from the identity on $U_i \cap U_j$. So φ_{ij} is an isomorphism, completing the proof.

39.2 Projective Closure

Let us now formalize extending closed sets of $\mathbb{A}_k^n$ to $\mathbb{P}_k^n$, and conversely restrict closed sets of $\mathbb{P}_k^n$ to any $U_i \cong \mathbb{A}_k^n$. Let us first take a closed subset $V \subseteq \mathbb{P}_k^n$, and consider its restriction to $U_i \cong \mathbb{A}_k^n$. As $U_i = D(x_i)$ is open, $V \cap U_i = W_i$ is open in V (the subspace topology on U_i and the Zariski topology transported by φ_i agree). Let us show that W_i is closed in $U_i \cong \mathbb{A}_k^n$, that is it is the zero set of the appropriate polynomials. If $f_1, \ldots, f_r$ are the homogeneous polynomials defining V[2] so that

$$f_1 = \cdots = f_n = 0$$

with $\deg f_i = n_i$, then on U_i each f_j is converted to:

$$x_i^{n_j} f_j \left(\frac{x_1}{x_j}, ..., 1_j, ..., \frac{x_{n+1}}{x_j}\right)$$

For example $f(x, y, x_3) = xy - x_3^2$ would be converted to $xy - 1$ in U_3. Then we can see that $V = \cup W_i$, that is each V can be covered by closed subsets from each U_i.

Conversely, if $W \subseteq \mathbb{A}_k^n$ is a closed subset, we may take the closure in $\mathbb{P}_k^n$, $\overline{W}$, which is the intersection of all closed sets containing W where we interpret W as being set in one of the U_i's. Some closed W are also closed in $\mathbb{P}_k^n$. For example $x^2 + y^2 - 1$ over $\mathbb{C}[x, y]$ when embedded becomes the zero set of $x^2 + y^2 - z^2$ whose points are $[x_0 : y_0 : 1]$ with $x_0^2 + y_0^2 = 1$, together with the two circular points at

[2] Recall that we are working over Noetherian rings, and hence each ideal is finitely generated

infinity of example 38.3.4. On the other hand, if we take $xy-1$ and consider $xy-z^2$, we get that the traditional zero's become:

$$\left[a : \frac{1}{a} : 1\right]$$

and we now get a new 0 when $z=0$ giving two more points:

$$[1:0:0] \qquad [0:1:0]$$

which we can think of as adding the two points at infinity of the graph of $y=1/x$. Another example would be $y-x^2$. When extending to $\mathbb{P}^2_k$, we get $yz-x^2$. By setting $x=0$, we get that $y=0$ is a solution (which already exists in $\mathbb{A}^2_k$) as well as the new solution:

$$[0:0:1]$$

which is a new point at infinity that makes the parabola shape akin to an infinite ellipse.

Summarizing our discussion and the pertinent consequences:

Proposition 39.2.1: Closure of Affine Variety

Let $I \subseteq k[x_1,...,x_n]$ be a (not necessarily homogeneous) ideal, $I^* = \{f^* \mid f \in I\}$, $V^* = \mathcal{Z}(I^*) \subseteq \mathbb{P}^n_k$. Take the last coordinate of $\mathbb{P}^n_k$ to be the coordinate at infinity, so that $\mathbb{A}^n_k$ embeds in $\mathbb{P}^n_k$ via $\iota_{n+1}\colon \mathbb{A}^n_k \xrightarrow{\sim} U_{n+1} \subseteq \mathbb{P}^n_k$. Let $(-)_*$ be the dehomogenization operation so that if $V = \mathcal{Z}(J) \subseteq \mathbb{P}^n_k$, then $I_* = \{f_* \mid f \in J\}$ where f_* is the dehomogenization at the coordinate at infinity, and $V_* = \mathcal{Z}(I_*)$. Let H_∞ represent the hyperplane at infinity (i.e. $\mathcal{Z}(x_{n+1})$). Then:

1. $\iota_{n+1}(V) = V^* \cap U_{n+1}$
2. $(V^*)_* = V$
3. If $V \subseteq W \subseteq \mathbb{A}^n_k$, then $V^* \subseteq W^* \subseteq \mathbb{P}^n_k$
4. If $V \subseteq W \subseteq \mathbb{P}^n_k$, then $V_* \subseteq W_* \subseteq \mathbb{A}^n_k$
5. If V is irreducible in $\mathbb{A}^n_k$, then V^* is irreducible in $\mathbb{P}^n_k$
6. If $V = \cup_i V_i$ is the irreducible decomposition of V in $\mathbb{A}^n_k$, then $V^* = \cup_i V_i^*$ is the irreducible decomposition of V^* in $\mathbb{P}^n_k$
7. If $V \subseteq \mathbb{A}^n_k$, then V^* is the closure of $\iota_{n+1}(V) \subseteq \mathbb{P}^n_k$ in the Zariski topology (i.e. it is the smallest algebraic set in $\mathbb{P}^n_k$ containing $\iota_{n+1}(V)$
8. If $\emptyset \neq V \subseteq \mathbb{A}^n_k$, then no irreducible component of V^* is contained in H_∞, though components may meet it
9. If $V \subseteq \mathbb{P}^n_k$ has no irreducible component contained in H_∞, then $(V_*)^* = V$

***Proof*:**
Parts (3) and (4) are immediate from the definitions, since homogenizing and dehomogenizing preserve containment of ideals and $\mathcal{Z}$ reverses it.

(1) and (2). A point of $\mathbb{A}_k^n$ satisfies f exactly when its image in U_{n+1} satisfies f^*, because f^* restricted to $x_{n+1} = 1$ is f by proposition 38.3.5(3). Intersecting with U_{n+1} therefore recovers $\iota_{n+1}(V)$, which is (1), and dehomogenizing recovers V, which is (2).

(7). By (1), V^* is a closed set whose trace on U_{n+1} is $\iota_{n+1}(V)$, so $V^* \supseteq \overline{\iota_{n+1}(V)}$. Conversely let W be any closed set containing $\iota_{n+1}(V)$, say $W = \mathcal{Z}_{\mathbb{P}}(J)$ with J homogeneous. Each $F \in J$ vanishes on $\iota_{n+1}(V)$, so F_* vanishes on V, so $F_* \in \mathcal{I}(V)$ and hence $F = x_{n+1}^r (F_*)^* \in I^*$ for some r, again by proposition 38.3.5(3). Therefore $V^* \subseteq W$, and V^* is the smallest such closed set.

(5) and (6). If V is irreducible then $\mathcal{I}(V)$ is prime, and the homogenization of a prime ideal is prime, because a product of homogeneous elements lies in I^* exactly when the product of their dehomogenizations lies in $\mathcal{I}(V)$. So V^* is irreducible, giving (5). Applying (5) and (7) to each component of $V = \bigcup_i V_i$ gives $V^* = \bigcup_i V_i^*$ with each V_i^* irreducible, and no containments among them since (3) and (2) make $V \mapsto V^*$ inclusion-reflecting; that is (6).

(8) and (9). A component of V^* contained in H_∞ would meet U_{n+1} in the empty set, so by (1) it would contribute nothing to V, contradicting (7)'s minimality. That is (8). For (9), the hypothesis makes V the projective closure of V_*, and (7) identifies that closure with $(V_*)^*$, as we sought to show.

Definition 39.2.2: Projective Closure

Let $V \subseteq \mathbb{A}_k^n$ be an algebraic set. Then $V^* \subseteq \mathbb{P}_k^n$ as defined in proposition 39.2.1 is called the *projective closure*.

Note that the homogenization of an ideal is *not* the homogenization of its generators

Example 39.2.3: Homogenization of Ideal and Generators

Let $I = (y - x^2, z - x^3)$ and $V = \mathcal{Z}(I)$ i.e. the twisted cubic in $\mathbb{A}_k^3$. Show that

1. $zw - xy \in I(V)^*$
2. $zw - xy \notin \left((y - x^2)^*, (z - x^3)^*\right)$

In other words, the ideal $(f_1^*, ..., f_n^*)$ is too small to capture all the new relations (in particular it usually adds a line at infinity).

Next, we define $k_{\mathbb{P}}(V)$ to be the localization of $k_{\mathbb{P}}[V]$. Note that if $f/g \in k(V)$ where $\deg(f) = \deg(g) = d$, then f/g is in fact a well-defined function on V, since:

$$\frac{f(\lambda x)}{g(\lambda x)} = \frac{\lambda^d f(x)}{\lambda^d g(x)} = \frac{f(x)}{g(x)}$$

there are thus many more rational functions defined on V than regular functions. The set of well-defined functions shall be given a name:

Definition 39.2.4: Function Field

Let V be a projective variety. Then:

$$\kappa(V) = \left\{ \frac{f}{g} \;\middle|\; f, g \in k_{\mathbb{P}}[V] \text{ homogeneous of the same degree, } g \notin \mathcal{I}_{\mathbb{P}}(V) \right\}$$

taken inside the fraction field of $k_{\mathbb{P}}[V]$, and modulo the usual identification $f/g = f'/g'$ when $fg' - f'g \in \mathcal{I}_{\mathbb{P}}(V)$. Elements of $\kappa(V)$ are the *rational functions* on V.

Homogeneity of f and g is what makes the ratio well defined on V: degree is not defined on a non-homogeneous element of $k_{\mathbb{P}}[V]$, and it is equality of the two degrees that makes the scaling factors λ^d cancel.

Proposition 39.2.5: Rational Functions over Projective and Affine Variety

Let $V \subseteq \mathbb{A}^n_k$ be an affine variety. Then:

$$k(V) \cong \kappa(V^*)$$

Similarly, if $V \subseteq \mathbb{P}^n_k$ is a projective variety not contained in the hyperplane at infinity. Then:

$$\kappa(V) \cong k(V_*)$$

***Proof*:**
Define a map in the direction of the claim by homogenizing:

$$\alpha\colon k(V) \to \kappa(V^*) \qquad \alpha\left(\frac{f}{g}\right) = \frac{x_{n+1}^{\deg g - \deg f} f^*}{g^*}$$

the power of x_{n+1} inserted so that numerator and denominator have the same degree, as definition 39.2.4 requires; when $\deg f > \deg g$ the correcting factor goes on the denominator instead.

Well defined. If $f/g = f'/g'$ in $k(V)$ then $fg' - f'g \in \mathcal{I}(V)$, and homogenizing that relation, using $(uv)^* = u^*v^*$ from proposition 38.3.5(1), puts the corresponding difference in $\mathcal{I}_{\mathbb{P}}(V^*)$ up to a power of x_{n+1}, which is a unit on U_{n+1} and so does not change the class.

Inverse. Dehomogenizing gives $\beta(F/G) = F_*/G_*$, and $\beta \circ \alpha = \mathrm{id}$ because $(f^*)_* = f$ for every f by proposition 38.3.5(3). For $\alpha \circ \beta = \mathrm{id}$, part (3) of that proposition gives $(F_*)^* = F$ up to a power of x_{n+1}; that power cancels between numerator and denominator since both are corrected to a common degree. Hence α is a bijection, and it is a ring homomorphism because homogenization is multiplicative and additive up to the same powers of x_{n+1}.

The second isomorphism is the first applied to V_*, using $(V_*)^* = V$ from proposition 39.2.1(9), which is exactly the hypothesis that V is not contained in the hyperplane at infinity, as we sought to show.

On the one hand, it may seem counter-intuitive that though we are restricting to degree 0 rational polynomials, we somehow get as many rational functions as when we allowed for any degree $r - s$

rational polynomial. On the other hand, this should not be too strange for the reader: the domain of definition is a dense open subset, and we shall show that V^* is the closure of V when embedded in $\mathbb{P}^n_k$.

We can define the *stalk* at p to be

$$\mathcal{O}_p(V) = \{f/g \in \kappa(V) \mid g(p) \neq 0\}$$

The same argument as proposition 33.2.10 shows $\mathcal{O}_p(V)$ is a local Noetherian domain.

Proposition 39.2.6: Stalk Defined Locally

Let $V \subseteq \mathbb{P}^n_k$ be a projective variety not contained in the hyperplane at infinity, let V_* be its dehomogenization, and let $p \in V_*$. Then:

$$\mathcal{O}_p(V) \cong \mathcal{O}_p(V_*)$$

This shows that the properties of a stalk are inherently "local", depending only on the information around the point p.

***Proof*:**
Restrict the isomorphism α of proposition 39.2.5. A rational function on V lies in $\mathcal{O}_p(V)$ exactly when it has a representative F/G with $G(p) \neq 0$; applying α and its inverse turns such representatives into representatives f/g on V_* with $g(p) \neq 0$, since dehomogenizing at x_{n+1} does not change whether a form vanishes at a point of U_{n+1}. So α carries $\mathcal{O}_p(V)$ onto $\mathcal{O}_p(V_*)$ and is a ring isomorphism between them, as we sought to show.

Next, notice there is more than one natural set of coordinates on projective space. It is natural to consider the coordinates of $\mathbb{P}^n_k$ to be given by degree 1 homogeneous functions, namely each point $x \in \mathbb{P}^n_k$ is of the form $[x_1 : \cdots : x_{n+1}]$ where $[\lambda x_1 : \cdots : \lambda x_{n+1}] = \lambda[x_1 : \cdots : x_{n+1}]$. However, we may also just as naturally choose to represent each point in any degree of homogeneity, namely:

$$[\lambda w_1 : \cdots : \lambda w_{n+1}] = [w_1 : \cdots : w_{n+1}]$$

where we can have $w_i = (x_i)^k$.

Finally, as all homogeneous polynomials must be of the same degree, we can give a rough classification of all hypersurfaces of projective space $\mathbb{P}^n_k$ of degree d. A hypersurface is defined by a single homogeneous equation. As there are $n+1$ variables, there are $\binom{n+d}{d} = N$ possible degree d monomials. Labeling them $M_1, ..., M_N$, any degree d homogeneous polynomial is of the form:

$$\sum_i^N a_i M_i$$

These hypersurface are naturally defined up to multiplication of a constant $c \in k$. But then, the coefficients determine the hypersurface up to a constant, meaning they can be associated to a point in $\mathbb{P}^N_k$, or said differently $\mathbb{P}^N_k$ *parameterizes* the degree d hypersurfaces of $\mathbb{P}^n_k$ or is the *moduli space* for the degree d hypersurfaces of $\mathbb{P}^n_k$.

Note that some points classify the same hypersurface, for example $x^2y = 0$ and $xy^2 = 0$ in $\mathbb{P}^2_k$, both of which cut out the union of the lines $x = 0$ and $y = 0$. The difference is in the multiplicity, information that would be distinguishable when working with *closed subschemes* instead of closed subsets.

39.3 Quasi-Projective Varieties

As we saw in the above, affine and projective varieties are naturally linked to each other. Many results that are proven in classical algebraic geometry apply both to projective and affine varieties. Furthermore, the open subset of projective variety (for example $\mathbb{P}^1_k$ minus the point at infinity and zero) have natural algebraic structure but are not the vanishing set of polynomials (they are the opposite, they are the non-vanishing set of polynomials). The properties of such sets often are strongly tied to varieties, or are even varieties themselves (for example $\mathbb{P}^1_k$ without the point at infinity is the closed set $\mathbb{A}^1_k$ in $\mathbb{A}^1_k$, but is an open set in $\mathbb{P}^1_k$). The definition of quasi-projective varieties aims to unify all of these.

If $X \subseteq \mathbb{P}^n_k$ is closed and $X_i = X \cap U_i$ is open in X, they are in fact *closed* in $U_i \cong \mathbb{A}^n_k$. This can be seen by de-homogenizing: if X is given by equations $f_0, ..., f_n$ where $\deg f_i = n_i$, then U_i is given by:

$$x_i^{-n_j} f_j = f(x_1, .., x_{i-1}, 1, x_{i+1}, ..., x_{n+1}) = 0$$

If we have $X_i \subseteq U_i$ which is closed, then we may consider the closure $\overline{X_i} \subseteq \mathbb{P}^n_k$ by taking the polynomials that generate X_i and homogenizing them, namely if f is one such polynomial where $\deg f = d$, then the equations describing $\overline{X_i}$ are of the form

$$x_i^l f(x_1/x_i, ..., x_{n+1}/x_i) = 0$$

Which implies that:

$$X_i = \overline{X_i} \cap U_i$$

Hence, if $X \subseteq \mathbb{P}^n_k$, then an open subset of X will correspond to a closed subset of $\mathbb{A}^n_k$. As X is an open subset of itself, it corresponds to an open subset of a closed projective algebraic set. Thus, open subsets of closed projective sets encapsulate affine and projective varieties:

Definition 39.3.1: Quasi-projective Variety

A *quasi-projective variety* is an open subset of a closed projective variety.

Example 39.3.2: Quasi-Projective Varieties

1. *Affine varieties are quasi-projective.* $\mathbb{A}^n_k$ is the standard chart $U_0 \subseteq \mathbb{P}^n_k$, an open subset, and a closed $V \subseteq \mathbb{A}^n_k$ is $\overline{V} \cap U_0$ for its projective closure. So every affine variety is open in a projective one.

2. *Projective varieties are quasi-projective*, taking the open set to be everything.

3. *Neither affine nor projective.* $\mathbb{A}^2_k \setminus \{(0,0)\}$ is open in $\mathbb{A}^2_k$, hence quasi-projective. It is not projective, carrying the nonconstant regular function x, and it is not affine: its ring of regular functions is $k[x, y]$, whose maximal ideals include one for the missing origin. The details are the fifth exercise of exercise set 39.5.1.

4. *The complement of a hypersurface.* For a form F of degree d, the set $\mathbb{P}^n_k \setminus \mathcal{Z}(F)$ is quasi-projective and in fact affine, being isomorphic to a closed subvariety of $\mathbb{A}^N$ under the Veronese of definition 41.1.1, which turns $\mathcal{Z}(F)$ into a hyperplane section.

5. *A non-example.* Over $\mathbb{C}$, the subset $\mathbb{Z} \subseteq \mathbb{C} = \mathbb{A}^1_{\mathbb{C}}$ is not quasi-projective. A locally closed

subset of $\mathbb{A}^1_{\mathbb{C}}$ is finite or cofinite, by the sixth exercise of exercise set 41.6.1, and $\mathbb{Z}$ is neither. So it is not even constructible, and by theorem 41.3.4 it is not the image of any regular map.

A closed subset $C \subseteq U$ of a quasi-projective variety is the intersection of C with a closed subset $\mathbb{P}^n_k$. The irreducible decomposition of theorem 32.3.5 carries over verbatim, since it used only that the space is Noetherian. If $Y \subseteq X \subseteq \mathbb{P}^n_k$ with Y quasi-projective, then Y is a *subvariety* of X.

It must be noted that the collection of quasi-projective varieties is larger than the collection affine and projective varieties. For example $\mathbb{A}^2_k \setminus \{(0,0)\}$ is a quasi-projective variety, but is not affine or projective.

Let X be a quasi-projective variety and $U \subseteq X$ an open subset. Define $\Gamma(U, \mathcal{O}_X) \subseteq \kappa(X)$ to be the collection of all rational functions on X that are defined at each $p \in U$. Equivalently:

$$\Gamma(U, \mathcal{O}_X) = \bigcap_{p \in U} \mathcal{O}_p(X)$$

Note that if $U = X$, then by proposition 33.2.9 and proposition 39.2.6,

$$\Gamma(X, \mathcal{O}_X) = k[X] = \Gamma(X)$$

showing this notation is consistent with our earlier definitions.

Next, let's see that checking that a quasi-projective variety is closed is an open-local condition:

Lemma 39.3.3: Closedness of Quasi-projective Variety is Open-local

Let $Y \subseteq X$ be a quasi-projective variety. Then Y is closed if and only if $X = \cup_\alpha U_\alpha$ where U_α is open and $Y \cap U_\alpha$ is closed for every α. Namely, closedness is open-local for quasi-projective varieties

***Proof*:**
If Y is closed then $Y \cap U_\alpha$ is closed in U_α for any open cover, which is the easy direction.

Conversely let $X = \bigcup_\alpha U_\alpha$ with each U_α open and each $Y \cap U_\alpha$ closed in U_α. Write $U_\alpha = X \setminus Z_\alpha$ with Z_α closed, and $Y \cap U_\alpha = T_\alpha \cap U_\alpha$ with T_α closed in X. We claim

$$Y = \bigcap_\alpha (Z_\alpha \cup T_\alpha)$$

which exhibits Y as an intersection of closed sets and so finishes the proof.

For $\subseteq$: let $y \in Y$ and fix α. Either $y \notin U_\alpha$, in which case $y \in Z_\alpha$; or $y \in U_\alpha$, in which case $y \in Y \cap U_\alpha \subseteq T_\alpha$. Either way $y \in Z_\alpha \cup T_\alpha$.

For $\supseteq$: let y lie in every $Z_\alpha \cup T_\alpha$. The U_α cover X, so $y \in U_\beta$ for some β, and then $y \notin Z_\beta$, forcing $y \in T_\beta$. Hence $y \in T_\beta \cap U_\beta = Y \cap U_\beta \subseteq Y$, as we sought to show.

The following shows that any variety is fundamentally locally affine:

Lemma 39.3.4: Varieties Are Locally Affine

Let X be a quasi-projective variety. Then every $x \in X$ has an open neighborhood that is isomorphic to an affine variety

***Proof*:**
Take $X \subseteq \mathbb{P}^n_k$. If $x \in U_{n+1}$, then $x \in X \cap U_{n+1}$ and by definition of a quasi-projective variety:

$$X \cap U_{n+1} = Y - Y_1$$

where Y_1, Y are closed subsets of U_{n+1}. As $x \in Y$, there exists a polynomial f with coordinates in U_{n+1} where $f = 0$ on Y_1 and $f(x) \neq 0$. Let $D(f) = Y \setminus \mathcal{Z}(f)$, the subset of Y on which f does not vanish. It is open in Y and contains x, and it misses Y_1 entirely since f vanishes there, so $D(f) \subseteq Y \setminus Y_1 = X \cap U_{n+1}$ is an open neighbourhood of x inside X.

I claim this neighborhood is isomorphic to an affine variety. If $(f_1, ..., f_m)$ is the ideal associated to $Y \subseteq U_{n+1}$, then define the variety in $\mathbb{A}^{n+1}_k$ via:

$$f_1(x_1, ..., x_n) = \cdots = f_m(x_1, ..., x_n) = 0 \qquad f(x_1, ..., x_n)x_{n+1} = 1$$

i.e.

$$Z = \mathcal{Z}(f_1, ..., f_m, f \cdot x_{n+1} - 1)$$

Then the mapping

$$\varphi(x_1, ..., x_{n+1}) \to (x_1, ..., x_n)$$

gives a regular mapping from Z into $D(f)$, and

$$\psi(x_1, ..., x_n) \to (x_1, ..., x_n, f(x_1, ..., x_n)^{-1})$$

is a regular mapping of $D(f)$ into Z. The two composites are the identity: $\varphi \circ \psi$ drops the last coordinate that ψ appended, and $\psi \circ \varphi$ restores it, since a point of Z satisfies $f \cdot x_{n+1} = 1$ and so has $x_{n+1} = f^{-1}$ determined by the others. Hence $D(f) \cong Z$, an affine variety, as we sought to show.

This result also showed that principal open sets (definition 31.3.5) are naturally associated to an affine algebraic set, and that the regular function on $D(f)$ are:

$$k[D(f)] = k[X][1/f]$$

In particular f is nonzero on $D(f)$, so this is well defined. Overall, when checking if a mapping between quasi-projective is regular, it suffices to check that any affine variety in the codomain has a closed pre-image.

39.4 Regular Maps

Let us now define regular mappings on quasi-projective varieties. This definition should extend that of affine varieties where a polynomial function was given for each coordinate.

Recall that a rational map on $\mathbb{P}^n_k$ is the quotient of two homogeneous polynomials, with degree $r - s$ where r, s is the degree of the numerator and denominator respectively. A regular point x of a rational function f would be a point where f can be represented by p/q with $q(x) \neq 0$. When working over projective varieties, we shall have that most rational polynomials are not rational functions; we shall require that $r = s$, that is it must be of degree 0.

Definition 39.4.1: Regular Point [on Quasi-projective Variety]

Let X be a quasi-projective variety and $f \in \kappa(X)$ a rational function. Then f is *regular at* $x \in X$ if it admits a representative $f = p/q$ with p, q homogeneous of the same degree and $q(x) \neq 0$. Such a q is then nonzero on the whole open set $D(q)$, so being regular at x is a condition on a neighbourhood of x rather than on x alone.

If f is regular at every point of X it is called *regular* on X. The *set* of regular functions on X is written $k[X]$.

When we defined a regular function before, it was an element of the coordinate ring. We have now defined it to be locally regular at all points. When k is algebraically closed, these two are in fact the same. If X is irreducible, then this is the result of proposition 33.2.2. For the general case, say $f = p_x/q_x$ where $q_x \neq 0$ on U_x so that on U_x:

$$q_x f = p_x \tag{39.1}$$

Then this equation holds on all of X. To see this, choose a regular functions that vanishes on $X \setminus U_x$ but not at x (recall that U_x is dense in X), and multiply it by $p_x q_x$. Then we see that (39.1) must hold outside of U_x as both sides of the equality will vanish. Then like the irreducible case, we can now find points $x_1, ..., x_n$ and regular functions $h_1, ..., h_n$ such that

$$\sum_i^n q_x h_i = 1$$

Then for each x_i, multiplying by h_i and adding up we get:

$$f = \sum_i^n p_x h_i$$

and hence f is regular in the same sense given in definition 32.1.2. Recall that it was mentioned that if $X = \mathbb{P}_k^n$ that $k[\mathbb{P}_k^n]$ consists of only constants functions. We shall soon show that if $X = V \subseteq \mathbb{P}_k^n$ is any projective variety that $k[V]$ is the collection of constant functions.

Definition 39.4.2: Regular Map [On Quasi-projective Variety]

Let $f\colon X \to Y$ be a map of quasi-projective varieties with $Y \subseteq \mathbb{P}_k^m$. Then f is *regular* if for every $x \in X$ there is a standard affine chart $U_i \subseteq \mathbb{P}_k^m$ containing $f(x)$ and an open neighbourhood W of x with $f(W) \subseteq U_i$, such that each of the m coordinate functions of $f|_W$ is regular in the sense of definition 39.4.1.

The collection of regular function is denoted $k[X]$, $\mathcal{O}_X(X)$, or $\Gamma(X)$[a], and the collection of regular mapping between two quasi-projective varieties is denoted $\mathrm{Hom}_{\mathbf{Reg}}(X, Y)$.

[a]This notation shall become more prominent in modern algebraic geometry

This definition of regular function is well-defined and is independent of choice of U_i: if $f(x) = (y_0, ..., \hat{1}_i, ..., y_m) \in U_i$ (where the hat indicates omission), it is also contained in U_j when $y_j \neq 0$, and the coordinates of this point in U_i are of the form:

$$(y_0/y_j, ..., 1/y_j, ..., \hat{1}_j, ..., y_m/y_j)$$

Hence, given the mapping $f : U \to U_i$ is given by

$$(f_0, .., \hat{1}_i, .., f_m)$$

then $f : U \to U_j^m$ is given by $(f_0/f_j, ..., 1/f_j, ..., \hat{1}_j, ..., f_m/f_j)$. As $f_j(x) \neq 0$ and the set U' of points of U where $f_j = 0$ is open. Then on U', the functions $f_0/f_j, ..., 1/f_j, ..., \hat{1}_j, ..., f_m/f_j$ are regular, and so $f : U' \to U_j^m$ is regular.

If we have an affine closed set, by theorem 32.1.5 the regular mapping $f\colon X \to Y$ is determined by the pullback $f^{\#}\colon k[Y] \to k[X]$. This is not the case if X, Y are projective, for as mentioned a few times already we shall have $k[X]$ and $k[Y]$ consist of only constant functions. However, it must be noted that for a general quasi-projective variety, $k[X]$ could be quite large[3]. If X is isomorphic to a closed subset of an affine space, it shall be called an *affine variety*, and if it isomorphic to a closed subset of projective space, it shall be called *projective variety*. Not all quasi-projective varieties are affine or projective (for example $\mathbb{A}_k^2 \setminus \{(0,0)\}$).

Let us now characterize regular maps form quasi-projective varieties to projective space[4]. To understand such a map, start with a regular mapping f on X and a point $x \in X$ where $f(x) \in \mathbb{A}_k^m = U_0^m$ so that there is an open neighborhood where $f = (f_1, ..., f_m) : U \to U_i^m$. Then as it is regular we can write $f_i = p_i/q_i$ where p_i, q_i are of the same degree in homogeneous coordinates and $q_i(x) \neq 0$. Taking the l.c.m. of such fractions we get that $f_i = F_i/F_0$ where $F_0, ..., F_m$ are forms of the same degree and $F_0(x) \neq 0$; overall we can think of the point $f(x) \in U_i^m$ as the point:

$$f(x) = [F_0(x) : \cdots : F_m(x)] \in \mathbb{P}_k^m$$

in projective space. Note that there is more than one representative for such a regular function, namely if

$$F(x) = [F_0(x) : \cdots : F_m(x)] \qquad G(x) = [G_0(x) : \cdots : G_m(x)]$$

then they are the same point if and only if $F_iG_j = F_jG_i$ on X for all $0 \leq i, j \leq m$. This gives us an explicit condition for when $Y = \mathbb{P}_k^m$:

Proposition 39.4.3: Equivalent Regular Function

Let $X \subseteq \mathbb{P}_k^n$ be an irreducible quasi-projective variety and $f\colon X \to \mathbb{P}_k^m$ a map of sets. Then f is regular if and only if it can be written as

$$f = [F_0 : \cdots : F_m]$$

for forms F_i of a common degree in the homogeneous coordinates of $\mathbb{P}_k^n$, not all vanishing at any point of X. Two such presentations $[F_0 : \cdots : F_m]$ and $[G_0 : \cdots : G_m]$ define the same map exactly when

$$F_iG_j = F_jG_i \text{ on } X \text{ for all } 0 \leq i, j \leq m$$

***Proof*:**

Suppose f has such a presentation and fix $x \in X$. Some $F_j(x) \neq 0$, and on the open set $D(F_j) \cap X$ the coordinates of f in the chart U_j are the ratios F_i/F_j, each a quotient of forms of equal degree with nonvanishing denominator. By definition 39.4.1 these are regular, so f is

[3]Shafarevich mentions that Rees and Nagata constructed an example where $k[X]$ is not finitely generated

[4]This is in fact a larger exploration that culminates in the theory of line bundles on a projective scheme

regular.

Conversely let f be regular and fix x with $f(x) \in U_j$. In that chart f has coordinates $f_i = p_i/q_i$ with p_i, q_i forms of equal degree and $q_i(x) \neq 0$. Clearing denominators over $Q = q_0 \cdots q_m$ rewrites these as $f_i = F_i/F_j$ with all F_i forms of one degree and $F_j(x) \neq 0$, which is the required presentation near x. Two such local presentations agree on the overlap of their domains, which is a nonempty open subset of the irreducible X and hence dense, so they agree wherever both are defined and glue.

For the last clause, the two presentations give the same point of $\mathbb{P}_k^m$ at x exactly when the vectors $(F_0(x), \ldots, F_m(x))$ and $(G_0(x), \ldots, G_m(x))$ are proportional, which is the vanishing of every 2×2 minor $F_iG_j - F_jG_i$, as in example 38.3.7(1). Requiring it at every point of X is the stated condition, as we sought to show.

Example 39.4.4: Regular Mappings

1. *Projection*: Let $E \subseteq \mathbb{P}_k^n$ be a d-dimensional subspace given by $n-d$ linearly independent linear equations $(L_1, ..., L_{n-d})$. In homogeneous coordinates, the equations L_i are called *linear forms*. The mapping:

$$\pi(x) = (L_1(x) : \cdots : L_{n-d}(x))$$

is well-defined and is called the projection with center E. Notice this set is regular on $\mathbb{P}_k^n \setminus E$ as the L_i's do not vanish simultaneously. Then for any $X \subseteq \mathbb{P}_k^n$ where $X \cap E = \emptyset$ and X is closed, we have a regular mapping

$$\pi : X \to \mathbb{P}_k^{n-d-1}$$

Geometrically, we can interpret the mapping as follows. Take any $(n-d-1)$-dimensional subspace $H \subseteq \mathbb{P}_k^n$ with $H \cap E = \emptyset$. Through any point $x \in \mathbb{P}_k^n \setminus E$ and the space E, there passes a unique $(d+1)$-dimensional subspace E_x. Then this subspace intersects H at a unique point, namely $\pi(x)$. If X intersects E, but does not contain it, then this is a rational mapping.

We have seen the case where $d = 0$ before (think of the hyperbola to $\mathbb{A}_k^1$)

2. Take $V = \mathcal{Z}(y - x^2, z - x^3)$ (i.e. the twisted cubic). This is a rational curve with parameterization:

$$t \mapsto (t, t^2, t^3)$$

Let us now homogenize this variety. The homogenization of this map is:

$$[s : t] \mapsto \left[1 : \frac{t}{s} : \frac{t^2}{s^2} : \frac{t^3}{s^3}\right] = \left[s^3 : ts^2 : t^2s : t^3\right]$$

3. Take $V = \mathcal{Z}(x^2 + y^2 - z^2)$; the projectivization of the circle. Define the map:

$$f : \mathbb{P}_k^1 \to V \qquad [s : t] \to [s^2 - t^2 : 2st : s^2 + t^2]$$

This is an isomorphism, with inverse $[x : y : z] \mapsto [x + z : y]$. Checking the composite, $(s^2 - t^2)^2 + (2st)^2 = (s^2 + t^2)^2$, so f lands in V; and at $f([s : t])$ we have $x + z = 2s^2$

and $y = 2st$, so $[x + z : y] = [2s^2 : 2st] = [s : t]$ whenever $s \neq 0$, the case $t \neq 0$ being symmetric. So a smooth conic in $\mathbb{P}^2_k$ is isomorphic to $\mathbb{P}^1_k$, which is the genus-zero case of example 38.5.4(3).

4. *The Veronese and Segre embeddings* give further regular maps into larger projective spaces, and are the tools that turn products and degree-d hypersurfaces into linear data. Section 40.1 constructs the Segre embedding and chapter 41 the Veronese.

39.5 Rational Functions on Quasi-Projective Varieties

When working with affine varieties, we had the quotient of two regular functions. However, mentioned a few times, on $\mathbb{P}^n_k$ there are only constant regular functions, and a rational function, being the ratio of two regular functions, would still be constant.

The solution is to recall the definition of $\mathcal{O}_X$, namely:

$$\mathcal{O}_X = \{\varphi = f/g \in k(x_1, \dots, x_{n+1}) \mid f, g \text{ homogeneous of equal degree, } g \notin \mathcal{I}_{\mathbb{P}}(X)\}$$

where f and g are of the same degree. Then take the subset $\mathfrak{m}_X = \{\varphi = f/g \in \mathcal{O}_X \mid f \in I(X)\}$.

Definition 39.5.1: Rational Function On quasi-projective Variety

Let X be a quasi-projective variety. Then the set of rational functions on X is given by:

$$k(X) \cong \mathcal{O}_X/\mathfrak{m}_X$$

By a reasoning similar to proposition 33.2.7, a homogeneous function vanishes on X if and only if it vanishes on an open subset $U \subseteq X$. Hence $k(X) = k(U)$. As a consequence:

$$k(X) = k(\overline{X})$$

Due to this, when studying rational functions on quasi-projective spaces, we may reduce to studying rational functions to affine or projective varieties, which often leads most results to focus on the irreducible case. The set of regular points shall be called the *domain of definition*. If $f\colon X \to \mathbb{P}^m_k$, then it is determined by specifying $m+1$ forms $[F_0 : \cdots : F_m]$ of $n+1$ homogeneous coordinates of projective space $\mathbb{P}^n_k$ containing X (where at least one form must not vanish on X). Furthermore, if f can be given by functions $[f_0 : \cdots f_m]$ where each f_i are regular at all $x \in X$ and not all vanish at this point, then the map is regular at x, and hence determines a regular mapping of some neighborhood x into $\mathbb{P}^m_k$.

We saw before that birational maps are weaker than isomorphisms. However, rational maps are regular on an open dense set (as the reader should verify with quasi-projective varieties). This leads to the following result:

Proposition 39.5.2: Reduction To Open Subset

Let X, Y be irreducible varieties. Then X and Y are birationally isomorphic if and only if they contain isomorphic open subsets $U \subseteq X$ and $V \subseteq Y$.

***Proof*:**
If X and Y contain isomorphic open subsets then those subsets are dense, since X and Y are irreducible, and an isomorphism between dense open sets is a birational map. That is the easy direction.

Conversely let $f\colon X \dashrightarrow Y$ be birational with inverse g. Let $U_1 \subseteq X$ and $V_1 \subseteq Y$ be their domains of definition, both dense open by lemma 33.2.4. Put

$$U = U_1 \cap f^{-1}(V_1) \qquad V = V_1 \cap g^{-1}(U_1)$$

Each is open, and each is nonempty: $f(U_1)$ is dense in Y so it meets the nonempty open V_1, and symmetrically.

Shrinking once more, replace U by $U \cap g(V)$ and V by $V \cap f(U)$, which are again nonempty and open because f and g are dominating. On these sets both composites are defined everywhere and agree with the identity on a dense subset, hence equal it: two regular maps into a variety agreeing on a dense subset are equal, since their equalizer is closed. So $f|_U : U \to V$ and $g|_V : V \to U$ are mutually inverse isomorphisms, as we sought to show.

Exercise 39.5.1

1. Write down the $n+1$ standard charts of $\mathbb{P}^n_k$ explicitly and compute the transition map between two of them for $n = 1$ and $n = 2$. Verify that the transitions are regular where defined, as corollary 39.1.3 asserts.
2. Show that the projective closure of the parabola $\mathcal{Z}(y - x^2) \subseteq \mathbb{A}^2_k$ is $\mathcal{Z}(yz - x^2)$, and identify the point it acquires at infinity. Do the same for the hyperbola $\mathcal{Z}(xy - 1)$.
3. Let $V \subseteq \mathbb{A}^3_k$ be the twisted cubic, with $\mathcal{I}(V) = (y - x^2,\, z - x^3)$. Homogenize those two generators and show that their common projective zero set is strictly larger than the projective closure of V. Conclude that the projective closure is obtained by homogenizing every element of $\mathcal{I}(V)$, not just a set of generators.
4. Show that a regular function on a quasi-projective variety is continuous for the Zariski topology, and deduce that the locus where two regular maps agree is closed.
5. Show that $\mathbb{A}^2_k \setminus \{0\}$ is a quasi-projective variety and that every regular function on it extends to $\mathbb{A}^2_k$. Deduce that it is not isomorphic to any affine variety.
6. Verify the irreducible decomposition theorem for quasi-projective varieties: every quasi-projective variety is a finite union of irreducible closed subsets, none containing another, and the decomposition is unique.
7. Show that $[s : t] \mapsto [s^2 : st : t^2]$ is an isomorphism of $\mathbb{P}^1_k$ onto the conic $\mathcal{Z}(xz - y^2) \subseteq \mathbb{P}^2_k$, and compare with example 39.4.4(3).
8. Show that a rational function on an irreducible quasi-projective variety is determined by its restriction to any nonempty open subset, which is proposition 39.5.2, and give an example showing this fails for reducible varieties.

40

Completeness and Finite Maps

The property that makes projective varieties worth the trouble is completeness: the projection $X \times Y \to Y$ is a closed map whenever X is projective. It is the algebraic counterpart of compactness, and it yields at once that the image of a projective variety under a regular map is closed and that the only regular functions on a projective variety are constant.

Proving it requires knowing what a product of projective varieties is, which is not the naive thing. From there the chapter turns to finite maps, the algebraic mirror of integral extensions, and the theorem that every variety is a finite cover of a space as simple as $\mathbb{A}^m$ or $\mathbb{P}^m$. It closes by measuring a map against its fibres: the dimension of the source is the dimension of the target plus the dimension of the generic fibre, and the special fibres can only be bigger.

40.1 Products and the Segre Embedding

The direct product of algebraic sets $X \subseteq \mathbb{A}_k^n$ and $Y \subseteq \mathbb{A}_k^m$ is again algebraic, and lives in $\mathbb{A}_k^{n+m}$. If $X' \subseteq \mathbb{A}_k^p$ and $Y' \subseteq \mathbb{A}_k^q$ are algebraic sets with $X \cong X'$ and $Y \cong Y'$, then $X \times Y \cong X' \times Y' \subseteq \mathbb{A}_k^{p+q}$, showing that this definition is embedding-independent. The projective case is not so simple. There is no N with $\mathbb{P}_k^n \times \mathbb{P}_k^m \cong \mathbb{P}_k^N$; what there is instead is a *closed embedding* into $\mathbb{P}_k^N$ for $N = (n+1)(m+1)-1$, whose image is a proper subvariety cut out by explicit quadratic equations. Finding that embedding is the business of this section. Defining the product also supplies the tool that section 40.2 needs.

To start, recall that $\mathbb{A}_k^n \times \mathbb{A}_k^m \cong \mathbb{A}_k^{n+m}$. A first attempt at understanding $\mathbb{P}_k^n \times \mathbb{P}_k^m$ would be to consider $\mathbb{P}_k^{n+m}$. However, this space is dependent on the representation of the homogeneous points in $\mathbb{P}_k^n$ and $\mathbb{P}_k^m$, for example if $[2:0] = [1:0] \in \mathbb{P}_k^1$, and $[3:0] = [1:0] \in \mathbb{P}_k^1$, then:

$$[1:1:0] \neq [2:3:0] \in \mathbb{P}_k^2$$

Furthermore, if we choose $[x_1 : x_2] \in \mathbb{P}_k^1$ and $[y_1 : y_2] \in \mathbb{P}_k^1$, which point in $\mathbb{P}_k^2$ ought to represent this point? To resolve this, we shall "twist-multiply"

$$[x_1y_1 : x_1y_2 : x_2y_1 : x_2y_2] \in \mathbb{P}_k^{(1+1)(1+1)-1}$$

Notice that for $[\lambda x_1 : \lambda x_2]$ and $[\mu y_1 : \mu y_2]$ then:

$$[\lambda\mu x_1y_1 : \lambda\mu x_1y_2 : \lambda\mu x_2y_1 : \lambda\mu x_2y_2] = [x_1y_1 : x_1y_2 : x_2y_1 : x_2y_2] \in \mathbb{P}_k^3$$

and hence is independent of representation. Generalizing this, we define for any

$$x = [x_0 : \cdots : x_n], y = [y_0 : \cdots : y_m] \qquad w = [w_{ij}] \in \mathbb{P}_k^{(n+1)(m+1)-1}, \ w_{ij} = x_iy_j$$

Consider now the embedding $\varphi : \mathbb{P}_k^n \times \mathbb{P}_k^m \to \mathbb{P}_k^{(n+1)(m+1)-1}$ given by the above. The image is indeed a closed subset, for it satisfies the equations:

$$w_{ij}w_{kl} - w_{il}w_{kj} = 0 \tag{40.1}$$

which hold because both sides equal $x_ix_ky_jy_l$ once $w_{ij} = x_iy_j$ is substituted. The construction is natural in the sense that it matches the standard affine charts on both sides. Write $\mathbb{A}^n$ for $\mathbb{A}_k^n$ and let $U_i \subseteq \mathbb{P}_k^n$ be the ith standard affine chart, so $U_i \cong \mathbb{A}^n$. Then:

$$\varphi(U_i \times U_j) = W_{ij} = \mathbb{A}_{ij}^N \cap \varphi(\mathbb{P}_k^n \times \mathbb{P}_k^m)$$

where $N = (n+1)(m+1) - 1$ and $\mathbb{A}_{ij}^N$ is the set of points of $\mathbb{P}_k^N$ where $w_{ij} \neq 0$. Consider now the set $\mathbb{A}_{00}^N$. Take a point in projective space where $w_{00} \neq 0$ so that it corresponds to a point in $\mathbb{A}_{00}^N$:

$$[w_{ij}] = \varphi(x, y) \in \mathbb{P}_k^N$$

Take $z_{ij} = w_{ij}/w_{00}$, $x_i = u_i/u_0$, $y_j = v_j/v_0$ as the inhomogeneous coordinates. Then:

$$z_{i0} = x_i \qquad z_{0j} = y_j \qquad z_{ij} = x_iy_j = z_{i0}z_{0j}$$

So $\mathbb{A}_{00}^N \cong \mathbb{A}^{n+m}$ with coordinates $(x_1, \ldots, x_n, y_1, \ldots, y_m)$, the isomorphism being induced by φ. Hence φ is indeed the natural choice for the embedding of $\mathbb{P}_k^n \times \mathbb{P}_k^m$. This may feel more natural if we recall that each point of projective space $[a_0 : \cdots a_n] \in \mathbb{P}_k^n$ is closed and given by a system of linear equations

$$a_ix_j - a_jx_i = 0$$

mirroring (40.1). Notice that we may interpret the point $[w_{ij}]$ as an $(n+1) \times (m+1)$ matrix given by multiplying the points x and y as a $(n+1, 1)$ matrix and a $(1, m+1)$ matrix respectively (note the resulting rank of the matrix will be 1). From this, we may define the product of two quasi-projective varieties

Definition 40.1.1: Segre Embedding: Product of Projective Space

Let $V \subseteq \mathbb{P}_k^n, W \subseteq \mathbb{P}_k^m$ be two quasi-projective varieties. Then:

$$V \times W \subseteq \varphi(\mathbb{P}_k^n \times \mathbb{P}_k^m) \subseteq \mathbb{P}_k^{(n+1)(m+1)-1}$$

is the product of the quasi-projective varieties V, W.

Example 40.1.2: Product of Projective Lines

Let $V = W = \mathbb{P}^1_k$ and consider $\varphi(\mathbb{P}^1_k \times \mathbb{P}^1_k) \subseteq \mathbb{P}^3_k$. This set satisfies the equation:

$$w_{11}w_{00} - w_{01}w_{10} = 0$$

which is a nondegenerate quadric Q in $\mathbb{P}^3_k$. Let us consider the set

$$\varphi(\{\alpha\} \times \mathbb{P}^1_k)$$

then given $\alpha = [\alpha_0 : \alpha_1]$, these are all points in $\mathbb{P}^3_k$ such that

$$\alpha_1 w_{00} - \alpha_0 w_{10} = 0 \qquad \alpha_1 w_{01} - \alpha_0 w_{11} = 0$$

These equations give lines in $\mathbb{P}^3_k$. Similarly for $\varphi(\mathbb{P}^1_k \times \{\beta\})$. The two rulings of the quadric are visible in the following picture:

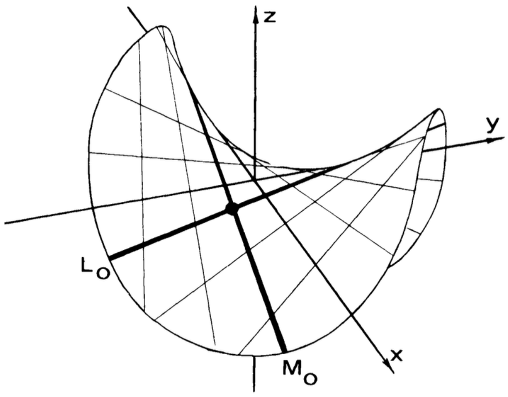

Figure 40.1: Segre Embedding of Product of Projective Lines

The closed subsets of im$\varphi \subseteq \mathbb{P}^{(n+1)(m+1)-1}_k$ correspond well with the closed subsets of $\mathbb{P}^n_k \times \mathbb{P}^m_k$. Let us start with seeing which subset of $\mathbb{P}^n_k \times \mathbb{P}^m_k$ are algebraic subsets under the Segre Embedding. Let $X \subseteq \mathbb{P}^{(n+1)(m+1)-1}_k$ be a sub-variety so that it is defined by homogeneous equations $f_i(w_{00}, ..., w_{nm})$. Then these induce the homogeneous polynomials $g_i(u_0, ..., u_n, v_0, ..., v_m)$ on $\mathbb{P}^n_k \times \mathbb{P}^m_k$ where the u_i, v_j are the same homogeneous degree. Conversely, if there are two systems of homogeneous equations taking variables of the same homogeneous degree in u_i, v_j, then there exists homogeneous polynomials taking variables in $u_i v_j$. If the degrees of the variables u_i and v_j differ, say the former are of degree r and the latter of degree s, then we can create the system of homogeneous equations:

$$v_j^{r-s} g_i(u_0, \ldots, u_n, v_0, \ldots, v_m) = 0$$

assuming $r > s$. One important consequence of this is that we can directly check for a set $Z \subseteq \mathbb{P}^n_k \times \mathbb{P}^m_k$ being closed by looking for a single polynomial in $\mathbb{P}^{(n+1)(m+1)-1}_k$ instead of looking for two polynomials in each separate projective space and verifying the set is the direct product of those two closed sets. Let us box this for future reference:

Proposition 40.1.3: Segre Embedding is Closed

Let $\varphi : \mathbb{P}^n_k \times \mathbb{P}^m_k \to \mathbb{P}^{(n+1)(m+1)-1}_k$ be the Segre embedding. Then $\mathrm{im}\varphi$ is closed. Furthermore, $X \subseteq \mathbb{P}^n_k \times \mathbb{P}^m_k$ is closed if and only if $\varphi(X) \subseteq \mathrm{im}\varphi$ is closed.

***Proof*:**
The image is closed. Substituting $w_{ij} = x_i y_j$ shows every point of $\mathrm{im}\varphi$ satisfies (40.1). Conversely let $w = [w_{ij}]$ satisfy all those relations, and pick (a, b) with $w_{ab} \neq 0$. Set $x_i = w_{ib}$ and $y_j = w_{aj}$. Then for all i, j,

$$x_i y_j = w_{ib} w_{aj} = w_{ij} w_{ab}$$

using (40.1), so $[x_i y_j] = [w_{ij}]$ after scaling by w_{ab}, and $w = \varphi([x], [y])$. Hence $\mathrm{im}\varphi = \mathcal{Z}(\{w_{ij}w_{kl} - w_{il}w_{kj}\})$ is closed. The same computation shows φ is injective, since $[x]$ and $[y]$ are recovered from w up to scalars.

Closed subsets correspond. If $\varphi(X)$ is closed in $\mathrm{im}\varphi$, then $X = \varphi^{-1}(\varphi(X))$ is closed because φ is continuous. Conversely let X be closed, cut out by bihomogeneous equations $g_i(u; v)$. By the degree-balancing displayed above we may assume each g_i has the same degree r in the u and in the v, and a bihomogeneous polynomial of bidegree (r, r) is a polynomial in the products $u_i v_j$, hence a form in the w_{ij}. Those forms cut out $\varphi(X)$ inside $\mathrm{im}\varphi$, as we sought to show.

Before leaving products, three facts about them are needed later, and none is formal. The first says the maps one expects to have are regular, the second is general topology in geometric clothing, and the third says that a product of irreducible varieties does not fall apart.

Proposition 40.1.4: Projections and Slices Are Regular

Let $X \subseteq \mathbb{P}^n_k$ and $Y \subseteq \mathbb{P}^m_k$ be quasi-projective varieties. Then both projections $\pi_1 \colon X \times Y \to X$ and $\pi_2 \colon X \times Y \to Y$ are regular. Moreover, for fixed $y \in Y$ the slice map $j_y \colon X \to X \times Y$, $x \mapsto (x, y)$, is an isomorphism onto $X \times \{y\}$, and symmetrically $i_x \colon Y \to X \times Y$ is an isomorphism onto $\{x\} \times Y$.

***Proof*:**
Work in the Segre coordinates $w_{ij} = x_i y_j$. Fix a and let $W_a \subseteq X \times Y$ be the open set where some $w_{aj} \neq 0$, which is where $x_a \neq 0$. On W_a,

$$[\, w_{a0} : \cdots : w_{am} \,] = [\, x_a y_0 : \cdots : x_a y_m \,] = [\, y_0 : \cdots : y_m \,]$$

so π_2 is given on W_a by $m + 1$ linear forms in the w_{ij}, not all zero there. The W_a cover $X \times Y$ and the formulas agree on overlaps, so π_2 is regular; the same argument with $[\, w_{0b} : \cdots : w_{nb} \,]$ handles π_1.

For the slices, fix $y = [b_0 : \cdots : b_m]$ and write $j_y(x) = [\, x_i b_j \,]$. The entries are linear forms in x, not all identically zero since some $b_j \neq 0$, so j_y is regular. Its image is $X \times \{y\}$, and $\pi_1 \circ j_y$ is the identity of X while $j_y \circ \pi_1$ is the identity of $X \times \{y\}$, so the two are mutually inverse isomorphisms. The map i_x is symmetric, as we sought to show.

Lemma 40.1.5: A Cover by Overlapping Irreducibles

Let Z be a topological space covered by open sets V_α, each irreducible, with $V_\alpha \cap V_\beta \neq \emptyset$ for every pair. Then Z is irreducible.

***Proof*:**
A space is irreducible exactly when each of its nonempty open subsets is dense. First, every V_α is dense in Z: given β, the set $V_\beta \cap V_\alpha$ is nonempty and open in V_β, hence dense in the irreducible V_β, so $V_\beta \subseteq \overline{V_\alpha}$; as the V_β cover Z this forces $\overline{V_\alpha} = Z$.

Now let $W \subseteq Z$ be nonempty and open. It meets some V_α, and $W \cap V_\alpha$ is a nonempty open subset of the irreducible V_α, hence dense in it, so $\overline{W} \supseteq V_\alpha$. Closures are closed, so $\overline{W} \supseteq \overline{V_\alpha} = Z$, as we sought to show.

Proposition 40.1.6: A Product of Irreducibles Is Irreducible

Let X and Y be irreducible quasi-projective varieties. Then $X \times Y$ is irreducible.

***Proof*:**
By proposition 40.1.4 each slice $\{x\} \times Y$ is isomorphic to Y, hence irreducible, and each slice map j_y is regular. Suppose $X \times Y = Z_1 \cup Z_2$ with both Z_i closed. For fixed x the slice $\{x\} \times Y$ is irreducible and is covered by the two relatively closed sets $Z_i \cap (\{x\} \times Y)$, so it lies wholly inside Z_1 or wholly inside Z_2. Set

$$X_i = \{x \in X \mid \{x\} \times Y \subseteq Z_i\}$$

so that $X = X_1 \cup X_2$. Each X_i is closed, being the intersection $X_i = \bigcap_{y \in Y} j_y^{-1}(Z_i)$ of closed sets. Since X is irreducible, $X = X_i$ for one of the two, and then $X \times Y = Z_i$, as we sought to show.

40.2 Completeness of Projective Varieties

The image of a regular map need not be closed: example 32.1.4 took $X = \mathcal{Z}(xy - 1)$, $Y = \mathbb{A}^1_k$ and $\pi(a, b) = a$, whose image is $\mathbb{A}^1_k \setminus \{0\}$. However, the image of a projective variety will always be projective! If the reader has done some analysis this should remind the reader of the fact that the image of compact sets are compact. Though all affine and projective algebraic sets are compact (they are closed subsets of the compact space $\mathbb{A}^n_k$ or $\mathbb{P}^n_k$), projective varieties behave more like compact sets. Scheme theory draws the distinction by calling projective varieties *proper*[1]. To see this, we require a few lemmas:

[1] In analysis a map is proper if the pre-image of every compact set is compact

Lemma 40.2.1: Graph of Regular Mapping

Let $\varphi : X \to Y$ be a regular mapping between quasi-projective varieties. Then the graph

$$\Gamma(\varphi) = \{(x, \varphi(x)) \mid x \in X\}$$

is closed in $X \times Y$

If the Zariski topology was Hausdorff, then we could have concluded using classical topological results, however some more care has to be done as the topology is not Hausdorff.

***Proof*:**
First, we may take Y to be a projective space; for an appropriate choice of m, $Y \subseteq \mathbb{P}_k^m$, so that $X \times Y \subseteq X \times \mathbb{P}_k^m$. Then by proposition 33.2.7, φ determines a mapping $\overline{\varphi} : X \to \mathbb{P}_k^m$ and $\Gamma_\varphi = \Gamma_{\overline{\varphi}} \cap (X \times Y)$. As $X \times Y$ is closed in $X \times \mathbb{P}_k^m$ by proposition 40.1.3, closed then Γ_f is closed.

Next define $(\overline{\varphi}, \mathrm{id})\colon X \times \mathbb{P}_k^m \to \mathbb{P}_k^m \times \mathbb{P}_k^m$. Then $\Gamma_{\overline{\varphi}}$ is the inverse image of the diagonal $\Delta = \Gamma_{\mathrm{id}}$ under this map. As this is a continuous map, the inverse image of a closed set is closed, and hence it suffices to show that Γ_i is closed.

Finally, the diagonal $\Delta \subseteq \mathbb{P}_k^m \times \mathbb{P}_k^m$ consists of the pairs $([u_0 : \cdots : u_m], [v_0 : \cdots : v_m])$ with $u_i v_j = u_j v_i$ for all i, j, which under the Segre embedding are exactly the points where the corresponding 2×2 minors vanish. By proposition 40.1.3 that is a closed condition, so Δ is closed, hence so is $\Gamma_{\overline{\varphi}}$ and therefore Γ_φ, completing the proof.

Proposition 40.2.2: Projection of Projective Variety

Let X be a projective variety and Y a quasi-projective variety. Then the projection map:

$$\pi_2 : X \times Y \to Y$$

is a closed map (the image of a closed set is closed)

Hence, the projection of a projective variety can always be written as a system of polynomial equations! This is not true for affine varieties: take $X = \mathcal{Z}(xy - 1)$ and $Y = \mathbb{A}_k^1$

***Proof*:**
Let us first reduce the problem: as $X \subseteq \mathbb{P}_k^n$ is closed, $X \times Y \subseteq \mathbb{P}_k^n \times Y$ is a closed subset, hence if $Z \subseteq X$ is closed, it is closed in $Z \times Y \subseteq \mathbb{P}_k^n \times Y$, and so it is enough to show it for the case of $X = \mathbb{P}_k^n$. Next, as being closed is affine local, it suffices to cover Y by affine open subsets U_i and prove the theorem on each of these. Thus, it suffices to assume that Y is an affine variety. Finally, as Y is closed in $\mathbb{A}_k^m$, $\mathbb{P}_k^n \times Y \subseteq \mathbb{P}_k^n \times \mathbb{A}_k^m$ is closed, and so we can reduce further to $Y = \mathbb{A}_k^m$.

Thus, let us characterize closed subsets $Z \subseteq \mathbb{P}_k^n \times \mathbb{A}_k^m$. By definition of the Zariski topology, and by a simple generalization of proposition 40.1.3, we see that Z is closed if and only if it is the zero set of the collection of polynomials

$$g_i([u_0 : \cdots : u_n], y_1, \ldots, y_m) \qquad 1 \leq i \leq t$$

In particular, we do not need to create two zero sets for each component and check that the their product produces Z: we can directly work with a set of polynomials. Let us write $g_i(u; y)$ to represent these polynomials with the two different inputs.

Now, take any $y_0 \in \mathbb{A}_k^m$. Then $\pi^{-1}(y_0)$ consists of all solutions (whether empty or non-empty) to the system of equations

$$g_i(u; y_0) = 0 \qquad 1 \le i \le t$$

Take the collection of y_0 such that the system of polynomials equations $g_i(u; y_0) = 0$ has a nonzero solution; call this collection $T \subseteq \mathbb{A}_k^m$. We want to show that T is closed, for then the projection π_2 is a closed map. By lemma 38.4.2, the system of polynomials equations $g_i(u; y_0) = 0$ has a nonzero solution if and only if:

$$I_s \not\subseteq (g_1(u, y_0), ..., g_t(u, y_0)) \qquad \forall s \in \mathbb{N}$$

where I_s is the irrelevant ideal of degree $s \ge 1$. Thus it suffices to show that the set T_s of points $y_0 \in \mathbb{A}_k^m$ for which $I_s \not\subseteq (g_1(u, y_0), ..., g_t(u, y_0))$ is closed, in particular if we find polynomial equations whose zero set is T_s, then as $T = \bigcap_s T_s$, T is closed which completing the proof.

To that end, let k_i be the homogeneous degree of $g_i(u; y)$ in the u_j variables. Let $(M^\alpha)_\alpha$ be the monomials of degree s in $u_0, ..., u_n$ with some total ordering (note this set is finite). Then $I_s \subseteq (g_1(u, y_0), ..., g_t(u, y_0))$ if and only if each monomial M^α can be expressed as:

$$M^\alpha = \sum_{i=1}^{t} g_i(u, y_0) F_{i,\alpha}(u) \tag{40.2}$$

As each g_i has homogeneous degree k_i, it must be that $F_{i,\alpha}$ has degree $s - k_i$ or $F_{i,\alpha} = 0$ if $k_i > s$. Then we may replace $F_{i,\alpha}$ with elements in $(N_i^\beta)_\beta$ which are monomial of degree $s - k_i$ written in some total ordering. Then (40.2) holds if and only if M^α is a linear combination of the polynomials $g_i(u, y_0)N_i^\beta$. As this is true for each M^α, this is equivalent to saying that the polynomials $g_i(u, y_0)N_i^\beta$ span the entire vector space S of homogeneous polynomials of degree s in $u_0, ..., u_n$. As $I_s \not\subseteq (g_1(u, y_0), ..., g_t(u, y_0))$, we have that the $g_i(u, y_0)N_i^\beta$ *do not* span S.

Now, take the matrix $(a_{\alpha\beta})$ that represents the coefficients of the M^α terms as a linear combination of the $g_i(u, y_0)N_i^\beta$. As not all M^α can be written as such terms, this matrix cannot be full rank. Hence all $\sigma \times \sigma$ minors (where $\sigma = \dim_k S$) are polynomials in the coefficients of the polynomials $g_i(u, y_0)$, in particular they are polynomials in the coordinates of the point y_0. So T_s is cut out by polynomial equations in y_0, hence closed.

Thus, since the arbitrary intersection of closed sets is closed $T = \bigcap_s T_s$ is closed, completing the proof.

For those interested in algebraic geometry, the above proof is in part in proving that projective varieties are *proper*.

Corollary 40.2.3: Image of Projective Variety is Closed

Let $f : X \to Y$ be a regular map where X is a projective variety. Then $\mathrm{im} f$ is closed

***Proof*:**
Let $\pi : X \times Y \to Y$ be the natural projection. Consider the graph $\Gamma_f \subseteq X \times Y$ of lemma 40.2.1. Then:

$$\mathrm{im} f = \pi(\Gamma_f)$$

and hence by proposition 40.2.2 $\mathrm{im} f$ is closed, completing the proof.

We can finally rigorously show that the collection of regular functions on projective space, and more generally projective varieties, are only constant functions:

Corollary 40.2.4: Regular Function on Projective Variety

Let φ be a regular function on an irreducible projective variety. Then $\varphi \in k$, i.e. φ is constant.

***Proof*:**
Take $\varphi : X \to \mathbb{A}^1_k$. As $\mathbb{A}^1_k$ is dense in $\mathbb{P}^1_k$, there is a unique extension to a regular map $\overline{\varphi} : X \to \mathbb{P}^1_k$. As X is a projective variety, by corollary 40.2.3 $\overline{\varphi}(X) \subseteq \mathbb{P}^1_k$ is closed. Since $\overline{\varphi}(X) \subseteq \mathbb{A}^1_k$, the point at infinity is not in the image, so $\overline{\varphi}(X)$ is a *proper* closed subset of $\mathbb{P}^1_k$. The proper closed subsets of $\mathbb{P}^1_k$ are exactly the finite sets, so $\overline{\varphi}(X)$ is finite. (It cannot be all of $\mathbb{A}^1_k$, which is not closed in $\mathbb{P}^1_k$.) Hence $\varphi(X)$ is a finite set of points. closed, their pre-image would make X the non-trivial union of closed sets, contradicting its irreducibility, and hence it must be that the image is a single point, in other words a constant, as we sought to show.

Corollary 40.2.5: Regular Map on Projective Variety

Let $f : X \to Y$ be a regular map from a projective variety to an affine variety. Then $\mathrm{im} f$ is a point

***Proof*:**
Take $f(x) = (\varphi_1(x), ..., \varphi_m(x))$ where each φ_i is a regular function. Then by corollary 40.2.4 these are all constant, but then

$$f(X) = (\alpha_1, ..., \alpha_m)$$

completing the proof.

40.2.6 Note: Completeness Is Elimination Theory The classical name for proposition 40.2.2 is *elimination theory.* Given equations in $x_1, \dots, x_n$ and $y_1, \dots, y_m$, one asks for the conditions on the y alone under which a solution in x exists; that is exactly asking for the image of a projection, and the theorem says the answer is again given by equations, provided the x range over projective space.
The classical tool is the resultant. For two one-variable polynomials

$$f = a_0 x^d + \cdots + a_d, \qquad g = b_0 x^e + \cdots + b_e$$

the resultant $\operatorname{Res}(f, g)$ is the determinant of the $(d+e) \times (d+e)$ Sylvester matrix in the coefficients, and it vanishes exactly when f and g have a common root, given a_0, b_0 not both zero. Since Res is a polynomial in the a_i and b_j, that is precisely a closed condition on the coefficients, and it eliminates x. Iterating in several variables is the classical proof of completeness, and section 19.6.3 develops the algebra.
The proof given above takes a different route, through lemma 38.4.2 and the irrelevant ideal, which is shorter and generalizes better. The resultant remains the computational tool: it is what a computer algebra system runs when asked to eliminate a variable, and example 42.4.1 could equally have been done by resultants.

40.3 Finite Maps

These maps shall be the mirror of integral extensions, and shall be one of the easiest examples of *proper morphisms* which is a somewhat complicated but fundamental type of morphism in scheme theory.

Definition 40.3.1: Finite Map [on Affine Varieties]

Let $f\colon X \to Y$ be a regular map of affine varieties with $f(X)$ dense in Y, so that the pullback $f^\#\colon k[Y] \hookrightarrow k[X]$ is injective. Then f is a *finite map* if $k[X]$ is integral over $f^\#(k[Y])$.

Example 40.3.2: Finite and Non-Finite Maps

1. *A finite map.* $\varphi\colon \mathbb{A}^1_k \to \mathbb{A}^1_k$, $\varphi(x) = x^2$. On coordinate rings it is $k[y] \to k[x]$, $y \mapsto x^2$, and $k[x]$ is generated as a $k[y]$-module by 1 and x, since $x^2 = y$. So the map is finite, and its fibres have one or two points: two over $a \neq 0$, one over 0.

2. *Finite maps are closed and surjective.* The image of φ is all of $\mathbb{A}^1_k$, as proposition 40.3.3 requires, because every a has a square root in the algebraically closed k.

3. *A non-example with finite fibres.* The projection $\mathcal{Z}(xy-1) \to \mathbb{A}^1_k$, $(x, y) \mapsto x$, has fibres of size at most one, yet it is not finite: $k[x, x^{-1}]$ is not a finitely generated $k[x]$-module, since no finite set of Laurent polynomials spans all negative powers. Its image misses the origin, so it is not even surjective. Finiteness is strictly stronger than having finite fibres.

4. *An open immersion is almost never finite.* The inclusion $D(x) \hookrightarrow \mathbb{A}^1_k$ is the previous example in disguise, by example 31.3.6(1).

The composition of finite maps is finite. If $f\colon X \to Y$ is finite then its fibres are finite. A reasonable assumption would be that a map is finite if and only if its fibers are finite, but that is not the case: an example of a non-finite map would be $\pi_1 : V(xy-1) \to \mathbb{A}^1_k$ as $k[x] \hookrightarrow k[x, 1/x]$ is not an integral extension. Instead, one way of thinking of a finite map $f : X \to Y$ is that given an element $y \in Y$, as y is moved around in Y and we look at $f^{-1}(y)$, none of the roots could tend to infinity, that is none can disappear. This intuition is captured by the following proposition:

Proposition 40.3.3: Finite Maps Are Surjective

Let $f : X \to Y$ be a finite map between affine varieties. Then f is surjective.

The tool is the lying-over property of integral extensions (theorem 26.3.2), in the following form: if B is integral over a subring A and $\mathfrak{a} \subsetneq A$ is a *proper* ideal, then $\mathfrak{a}B \neq B$. Equivalently, a proper ideal of A cannot generate the unit ideal of B. This is what stops a fibre from being empty.

***Proof*:**
Let $f : X \to Y$ be a finite map between affine varieties. Take any $y \in Y$ and let $\mathfrak{m}_y \subseteq k[Y]$ be the functions that take the value 0 at y: if $f \in \mathfrak{m}_y$, then $f(y) = 0$. Let $x_1, ..., x_n$ be coordinate functions on Y and $y = (\alpha_1, ..., \alpha_n)$ so that

$$\mathfrak{m}_y = (x_1 - \alpha_1, \ldots, x_n - \alpha_n)$$

Then the equations of the variety $f^{-1}(y)$ have the form:

$$f^{\#}(x_1) = \alpha_1, \quad \ldots, \quad f^{\#}(x_n) = \alpha_n$$

By the Nullstellensatz, $f^{-1}(y) = \emptyset$ if and only if the elements $f^{\#}(x_i) - \alpha_i$ generate the unit ideal, that is:

$$(f^*(x_1) - \alpha_1, ..., f^*(x_n) - \alpha_n) = k[X]$$

Viewing $k[Y]$ as a subring of $k[X]$, we see that the above is equivalent to:

$$(x_1 - \alpha_1, \ldots, x_n - \alpha_n)\, k[X] = k[X]$$

In other words, $f^{-1}(y) = \emptyset$ would force $\mathfrak{m}_y k[X] = k[X]$. But $\mathfrak{m}_y$ is maximal, hence a proper ideal of $k[Y]$, and $k[X]$ is integral over it, so lying over gives $\mathfrak{m}_y k[X] \neq k[X]$. The two are contradictory, so $f^{-1}(y) \neq \emptyset$. As y was arbitrary, f is surjective, completing the proof.

Corollary 40.3.4: Finite Maps Are Closed Maps

Let $f : X \to Y$ be a finite map between affine varieties. Then f is a closed map.

***Proof*:**
It suffices to check on irreducible closed subsets $Z \subseteq X$. By the above theorem the restriction of f to Z, $f|_Z : Z \to \overline{f(Z)}$, is a finite map between affine varieties, and so by surjectivity we get $f(Z) = \overline{f(Z)}$, but then $f(Z)$ is closed, completing the proof.

Let us now build-up to defining finite maps for quasi-projective varieties. For that, we start by showing that finiteness is a local property:

Lemma 40.3.5: Finiteness is Local

Let $f : X \to Y$ be a regular map of affine varieties. Then if for every point $y \in Y$, there is an affine neighborhood U of y such that $V = f^{-1}(U)$ is affine and $f : V \to U$ is finite, then f is finite

***Proof*:**
Let $k[Y] = A$ and $k[X] = B$. Take the principal open set around each point of Y, and as Y is compact take a finite subcover, label these $D(g_\alpha)$ so that $Y = \bigcup_\alpha D(g_\alpha)$. Then:

$$V_\alpha = f^{-1}(D(g_\alpha)) = D(f^{\#}(g_\alpha))$$

and

$$k[D(g_\alpha)] = A[1/g_\alpha] \qquad k[V_\alpha] = B[1/f^{\#}(g_\alpha)]$$

As f is finite on this chart, $B[1/g_\alpha]$ is a finite module over $A[1/g_\alpha]$; fix a finite generating set $w_{i,\alpha}$. (Generating set, not basis: a finite module over a ring need not be free, and freeness is never used below.) We may take $w_{i,\alpha} \in B$, since clearing the denominator of $w_{i,\alpha}/g_\alpha^{m_i}$ multiplies by a unit of $A[1/g_\alpha]$ and so preserves generation.

Now take the union of all these finite sets. We claim they generate B as an A-module. To see this, take any $b \in B$. Then for each α we can write it as :

$$b = \sum_i \frac{a_{i,\alpha}}{g_\alpha^{n_\alpha}} w_{i,\alpha}$$

As the $g_\alpha^{n_\alpha}$ generate the unit ideal of A (the sets $D(g_\alpha)$ cover Y), there exists $h_\alpha \in A$ such that

$$\sum_\alpha g_\alpha^{n_\alpha} h_\alpha = 1$$

Thus:

$$b = b \sum_\alpha g_\alpha^{n_\alpha} h_\alpha = \sum_i \sum_\alpha a_{i,\alpha} h_\alpha w_{i,\alpha}$$

which exhibits an arbitrary $b \in B$ as an A-combination of the $w_{i,\alpha}$. Hence B is a finite A-module and f is finite, as we sought to show.

Thus, we can define finite maps for quasi-projective varieties:

Definition 40.3.6: Finite Map [on Quasi-Projective Varieties]

Let $f : X \to Y$ be a regular map between quasi-projective varieties. Then f is said to be *finite* if any point $y \in Y$ has an affine local neighborhood V such that $U = f^{-1}(V)$ is affine and $f : U \to V$ is a finite map between affine varieties.

Naturally, $f^{-1}(y)$ is finite for every $y \in Y$, and it follows easily that any finite map is surjective. Note that the density condition is now a local condition. One consequence of these results that we shall not prove is that if $f : X \to Y$ between quasi-projective is a regular map (not necessarily finite) and $f(X)$ dense in Y, then $f(X)$ contains an open subset of Y. This is *not* true in analysis, the canonical example being the wrapping of the real line around the torus with an irrational period which will be a dense map with empty interior.

40.4 Noether Normalization, Geometrically

An important culminating result is that every irreducible projective variety is in some way only a "finite extension" from projective space. These results reduce many arguments about irreducible varieties to arguments about affine or projective space. These ideas return in scheme-theoretic form in *Algebraic Geometry* [5]. We first need a technical lemma:

40.4.1 Normalization and Singularities Note that this is *not* to be confused with normalization of singularities! Rather confusingly, normalization of singularities shall be the map in the *opposite direction* to the normalization map that will be defined here. The two uses of the word are unrelated, and it is not the case that a normal resolution of singularities results in a map $\mathbb{A}_k^n \to X$ or $\mathbb{P}_k^n \to X$ for a variety X (where the normalization map we shall do will be map of the form $X \twoheadrightarrow \mathbb{A}_k^n$ or $X \twoheadrightarrow \mathbb{P}_k^n$).

Lemma 40.4.2: Projection is Finite Mapping

Let X be closed in $\mathbb{P}^n$ with $X \subset \mathbb{P}^n \setminus E$, where E is a d-dimensional linear subspace. Then the projection $\pi : X \to \mathbb{P}^{n-d-1}$ with center at E determines a finite mapping $X \to \pi(X)$.

***Proof*:**
Let $y_0, \dots, y_{n-d-1}$ be homogeneous coordinates in $\mathbb{P}^{n-d-1}$ and let π be given by the formulae $y_j = L_j(x)$, $x \in X$ $(j = 0, \dots, n-d-1)$. Naturally, $U_i = \pi^{-1}(\mathbb{A}^{n-d-1}) \cap X$ is given by the condition $L_i(x) \neq 0$ and is an affine open subset of X. We want to show that $\pi : U_i \to \mathbb{A}^{n-d-1} \cap \pi(X)$ is a finite mapping. To that end, first note that every function $g \in k[U_i]$ is of the form $g = G_i(x_0, \dots, x_n)/L_i^m$, where G_i is a form of degree m. Consider the mapping $\pi_1 : X \to \mathbb{P}^{n-d} : z_j = L_j^m(x)$ $(j = 0, \dots, n-d-1)$, $z_{n-d} = G_i(x)$, where $z_0, \dots, z_{n-d}$ are homogeneous coordinates in $\mathbb{P}^{n-d}$. It is a regular mapping and its image $\pi_1(X)$ is closed in $\mathbb{P}^{n-d}$. Let $F_1 = \cdots = F_s = 0$ be its equations. Since $X \subset \mathbb{P}^n - E$, the forms $L_i (i = 0, \dots, n-d-1)$ do not vanish simultaneously on X. Hence the point $[0 : \cdots : 0 : 1]$ is not contained in $\pi_1(X)$, in other words, that the equations $z_0 = \cdots = z_{n-d-1} = F_1 = \cdots = F_s = 0$ have no solution in $\mathbb{P}^{n-d}$. Hence by lemma 38.4.2, for some $l > 0$:

$$(z_0, \dots, z_{n-d-1}, F_1, \dots, F_s) \supseteq \mathfrak{m}^l$$

in particular, $z_{n-d}^l \in (z_0, \dots, z_{n-d-1}, F_1, \dots, F_s)$. This means that

$$z_{n-d}^l = \sum_{j=0}^{n-d-1} z_j H_j + \sum_{j=1}^{s} F_j P_j,$$

where H_j and P_j are polynomials. Denote by $H^{(q)}$ the homogeneous component of H of degree q. Then:

$$\Phi(z_0, \dots, z_{n-d}) = z_{n-d}^l - \sum z_j H_j^{(l-1)} = 0 \quad \text{on } \pi_1(X) \tag{40.3}$$

The homogeneous polynomial Φ is of degree l and as a polynomial in z_{n-d} it has the leading coefficient 1:

$$\Phi = z_{n-d}^l - \sum_{j=0}^{l-1} A_{l-j}(z_0, \ldots, z_{n-d-1}) z_{n-d}^j \tag{40.4}$$

Substituting the transformation formulae for π_1 in (40.3) we find that $\Phi(L_0^m, \ldots, L_{n-d-1}^m, G_i) = 0$ on X, with Φ of the form (40.4). Dividing this relation by L_i^{ml} we obtain the required relation

$$g^l + \sum_{j=0}^{l-1} A_{l-j}(x_0, \ldots, 1, \ldots, x_{n-d-1}) g^j = 0,$$

where $x_r = y_r/y_i$ are coordinates in $\mathbb{A}^{n-d-1}$. But then we have that the mapping is finite, completing the proof.

Theorem 40.4.3: Normalization of Projective Variety

Let X be an irreducible projective variety. Then there exists a finite mapping $\varphi : X \twoheadrightarrow \mathbb{P}_k^m$ for appropriate m.

***Proof*:**
Take $X \subseteq \mathbb{P}_k^n$. If $X = \mathbb{P}_k^n$ we're done so take $X \neq \mathbb{P}_k^n$. Take $x \in \mathbb{P}_k^n \setminus X$ and take the projection from x, $\varphi_x : X \to \mathbb{P}_k^{n-1}$. This map is regular by example 39.4.4, and the image is closed, hence projective. It is furthermore finite by lemma 40.4.2. If $\varphi(X) \neq \mathbb{P}_k^{n-1}$ we repeat the argument. is closed/finite. Each projection lowers the ambient dimension by one, so after finitely many steps the image fills its ambient space: the dimension cannot fall below $\dim X$, and a proper closed subvariety of the same dimension as its ambient is impossible by proposition 34.3.5. Composing the projections gives a finite surjection

$$\varphi \colon X \twoheadrightarrow \mathbb{P}_k^m \qquad m = \dim X$$

completing the proof.

Theorem 40.4.4: Normalization of Affine Variety

Let X be an irreducible affine variety. Then there exists a finite mapping $\varphi : X \twoheadrightarrow \mathbb{A}_k^m$ for appropriate m.

Note that this is the analog of Noether's Normalization theorem for rings that are finitely generated k-algebras without zero-divisors, and in fact can be proven using it: see the fifth exercise of exercise set 40.6.1.

***Proof*:**
Take $X \subseteq \mathbb{A}_k^n$ and suppose $X \neq \mathbb{A}_k^n$, the other case being trivial. Identify $\mathbb{A}_k^n$ with the chart $U_{n+1} \subseteq \mathbb{P}_k^n$. Then X is *closed in* $\mathbb{A}_k^n$, hence locally closed in $\mathbb{P}_k^n$, and we may take its projective closure $\overline{X}$.

Since X is a proper closed subvariety of $\mathbb{A}_k^n$ we have $\dim X < n$ by proposition 34.3.5, so $\overline{X}$ cannot contain the whole hyperplane at infinity; choose $x \in H_\infty$ with $x \notin \overline{X}$. Projecting from x

gives a finite map $\overline{X} \to \mathbb{P}_k^{n-1}$ by lemma 40.4.2, and since the centre lies at infinity the projection carries X into the affine chart, giving a finite map $X \to \mathbb{A}_k^{n-1}$.

Repeating as in theorem 40.4.3 yields a finite surjection

$$\varphi\colon X \twoheadrightarrow \mathbb{A}_k^m \qquad m = \dim X$$

completing the proof.

Thus, though not all varieties are rational, all varieties are a finite cover of affine or projective space, and hence the study of which varieties are not rational will naturally lead to the question of how far away are they from being rational[2]. More on this in the exercises.

Example 40.4.5: Finite Maps and Normalization

Consider the curve $f : \mathbb{A}_k^1 \to \mathbb{A}_k^2$ given by $f(t) = (t^2, t^3)$. This is associated to the pullback on coordinate rings $f^{\#}\colon k[x, y] \to k[t]$, $x \mapsto t^2$, $y \mapsto t^3$. Taking the quotient of the domain gives $k[x, y]/(x^3 - y^2) \cong k[t^2, t^3] \hookrightarrow k[t]$, which is injective but *not surjective*: nothing maps to t. As $(x^3 - y^2)$ is prime, we take the field of fraction and extend the map, which has $t^3/t^2 = t$ we have that $\mathrm{Frac}(k[t^2, t^3]) = k(t)$ giving a field isomorphism.

This is a 1-to-1 map. Define an n-to-1[a] map $f : \mathbb{A}_k^1 \to \mathbb{A}_k^2$ given by $t \mapsto (t^{2n}, t^{3n})$. Notice the image is the same. The global section's are also isomorphic as $k[t^2, t^3] \cong k[t^{2n}, t^{3n}]$. Thus the field of fractions are isomorphic, $k(t) \cong k(t^n)$. Working with a specific n-to-1 map, the field of fraction of the global section of the image is $k(t^n)$ which has index n in the field of fractions of the domain, namely $k(t)$. This reflects the geometric nature of finite maps in algebraic properties.

Notice that $x^2 - y^3$ forms a curve with a cusp; it has a singularity at $(0, 0)$. This curve maps onto

[a] note it is important to assume that either k is algebraically closed, or at minimum that k contains all the roots of unity

40.5 Dimension of Fibres

A map between varieties should decrease dimension by the dimension of its fibres, and this section makes that precise. The statement has three parts, and only the middle one is delicate: fibres can jump *up* in dimension over special points, but never down.

Theorem 40.5.1: Dimension of Fibres

Let $f\colon X \to Y$ be a dominating regular map of irreducible varieties, with $\dim X = n$ and $\dim Y = m$. Then:

1. $m \leq n$;
2. for every $y \in f(X)$, every irreducible component of the fibre $f^{-1}(y)$ has dimension at least $n - m$;
3. there is a nonempty open $U \subseteq Y$ such that $\dim f^{-1}(y) = n - m$ for every $y \in U$.

[2] Chevalley's theorem (chapter 41) is the statement in this direction that survives without the finiteness hypothesis: the image of a regular map is constructible even when it is neither open nor closed.

***Proof*:**
(1). Since f is dominating, $f^\#$ embeds $k(Y)$ into $k(X)$ by proposition 33.3.4(2), and transcendence degree cannot decrease under a field extension, so $m = \mathrm{trdeg}_k k(Y) \leq \mathrm{trdeg}_k k(X) = n$.

(2). The question is local on Y, so replace Y by an affine neighbourhood of y and X by its preimage. The local ring $\mathcal{O}_y(Y)$ has dimension m, so it admits a system of parameters (definition 29.5.1): m functions $g_1, \dots, g_m$ generating an ideal whose zero set is $\{y\}$ near y. Then, near any point of the fibre,

$$f^{-1}(y) = \mathcal{Z}\big(f^\#(g_1), \dots, f^\#(g_m)\big)$$

is cut out of X by m equations. Applying theorem 34.4.1 once for each equation drops the dimension by at most one each time, so every component of the result has dimension at least $n - m$.

(3). Choose affine open sets so that f corresponds to an injection $k[Y] \hookrightarrow k[X]$ of finitely generated domains. Over the fraction field $K = k(Y)$, the ring $k[X] \otimes_{k[Y]} K$ is a finitely generated K-algebra of dimension $n - m$, since its fraction field is $k(X)$ and $\mathrm{trdeg}_K k(X) = n - m$. Apply Noether normalization over K: there are $t_1, \dots, t_{n-m}$ with $k[X] \otimes K$ finite over $K[t_1, \dots, t_{n-m}]$. Each of the finitely many integral equations involved has coefficients in $k(Y)$; let $g \in k[Y]$ be a common denominator. Then over the open set $U = D(g)$,

$$k[X]_g \text{ is finite over } k[Y]_g[t_1, \dots, t_{n-m}]$$

Hence for $y \in U$ the fibre $f^{-1}(y)$ is finite over $\mathbb{A}_k^{n-m}$, and a finite surjection preserves dimension by proposition 34.2.5, so $\dim f^{-1}(y) = n - m$, as we sought to show.

Part (2) is the useful half in practice, and it is worth saying what it does not claim. It gives a *lower* bound on fibre dimension, valid at every point; the matching upper bound holds only generically, which is part (3). Fibres genuinely do jump.

Example 40.5.2: Fibres That Jump
Let $X = \mathcal{Z}(xz - y) \subseteq \mathbb{A}_k^3$ and $f \colon X \to \mathbb{A}_k^1$ the projection $(x, y, z) \mapsto x$. Then X is isomorphic to $\mathbb{A}_k^2$ with coordinates (x, z), since y is determined, so $n = 2$ and $m = 1$, giving an expected fibre dimension of 1. Over $x = a \neq 0$ the fibre is the line $\{(a, az, z) \mid z \in k\}$, of dimension 1 as predicted. Over $x = 0$ it is $\{(0, 0, z) \mid z \in k\}$, again dimension 1.

Now blow the picture up: let $g \colon \mathbb{A}_k^2 \to \mathbb{A}_k^2$ be $(u, v) \mapsto (u, uv)$. Here $n = m = 2$, so the expected fibre dimension is 0. Over (a, b) with $a \neq 0$ the fibre is the single point $(a, b/a)$; but over $(0, 0)$ the fibre is the whole line $\{(0, v) \mid v \in k\}$, of dimension 1. The fibre has jumped, exactly as part (2) permits and part (3) confines to a proper closed subset. This map is the restriction to one chart of the blow-up of chapter 47, computed there as proposition 47.1.2(1).

A count that will be used in chapter 41 follows immediately by adding dimensions along a map whose fibres are all of the same dimension.

Corollary 40.5.3: Dimension of a Total Space

Let $f\colon X \to Y$ be a surjective regular map of irreducible varieties whose fibres are all irreducible of the same dimension d. Then $\dim X = \dim Y + d$.

***Proof*:**
By theorem 40.5.1(3) the generic fibre has dimension $\dim X - \dim Y$, and by hypothesis every fibre has dimension d, so $\dim X - \dim Y = d$, completing the proof.

Applied to a projection, this settles the dimension of a product, which chapter 34 could only gesture at because products of projective varieties were not yet available.

Corollary 40.5.4: Dimension of a Product

Let X and Y be irreducible quasi-projective varieties. Then $\dim(X \times Y) = \dim X + \dim Y$.

***Proof*:**
$X \times Y$ is irreducible by proposition 40.1.6, and the projection $\pi\colon X \times Y \to X$ is a surjective regular map whose fibre over x is the slice $\{x\} \times Y \cong Y$, irreducible of dimension $\dim Y$ at every point. Corollary 40.5.3 applies and gives the claim.

40.6 The Dimension of an Intersection

Theorem 34.4.1 says that cutting an affine variety by one equation costs at most one dimension. Iterating it bounds the dimension of an intersection, but only when one of the two varieties is cut out by as many equations as its codimension, and that fails in general: the twisted cubic of example 38.3.7 has codimension two in $\mathbb{P}^3_k$ and needs three equations. The repair is to intersect with the diagonal instead, and it costs nothing now that products are available.

Proposition 40.6.1: The Affine Dimension Theorem

Let $X, Y \subseteq \mathbb{A}^n_k$ be irreducible affine varieties with $\dim X = r$ and $\dim Y = s$. Then every irreducible component of $X \cap Y$ has dimension at least $r + s - n$.

***Proof*:**
Let $\Delta = \{(a, a) \mid a \in \mathbb{A}^n_k\} \subseteq \mathbb{A}^{2n}_k$ be the diagonal, which is $\mathcal{Z}(x_1 - y_1, \ldots, x_n - y_n)$, cut out by exactly n equations. The map $a \mapsto (a, a)$ is an isomorphism

$$X \cap Y \xrightarrow{\sim} (X \times Y) \cap \Delta$$

with inverse the first projection, both regular.

Now $X \times Y$ is irreducible by proposition 40.1.6 and has dimension $r + s$ by corollary 40.5.4. Cutting it by the n equations one at a time and applying theorem 34.4.1 at each step, every component of the result has dimension at least $r + s - n$, since each equation costs at most one dimension: an equation either vanishes identically on a component, leaving it untouched, or cuts it by exactly one. Transporting through the isomorphism gives the claim, as we sought to show.

Passing to affine cones turns this into the projective statement, and the projective statement is strictly stronger: it also asserts that the intersection is nonempty.

Proposition 40.6.2: Dimension of the Affine Cone

Let $\emptyset \neq V \subseteq \mathbb{P}^n_k$ be a projective variety. Then $C(V)$ is an irreducible affine variety and

$$\dim C(V) = \dim V + 1$$

***Proof*:**
Irreducibility: $\mathcal{I}_{\mathbb{A}}(C(V)) = \mathcal{I}_{\mathbb{P}}(V)$ by proposition 38.3.2, and the latter is prime because V is a variety, so $k[C(V)] = S(V)$ is a domain.

For the dimension, choose a linear form t not vanishing identically on V, possible since $V \neq \emptyset$. Every element of $\operatorname{Frac}(S(V))$ is a ratio f/g of homogeneous elements, and

$$\frac{f}{g} = \frac{f/t^{\deg f}}{g/t^{\deg g}} \cdot t^{\deg f - \deg g}$$

exhibits it as a rational function of t with coefficients in the degree-zero part, which is $k(V)$ by definition 39.2.4. So $\operatorname{Frac}(S(V)) = k(V)(t)$, and t is transcendental over $k(V)$ because it has degree 1 while $k(V)$ sits in degree 0. Hence

$$\dim C(V) = \operatorname{kdim} S(V) = \operatorname{trdeg}_k \operatorname{Frac}(S(V)) = \operatorname{trdeg}_k k(V) + 1 = \dim V + 1$$

using proposition 34.2.5 twice, as we sought to show.

Theorem 40.6.3: The Projective Dimension Theorem

Let $X, Y \subseteq \mathbb{P}^n_k$ be projective varieties with $\dim X = r$ and $\dim Y = s$. Then every irreducible component of $X \cap Y$ has dimension at least $r + s - n$. If moreover $r + s - n \geq 0$, then $X \cap Y \neq \emptyset$.

***Proof*:**
Pass to the affine cones in $\mathbb{A}^{n+1}_k$. By proposition 40.6.2 they are irreducible of dimensions $r+1$ and $s+1$, so proposition 40.6.1 says every component of $C(X) \cap C(Y)$ has dimension at least

$$(r+1) + (s+1) - (n+1) = r + s - n + 1$$

By proposition 38.3.2 the components of $C(X) \cap C(Y)$ other than the origin are the cones over the components of $X \cap Y$, whose dimensions are one less by proposition 40.6.2. That gives the bound $r + s - n$.

For nonemptiness, note that both cones contain the origin, so $C(X) \cap C(Y)$ is nonempty and the bound applies to a component through the origin: it has dimension at least $r + s - n + 1 \geq 1$. A variety of dimension at least 1 is not a single point, so that component contains some $a \neq 0$, and a determines a point of $\mathbb{P}^n_k$ lying on both X and Y, as we sought to show.

The nonemptiness clause is what separates projective space from affine space. Both cones always meet, at the origin; the content is that when the dimensions are large enough they meet in more than the origin. No such statement is available affinely: in $\mathbb{A}^2_k$ the parallel lines $\mathcal{Z}(y)$ and $\mathcal{Z}(y-1)$ have $r = s = 1$ and $n = 2$, so $r + s - n = 0$, and they are disjoint.

Example 40.6.4: Dimension Counts in Projective Space

1. *Two curves in* $\mathbb{P}^2_k$. Here $r = s = 1$ and $n = 2$, so $r + s - n = 0$ and any two projective plane curves meet. Chapter 43 refines this into a count of the intersection points; the present theorem gives only that there is one, but it needs no hypothesis beyond dimension.
2. *A curve and a surface in* $\mathbb{P}^3_k$. With $r = 1$, $s = 2$, $n = 3$ the bound is 0, so a curve and a surface in $\mathbb{P}^3_k$ always meet.
3. *Two curves in* $\mathbb{P}^3_k$. Now $r + s - n = -1$ and the theorem says nothing, correctly: two disjoint lines in $\mathbb{P}^3_k$ exist, as exercise set 38.5.1(4) exhibits.
4. *Hypersurfaces.* If $Y = \mathcal{Z}(F)$ is a hypersurface then $s = n - 1$ and the bound reads $r - 1$, with nonemptiness as soon as $\dim X \geq 1$. So a projective variety of positive dimension meets every hypersurface, which is another way of seeing why it carries no nonconstant regular function.

Exercise 40.6.1

1. Show that the image of the Segre embedding $\mathbb{P}^1_k \times \mathbb{P}^1_k \to \mathbb{P}^3_k$ is the quadric $\mathcal{Z}(w_{00}w_{11} - w_{01}w_{10})$, and that it contains two families of pairwise disjoint lines. Deduce, using exercise set 38.5.1(4), that this quadric is not isomorphic to $\mathbb{P}^2_k$.
2. Show that a variety that is both projective and affine is a single point.
3. Show that the map $\mathbb{A}^1_k \to \mathbb{A}^1_k$, $x \mapsto x^2$, is finite, and that the inclusion $\mathbb{A}^2_k \setminus \{0\} \hookrightarrow \mathbb{A}^2_k$ is not. For the second, which hypothesis of proposition 40.3.3 fails?
4. Exhibit a finite surjection $\mathcal{Z}(xy - 1) \to \mathbb{A}^1_k$, and check directly that it is finite by writing the coordinate ring as a module over the image.
5. Prove the affine normalization theorem using Noether's normalization theorem (theorem 32.4.1): every affine variety admits a finite surjective map onto some $\mathbb{A}^m_k$, with m its dimension.
6. For $f\colon \mathbb{A}^2_k \to \mathbb{A}^2_k$, $(u, v) \mapsto (u, uv)$, compute every fibre and verify all three parts of theorem 40.5.1 by hand. Which part fails if the word "component" is dropped from part (2)?
7. Using corollary 40.5.4, compute $\dim(\mathbb{P}^n_k \times \mathbb{P}^m_k)$ and check the answer against the Segre embedding for $n = m = 1$.
8. Show that the two projections $\mathbb{P}^1_k \times \mathbb{P}^1_k \to \mathbb{P}^1_k$ have all fibres isomorphic to $\mathbb{P}^1_k$, and use corollary 40.5.3 to recover the dimension of the product.

41

Projective Embeddings and Constructible Sets

Projective space carries more embeddings of itself than the linear ones, and the useful ones turn products, hypersurfaces, and linear subspaces into points of a larger projective space. This chapter collects them: the Veronese embedding, which linearizes degree, and the Plücker embedding, which realizes the Grassmannian of d-planes as a projective variety.

Then comes Chevalley's theorem. The image of a regular map is neither open nor closed in general, but it is always constructible, a finite union of locally closed sets, and that is the correct replacement for the closedness that chapter 40 supplies only in the projective case.

The chapter ends by putting the two halves together. Counting the lines that lie on a cubic surface needs the Grassmannian to parameterize the lines, projective space to parameterize the surfaces, and theorem 40.5.1 to conclude that the count is finite. It is the first argument in this book where the answer is a number nobody could have guessed.

41.1 The Veronese Embedding

A hypersurface of degree d in $\mathbb{P}^n$ is cut out by one equation, but that equation is not linear, and linear conditions are the ones that are easy to count. The Veronese embedding trades the degree for a dimension: it realizes $\mathbb{P}^n$ inside a much larger projective space in such a way that degree-d hypersurfaces downstairs become *hyperplane sections* upstairs.

Definition 41.1.1: Veronese Embedding

Fix $n, d \geq 1$ and let $M_0, \ldots, M_N$ be the monomials of degree d in $x_0, \ldots, x_n$, in some fixed order, where

$$N = \binom{n+d}{d} - 1$$

The *Veronese embedding* of degree d is

$$v_d \colon \mathbb{P}^n_k \to \mathbb{P}^N_k \qquad v_d([x_0 : \cdots : x_n]) = [M_0(x) : \cdots : M_N(x)]$$

The map is well defined: every M_i is homogeneous of the same degree d, so scaling x by λ scales every coordinate by λ^d, and the M_i never vanish simultaneously, since x_j^d is among them and some $x_j \neq 0$.

Theorem 41.1.2: The Veronese Is a Closed Embedding

v_d is injective, its image $V_{n,d} = v_d(\mathbb{P}^n_k)$ is closed in $\mathbb{P}^N_k$, and v_d is an isomorphism onto its image.

***Proof*:**
Injective. Write z_α for the coordinate of $\mathbb{P}^N$ attached to the monomial x^α. Suppose $v_d(x) = v_d(y)$. Some $x_j \neq 0$, so $z_{de_j} \neq 0$ at that point, hence $y_j \neq 0$ as well. Rescaling, take $x_j = y_j = 1$. Then the coordinate attached to $x_j^{d-1} x_i$ reads off x_i and y_i directly, so $x = y$.

Closed. The image satisfies the relations

$$z_\alpha z_\beta = z_\gamma z_\delta \qquad \text{whenever } \alpha + \beta = \gamma + \delta$$

since both sides equal $x^{\alpha+\beta}$. Conversely, suppose z satisfies them all and $z_{de_j} \neq 0$ for some j; normalize $z_{de_j} = 1$ and set $x_i = z_{(d-1)e_j + e_i}$. The relations then force $z_\alpha = x^\alpha$ for every α, by induction on how far α is from de_j. Hence the image is exactly the closed set cut out by those quadrics.

Isomorphism onto the image. The inverse is given on the open set $z_{de_j} \neq 0$ by $z \mapsto [z_{(d-1)e_j+e_0} : \cdots : z_{(d-1)e_j+e_n}]$, a tuple of forms of the same degree with no common zero there, hence regular by proposition 39.4.3. These agree on overlaps because both compute the same point, so they glue to a regular inverse, as we sought to show.

The payoff is the promised trade.

Corollary 41.1.3: Hypersurfaces Become Hyperplane Sections

Let F be a form of degree d in $x_0, \ldots, x_n$. Then there is a hyperplane $H \subseteq \mathbb{P}^N_k$ with

$$v_d\big(\mathcal{Z}(F)\big) = V_{n,d} \cap H$$

Consequently every degree-d hypersurface in $\mathbb{P}^n_k$ is the pullback of a hyperplane under v_d.

***Proof*:**
Write $F = \sum_\alpha c_\alpha x^\alpha$, the sum over monomials of degree d. Let $H = \mathcal{Z}(L)$ where $L = \sum_\alpha c_\alpha z_\alpha$, a linear form. Then $L(v_d(x)) = \sum_\alpha c_\alpha x^\alpha = F(x)$, so $v_d(x) \in H$ if and only if $F(x) = 0$, as we sought to show.

Example 41.1.4: Small Veronese Embeddings

1. $v_2 \colon \mathbb{P}^1_k \to \mathbb{P}^2_k$, $[s : t] \mapsto [s^2 : st : t^2]$. Here $N = \binom{3}{2} - 1 = 2$ and the image is the conic $\mathcal{Z}(z_0 z_2 - z_1^2)$. This is the isomorphism $\mathbb{P}^1 \cong$ smooth conic met in example 39.4.4(3), in coordinates.

2. $v_3 \colon \mathbb{P}^1_k \to \mathbb{P}^3_k$, $[s : t] \mapsto [s^3 : s^2t : st^2 : t^3]$, whose image is the twisted cubic of example 38.3.7(4). So the twisted cubic is a Veronese image, which is another way of seeing that it is rational.

3. $v_2 \colon \mathbb{P}^2_k \to \mathbb{P}^5_k$ is the *Veronese surface*, the classical example of a smooth surface in $\mathbb{P}^5$ that is not contained in any hyperplane.

The construction also gives a clean way to think about the parameter space of section 39.2: the degree-d forms on $\mathbb{P}^n$, taken up to scalar, are the points of $\mathbb{P}^N_k$, and corollary 41.1.3 says the hypersurface a point cuts out is the corresponding hyperplane section of the Veronese. The following is a first payoff.

Proposition 41.1.5: Parameterizing Reducible Hypersurfaces

Fix n and d, and let $\mathbb{P}^N_k$, $N = \binom{n+d}{d} - 1$, be the projective space parameterizing degree-d forms in $n+1$ variables up to scalar, as in section 39.2. Then the set of points corresponding to *reducible* forms is closed in $\mathbb{P}^N_k$.

***Proof*:**
A reducible form of degree d factors as a product of forms of degrees j and $d - j$ for some $1 \le j \le d - 1$. Writing Z_j for the set of points of $\mathbb{P}^N_k$ arising this way, the set of reducible forms is $\bigcup_{j=1}^{d-1} Z_j$, a finite union, so it suffices to show each Z_j is closed.

Let $N_j = \binom{n+j}{j} - 1$ and $N_{d-j} = \binom{n+d-j}{d-j} - 1$ be the corresponding parameter spaces. Multiplication of forms gives a map

$$\mu \colon \mathbb{P}^{N_j}_k \times \mathbb{P}^{N_{d-j}}_k \to \mathbb{P}^N_k$$

which is well defined, since scaling either factor scales the product, and regular, since the coefficients of a product are bilinear in the coefficients of the factors. Its image is exactly Z_j.

The source is a product of projective spaces, hence a projective variety by proposition 40.1.3, so $Z_j = \mu(\mathbb{P}^{N_j}_k \times \mathbb{P}^{N_{d-j}}_k)$ is closed by corollary 40.2.3. That is the whole point of completeness: the image of a projective variety is closed, which for an affine source would fail. Hence the reducible locus is closed, as we sought to show.

For $n = 1$ and $d = 2$ this recovers a familiar fact: a binary quadratic form $ax^2 + bxy + cy^2$ is reducible exactly when its discriminant $b^2 - 4ac$ vanishes, a single equation in the coefficients.

41.2 Grassmannians and the Plücker Embedding

The Veronese parameterizes hypersurfaces. The Grassmannian parameterizes linear subspaces, and it is the space one needs in order to ask questions like "how many lines lie on a surface". As with the Veronese, the construction realizes a set of geometric objects as the points of a projective variety.

Definition 41.2.1: Grassmannian

Let $0 < r < n$. The *Grassmannian* $G(r, n)$ is the set of r-dimensional linear subspaces of k^n. Equivalently, since an r-dimensional subspace of k^n is an $(r-1)$-dimensional linear subspace of $\mathbb{P}^{n-1}_k$, it is the set of $(r-1)$-planes in $\mathbb{P}^{n-1}_k$.

The two readings differ only by a shift, and both are used: $G(2, 4)$ is the space of 2-dimensional subspaces of k^4, which is the space of *lines* in $\mathbb{P}^3_k$. That is the case section 41.4 needs, and there the columns of k^4 are indexed by $0, 1, 2, 3$ to match the coordinates $x_0, \dots, x_3$ on $\mathbb{P}^3_k$, writing the Plücker coordinates as p_{ij} with $0 \le i < j \le 3$.

To make $G(r, n)$ a variety, represent a subspace by a basis and kill the ambiguity in that choice.

Definition 41.2.2: Plücker Embedding

Let $W \subseteq k^n$ be an r-dimensional subspace with basis $w_1, \dots, w_r$. Writing the w_i as the rows of an $r \times n$ matrix, let $p_{i_1 \cdots i_r}$ be the $r \times r$ minor on columns $i_1 < \cdots < i_r$. The *Plücker embedding* is

$$\rho\colon G(r, n) \to \mathbb{P}^{\binom{n}{r}-1}_k \qquad \rho(W) = [p_{i_1 \cdots i_r}]_{i_1 < \cdots < i_r}$$

Proposition 41.2.3: The Plücker Embedding Is Well Defined and Injective

ρ does not depend on the choice of basis, and it is injective.

***Proof*:**
Changing basis replaces the matrix A by gA for some $g \in \mathrm{GL}_r(k)$, and the Cauchy-Binet formula multiplies every maximal minor by the single scalar $\det g \neq 0$. So the tuple of minors changes by an overall scalar and its class in projective space is unchanged. Not all minors vanish, since the rows are independent and so some r columns are independent.

For injectivity, recover W from $\rho(W)$: a vector $v \in k^n$ lies in W exactly when the $(r + 1) \times n$ matrix obtained by appending v has all its maximal minors zero, and expanding those minors along the appended row writes each as a linear form in v with coefficients among the $p_{i_1 \cdots i_r}$. So the Plücker coordinates determine W as the common zero set of an explicit system of linear equations, as we sought to show.

Theorem 41.2.4: The Grassmannian Is a Projective Variety

The image of ρ is closed in $\mathbb{P}_k^{\binom{n}{r}-1}$, so $G(r,n)$ is a projective variety. Its dimension is

$$\dim G(r,n) = r(n-r)$$

***Proof*:**
Closed. The image is cut out by the *Plücker relations*, the quadratic equations expressing that a tuple of $\binom{n}{r}$ numbers arises as the maximal minors of an $r \times n$ matrix. These are quadrics in the $p_{i_1 \cdots i_r}$; example 41.2.5(2) writes them out in the first case where there is more than one. Their zero set is closed, and the argument of proposition 41.2.3 shows a point satisfying them determines an r-dimensional subspace, so the zero set is exactly imρ.

Dimension. Cover $G(r,n)$ by the open sets $U_{i_1 \cdots i_r} = \{p_{i_1 \cdots i_r} \neq 0\}$. On $U_{1 \cdots r}$, every subspace has a unique basis whose matrix is $[\, I_r \big| B\,]$ with B an arbitrary $r \times (n-r)$ matrix: row-reduce using the invertible left block. The entries of B are free coordinates, giving $U_{1 \cdots r} \cong \mathbb{A}_k^{r(n-r)}$. These charts are irreducible and pairwise meet, since any two nonempty open subsets of an irreducible space do, so $G(r,n)$ is irreducible by lemma 40.1.5, and corollary 34.3.3 reads its dimension off a single chart as $r(n-r)$, as we sought to show.

Example 41.2.5: Grassmannians

1. $G(1,n) = \mathbb{P}_k^{n-1}$: a line through the origin in k^n is a point of $\mathbb{P}^{n-1}$, and the Plücker map is the identity. Dimension $1 \cdot (n-1) = n-1$, as it should be.
2. $G(2,4)$, the lines in $\mathbb{P}_k^3$. Here $\binom{4}{2} = 6$, so ρ lands in $\mathbb{P}_k^5$ with coordinates $p_{12}, p_{13}, p_{14}, p_{23}, p_{24}, p_{34}$, and there is exactly one Plücker relation:

$$p_{12}p_{34} - p_{13}p_{24} + p_{14}p_{23} = 0$$

   So $G(2,4)$ is a quadric hypersurface in $\mathbb{P}_k^5$, of dimension $2 \cdot 2 = 4$, matching theorem 34.4.1, which gives $5 - 1 = 4$.
3. $G(r,n) \cong G(n-r,n)$, by sending a subspace to its annihilator in the dual space. So the lines in $\mathbb{P}^3$ and the planes in $\mathbb{P}^3$ form isomorphic families, both of dimension 4.

The count in item (2) is the one section 41.4 runs on: the lines in $\mathbb{P}^3$ form a 4-dimensional family, and asking how many of them lie on a given surface is a question about intersecting that family with a condition.

41.3 Constructible Sets and Chevalley's Theorem

Chapter 40 showed that the image of a *projective* variety under a regular map is closed. For a general regular map the image can be neither closed nor open: the projection of $\mathcal{Z}(xy-1)$ to the x-axis is $\mathbb{A}_k^1 \setminus \{0\}$, which is open, while the image of $(x,y) \mapsto (x,xy)$ is $(\mathbb{A}_k^1 \setminus \{0\}) \times \mathbb{A}_k^1$ together with the single point $(0,0)$, which is neither. Chevalley's theorem says the second example is as bad as it gets: images are always finite unions of pieces of that shape.

Definition 41.3.1: Locally Closed and Constructible Sets

Let X be a variety. A subset $S \subseteq X$ is *locally closed* if $S = U \cap Z$ with U open and Z closed, equivalently if S is open in its own closure. A subset is *constructible* if it is a finite union of locally closed sets.

Proposition 41.3.2: Constructible Sets Form a Boolean Algebra

The constructible subsets of X are closed under finite union, finite intersection, and complement. They are the smallest such family containing the open sets.

***Proof*:**
Closure under finite union is the definition. For intersection, $(U_1 \cap Z_1) \cap (U_2 \cap Z_2) = (U_1 \cap U_2) \cap (Z_1 \cap Z_2)$ is locally closed, and intersection distributes over the finite unions.

For complement, it suffices to complement one locally closed set, since the complement of a finite union is the finite intersection of the complements and intersections are handled. And

$$X \setminus (U \cap Z) = (X \setminus U) \cup (X \setminus Z)$$

a union of a closed set and an open set, both locally closed. Finally any family closed under these operations and containing the opens contains every $U \cap Z$, hence every constructible set, as we sought to show.

The theorem rests on the fact that a dominating map hits a dense open set. Section 40.3 stated this without proof; it follows from the generic finiteness of theorem 40.5.1(3).

Lemma 41.3.3: A Dominating Image Contains a Dense Open Set

Let $f\colon X \to Y$ be a dominating regular map of irreducible varieties. Then $f(X)$ contains a nonempty open subset of Y.

***Proof*:**
Passing to affine open subsets changes neither hypothesis nor conclusion, so assume X and Y affine. The proof of theorem 40.5.1(3) produced $g \in k[Y]$ and $t_1, \dots, t_{n-m}$ such that

$$k[X]_g \text{ is finite over } k[Y]_g[t_1, \dots, t_{n-m}]$$

Geometrically this says f restricted over $D(g)$ factors as a finite map followed by a projection $D(g) \times \mathbb{A}^{n-m}_k \to D(g)$. A finite map is surjective by proposition 40.3.3, and the projection is surjective, so the composite is surjective onto $D(g)$. Hence $f(X) \supseteq D(g)$, a nonempty open subset of Y, as we sought to show.

Theorem 41.3.4: Chevalley's Theorem

Let $f\colon X \to Y$ be a regular map of varieties. Then f carries constructible sets to constructible sets. In particular $f(X)$ is constructible.

***Proof*:**
Since a constructible set is a finite union of locally closed sets, and the image of a union is the union of the images, it suffices to treat $f(X)$ itself, with X replaced by a locally closed subset. Decomposing X into irreducible components (theorem 32.3.5) and Y into the closure of the image, we may assume X and Y irreducible and f dominating.

Argue by Noetherian induction on Y: suppose the result holds for every proper closed subvariety of Y. By lemma 41.3.3 there is a nonempty open $U \subseteq Y$ with $U \subseteq f(X)$. Then

$$f(X) = U \cup f\bigl(X \setminus f^{-1}(U)\bigr)$$

The set $X' = X \setminus f^{-1}(U)$ is closed in X, and $f(X') \subseteq Y \setminus U$, a proper closed subset of Y. Applying the inductive hypothesis to $f|_{X'}\colon X' \to Y \setminus U$, which is a regular map of varieties with strictly smaller target, shows $f(X')$ is constructible. As U is open, hence constructible, and constructible sets are closed under finite union (proposition 41.3.2), $f(X)$ is constructible.

The induction terminates because Y is a Noetherian topological space (proposition 31.3.7), so there is no infinite strictly descending chain of closed subsets, completing the proof.

Chevalley's theorem is the right general statement, and the closed-image theorem of corollary 40.2.3 is the special case where properness upgrades "constructible" to "closed". It is also the statement that survives into scheme theory unchanged, where it becomes the assertion that a finite-type morphism of Noetherian schemes has constructible image.

Example 41.3.5: The Image That Is Neither Open Nor Closed
Take $f\colon \mathbb{A}^2_k \to \mathbb{A}^2_k$, $f(x,y) = (x, xy)$. For $x = a \neq 0$ the fibre over (a,b) is the single point $(a, b/a)$, so every such (a,b) is hit; for $x = 0$ the image of the line $x = 0$ is the single point $(0,0)$. Hence

$$\operatorname{im} f = \bigl((\mathbb{A}^1_k \setminus \{0\}) \times \mathbb{A}^1_k\bigr) \;\cup\; \{(0,0)\}$$

The first piece is open, the second is closed, and the union is neither. It is constructible, being a union of two locally closed sets, exactly as theorem 41.3.4 requires. This is also the map of example 40.5.2, whose fibre over the origin jumped in dimension; the jump and the failure of openness are the same phenomenon.

41.4 Application: Lines on a Cubic Surface

The Grassmannian and the fibre-dimension theorem together answer a question that would otherwise be inaccessible: how many lines lie on a surface in $\mathbb{P}^3$? For a general cubic surface the answer is a finite number, and the argument that it is finite is a dimension count of exactly the kind this Part was built to support.

Fix the two parameter spaces. Lines in $\mathbb{P}^3_k$ form $G = G(2,4)$, of dimension 4 by theorem 41.2.4.

Cubic surfaces in $\mathbb{P}^3_k$ are the nonzero degree-3 forms in four variables up to scalar, so they form $\mathbb{P}^{19}_k$: there are $\binom{3+3}{3} = 20$ monomials of degree 3 in four variables. Note that this parameter space contains reducible and singular surfaces too, which is harmless and in fact necessary, since a parameter space has to be complete to be useful.

The strategy is to put lines and surfaces into a single variety and project it two ways. Set

$$I = \{(\ell, S) \in G \times \mathbb{P}^{19}_k \mid \ell \subseteq S\}$$

Projecting to G organizes I by the line; over a fixed line the cubics containing it form a linear system, and that side computes $\dim I$. Projecting to $\mathbb{P}^{19}$ organizes I by the surface, and its fibres are the sets of lines to be counted.

Lemma 41.4.1: The Incidence Variety

I is an irreducible projective variety of dimension 19, and $\pi_1 : I \to G$ is surjective with every fibre a linear subspace $\mathbb{P}^{15} \subseteq \mathbb{P}^{19}$.

***Proof*:**
Work chart by chart on G. By the proof of theorem 41.2.4 the open set $U \subseteq G$ where $p_{01} \neq 0$ is isomorphic to $\mathbb{A}^4_k$, with coordinates a, b, c, d naming the plane spanned by $(1, 0, a, b)$ and $(0, 1, c, d)$; the corresponding line $\ell_{abcd} \subseteq \mathbb{P}^3_k$ is the image of

$$[s : t] \longmapsto [\, s : t : as + ct : bs + dt \,]$$

Let $T = T_{abcd}$ be the linear automorphism of k^4 fixing e_2, e_3 and sending e_0, e_1 to $(1, 0, a, b)$ and $(0, 1, c, d)$. Its matrix is lower triangular with 1s on the diagonal, so $\det T = 1$, and both T and T^{-1} have entries that are polynomials in a, b, c, d. By construction T carries the line $\mathcal{Z}(x_2, x_3)$ onto ℓ_{abcd}, so for a cubic form F,

$$F \text{ vanishes on } \ell_{abcd} \iff F \circ T \text{ vanishes on } \mathcal{Z}(x_2, x_3) \iff F \circ T \text{ has no term in } x_0, x_1 \text{ alone}$$

the last step because the restriction of $F \circ T$ to $\mathcal{Z}(x_2, x_3)$ is obtained by setting $x_2 = x_3 = 0$, leaving exactly the four terms $x_0^3, x_0^2 x_1, x_0 x_1^2, x_1^3$.

Now consider

$$\Psi : U \times \mathbb{P}^{19}_k \to U \times \mathbb{P}^{19}_k \qquad \big((a, b, c, d), [F]\big) \mapsto \big((a, b, c, d), [F \circ T_{abcd}]\big)$$

The coefficients of $F \circ T$ are linear in those of F with coefficients polynomial in a, b, c, d, and $F \circ T \neq 0$ because T is invertible, so Ψ is a regular map; the same formula with T^{-1} gives its inverse, so Ψ is an isomorphism. The displayed equivalence says precisely that Ψ carries $\pi_1^{-1}(U)$ onto $U \times L$, where $L \subseteq \mathbb{P}^{19}$ is the *fixed* linear subspace of cubics whose four coefficients on $x_0^3, x_0^2 x_1, x_0 x_1^2, x_1^3$ vanish. Those four coordinates are independent, so $L \cong \mathbb{P}^{15}$, and

$$\pi_1^{-1}(U) \cong \mathbb{A}^4_k \times \mathbb{P}^{15}_k$$

Three consequences follow, all of them local statements verified on each of the six charts of G in turn, the computation being identical after permuting coordinates.

I is closed. $U \times L$ is closed in $U \times \mathbb{P}^{19}$, hence so is $\pi_1^{-1}(U)$, and being closed is a local condition on a cover. Since $G \times \mathbb{P}^{19}$ is projective by proposition 40.1.3, I is a projective variety.

π_1 is surjective with fibre $\mathbb{P}^{15}$. Under Ψ the fibre over (a, b, c, d) becomes $\{(a, b, c, d)\} \times L$, so it is a linear $\mathbb{P}^{15}$, in particular nonempty and irreducible of dimension 15.

I is irreducible of dimension 19. Each $\pi_1^{-1}(U)$ is irreducible by proposition 40.1.6, and any two of the six meet, since the charts of the irreducible G do and the fibres of π_1 are nonempty. Lemma 40.1.5 makes I irreducible, and then corollary 40.5.3 applied to π_1 gives $\dim I = 4+15 = 19$, as we sought to show.

The count now hinges on a single input from outside the dimension theory: one cubic surface whose lines can be counted by hand, and which has finitely many. The Fermat cubic is the traditional choice, but its 27 lines take work to enumerate; the following surface is singular, has only three lines, and settles the matter in half a page.

Lemma 41.4.2: A Cubic Surface With Exactly Three Lines

Let $S_0 = \mathcal{Z}(x_0x_1x_2 - x_3^3) \subseteq \mathbb{P}^3_k$. Then S_0 is an irreducible cubic surface, and the only lines contained in it are $\mathcal{Z}(x_3, x_0)$, $\mathcal{Z}(x_3, x_1)$ and $\mathcal{Z}(x_3, x_2)$.

***Proof*:**
Irreducibility. Read $x_0x_1x_2 - x_3^3$ as a polynomial in x_3 over the unique factorization domain $k[x_0, x_1, x_2]$. Its leading coefficient is -1, its middle coefficients are 0, and its constant term $x_0x_1x_2$ lies in (x_0) but not in (x_0^2). Eisenstein's criterion at the prime x_0 applies, so the polynomial is irreducible and S_0 is a variety.

The three lines lie on it. On $\mathcal{Z}(x_3, x_i)$ both $x_0x_1x_2$ and x_3^3 vanish identically.

There are no others. Let $\ell \subseteq S_0$ be a line, parameterized by $[s : t] \mapsto [g_0 : g_1 : g_2 : g_3]$, where the g_i are linear forms in s, t spanning a two-dimensional space, that being what makes the image a line rather than a point. The defining equation restricts to $g_0g_1g_2 = g_3^3$ in $k[s, t]$.

If $g_3 \equiv 0$ then $g_0g_1g_2 \equiv 0$, and $k[s, t]$ is a domain, so $g_i \equiv 0$ for some $i \leq 2$; then $\ell \subseteq \mathcal{Z}(x_3, x_i)$, and as both are lines they are equal.

If $g_3 \not\equiv 0$, change coordinates on the source $\mathbb{P}^1$ so that $g_3 = t$, which is possible because g_3 is a nonzero linear form. Then $g_0g_1g_2 = t^3$. None of g_0, g_1, g_2 is zero, and each divides t^3 in the unique factorization domain $k[s, t]$, in which t is prime; the only linear divisors of t^3 are the scalar multiples of t. So $g_i = c_it$ for every $i \leq 2$ as well, making all four g_i proportional, which contradicts the requirement that they span a two-dimensional space of linear forms. Hence this case does not occur, as we sought to show.

Theorem 41.4.3: Lines on a Cubic Surface

Every cubic surface in $\mathbb{P}^3_k$ contains a line, and there is a nonempty open subset $U \subseteq \mathbb{P}^{19}_k$ such that a cubic surface parameterized by a point of U contains only finitely many.

***Proof*:**
Write $\pi_2 \colon I \to \mathbb{P}^{19}_k$ for the second projection. By lemma 41.4.1 the source is an irreducible projective variety with $\dim I = 19 = \dim \mathbb{P}^{19}_k$, so $\pi_2(I)$ is closed by corollary 40.2.3 and irreducible, being the continuous image of an irreducible space.

π_2 *is surjective.* The fibre $\pi_2^{-1}(S_0)$ over the surface of lemma 41.4.2 is a set of three points, so it is nonempty of dimension 0; in particular $S_0 \in \pi_2(I)$. Suppose $\pi_2(I) \neq \mathbb{P}^{19}$. Then $\pi_2(I)$ is a proper closed subvariety, so $\dim \pi_2(I) \leq 18$ by proposition 34.3.5. Applying theorem 40.5.1(2) to the dominating map $\pi_2 \colon I \to \pi_2(I)$ forces every component of every fibre to have dimension at least $19 - 18 = 1$, contradicting the fibre over S_0. Hence $\pi_2(I) = \mathbb{P}^{19}$, which says exactly that every cubic surface contains a line.

The general fibre is finite. Now π_2 is a dominating map of irreducible varieties with $\dim I = \dim \mathbb{P}^{19}$, so theorem 40.5.1(3) supplies a nonempty open $U \subseteq \mathbb{P}^{19}$ with $\dim \pi_2^{-1}(S) = 19 - 19 = 0$ for every $S \in U$. Such a fibre is closed in the projective I, hence an algebraic set, and by theorem 32.3.5 it has finitely many irreducible components. Each component is closed, irreducible and of dimension 0, hence a single point: a closed irreducible set with two distinct points $p \neq q$ contains the proper closed subset $\{p\}$, giving a chain of length 1 and so dimension at least 1. The fibre is therefore finite, as we sought to show.

The dimension count says “finitely many”. The classical refinement, that a *smooth* cubic surface contains exactly 27 lines, needs more than dimension theory: one exhibits the 27 on a single smooth cubic and then shows the number is constant across the smooth locus of the family. On the Fermat cubic $\mathcal{Z}(x_0^3 + x_1^3 + x_2^3 + x_3^3)$, in characteristic zero, they are the lines

$$x_0 = \alpha x_1, \quad x_2 = \beta x_3 \qquad \alpha^3 = \beta^3 = -1$$

together with the images of these nine under the two other ways of splitting $\{x_0, x_1, x_2, x_3\}$ into pairs, giving $3 \times 9 = 27$. The count is due to Cayley and Salmon in 1849; a full treatment is in Shafarevich or in Hartshorne’s chapter on surfaces.

41.4.4 Note: Where the Numbers Come From The two numbers in the proof are worth keeping straight. The 19 is $\binom{6}{3} - 1$: cubic forms in four variables, up to scalar. The 15 is $19 - 4$, where the 4 counts the coefficients of a binary cubic, that is the number of conditions imposed by requiring a cubic to vanish on a fixed line. The coincidence $\dim I = \dim \mathbb{P}^{19}$ is exactly what makes the answer finite and nonzero. Had the incidence variety been larger, every cubic would carry infinitely many lines; had it been smaller, the general cubic would carry none, which is what happens for surfaces of degree 4 and above.

41.5 Degree, Linear Sections, and Bézout in $\mathbb{P}^n$

Definition 38.5.3 defined the degree of a projective variety as $d!$ times the leading coefficient of its Hilbert polynomial. That is a definition one can compute with and not one that says anything geometric. This section supplies the geometry: the degree counts points, and degrees multiply under intersection. Both statements need theorem 40.6.3 to know that the intersections in question are nonempty and of the right size.

Theorem 41.5.1: Degree Counts Points of a Linear Section

Let $X \subseteq \mathbb{P}^n_k$ be a projective variety of dimension r and degree d. Then for a general linear subspace $L \subseteq \mathbb{P}^n_k$ of dimension $n - r$, the intersection $X \cap L$ is a finite set of exactly d points.

***Proof*:**
The intersection is finite and nonempty. By theorem 40.6.3 every component of $X \cap L$ has dimension at least $r + (n-r) - n = 0$, and the intersection is nonempty. For a general L the dimension is exactly 0: choosing L as an intersection of r hyperplanes, each successive hyperplane may be chosen to contain no component of what remains, since a component is a proper closed subset of $\mathbb{P}^n_k$ and the hyperplanes containing a fixed subvariety form a proper linear subspace of the dual space. Each such cut drops the dimension by exactly one by theorem 34.4.1, so after r cuts the dimension is 0 and the set is finite.

The count. Write $S = S(X)$ for the homogeneous coordinate ring and let $\ell_1, \ldots, \ell_r$ be the linear forms cutting out L. Since no ℓ_i vanishes on a component of the successive intersections, each ℓ_i is a nonzerodivisor on the successive quotients, so

$$H_{X\cap L}(m) = \dim_k \left(S/(\ell_1, \ldots, \ell_r)\right)_m$$

and each quotient by a nonzerodivisor of degree 1 takes the mth graded piece to the difference of the mth and $(m-1)$st. Iterating r times, the Hilbert polynomial of $X \cap L$ is the rth finite difference of h_X. As h_X has degree r with leading coefficient $d/r!$, its rth finite difference is the constant d.

Finally $X \cap L$ is a finite set of points, and the Hilbert polynomial of a finite set of N distinct points in $\mathbb{P}^n_k$ is the constant N: the restriction map from forms of degree m to functions on the points is surjective for m large, by choosing forms separating the points. Hence $N = d$, as we sought to show.

So the degree of a plane curve is the number of points in which a general line meets it, the degree of the twisted cubic is the number of points in which a general plane meets it, which example 38.5.4(4) computed as 3, and the degree of $\mathbb{P}^r$ itself is 1, a general linear space of complementary dimension meeting it once.

The same bookkeeping gives the general form of Bézout's theorem. Stated for hypersurfaces it is a count of degrees; the plane-curve case of chapter 43 is the case $n = 2$, refined there to include local multiplicities.

Theorem 41.5.2: Bézout's Theorem in $\mathbb{P}^n$

Let $F_1, \ldots, F_r$ be forms in $k[x_0, \ldots, x_n]$ of degrees $d_1, \ldots, d_r$ with $r \le n$, and suppose $X = \mathcal{Z}(F_1, \ldots, F_r)$ has dimension exactly $n - r$, the smallest its dimension can be. Then X has degree

$$\deg X = d_1 d_2 \cdots d_r$$

counting components with multiplicity.

***Proof*:**
Induct on r. For $r = 1$, the computation of example 38.5.4(2) gives $H_X(m) = \binom{m+n}{n} - \binom{m-d_1+n}{n}$, whose leading term is $d_1 m^{n-1}/(n-1)!$, so $\deg X = d_1$: the degree of a hypersurface is the degree of its equation.

For the inductive step, let $X' = \mathcal{Z}(F_1, \ldots, F_{r-1})$, of dimension $n - r + 1$ by the hypothesis that each cut is proper, and of degree $d_1 \cdots d_{r-1}$ by induction. Cutting X' by F_r drops the dimension by exactly one, so F_r vanishes on no component of X' and is therefore a nonzerodivisor on

$S(X')$. Multiplication by F_r is then injective and raises degree by d_r, giving the exact sequence of graded pieces

$$0 \to S(X')_{m-d_r} \to S(X')_m \to S(X)_m \to 0$$

so $h_X(m) = h_{X'}(m) - h_{X'}(m - d_r)$. Write $N = n - r + 1$ and $h_{X'}(m) = \frac{e}{N!}m^N + \cdots$ with $e = \deg X'$. Since $m^N - (m - d_r)^N = N d_r m^{N-1} + \cdots$, the difference has degree $N - 1 = n - r$ with leading coefficient

$$\frac{e}{N!} \cdot N d_r \;=\; \frac{e\, d_r}{(N-1)!} \;=\; \frac{e\, d_r}{(n-r)!}$$

By definition 38.5.3 the degree of X is $(n - r)!$ times that leading coefficient, namely $e\, d_r = d_1 \cdots d_r$, as we sought to show.

Example 41.5.3: Degrees of Intersections

1. *Two quadric surfaces in* $\mathbb{P}^3_k$. Each has degree 2, and if their intersection is a curve then theorem 41.5.2 gives it degree 4. A general such curve is the elliptic quartic; it is not a plane curve, since a plane curve of degree 4 has genus 3 by definition 44.4.1 while this one has genus 1.

2. *The twisted cubic is not a complete intersection.* It has degree 3 and codimension 2 in $\mathbb{P}^3_k$. Were it $\mathcal{Z}(F_1, F_2)$ with $\deg F_i = d_i$, theorem 41.5.2 would force $d_1 d_2 = 3$, so $\{d_1, d_2\} = \{1, 3\}$ and the curve would lie in the plane $\mathcal{Z}(F_1)$. It does not: its parameterization $[s^3 : s^2t : st^2 : t^3]$ spans $\mathbb{P}^3_k$, since the four coordinate functions are linearly independent. This is the promise made in example 38.3.7.

3. *A line and a plane in* $\mathbb{P}^3_k$. Degrees 1 and 1, dimensions 1 and 2, so the intersection has dimension 0 and degree 1: exactly one point, which is the familiar statement that a line not contained in a plane meets it once.

41.6 Cones, Projections, and Secant Varieties

The embeddings of the previous sections all enlarge the ambient space. This one goes the other way: given a variety in $\mathbb{P}^N_k$, project it into a smaller projective space and ask when nothing is lost. The construction has already been used twice without being set up — to identify a conic with $\mathbb{P}^1_k$ in theorem 44.4.2, and to exhibit a finite map in section 40.3 — and the obstruction to it is a variety worth naming in its own right.

Definition 41.6.1: Cone and Join

Let $X, Y \subseteq \mathbb{P}^N_k$ be disjoint projective varieties. The *join* $J(X, Y)$ is the closure of the union of the lines $\overline{xy}$ for $x \in X$ and $y \in Y$. When $Y = \{p\}$ is a single point, $J(X, p)$ is the *cone* over X with vertex p.

Definition 41.6.2: Projection from a Point

Let $p \in \mathbb{P}^N_k$ and let $H \cong \mathbb{P}^{N-1}_k$ be a hyperplane not containing p. The *projection from* p is

$$\pi_p \colon \mathbb{P}^N_k \setminus \{p\} \to H \qquad q \mapsto \overline{pq} \cap H$$

In coordinates with $p = [0 : \cdots : 0 : 1]$ and $H = \mathcal{Z}(x_N)$, it is $[x_0 : \cdots : x_N] \mapsto [x_0 : \cdots : x_{N-1}]$, visibly regular away from p.

Proposition 41.6.3: Projection Is a Finite Morphism

Let $X \subseteq \mathbb{P}^N_k$ be a projective variety and $p \notin X$. Then π_p restricts to a morphism $X \to \mathbb{P}^{N-1}_k$ whose image is closed of the same dimension as X, and whose fibres are finite.

***Proof*:**
Since $p \notin X$, the map π_p is defined at every point of X, and it is regular there by definition 41.6.2. Its image is closed by corollary 40.2.3, X being projective.

The fibre over a point h is $X \cap \overline{ph}$, the intersection of X with a line through p. That line is not contained in X, since $p \notin X$, so the intersection is a proper closed subset of the line and hence finite. Finiteness of the fibres forces $\dim \pi_p(X) = \dim X$ by theorem 40.5.1(3), whose generic fibre dimension is then 0, as we sought to show.

Projection is injective on X exactly when no line through p meets X twice, and it is an immersion when in addition no tangent line to X passes through p. Both conditions say that p avoids a certain subvariety, and naming those subvarieties is what makes the argument work.

Definition 41.6.4: Secant and Tangent Varieties

Let $X \subseteq \mathbb{P}^N_k$ be a projective variety. The *secant variety* $\operatorname{Sec}(X)$ is the closure of the union of the lines $\overline{xy}$ over pairs of distinct points $x, y \in X$. The *tangent variety* $\operatorname{Tan}(X)$ is the closure of the union of the embedded tangent spaces $T_xX \cong \mathbb{P}^r_k$ over the nonsingular points x of X, where $r = \dim X$.

Proposition 41.6.5: Dimension of the Secant Variety

Let $X \subseteq \mathbb{P}^N_k$ be a projective variety of dimension r. Then

$$\dim \operatorname{Sec}(X) \le 2r + 1 \qquad \dim \operatorname{Tan}(X) \le 2r$$

***Proof*:**
Consider the incidence variety

$$I = \overline{\{(x, y, z) \mid x \neq y \in X,\ z \in \overline{xy}\}} \ \subseteq\ X \times X \times \mathbb{P}^N_k$$

Projecting to $X \times X$ has fibre the line $\overline{xy}$, of dimension 1, over the open set where $x \neq y$. So $\dim I \le \dim(X \times X) + 1 = 2r + 1$ by corollary 40.5.4 and theorem 40.5.1. Now $\operatorname{Sec}(X)$ is the image of I under the third projection, and the image of a projective variety is closed of dimension at most that of the source, by corollary 40.2.3 and theorem 40.5.1(1). Hence $\dim \mathrm{Sec}(X) \leq 2r+1$.

For $\mathrm{Tan}(X)$ run the same argument over X alone. The incidence $\{(x,z) \mid x \in X \text{ nonsingular},\ z \in T_xX\}$ projects to the smooth locus of X, of dimension r, with fibre the embedded tangent space T_xX, of dimension r. So it has dimension at most $2r$, and $\mathrm{Tan}(X)$, being its image, has dimension at most $2r$, as we sought to show.

The bound is what makes projection useful: as soon as the ambient space is large enough, a point can be chosen outside the secant variety, and projecting from it loses nothing.

Theorem 41.6.6: Every Projective Variety Embeds in $\mathbb{P}^{2r+1}$

Let $X \subseteq \mathbb{P}^N_k$ be a projective variety of dimension r. If $N > 2r+1$, then there is a point $p \notin \mathrm{Sec}(X)$, and π_p maps X isomorphically onto its image in $\mathbb{P}^{N-1}_k$. Iterating, X is isomorphic to a projective variety in $\mathbb{P}^{2r+1}_k$.

***Proof*:**
By proposition 41.6.5, $\dim \mathrm{Sec}(X) \leq 2r+1 < N$, so $\mathrm{Sec}(X)$ is a proper closed subset of $\mathbb{P}^N_k$ and a point p outside it exists. Note $X \subseteq \mathrm{Sec}(X)$ whenever $\dim X \geq 1$, so $p \notin X$ and proposition 41.6.3 applies.

π_p is injective on X: if $\pi_p(x) = \pi_p(y)$ with $x \neq y$ then p lies on the line $\overline{xy}$, hence in $\mathrm{Sec}(X)$, contrary to choice. It is also an immersion: a tangent line to X is a limit of secant lines, so $\mathrm{Tan}(X) \subseteq \mathrm{Sec}(X)$ and no tangent line to X passes through p either. An injective morphism of projective varieties that is an immersion is an isomorphism onto its closed image.

Repeating drops the ambient dimension by one each time and stops at $N = 2r+1$, as we sought to show.

Example 41.6.7: Projections in Practice

1. *A curve in* $\mathbb{P}^3_k$. Here $r = 1$, so $2r+1 = 3$ and theorem 41.6.6 says every projective curve embeds in $\mathbb{P}^3_k$. It does not say $\mathbb{P}^2_k$: projecting once more from a point of $\mathrm{Sec}(X)$ is unavoidable when $N = 3$, and the image acquires singularities. That is why plane curves are special and why chapter 42 must handle singular ones.

2. *The twisted cubic.* Its secant variety is all of $\mathbb{P}^3_k$, since $\dim \mathrm{Sec} \leq 3$ and the secant lines already sweep out a three-dimensional set. So no projection to $\mathbb{P}^2_k$ is an isomorphism, consistent with the twisted cubic being a rational curve of degree 3 while every plane cubic has genus 1.

3. *A conic.* Projection from a point of the conic itself, rather than from outside it, is the map of theorem 44.4.2: a line through p meets the conic once more, so the projection is a bijection to $\mathbb{P}^1_k$. This is the degenerate case $p \in X$, excluded from proposition 41.6.3, and it lowers the dimension of the image rather than preserving it.

Exercise 41.6.1

1. Write out the Veronese embedding $\mathbb{P}^1_k \to \mathbb{P}^2_k$ for $d = 2$ and identify its image. Then do $d = 3$ and show the image is the twisted cubic of example 38.3.7.
2. Compute $N = \binom{n+d}{d} - 1$ for $(n, d) = (2, 2)$ and describe the Veronese surface in $\mathbb{P}^5_k$. Show that it contains no lines, although it is covered by conics.
3. Verify corollary 41.1.3 explicitly for $n = 1$, $d = 2$: exhibit the hyperplane of $\mathbb{P}^2_k$ cutting out a prescribed pair of points of $\mathbb{P}^1_k$.
4. Take the 2-plane in k^4 spanned by $(1, 0, a, b)$ and $(0, 1, c, d)$. Compute its six Plücker coordinates and verify the relation $p_{01}p_{23} - p_{02}p_{13} + p_{03}p_{12} = 0$ directly.
5. Show that $G(1, n) \cong \mathbb{P}^{n-1}_k$ and that $G(n-1, n) \cong \mathbb{P}^{n-1}_k$, and check both against the dimension formula of theorem 41.2.4.
6. Show that a subset of $\mathbb{A}^1_k$ is constructible if and only if it is finite or cofinite. Deduce that every constructible subset of $\mathbb{A}^1_k$ is either open or closed, so the phenomenon of example 41.3.5 needs at least two dimensions.
7. Give a dominating regular map whose image is not open, and one whose image is not closed. Explain how theorem 41.3.4 accommodates both.
8. Repeat the dimension count of section 41.4 for surfaces of degree e in $\mathbb{P}^3_k$: show that the incidence variety has dimension $\binom{e+3}{3} - 1 + 3 - e$ and conclude that a general surface of degree $e \geq 4$ contains no line, while every quadric contains a one-parameter family.

Part IX

Curves

The fundamental theorem of algebra counts the roots of a polynomial in one variable, and does so exactly because $\mathbb{C}$ is algebraically closed. This Part asks for the two-variable analogue: given two plane curves, how many points do they share? Over $\mathbb{A}^2$ the question has no clean answer, since curves can miss each other or meet at infinity. In $\mathbb{P}^2$ it does, and the answer, Bézout's theorem, is that two curves of degrees m and n meet in exactly mn points.

Making that exact requires deciding what a point of intersection is worth, which is the intersection number of chapter 42. The counting then organizes itself into a group, the divisor class group of chapter 44, whose appearance on a cubic curve is the classical group law. The Part closes by removing the singularities that made the counting delicate in the first place.

42

Intersection Multiplicity

Two curves meeting at a point may cross transversally, be tangent, or meet at a singularity of one or both. Any count of intersections that is to be well behaved must weigh these cases differently. This chapter constructs the weight.

The route runs through the local ring at the point. The multiplicity of a curve at a point turns out to be readable off that ring alone, and at a nonsingular point the ring is a discrete valuation ring, so it carries an order function that already sees tangency. The intersection number of two curves is then the dimension of a single quotient of the local ring of the plane, and it is pinned down by eight properties which double as an algorithm for computing it.

42.1 Plane Curves, Multiplicity, and Tangent Lines

The fundamental theorem of algebra counts the roots of a one-variable polynomial over an algebraically closed field, and it can be read geometrically: a curve of degree n meets the line $x = 0$ in n points, provided the points are weighted correctly. This Part generalizes that reading to two curves, and the weight is what this chapter constructs.

Affine space is the wrong home for the statement. Take the two concentric circles $x^2 + y^2 - 1$ and $x^2 + y^2 - 4$ in $\mathbb{A}^2_{\mathbb{C}}$: both have degree 2, so the count should be 4, and yet they share no point at all. Passing to $\mathbb{P}^2_{\mathbb{C}}$ repairs it. The homogenizations $x^2 + y^2 - z^2$ and $x^2 + y^2 - 4z^2$ meet where $z = 0$ and $x^2 + y^2 = 0$, which is the pair of *circular points* $[1 : \pm i : 0]$ already met in example 38.3.4. Two points, not four, so the weights must be 2 each, and indeed the two circles are tangent to each other at both. The rest of this chapter builds the notion of weight that makes such counts come out, and chapter 43 proves they always do.

The development follows Fulton [54]. Throughout, k is algebraically closed.

A plane curve in the sense of this Part is not quite a variety. The point of the intersection theory is to count with multiplicity, and multiplicity is information that $\mathcal{Z}(f)$ throws away: $\mathcal{Z}(f)$ and $\mathcal{Z}(f^2)$ are the same set. So the object of study is the polynomial, taken up to scalar.

Definition 42.1.1: Plane Curve

An *affine plane curve* is an equivalence class of nonconstant polynomials in $k[x, y]$, where $f \sim g$ if and only if $f = \alpha g$ for some $\alpha \in k^*$. A *projective plane curve* is the same with $k[x, y]$ replaced by the nonconstant homogeneous polynomials of $k[x, y, z]$. The *degree* of a curve is the degree of any of its representatives.

This is a deliberate departure from definition 34.3.4, where a curve was a one-dimensional variety. The two agree on the underlying point set, since $\mathcal{Z}(f)$ for $f \in k[x, y]$ nonconstant is a hypersurface in $\mathbb{A}^2_k$ and so has dimension 1 by theorem 34.4.2; they differ in that the present notion remembers repeated factors. Homogenizing an affine plane curve and taking the closure in $\mathbb{P}^2_k$ gives a projective plane curve, as in section 38.3, and the two constructions are inverse away from the line at infinity.

Write $f = \prod_{i=1}^n f_i^{e_i}$ for the factorization into distinct irreducible factors, which is available because $k[x, y]$ and $k[x, y, z]$ are unique factorization domains. The curve f is *irreducible* if $n = 1$ and $e_1 = 1$; the component f_i is *simple* if $e_i = 1$ and *multiple* otherwise[1].

The local ring at a point is the algebraic object that stores intersection data, and it was already constructed in chapter 32.

Example 42.1.2: Curves Versus Their Zero Sets

1. Let $f = y - x^2$ and $g = (y - x^2)^2$. Then $\mathcal{Z}(f) = \mathcal{Z}(g)$ as subsets of $\mathbb{A}^2_k$, both being the parabola, yet f and g are different plane curves in the sense of definition 42.1.1: one has degree 2 and the other degree 4. Everything this Part counts distinguishes them. A general line meets $\mathcal{Z}(f)$ in 2 points and $\mathcal{Z}(g)$ in 4, once multiplicity is accounted for, which is what theorem 43.1.1 will record.

2. The multiplicity at a point behaves the same way. At the origin, $f = y - x^2$ has lowest form y, so $m_0(f) = 1$ and the origin is a nonsingular point; while $g = (y - x^2)^2$ has lowest form y^2, so $m_0(g) = 2$. The zero set is nonsingular as a set and the curve g is not.

3. *Irreducible components with multiplicity.* The curve $h = x^2 y = x \cdot x \cdot y$ has $\mathcal{Z}(h) = \mathcal{Z}(xy)$, the union of the two axes, but as a curve h has the y-axis as a *double* component and the x-axis as a simple one. The factorization $h = \prod f_i^{e_i}$ records $e = (2, 1)$, and proposition 42.1.7 will read $m_0(h) = 2 \cdot 1 + 1 \cdot 1 = 3$ off it.

Keeping the polynomial rather than its zero set is exactly what lets these distinctions be made, and it is the reason chapter 49 points at schemes, where the same information is carried intrinsically.

[1] In [5] schemes recover this information intrinsically: the scheme $\operatorname{Spec} k[x, y]/(f^2)$ is not the scheme $\operatorname{Spec} k[x, y]/(f)$, even though the two have the same points. Working with polynomials up to scalar is the classical workaround.

Definition 42.1.3: Recall: Stalk At A Point

Let V be a variety and $p \in V$ a point. The *stalk* at p is

$$\mathcal{O}_p(V) = \{f/g \in k(V) \mid g(p) \neq 0\}$$

By proposition 33.2.10 it is a Noetherian local domain, with maximal ideal $\mathfrak{m}_p(V) = \{f/g \in \mathcal{O}_p(V) \mid f(p) = 0\}$.

The intuition is that $\mathcal{O}_p(V)$ holds exactly the rational functions defined at p, which is why a denominator is allowed as long as it does not vanish there. For a curve f, write $\mathcal{O}_p(f)$ for the stalk of $\mathcal{Z}(f)$, and $\mathfrak{m}_p(f)$ for its maximal ideal.

Almost every computation below is easier at the origin, and moving a point there costs nothing.

Definition 42.1.4: Linear Coordinate Change

Let $\mathbb{A}^n_k$ be affine space with coordinate ring $k[x_1, \ldots, x_n]$. A bijective affine transformation $T \colon \mathbb{A}^n_k \to \mathbb{A}^n_k$ is called a *linear change of coordinates.*

If $T = (T_1, \ldots, T_n)$ then T acts on functions by $f(x_1, \ldots, x_n) \mapsto f(T_1, \ldots, T_n)$, and any such T decomposes into a translation followed by a bijective linear transformation. The first invariant to define this way is the multiplicity, obtained by translating the point of interest to the origin and reading off the lowest-degree term.

Definition 42.1.5: Multiplicity

Let $f \in k[x, y]$ be an affine plane curve and $p \in \mathcal{Z}(f)$. After a translation taking p to the origin, write

$$f = f_m + f_{m+1} + \cdots + f_d$$

for the decomposition into homogeneous components, where $f_m \neq 0$. The *multiplicity* of f at p, written $m_p(f)$, is m.

The definition does not depend on the translation chosen, since a translation carrying the origin to itself is the identity, and $m_p(f) \geq 1$ exactly because $f(p) = 0$. The multiplicity measures how badly the curve degenerates at p: it is 1 precisely when p is a nonsingular point of f in the sense of chapter 35, because f_1 is the differential of f at the origin and $f_1 \neq 0$ is the condition that some partial derivative survive.

The lowest form f_m carries more than its degree. Over an algebraically closed field a nonzero binary form factors completely into linear factors, so

$$f_m = \prod_{i=1}^{s} L_i^{r_i} \qquad \sum_i r_i = m$$

with the L_i pairwise non-proportional linear forms.

Definition 42.1.6: Tangent Lines of a Plane Curve

With notation as above, the lines $\mathcal{Z}(L_i)$ are the *tangent lines* to f at p, and r_i is the multiplicity of $\mathcal{Z}(L_i)$ as a tangent. A line through p that is not one of the $\mathcal{Z}(L_i)$ is assigned tangent multiplicity 0. The form f_m itself is the *tangent cone*.
The point p is an *ordinary multiple point* if f has $m = m_p(f)$ distinct tangent lines there, that is if every $r_i = 1$. An ordinary double point is a *node*.

This is the plane-curve case of definition 36.1.2: the initial form f_m generates the initial ideal of (f), so the tangent cone algebra is $k[x, y]/(f_m)$ and its zero set is the union of the tangent lines, while $m_p(f)$ agrees with the multiplicity of definition 36.1.4 by proposition 36.1.5. What the plane case adds is the factorization: a binary form splits into linear factors over the algebraically closed k, so the cone is literally a union of lines counted with multiplicity, which is false for a cone in three or more variables.

At a nonsingular point $m = 1$, so there is a single tangent line $\mathcal{Z}(f_1)$, and f_1 is the linear part of f. That recovers the familiar formula: for $p = (a, b)$ a nonsingular point of f, the tangent line is

$$\frac{\partial f}{\partial x}(p)\,(x - a) + \frac{\partial f}{\partial y}(p)\,(y - b) = 0$$

which is the definition of chapter 35 specialized to a plane curve. For a projective plane curve $F \in k[x, y, z]$ the point p is nonsingular when the three partials $\partial_x F, \partial_y F, \partial_z F$ do not all vanish at p, and the tangent line is then $\mathcal{Z}\big(\sum_i \partial_i F(p)\, x_i\big)$; passing to an affine chart recovers the two-variable statement.

Multiplicities and tangents both behave multiplicatively across the factorization of f.

Proposition 42.1.7: Multiplicity Across Components

Let $f = \prod_i f_i^{e_i}$ be an affine plane curve, factored into distinct irreducibles, and let $p \in \mathcal{Z}(f)$. Then

$$m_p(f) = \sum_i e_i\, m_p(f_i)$$

and a line L tangent to f_i with multiplicity r_i is tangent to f with multiplicity $\sum_i e_i r_i$. Consequently p is a nonsingular point of f if and only if it lies on exactly one f_i, that component is simple, and p is a nonsingular point of it.

***Proof*:**
Translate p to the origin. In the graded domain $k[x, y]$ the lowest form of a product is the product of the lowest forms, so the lowest form of f is $\prod_i (f_i)_{m_i}^{e_i}$ where $m_i = m_p(f_i)$; taking degrees gives the first claim, and reading off the linear factors gives the second.

For the last claim, $m_p(f) = 1$ forces exactly one term of $\sum_i e_i m_p(f_i)$ to be nonzero and equal to 1, so exactly one f_i passes through p, its exponent e_i is 1, and $m_p(f_i) = 1$. The converse is the same computation read backwards, as we sought to show.

42.2 Local Rings of Plane Curves

The multiplicity was defined by writing down a polynomial and looking at its lowest term, which is a coordinate-dependent recipe even if the answer is not. This section shows that $m_p(f)$ is visible inside the local ring $\mathcal{O}_p(f)$ alone, and that the nonsingular points are exactly those where that ring is as simple as a one-dimensional local ring can be.

Theorem 42.2.1: Multiplicity and Local Ring

Let f be an irreducible affine plane curve and $p \in \mathcal{Z}(f)$. Write $\mathcal{O} = \mathcal{O}_p(f)$ and $\mathfrak{m}$ for its maximal ideal. Then for all sufficiently large n,

$$m_p(f) = \dim_k \left(\frac{\mathfrak{m}^n}{\mathfrak{m}^{n+1}} \right)$$

so the multiplicity of f at p is determined by the local ring $\mathcal{O}_p(f)$.

***Proof*:**
The quotient maps $\mathcal{O}/\mathfrak{m}^{n+1} \to \mathcal{O}/\mathfrak{m}^n$ have kernel $\mathfrak{m}^n/\mathfrak{m}^{n+1}$, giving a short exact sequence of k-vector spaces

$$0 \to \mathfrak{m}^n/\mathfrak{m}^{n+1} \to \mathcal{O}/\mathfrak{m}^{n+1} \to \mathcal{O}/\mathfrak{m}^n \to 0$$

Dimension is additive along a short exact sequence of finite-dimensional vector spaces, so it suffices to prove

$$\dim_k (\mathcal{O}/\mathfrak{m}^n) = n\, m_p(f) + s$$

for a constant s independent of n and all $n \geq m_p(f)$; subtracting consecutive values then leaves $m_p(f)$.

Translate so that $p = (0,0)$ and write $I = (x, y) \subseteq k[x, y]$, so that $\mathcal{I}(\{p\}) = I$. Since $\mathcal{Z}(I^n) = \{p\}$, corollary 42.2.7 and the third exercise of exercise set 42.4.1 give

$$\frac{k[x,y]}{(I^n, f)} \cong \frac{\mathcal{O}_p(\mathbb{A}^2_k)}{(I^n, f)\mathcal{O}_p(\mathbb{A}^2_k)} \cong \frac{\mathcal{O}_p(f)}{I^n\mathcal{O}_p(f)} \cong \mathcal{O}/\mathfrak{m}^n$$

the last isomorphism because $\mathfrak{m}$ is generated by the images of x and y. So the problem is to compute $\dim_k k[x, y]/(I^n, f)$.

Let $m = m_p(f)$. Multiplication by f gives a map

$$\psi\colon \frac{k[x,y]}{I^{n-m}} \to \frac{k[x,y]}{I^n} \qquad \psi(\overline{g}) = \overline{fg}$$

which is well defined because $f \in I^m$, and injective: $k[x, y]$ is a graded domain, so the lowest form of fg is the product of those of f and g, whence $fg \in I^n$ forces $g \in I^{n-m}$. Its image is $(I^n, f)/I^n$, the kernel of the projection $\varphi\colon k[x, y]/I^n \to k[x, y]/(I^n, f)$, so

$$0 \to \frac{k[x,y]}{I^{n-m}} \xrightarrow{\psi} \frac{k[x,y]}{I^n} \xrightarrow{\varphi} \frac{k[x,y]}{(I^n, f)} \to 0$$

is exact. Now $k[x, y]/I^t$ has as a basis the monomials of degree less than t, of which there are $1 + 2 + \cdots + t = \frac{t(t+1)}{2}$, as the second exercise of exercise set 42.4.1 records. Additivity therefore gives

$$\dim_k (\mathcal{O}/\mathfrak{m}^n) = \frac{n(n+1)}{2} - \frac{(n-m)(n-m+1)}{2} = nm - \frac{m(m-1)}{2}$$

valid for all $n \geq m$. This has the required shape with $s = -\frac{m(m-1)}{2}$, a constant, as we sought to show.

Example 42.2.2: Multiplicity from the Local Ring

Take p the origin and compute $\dim_k \mathfrak{m}^n/\mathfrak{m}^{n+1}$ in each case, which theorem 42.2.1 says stabilizes at $m_p(f)$.

1. *A nonsingular point.* $f = y - x^2$. Here $\mathcal{O}_p(f) \cong k[x]_{(x)}$, since $y = x^2$ on the curve, and $\mathfrak{m} = (x)$. So $\mathfrak{m}^n/\mathfrak{m}^{n+1}$ is spanned by x^n alone and has dimension 1 for every n. That matches $m_p(f) = 1$.
2. *The node.* $f = y^2 - x^2 - x^3$, with $m_p(f) = 2$. The formula of the proof gives $\dim_k \mathcal{O}/\mathfrak{m}^n = 2n - \binom{2}{2} = 2n - 1$ for $n \geq 2$, so $\dim_k \mathfrak{m}^n/\mathfrak{m}^{n+1} = (2n+1) - (2n-1) = 2$ for $n \geq 2$, matching $m_p(f) = 2$.
3. *The cusp.* $f = y^2 - x^3$, again with $m_p(f) = 2$ since the lowest form is y^2. The same computation gives 2 again.

The node and the cusp have the same multiplicity and the same sequence of dimensions, so the local ring sees the multiplicity and not the tangent cone. What separates them is the number of tangent lines, which is definition 42.1.6, or equivalently the number of branches, which example 47.3.3 separates by blowing up.

The theorem already separates the nonsingular points from the rest, since they are the ones where the successive quotients have dimension 1. The next result says what that means ring-theoretically.

Corollary 42.2.3: Simple Points and Multiplicity

Let f be an irreducible affine plane curve and $p \in \mathcal{Z}(f)$. Then p is a nonsingular point of f if and only if $\mathcal{O}_p(f)$ is a discrete valuation ring. In that case, if L is a line through p that is not tangent to f at p, the image of its defining linear form generates $\mathfrak{m}_p(f)$.

***Proof*:**

Suppose p is nonsingular and L is a line through p that is not tangent there. Change coordinates so that $p = (0,0)$, the tangent line is $\mathcal{Z}(y)$, and $L = \mathcal{Z}(x)$. It suffices to show that $\mathfrak{m} = \mathfrak{m}_p(f)$ is generated by the image of x, since $\mathfrak{m}$ is generated by the images of x and y.

Because $\mathcal{Z}(y)$ is the tangent line, the lowest form of f is a nonzero multiple of y, and after scaling f we may take $f = y + (\text{terms of degree} \geq 2)$. Collect the terms containing y: what remains involves x alone and has degree at least 2, since the only degree-one term of f is y. Hence

$$f = yg - x^2h \qquad g = 1 + (\text{terms of positive degree}), \quad h \in k[x,y]$$

In $k[\mathcal{Z}(f)]$ this reads $yg = x^2h$, and $g(p) = 1 \neq 0$ makes g a unit in $\mathcal{O}_p(f)$, so

$$y = x^2hg^{-1} \in (x)$$

Therefore $\mathfrak{m} = (x)$ is principal. By proposition 33.2.10 the ring $\mathcal{O}_p(f)$ is a Noetherian local domain, and it has Krull dimension 1 by proposition 34.3.2, since $\mathcal{Z}(f)$ is a curve and $\{p\}$ has codimension 1 in it. So proposition 35.5.2 applies, and its implication (4) $\Rightarrow$ (2) makes $\mathcal{O}_p(f)$ a discrete valuation ring.

Conversely, if $\mathcal{O}_p(f)$ is a discrete valuation ring then $\mathfrak{m}/\mathfrak{m}^2$ is one-dimensional, generated by the image of a uniformizer, and the same holds for every $\mathfrak{m}^n/\mathfrak{m}^{n+1}$. By theorem 42.2.1 this common dimension is $m_p(f)$, so $m_p(f) = 1$ and p is nonsingular, completing the proof.

Now that $\mathcal{O}_p(f)$ is known to be a discrete valuation ring at a nonsingular point, its valuation can be named. This is the invariant that chapter 43 uses to read off intersection numbers.

Definition 42.2.4: Order Function at a Simple Point

Let f be an irreducible plane curve and p a nonsingular point of f, so that $\mathcal{O}_p(f)$ is a discrete valuation ring by corollary 42.2.3. The *order function* at p

$$\operatorname{ord}_p^f \colon \mathcal{O}_p(f) \setminus \{0\} \to \mathbb{N}$$

is the discrete valuation of $\mathcal{O}_p(f)$: writing t for a uniformizing parameter, $\operatorname{ord}_p^f(g)$ is the unique m with $g = ut^m$ for a unit $u \in \mathcal{O}_p(f)$. By convention $\operatorname{ord}_p^f(0) = \infty$. The definition extends to $k(f)$ by $\operatorname{ord}_p^f(g/h) = \operatorname{ord}_p^f(g) - \operatorname{ord}_p^f(h)$, taking values in $\mathbb{Z}$.

Geometrically $\operatorname{ord}_p^f(g)$ counts how many times g vanishes at p along f, and the computation just made says that the order function sees tangency. A line L meeting f transversally at p has $\operatorname{ord}_p^f(L) = 1$, because its linear form generates $\mathfrak{m}$. The tangent line has order at least 2: in the coordinates of the proof it is $\mathcal{Z}(y)$, and

$$\operatorname{ord}_p^f(y) = \operatorname{ord}_p^f(x^2hg^{-1}) = 2\operatorname{ord}_p^f(x) + \operatorname{ord}_p^f(hg^{-1}) \geq 2$$

since g^{-1} is a unit and $h \in \mathcal{O}_p(f)$.

The last ingredient of the chapter is a decomposition for the coordinate ring of a finite set of points. It says that such a ring sees each of its points separately, which is what will let a global intersection count be assembled from local ones.

Lemma 42.2.5: Coordinate Ring For Finite Points

Let $I \subseteq k[x_1, \ldots, x_n]$ be an ideal with $\mathcal{Z}(I) = \{p_1, \ldots, p_m\}$ finite, and write $\mathcal{O}_i = \mathcal{O}_{p_i}(\mathbb{A}_k^n)$. Then

$$\frac{k[x_1, \ldots, x_n]}{I} \cong \prod_{i=1}^{m} \frac{\mathcal{O}_i}{I\mathcal{O}_i}$$

and in particular the left side is a finite-dimensional k-vector space.

***Proof*:**
Put $R = k[x_1, \ldots, x_n]/I$. Its maximal ideals correspond by the Nullstellensatz (theorem 32.4.4) to the points of $\mathcal{Z}(I)$, so there are m of them and every prime of R is maximal, that is $\operatorname{kdim} R = 0$. As R is a finitely generated k-algebra it is Noetherian, so corollary 28.1.9 makes R Artinian, and corollary 28.1.10 makes it finite-dimensional over k.

Now theorem 28.1.6 decomposes R as a finite product of local Artinian rings, one for each maximal ideal, the factors being the localizations $R_{\mathfrak{m}_i}$. It remains only to identify $R_{\mathfrak{m}_i}$ geometrically: localizing $k[x_1, \ldots, x_n]/I$ at the maximal ideal of p_i is the same as localizing $k[x_1, \ldots, x_n]$ there and then dividing by the extended ideal, since localization is exact, and that is $\mathcal{O}_i/I\mathcal{O}_i$, as we sought to show.

This is a case where the algebra was done once upstream and should not be done again. The classical proof constructs idempotents e_i by hand and verifies the Chinese-remainder decomposition directly; the Artinian structure theorem is that construction in general form, and the only genuinely geometric step is the Nullstellensatz translation at the start.

Corollary 42.2.6: Dimension of Coordinate Ring of Finite Points

With notation as above,

$$\dim_k \frac{k[x_1, \ldots, x_n]}{I} = \sum_{i=1}^{m} \dim_k (\mathcal{O}_i/I\mathcal{O}_i)$$

***Proof*:**
Dimension is additive over a finite direct product of vector spaces, so this is lemma 42.2.5 read on dimensions, completing the proof.

Corollary 42.2.7: Coordinate Ring at a Single Point

Let $I \subseteq k[x_1, \ldots, x_n]$ satisfy $\mathcal{Z}(I) = \{p\}$. Then

$$\frac{k[x_1, \ldots, x_n]}{I} \cong \frac{\mathcal{O}_p(\mathbb{A}_k^n)}{I\,\mathcal{O}_p(\mathbb{A}_k^n)}$$

***Proof*:**
This is lemma 42.2.5 with $m = 1$, completing the proof.

One further consequence of the local rings being discrete valuation rings deserves recording here, since chapter 45 needs it: on a smooth curve, a rational map to a projective variety has no points of indeterminacy at all.

Lemma 42.2.8: Rational Maps on Smooth Curves

Let C be an irreducible curve, $V \subseteq \mathbb{P}_k^N$ a *projective* variety, and $\varphi\colon C \dashrightarrow V$ a rational map. If $p \in C$ is a nonsingular point, then φ is regular at p. If C is smooth, then φ is a regular morphism.

***Proof*:**
Since p is a nonsingular point of the curve C, the local ring $\mathcal{O}_p(C)$ is a Noetherian local domain of Krull dimension 1 which is regular, hence a discrete valuation ring by proposition 35.5.2; write ord_p for its valuation and t for a uniformizer. Represent φ near p as $[f_0 : \cdots : f_N]$ with

$f_i \in k(C)$ not all zero, and set

$$e = \min_{0 \le i \le N} \operatorname{ord}_p(f_i)$$

Then $\operatorname{ord}_p(t^{-e} f_i) \ge 0$ for every i, so each $t^{-e} f_i$ lies in $\mathcal{O}_p(C)$ and is defined at p, while $\operatorname{ord}_p(t^{-e} f_j) = 0$ for the index j achieving the minimum, so $t^{-e} f_j(p) \neq 0$ and the tuple is not identically zero at p. Since

$$[t^{-e} f_0 : \cdots : t^{-e} f_N] = [f_0 : \cdots : f_N]$$

as maps to $\mathbb{P}^N_k$, this exhibits φ as regular at p. The image lands in V because V is closed and $\varphi(C)$ is dense in it. If every point of C is nonsingular the argument applies at each, so φ is regular everywhere, as we sought to show.

Projectivity of the target is essential: the rational map $\mathbb{A}^1_k \dashrightarrow \mathbb{A}^1_k$ given by $t \mapsto 1/t$ is undefined at the origin and stays undefined, whereas the same formula into $\mathbb{P}^1_k$ extends by sending 0 to the point at infinity.

42.3 The Intersection Number

Let $f, g \in k[x, y]$ be affine plane curves and $p \in \mathbb{A}^2_k$. The goal is a number $I(p, f \cap g)$ counting how many times the two curves meet at p. Several plausible definitions present themselves, and rather than choose one and hope, the strategy is to write down the properties such a number must have and show that they pin it down uniquely. The list below is Fulton's [54, section 3.3]; for a complementary treatment leaning on complex analysis and on the local picture introduced in chapter 25, see [1].

The list is deliberately not minimal. Computations rarely need its full strength, but proving that the intersection number satisfies all of it is what makes the number usable.

Say that f and g *intersect properly* at p if they have no common component passing through p. The properties are:

1. $I(p, f \cap g)$ is a non-negative integer whenever f and g intersect properly at p, and $I(p, f \cap g) = \infty$ otherwise.
2. $I(p, f \cap g) = 0$ if and only if $p \notin \mathcal{Z}(f) \cap \mathcal{Z}(g)$. In particular $I(p, f \cap g) = 0$ whenever f or g is a nonzero constant.
3. $I(p, f \cap g)$ depends only on the components of f and of g that pass through p.
4. $I(p, f \cap g) = I(p, g \cap f)$.
5. $I(p, f \cap g)$ is invariant under a linear change of coordinates: if T is one and $q = T^{-1}(p)$, then $I(q, f^T \cap g^T) = I(p, f \cap g)$.
6. $I(p, f \cap g) \ge m_p(f)\, m_p(g)$, with equality if and only if f and g have no tangent line in common at p. In particular two curves meeting transversally at a point nonsingular on both have intersection number 1.
7. If $f = \prod_i f_i^{r_i}$ and $g = \prod_j g_j^{s_j}$, then

$$I(p, f \cap g) = \sum_{i,j} r_i s_j\, I(p, f_i \cap g_j)$$

8. $I(p, f \cap g) = I(p, f \cap (g + hf))$ for every $h \in k[x, y]$.

Property (8) is the one that does the work: it says the intersection number sees the ideal (f, g) and not the particular generators, which is exactly the licence needed to run a Euclidean algorithm on the pair.

Theorem 42.3.1: Intersection Number

There is exactly one function $I(p, f \cap g)$ of a point and a pair of affine plane curves satisfying properties (1) through (8), namely

$$I(p, f \cap g) = \dim_k \left(\frac{\mathcal{O}_p(\mathbb{A}_k^2)}{(f, g)} \right)$$

***Proof*:**
Uniqueness. Suppose $I(p, f \cap g)$ satisfies the eight properties. The properties then determine its value, by an algorithm. By (1) it is enough to treat curves intersecting properly at p, and by (5) we may translate so that $p = (0, 0)$. If p does not lie on both curves, (2) gives the value 0, so assume $0 < I(p, f \cap g) < \infty$ and argue by strong induction: suppose the value is known whenever it is smaller than n, and let $I(p, f \cap g) = n$.

Consider the one-variable restrictions $f(x, 0)$ and $g(x, 0)$, of degrees r and s respectively, with the convention that the zero polynomial has degree $-\infty$. By (4) we may assume $r \leq s$.

1. *Case* $f(x, 0) \equiv 0$. Then $y \big| f$, say $f = yh$, and (7) gives

$$I(p, f \cap g) = I(p, y \cap g) + I(p, h \cap g)$$

   Write $g(x, 0) = x^\ell(a_0 + a_1 x + \cdots)$ with $a_0 \neq 0$; here $\ell > 0$ because $g(0, 0) = 0$. Since $g(x, y) - g(x, 0)$ vanishes on the line $y = 0$, it is divisible by y, so property (8) applied to the pair (y, g) replaces g by $g(x, 0)$ without changing the value. Then (7) splits off the factor $a_0 + a_1 x + \cdots$, which does not vanish at p and so contributes nothing by (2):

$$I(p, y \cap g) = I(p, y \cap g(x, 0)) = I(p, y \cap x^\ell) = \ell\, I(p, y \cap x) = \ell$$

   the last step by (6), the two lines meeting transversally. Since $\ell > 0$, the remaining term $I(p, h \cap g)$ is strictly less than n and the induction applies.

2. *Case* $r \geq 0$. Scale so that $f(x, 0)$ and $g(x, 0)$ are monic and put $h = g - x^{s-r} f$. The leading terms cancel, so $\deg h(x, 0) = t < s$, while (8) gives

$$I(p, f \cap g) = I(p, f \cap h)$$

   Repeat on the pair (f, h), interchanging the two by (4) whenever $t < r$. Each step replaces the degree pair (r, s) by (r, t) with $t < s$, so the sum of the two degrees strictly decreases. It cannot decrease forever, so after finitely many steps one of the two restrictions is identically zero and the previous case applies.

So the eight properties leave no freedom, and at most one such function exists.

Existence. It remains to check that $\dim_k \mathcal{O}/(f, g)$, where $\mathcal{O} = \mathcal{O}_p(\mathbb{A}_k^2)$, has the eight properties. Properties (4), (5) and (8) are immediate, since the quantity depends only on the ideal $(f, g)\mathcal{O}$, which is symmetric in f and g, unchanged by $g \mapsto g + hf$, and carried to the corresponding ideal by a linear change of coordinates. Property (3) holds because a component of f not passing through p is a unit in $\mathcal{O}$ and so contributes nothing to the ideal. Property (2) holds because $\mathcal{O}/(f, g)$ is the zero ring exactly when $(f, g)\mathcal{O} = \mathcal{O}$, that is when some f or g fails to vanish at p. Translating by (5), assume from now on that $p = (0, 0)$ and every component of f and g passes through p. What is left is (1), (6) and (7).

Property (1). If f and g have no common component then $\mathcal{Z}(f, g)$ is finite, so corollary 42.2.6 makes $\dim_k \mathcal{O}/(f, g)$ finite. If instead h is a common component, then $(f, g) \subseteq (h)$ and there is a surjection

$$\frac{\mathcal{O}}{(f, g)} \twoheadrightarrow \frac{\mathcal{O}}{(h)}$$

Now $\mathcal{O}/(h) \cong \mathcal{O}_p(\mathcal{Z}(h))$ contains $k[\mathcal{Z}(h)]$, which is infinite-dimensional over k because $\mathcal{Z}(h)$ is a curve. So the left side is infinite-dimensional too.

Property (7). By induction and symmetry it is enough to prove

$$I(p, f \cap gh) = I(p, f \cap g) + I(p, f \cap h)$$

By (1) we may assume f and gh have no common component. Let $\varphi\colon \mathcal{O}/(f, gh) \to \mathcal{O}/(f, g)$ be the natural surjection and let $\psi\colon \mathcal{O}/(f, h) \to \mathcal{O}/(f, gh)$ be the k-linear map $\psi(\overline{z}) = \overline{gz}$. Since dimension is additive along a short exact sequence, it suffices to show that

$$0 \to \frac{\mathcal{O}}{(f, h)} \xrightarrow{\psi} \frac{\mathcal{O}}{(f, gh)} \xrightarrow{\varphi} \frac{\mathcal{O}}{(f, g)} \to 0$$

is exact. Surjectivity of φ is clear, and $\mathrm{im}\psi = \ker\varphi$ because $\ker\varphi = (f, g)/(f, gh)$ is generated by the images of f and g, the first being zero. For injectivity of ψ, suppose $\overline{gz} = \overline{0}$, so that $gz = uf + vgh$ with $u, v \in \mathcal{O}$. Choose $s \in k[x, y]$ with $s(p) \neq 0$ clearing all denominators, and set $A = su$, $B = sv$, $C = sz$, all in $k[x, y]$. Then $gC = Af + Bgh$, that is

$$g(C - Bh) = Af$$

Since f and g have no common factor and $k[x, y]$ is a unique factorization domain, f divides $C - Bh$, say $C - Bh = Df$. Dividing by s, which is a unit in $\mathcal{O}$,

$$z = \frac{B}{s}h + \frac{D}{s}f \in (f, h)\mathcal{O}$$

so $\overline{z} = \overline{0}$ and ψ is injective.

Property (6). Let $m = m_p(f)$, $n = m_p(g)$ and $I = (x, y) \subseteq k[x, y]$. Consider

$$\begin{tikzcd}
\frac{k[x,y]}{I^n} \times \frac{k[x,y]}{I^m} \arrow[r, "\psi"] & \frac{k[x,y]}{I^{n+m}} \arrow[r, "\varphi"] & \frac{k[x,y]}{(I^{n+m}, f, g)} \arrow[r] \arrow[d, "\alpha"] & 0 \\
& \frac{\mathcal{O}}{(f,g)} \arrow[r, "\pi"] & \frac{\mathcal{O}}{(I^{n+m}, f, g)} \arrow[r] & 0
\end{tikzcd}$$

where φ, π, α are the natural maps and $\psi(\overline{a}, \overline{b}) = \overline{af + bg}$, which is well defined because $f \in I^m$ and $g \in I^n$. The top row is exact at the middle and right, though ψ need not be injective, and α is an isomorphism by corollary 42.2.7, since $\mathcal{Z}(I^{n+m}, f, g) \subseteq \{p\}$. Exactness gives

$$\dim_k \frac{k[x, y]}{(I^{n+m}, f, g)} = \dim_k \frac{k[x, y]}{I^{n+m}} - \dim_k \ker\varphi \qquad \dim_k \ker\varphi \leq \dim_k \frac{k[x, y]}{I^n} + \dim_k \frac{k[x, y]}{I^m}$$

with equality in the second exactly when ψ is injective. Since π is surjective, chaining these and using $\dim_k k[x,y]/I^t = \frac{t(t+1)}{2}$ gives

$$\begin{aligned} I(p, f \cap g) &= \dim_k \frac{\mathcal{O}}{(f,g)} \\ &\geq \dim_k \frac{\mathcal{O}}{(I^{n+m}, f, g)} \\ &= \dim_k \frac{k[x,y]}{(I^{n+m}, f, g)} \\ &\geq \dim_k \frac{k[x,y]}{I^{n+m}} - \dim_k \frac{k[x,y]}{I^n} - \dim_k \frac{k[x,y]}{I^m} \\ &= \frac{(n+m)(n+m+1)}{2} - \frac{n(n+1)}{2} - \frac{m(m+1)}{2} = mn \end{aligned}$$

which is the inequality. Equality holds exactly when both steps are equalities, that is when π is an isomorphism, equivalently $I^{n+m} \subseteq (f,g)\mathcal{O}$, and when ψ is injective. That both hold precisely when f and g have no common tangent is lemma 42.3.2, which completes the proof.

The lemma the last step needs is where the tangent lines finally enter the argument, and it is worth isolating because both of its parts are used again in chapter 43.

Lemma 42.3.2: Technical Lemma - Intersection and Tangents

Let f, g be affine plane curves meeting properly at $p = (0,0)$, with $m = m_p(f)$, $n = m_p(g)$, and let $I = (x,y)$. Write ψ for the map of theorem 42.3.1. Then

1. If f and g have no common tangent line at p, then $I^t \subseteq (f,g)\mathcal{O}$ for every $t \geq m+n-1$.
2. ψ is injective if and only if f and g have no common tangent line at p.

***Proof*:**
Let $L_1, \ldots, L_m$ be the tangent lines of f at p, listed with multiplicity, and $M_1, \ldots, M_n$ those of g. Extend the lists by $L_i = L_m$ for $i > m$ and $M_j = M_n$ for $j > n$, and set

$$A_{ij} = L_1 L_2 \cdots L_i \, M_1 M_2 \cdots M_j$$

with $A_{00} = 1$, so A_{ij} is a form of degree $i + j$. The whole argument rests on the following claim.

Claim: if f and g have no common tangent, then $\{A_{ij} \mid i + j = t\}$ is a k-basis for the space of forms of degree t. There are $t+1$ of them and the space has dimension $t+1$, so it suffices to prove independence. Write $P_i = L_1 \cdots L_i$ and $Q_j = M_1 \cdots M_j$ and suppose $\sum_{i=0}^{t} c_i P_i Q_{t-i} = 0$ with not all c_i zero. Let a be the least and b the greatest index with $c_i \neq 0$. If $a = b$ the relation reads $c_a P_a Q_{t-a} = 0$, impossible in the domain $k[x,y]$. So $a < b$. Every P_i with $i \geq a$ is divisible by P_a, and every Q_{t-i} with $i \leq b$ is divisible by Q_{t-b}, so dividing the relation by $P_a Q_{t-b}$ leaves

$$\sum_{i=a}^{b} c_i \frac{P_i}{P_a} \cdot \frac{Q_{t-i}}{Q_{t-b}} = 0$$

Every term with $i > a$ is divisible by L_{a+1}. Hence L_{a+1} divides the $i = a$ term, which is $c_a \, Q_{t-a}/Q_{t-b}$, a nonzero scalar times a nonempty product of the M_j. But L_{a+1} is a tangent of

f and no M_j is proportional to it, contradicting unique factorization. This proves the claim, and shows exactly where the hypothesis is used.

Part (1). First, $I^t \subseteq (f,g)\mathcal{O}$ for all sufficiently large t. Write $\mathcal{Z}(f,g) = \{p, q_1, \ldots, q_s\}$, which is finite since f and g meet properly, and choose a polynomial h with $h(q_i) = 0$ for every i and $h(p) \neq 0$. Then xh and yh vanish on $\mathcal{Z}(f,g)$, so by the Nullstellensatz (theorem 32.4.4) there is N with $(xh)^N, (yh)^N \in (f,g)$. As h^N is a unit in $\mathcal{O}$, this gives $x^N, y^N \in (f,g)\mathcal{O}$, and every monomial of degree at least $2N$ is divisible by x^N or by y^N, so $I^{2N} \subseteq (f,g)\mathcal{O}$.

Now argue by descending induction on $i+j$ that $A_{ij} \in (f,g)\mathcal{O}$ whenever $i+j \geq m+n-1$, the case $i+j \geq 2N$ being covered by the previous paragraph together with the claim. Given $i+j \geq m+n-1$, one of $i \geq m$ or $j \geq n$ holds; say $i \geq m$, the other case being symmetric with g in place of f. Then $A_{ij} = A_{m0}B$ with $\deg B = i+j-m$. After scaling f so that its lowest form is exactly A_{m0}, write $f = A_{m0} + f'$ with every term of f' of degree at least $m+1$. Multiplying by B and rearranging,

$$A_{ij} = Bf - Bf'$$

Here $Bf \in (f,g)\mathcal{O}$, and every term of Bf' is a form of degree at least $i+j+1$, hence by the claim a combination of the $A_{i'j'}$ with $i'+j' \geq i+j+1$, which lie in $(f,g)\mathcal{O}$ by the inductive hypothesis. So $A_{ij} \in (f,g)\mathcal{O}$. Since the A_{ij} with $i+j=t$ span the forms of degree t, and I^t is spanned by forms of degree at least t, this gives $I^t \subseteq (f,g)\mathcal{O}$ for $t \geq m+n-1$.

Part (2). Suppose first that f and g have no common tangent, and let $\psi(\overline{A}, \overline{B}) = \overline{Af+Bg} = 0$, so that $Af + Bg \in I^{n+m}$. The domain of ψ is $\frac{k[x,y]}{I^n} \times \frac{k[x,y]}{I^m}$, so $\overline{A} \neq 0$ means $r < n$ and $\overline{B} \neq 0$ means $s < m$, where r and s are the orders of A and B, with lowest forms A_r and B_s. Assume for contradiction that $(\overline{A}, \overline{B}) \neq 0$ and consider the possibilities.

If $\overline{B} = 0$ then $B \in I^m$, so $Bg \in I^{m+n}$ and hence $Af \in I^{m+n}$. As $k[x,y]$ is a graded domain the order of Af is $r+m$, so $r+m \geq n+m$, giving $r \geq n$ and $\overline{A} = 0$, contrary to assumption. The case $\overline{A} = 0$ is symmetric.

So $\overline{A} \neq 0 \neq \overline{B}$, that is $r < n$ and $s < m$. The orders of Af and Bg are $r+m$ and $s+n$, both strictly less than $n+m$, so they must be equal, else $Af+Bg$ would have order less than $n+m$. Thus $r+m = s+n$ and the terms of that degree cancel:

$$A_r f_m = -B_s g_n$$

Now f_m and g_n have no common factor, since a common irreducible factor would be a linear form tangent to both curves. So $f_m \big| B_s$ and $g_n \big| A_r$, forcing $s \geq m$ and $r \geq n$ and contradicting $r < n$, $s < m$. Hence $(\overline{A}, \overline{B}) = 0$ and ψ is injective.

Conversely, suppose L is a common tangent and write $f_m = Lf'$, $g_n = Lg'$, so that $\deg f' = m-1$ and $\deg g' = n-1$. Then $\overline{g'} \neq 0$ in $k[x,y]/I^n$ and $\overline{f'} \neq 0$ in $k[x,y]/I^m$, and

$$\psi(\overline{g'}, \overline{-f'}) = \overline{g'f - f'g}$$

The two products $g'f$ and $f'g$ both have order $n+m-1$, and their forms of that degree are $g'f_m = g'Lf'$ and $f'g_n = f'Lg'$, which are equal. So they cancel, $g'f - f'g \in I^{n+m}$, and the image is zero on a nonzero element. Hence ψ is not injective, as we sought to show.

42.4 Computing Intersection Numbers

The proof of theorem 42.3.1 contains an algorithm, and in practice one rarely runs it to the end. Properties (7) and (8) do most of the work: (8) replaces a curve by any convenient representative of the same ideal, and (7) splits off factors. Property (6) then closes out any pair with no common tangent without further computation. The following example is worth working through slowly, because every step is one of those three.

Example 42.4.1: Intersection Number

Let

$$E = (x^2+y^2)^2 + 3x^2y - y^3 = x^4 + 2x^2y^2 + 3x^2y + y^4 - y^3$$
$$F = (x^2+y^2)^3 - 4x^2y^2 = x^6 + 3x^4y^2 + 3x^2y^4 - 4x^2y^2 + y^6$$

and $p = (0,0)$. Over the reals these are the three-leaf and four-leaf roses, $r = -\sin 3\theta$ and $r = |\sin 2\theta|$ in polar coordinates:

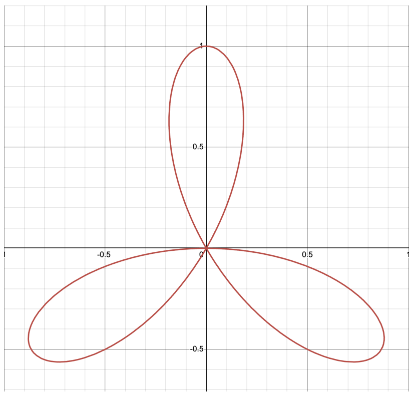

Figure 42.1: Three-Leaf Curve

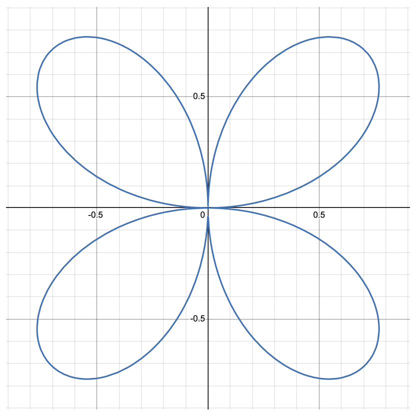

Figure 42.2: Four-Leaf Curve

Both pass through the origin, one with three branches and one with four, so the intersection number there should be substantial.

By (8) replace F with $F - (x^2+y^2)E$, which is

$$-4x^2y^2 - (x^2+y^2)(3x^2y - y^3) = y\big((x^2+y^2)(y^2-3x^2) - 4x^2y\big) = yG$$

so that by (7)

$$I(p, E\cap F) = I(p, E\cap yG) = I(p, E\cap y) + I(p, E\cap G)$$

For the second term, eliminate the quartic part of $G = -3x^4 - 2x^2y^2 - 4x^2y + y^4$ by replacing G with $G + 3E$, again legitimate by (8):

$$G + 3E = 4x^2y^2 + 5x^2y + 4y^4 - 3y^3 = y\big(5x^2 - 3y^2 + 4x^2y + 4y^3\big) = yH$$

Applying (7) once more,

$$I(p, E\cap F) = 2\,I(p, E\cap y) + I(p, E\cap H)$$

The first term is a one-variable computation: $E(x,0) = x^4$, so by (8), (7) and (6),

$$I(p, E \cap y) = I(p, x^4 \cap y) = 4\, I(p, x \cap y) = 4$$

For the second, read off the tangent cones. The lowest form of E is $3x^2y - y^3 = y(\sqrt{3}x - y)(\sqrt{3}x + y)$, so $m_p(E) = 3$ with three distinct tangents; the lowest form of H is $5x^2 - 3y^2 = (\sqrt{5}x - \sqrt{3}y)(\sqrt{5}x + \sqrt{3}y)$, so $m_p(H) = 2$ with two more. No tangent of E is proportional to one of H, so (6) applies with equality and no further computation is needed:

$$I(p, E \cap H) = m_p(E)\, m_p(H) = 3 \cdot 2 = 6$$

Altogether

$$I(p, E \cap F) = 2 \cdot 4 + 6 = 14$$

Two consequences of theorem 42.3.1 are recorded here as further properties, continuing the numbering of the list. The first identifies the intersection number with the order function of definition 42.2.4 whenever one of the curves is nonsingular at p, which is the form chapter 43 uses. The second globalizes: the intersection numbers at all points assemble into a single dimension count.

Corollary 42.4.2: Intersection Number, Order, and the Global Count

Let f, g be affine plane curves. Then

9. If p is a nonsingular point of f, then $I(p, f \cap g) = \operatorname{ord}_p^f(g)$.
10. If f and g have no common component, so that $\mathcal{Z}(f) \cap \mathcal{Z}(g)$ is finite, then

$$\sum_p I(p, f \cap g) = \dim_k \frac{k[x,y]}{(f,g)}$$

***Proof*:**
(9). Since p is a nonsingular point of f, it lies on exactly one component of f and that component is simple by proposition 42.1.7; by property (3) we may replace f by that component and assume f irreducible. Then $\mathcal{O}_p(f)$ is a discrete valuation ring by corollary 42.2.3; let t be a uniformizer and $e = \operatorname{ord}_p^f(\overline{g})$, so that $\overline{g} = ut^e$ for a unit u. Hence $(\overline{g}) = (t^e)$ and

$$\frac{\mathcal{O}_p(f)}{(\overline{g})} = \frac{\mathcal{O}_p(f)}{(t^e)}$$

has $1, t, \ldots, t^{e-1}$ as a k-basis, the residue field being k because k is algebraically closed, so its dimension is e. Finally $\mathcal{O}_p(f) \cong \mathcal{O}_p(\mathbb{A}^2_k)/(f)$ by the third exercise of exercise set 42.4.1, so

$$\frac{\mathcal{O}_p(f)}{(\overline{g})} \cong \frac{\mathcal{O}_p(\mathbb{A}^2_k)}{(f,g)}$$

whose dimension is $I(p, f \cap g)$ by theorem 42.3.1.

(10). With no common component, $\mathcal{Z}(f,g)$ is finite, so corollary 42.2.6 applied to $I = (f,g)$ gives

$$\dim_k \frac{k[x,y]}{(f,g)} = \sum_i \dim_k \frac{\mathcal{O}_{p_i}(\mathbb{A}^2_k)}{(f,g)\mathcal{O}_{p_i}(\mathbb{A}^2_k)} = \sum_i I(p_i, f \cap g)$$

and the points not in $\mathcal{Z}(f, g)$ contribute 0 by property (2), so the sum over all p is the same, completing the proof.

The second statement is the bridge to chapter 43: it converts a sum of local invariants into the dimension of a single ring, and Bézout's theorem is what happens when that ring is computed for two projective curves by a graded argument.

Exercise 42.4.1

1. Let $p = (0, \ldots, 0) \in \mathbb{A}^n_k$. Show that the maximal ideal $\mathfrak{m} \subseteq \mathcal{O}_p(\mathbb{A}^n_k)$ is generated by $x_1, \ldots, x_n$.

2. Let $I = (x, y) \subseteq k[x, y]$. Show that the monomials of degree less than n form a k-basis of $k[x, y]/I^n$, and deduce that
$$\dim_k \left(\frac{k[x, y]}{I^n} \right) = 1 + 2 + \cdots + n = \frac{n(n+1)}{2}$$

3. Let $V \subseteq \mathbb{A}^n_k$ be a variety with ideal $\mathcal{I}(V) \subseteq R = k[x_1, \ldots, x_n]$, let $p \in V$, and let $J \subseteq R$ be an ideal containing $\mathcal{I}(V)$, with image $\overline{J}$ in $k[V]$. Show that
$$\frac{\mathcal{O}_p(\mathbb{A}^n_k)}{J\, \mathcal{O}_p(\mathbb{A}^n_k)} \cong \frac{\mathcal{O}_p(V)}{\overline{J}\, \mathcal{O}_p(V)}$$
and deduce the case $J = \mathcal{I}(V)$, namely $\mathcal{O}_p(\mathbb{A}^n_k)/\mathcal{I}(V)\mathcal{O}_p(\mathbb{A}^n_k) \cong \mathcal{O}_p(V)$.

4. Compute $m_p(f)$ and the tangent lines at the origin for $f = y^2 - x^3$, $f = y^2 - x^2 - x^3$, $f = x^4 - x^2y^2 + y^4$ and $f = (x^2 + y^2)^2 + 3x^2y - y^3$. Which of the four have an ordinary singular point there?

5. Compute $I(p, f \cap g)$ at the origin for $f = y - x^2,\ g = y$; then for $f = y^2 - x^3,\ g = y$; then for $f = y^2 - x^3,\ g = x$. Check each against property (6).

6. Show that $I(p, f \cap g) = 1$ if and only if p is a nonsingular point of both curves and their tangent lines there are distinct.

7. Let f be an irreducible plane curve and p a nonsingular point of it. Show directly from definition 42.2.4 that $\operatorname{ord}^f_p(gh) = \operatorname{ord}^f_p(g) + \operatorname{ord}^f_p(h)$ and that $\operatorname{ord}^f_p(g + h) \geq \min(\operatorname{ord}^f_p(g), \operatorname{ord}^f_p(h))$, with an example where the second is strict.

43

Bézout's Theorem and Max Noether's Theorem

With the intersection number in hand the counting theorem is within reach. The proof is a dimension count in a graded ring: two curves with no common component generate an ideal whose quotient has dimension mn in every large degree, and the sum of the intersection numbers is exactly that dimension. Everything the theorem says about individual points is a consequence of that one budget being finite.

Max Noether's theorem then answers the converse question. Given that a curve passes through the points where two others meet, when is it an algebraic combination of them? The answer is local: a condition at each intersection point suffices, and checking it is cheap wherever the intersection is transversal. The chapter closes with two theorems of classical projective geometry, Pascal's and Pappus's, which fall out of a single application of that criterion to a cubic that splits into three lines.

43.1 Bézout's Theorem

Projective space was introduced so that intersections would stop disappearing, and for plane curves it delivers completely: two curves with no common component always meet, and the number of points, weighted by the intersection numbers of chapter 42, is exactly the product of the degrees.

The result is special to curves in $\mathbb{P}^2_k$, not a general feature of projective varieties. In $\mathbb{P}^3_k$ the point $\mathcal{Z}(x, y, w)$ and the plane $\mathcal{Z}(z)$ do not meet at all, and there is no weighting that would make them. What makes the plane-curve case work is that two curves in $\mathbb{P}^2_k$ have complementary dimension, so theorem 40.6.3 already guarantees they meet. Bézout's theorem sharpens that from "at least one point" to an exact count.

Theorem 43.1.1: Bézout's Theorem

Let f and g be projective plane curves of degrees m and n with no common component. Then $\mathcal{Z}(f) \cap \mathcal{Z}(g)$ is finite and

$$\sum_{p \in \mathbb{P}^2_k} I(p, f \cap g) = mn$$

***Proof*:**
Setting up. Since f and g have no common component, $\mathcal{Z}(f) \cap \mathcal{Z}(g)$ is a proper closed subset of the curve $\mathcal{Z}(f)$, hence has dimension 0 and is finite. The field k is infinite, so a linear change of coordinates moves the line at infinity off that finite set; assume from now on that no point of $\mathcal{Z}(f) \cap \mathcal{Z}(g)$ lies on $\mathcal{Z}(z)$. Write $f_* = f(x, y, 1)$ and $g_* = g(x, y, 1)$ for the dehomogenizations. Every intersection point now lies in the standard affine chart, where the intersection numbers agree with the affine ones, so property (10) of corollary 42.4.2 gives

$$\sum_p I(p, f \cap g) = \sum_p I(p, f_* \cap g_*) = \dim_k \frac{k[x, y]}{(f_*, g_*)}$$

Abbreviate

$$\Gamma_* = \frac{k[x, y]}{(f_*, g_*)} \qquad \Gamma = \frac{k[x, y, z]}{(f, g)} \qquad R = k[x, y, z]$$

Here R and Γ are graded, and R_d, Γ_d denote their degree-d pieces. The theorem follows from the two claims

$$\dim_k \Gamma_* \overset{1}{=} \dim_k \Gamma_d \overset{2}{=} mn \qquad (d \geq m + n)$$

Claim 2: $\dim_k \Gamma_d = mn$ *for* $d \geq m + n$*.* Define

$$\begin{aligned} \psi \colon R &\to R \times R & \psi(c) &= (gc, -fc) \\ \varphi \colon R \times R &\to R & \varphi(a, b) &= af + bg \\ \pi \colon R &\to \Gamma & \pi(h) &= \overline{h} \end{aligned}$$

The sequence

$$0 \to R \xrightarrow{\psi} R \times R \xrightarrow{\varphi} R \xrightarrow{\pi} \Gamma \to 0$$

is exact. Indeed ψ is injective because R is a domain; $\varphi\psi = 0$ by inspection; if $\varphi(a, b) = 0$ then $af = -bg$, and as f, g have no common factor in the unique factorization domain R we get $g \big| a$, say $a = gc$, whence $b = -fc$ and $(a, b) = \psi(c)$; finally $\operatorname{im}\varphi = (f, g) = \ker \pi$.

Everything is homogeneous, so the sequence restricts in each degree. Since $\deg f = m$ and $\deg g = n$,

$$0 \to R_{d-m-n} \xrightarrow{\psi} R_{d-m} \times R_{d-n} \xrightarrow{\varphi} R_d \xrightarrow{\pi} \Gamma_d \to 0$$

is exact, and for $d \geq m + n$ every term is a finite-dimensional space of forms, with $\dim_k R_j = \binom{j+2}{2} = \frac{(j+1)(j+2)}{2}$ for $j \geq 0$. Alternating dimensions along an exact sequence sum to zero, so

$$\dim_k \Gamma_d = \dim_k R_d - \dim_k R_{d-m} - \dim_k R_{d-n} + \dim_k R_{d-m-n}$$

Writing $P(j) = (j + 1)(j + 2)$, this is $\frac{1}{2}\big[P(d) - P(d - m) - P(d - n) + P(d - m - n)\big]$. The linear and constant parts of P cancel in that combination, leaving only the quadratic part:

$$d^2 - (d - m)^2 - (d - n)^2 + (d - m - n)^2 = 2mn$$

so $\dim_k \Gamma_d = mn$, which is Claim 2.

Multiplication by z is injective on Γ. This is the technical heart of Claim 1, and it is also used again in theorem 43.3.2. Let $\alpha\colon \Gamma \to \Gamma$ be $\alpha(\overline{h}) = \overline{zh}$ and suppose $\overline{zh} = \overline{0}$, so $zh = af + bg$ for some $a, b \in R$. For a form $u \in R$ write $u_0 = u(x, y, 0)$ for its restriction to the line at infinity. Because $\mathcal{Z}(f) \cap \mathcal{Z}(g) \cap \mathcal{Z}(z) = \emptyset$, the forms f_0 and g_0 have no common zero in $\mathbb{P}^1_k$ and so are relatively prime in $k[x, y]$. Setting $z = 0$ in $zh = af + bg$ gives

$$0 = a_0 f_0 + b_0 g_0$$

so $a_0 f_0 = -b_0 g_0$, and coprimality yields $c \in k[x, y]$ with

$$b_0 = f_0 c \qquad a_0 = -g_0 c$$

Now put $a_1 = a + cg$ and $b_1 = b - cf$. Then $a_1 f + b_1 g = af + bg + cgf - cfg = zh$, while

$$(a_1)_0 = -g_0 c + cg_0 = 0 \qquad (b_1)_0 = f_0 c - cf_0 = 0$$

so both are divisible by z, say $a_1 = za'$ and $b_1 = zb'$. Then $z(a'f + b'g) = zh$, and cancelling z in the domain R gives $h = a'f + b'g$, that is $\overline{h} = \overline{0}$. So α is injective.

Claim 1: $\dim_k \Gamma_* = \dim_k \Gamma_d$ *for* $d \geq m+n$. By the previous paragraph α restricts to an injection $\Gamma_d \hookrightarrow \Gamma_{d+1}$, and both have dimension mn by Claim 2, so it is an isomorphism. Consequently, if $\beta_1, \ldots, \beta_{mn} \in R_d$ have residues forming a basis of Γ_d, then for every $r \geq 0$ the residues of $z^r\beta_1, \ldots, z^r\beta_{mn}$ form a basis of Γ_{d+r}.

Let $b_i \in \Gamma_*$ be the residue of $(\beta_i)_* = \beta_i(x, y, 1)$. These span: given $\overline{h} \in \Gamma_*$ with $h \in k[x, y]$, let h^* be its homogenization, of some degree e, and choose r with $d + r \geq e$. Then $z^{d+r-e}h^*$ is a form of degree $d + r$, so

$$z^{d+r-e}h^* = \sum_{i=1}^{mn} \lambda_i z^r \beta_i + Af + Bg$$

for scalars λ_i and forms A, B. Dehomogenizing, that is setting $z = 1$, gives

$$h = \sum_i \lambda_i (\beta_i)_* + A_* f_* + B_* g_*$$

so $\overline{h} = \sum_i \lambda_i b_i$.

They are independent: suppose $\sum_i \lambda_i b_i = 0$, so that $\sum_i \lambda_i (\beta_i)_* = Af_* + Bg_*$ for some $A, B \in k[x, y]$. Homogenizing and clearing the powers of z that appear gives $r, s, t \geq 0$ with

$$z^r \sum_i \lambda_i \beta_i = z^s A^* f + z^t B^* g$$

so $\sum_i \lambda_i \overline{z^r \beta_i} = \overline{0}$ in Γ_{d+r}. As those residues form a basis, every $\lambda_i = 0$.

So $b_1, \ldots, b_{mn}$ is a basis of Γ_* and $\dim_k \Gamma_* = mn$, as we sought to show.

Example 43.1.2: Bézout in Practice
Every count below is over an algebraically closed field and in $\mathbb{P}^2_k$, where alone the statement holds.

1. *Two conics.* Degrees 2 and 2, so the intersection has total weight 4. For $\mathcal{Z}(x^2+y^2-z^2)$ and $\mathcal{Z}(x^2-yz)$ a direct substitution gives four distinct points, each counted once. Two general conics meet in four points.

2. *Tangency absorbs the count.* For the circle $\mathcal{Z}(x^2+y^2-z^2)$ and the line $\mathcal{Z}(y-z)$, substituting $y=z$ gives $x^2=0$, a double root: the line is tangent at $[0:1:1]$, and $I(p, C\cap L)=2$. The total is still $2\cdot 1=2$, all concentrated at one point.

3. *Where affine intuition fails.* The two parabolas $\mathcal{Z}(y-x^2)$ and $\mathcal{Z}(y-x^2-1)$ do not meet in $\mathbb{A}^2_k$ at all. Homogenizing gives $\mathcal{Z}(yz-x^2)$ and $\mathcal{Z}(yz-x^2-z^2)$, and subtracting, $z^2=0$: the two meet only where $z=0$, at $[0:1:0]$, with $I=4$. The four intersections predicted by $2\cdot 2$ are all at infinity, which is what projective space was introduced to see.

4. *A line and a cubic.* Degrees 1 and 3 give three points. For the cubic $\mathcal{Z}(y^2z-x^3+xz^2)$ and the line $\mathcal{Z}(z)$, substituting $z=0$ gives $x^3=0$: the line at infinity meets the cubic only at $[0:1:0]$, with multiplicity 3. That point is an inflection, which is why theorem 48.4.4 can put a genus-one curve in Weierstrass form with its base point there.

43.2 Consequences and Bounds on Multiplicity

Bézout's theorem is a budget: mn is all the intersection there is, and every local contribution is drawn against it. Most of its corollaries are that observation combined with the lower bound $I(p, f\cap g)\geq m_p(f)m_p(g)$ from property (6).

Corollary 43.2.1: Degree and Multiplicity

Let f, g be projective plane curves with no common component. Then

$$\sum_p m_p(f)\, m_p(g) \leq \deg(f)\deg(g)$$

***Proof*:**
Property (6) of the intersection number gives $I(p, f\cap g)\geq m_p(f)m_p(g)$ at every p, and summing over p against theorem 43.1.1 bounds the total by $\deg(f)\deg(g)$, completing the proof.

Corollary 43.2.2: Intersection and Simple Points

Let f, g be projective plane curves of degrees m and n with no common component. If $\mathcal{Z}(f)$ and $\mathcal{Z}(g)$ meet in mn distinct points, then every one of those points is a nonsingular point of both curves, and the two curves are transversal there.

***Proof*:**
The mn points each contribute at least 1 to a total of mn by theorem 43.1.1, so each contributes exactly 1. Property (6) then forces $m_p(f)m_p(g) \leq 1$, so both multiplicities are 1 and p is nonsingular on both by definition 42.1.5. Equality in (6) additionally says the curves share no tangent at p, which for two nonsingular points is transversality, completing the proof.

Corollary 43.2.3: Intersection and Common Component

If two projective plane curves of degrees m and n have more than mn points in common, they have a common component.

***Proof*:**
Were there no common component, theorem 43.1.1 would bound the number of common points by $\sum_p I(p, f \cap g) = mn$, since each contributes at least 1 by property (2), completing the proof.

The next bound goes the other way: it limits how singular a single irreducible curve can be. Both the crude and the sharp form are worth having, and the crude one is what licenses the argument for the sharp one.

Corollary 43.2.4: Bounding Multiplicity

Let f be an irreducible projective plane curve of degree n. Then f has finitely many singular points and

$$\sum_p \frac{m_p(f)\big(m_p(f)-1\big)}{2} \leq \frac{n(n-1)}{2}$$

***Proof*:**
Not every partial derivative of f vanishes identically. In characteristic zero this is because f is nonconstant. In characteristic $\rho > 0$, if all three vanished then every exponent appearing in f would be divisible by ρ, so $f \in k[x^\rho, y^\rho, z^\rho]$; as k is algebraically closed its elements are ρ-th powers, and the Frobenius is a ring homomorphism, so $f = h^\rho$ for some h, contradicting irreducibility. Let g be a nonzero partial derivative of f, a form of degree $n-1$.

At every point p, $m_p(g) \geq m_p(f) - 1$. Change coordinates so that $p = [0:0:1]$ and work in the chart $z = 1$, writing $f_* = f(x, y, 1)$ and $m = m_p(f)$. A linear change of coordinates replaces each partial derivative by a linear combination of the three partials, and multiplicity of a sum is at least the minimum of the multiplicities, so it is enough to check the bound for all three partials of the transformed form. Dehomogenization commutes with ∂_x and ∂_y, and differentiating drops the degree of each homogeneous piece of f_* by one, so $m_p(\partial_x f_*)$ and $m_p(\partial_y f_*)$ are both at least $m-1$. For the third, Euler's relation (exercise set 38.5.1(5)) $nf = x\partial_x f + y\partial_y f + z\partial_z f$ dehomogenizes to

$$(\partial_z f)_* = nf_* - x\,\partial_x f_* - y\,\partial_y f_*$$

Each term on the right has multiplicity at least m at the origin, the last two because a factor of x or y adds one to a multiplicity of at least $m-1$. So $m_p((\partial_z f)_*) \geq m$, which is more than required.

Since f is irreducible of degree n and g is a nonzero form of degree $n-1 < n$, they have no common component. Corollary 43.2.1 therefore gives

$$\sum_p m_p(f)\big(m_p(f)-1\big) \le \sum_p m_p(f)\, m_p(g) \le n(n-1)$$

which is the inequality after dividing by 2. In particular only finitely many p have $m_p(f) \ge 2$, so the singular points are finite in number, as we sought to show.

The sharp form replaces n by $n-1$ on the right, and its proof is the standard count of how many conditions singularities impose on curves of degree $n-1$.

Corollary 43.2.5: Sharp Bound on Multiplicity

Let f be an irreducible projective plane curve of degree n. Then

$$\sum_p \frac{m_p(f)\big(m_p(f)-1\big)}{2} \le \frac{(n-1)(n-2)}{2}$$

***Proof*:**
Write $m_p = m_p(f)$ and $M = \sum_p \binom{m_p}{2}$, a finite sum by corollary 43.2.4. The forms of degree $n-1$ in three variables constitute a projective space of dimension $\binom{n+1}{2} - 1 = \frac{(n-1)(n+2)}{2}$. Requiring a curve g of degree $n-1$ to satisfy $m_p(g) \ge m_p - 1$ is the vanishing of all partial derivatives of order less than $m_p - 1$ at p, which is $\binom{m_p}{2}$ linear conditions, and requiring g to pass through a further point is one more. Set

$$r = \frac{(n-1)(n+2)}{2} - M$$

This is non-negative: corollary 43.2.4 gives $M \le \frac{n(n-1)}{2}$, and $\frac{n(n-1)}{2} \le \frac{(n-1)(n+2)}{2}$. So r further conditions may be imposed, and since f has infinitely many points while only finitely many are singular, nonsingular points $q_1, \ldots, q_r \in \mathcal{Z}(f)$ may be chosen. The $M + r$ conditions cannot exhaust a projective space of dimension $M + r$, so a curve g of degree $n-1$ exists with $m_p(g) \ge m_p - 1$ at every singular point of f and $m_{q_i}(g) \ge 1$ for each i.

As before f is irreducible of degree n and g is a nonzero form of degree $n-1$, so they share no component and corollary 43.2.1 applies:

$$n(n-1) \;\ge\; \sum_p m_p(m_p-1) \;+\; r \;=\; 2M + \frac{(n-1)(n+2)}{2} - M$$

the r appearing because each q_i contributes $m_{q_i}(f)m_{q_i}(g) \ge 1$ and is not among the singular points already counted. Rearranging,

$$M \le n(n-1) - \frac{(n-1)(n+2)}{2} = (n-1)\cdot\frac{2n-n-2}{2} = \frac{(n-1)(n-2)}{2}$$

as we sought to show.

The sharp bound is attained: the curve $\mathcal{Z}(x^n + y^{n-1}z)$ is irreducible of degree n and has multiplicity $n-1$ at $[0:0:1]$, since dehomogenizing there leaves $x^n + y^{n-1}$ with lowest form y^{n-1}. That single point already contributes $\binom{n-1}{2}$, so no other singularity is available. The quantity $\frac{(n-1)(n-2)}{2}$ is the *arithmetic genus* of a plane curve of degree n, and chapter 44 will meet it again.

43.3 Max Noether's Fundamental Theorem

Bézout's theorem counts the intersection of two curves; the natural next question is what that intersection determines. The data of an intersection is a set of points together with a weight at each, and such data forms a group under addition.

Definition 43.3.1: Zero-cycle

A *zero-cycle* on $\mathbb{P}^2_k$ is a formal sum $\sum_p n_p\, p$ over points $p \in \mathbb{P}^2_k$ with $n_p \in \mathbb{Z}$ and all but finitely many $n_p = 0$. Its *degree* is $\sum_p n_p$.

Adding coefficientwise makes the zero-cycles an abelian group, and writing $\sum_p n_p p \leq \sum_p m_p p$ when $n_p \leq m_p$ for every p orders it. For projective plane curves f, g with no common component, the *intersection cycle* is

$$f \bullet g = \sum_{p \in \mathbb{P}^2_k} I(p, f \cap g)\, p$$

which is a zero-cycle of degree $\deg(f)\deg(g)$ by theorem 43.1.1. The properties of the intersection number transfer directly:

1. $f \bullet g = g \bullet f$;
2. $f \bullet (gh) = f \bullet g + f \bullet h$;
3. $f \bullet (g + af) = f \bullet g$ for every form a of degree $\deg(g) - \deg(f)$.

It is tempting to hope that every effective zero-cycle, meaning one with all $n_p \geq 0$, arises as an intersection cycle. It does not. Take three points of $\mathbb{P}^2_k$ in general position and the cycle $p_1 + p_2 + p_3$, of degree 3. Realizing it as $f \bullet g$ would need $\deg(f)\deg(g) = 3$, so one of the curves is a line, and that line would have to contain all three points, which they are not chosen to admit. The obstruction is exactly the phenomenon that chapter 44 organizes into the divisor class group: which formal sums of points are cut out by equations is a question with a non-trivial answer, and the answer is an invariant of the curve.

The question this section settles is the relative version. Suppose f, g, h are curves with $g \bullet f \leq h \bullet f$, so that h meets f at least as heavily as g does at every point. Is the difference itself an intersection cycle, that is, is there a curve b with

$$b \bullet f = h \bullet f - g \bullet f$$

Comparing degrees, such a b must have degree $\deg(h) - \deg(g)$. And it is enough to find forms a, b with

$$h = af + bg$$

for then property (3) followed by property (2) gives $h \bullet f = (bg) \bullet f = b \bullet f + g \bullet f$, which rearranges to the display. So the geometric question reduces to an algebraic one: when does h lie in the ideal generated by f and g, with the degrees working out? Max Noether's theorem answers it, and the answer is local.

Theorem 43.3.2: Max Noether's Fundamental Theorem

Let f, g, h be projective plane curves with f and g having no common component. Then there exist forms a, b of degrees $\deg(h) - \deg(f)$ and $\deg(h) - \deg(g)$ with

$$h = af + bg$$

if and only if for every $p \in \mathcal{Z}(f) \cap \mathcal{Z}(g)$ the local condition

$$h_* \in (f_*, g_*)\, \mathcal{O}_p(\mathbb{P}^2_k)$$

holds, where the subscript denotes dehomogenization in an affine chart containing p.

The local condition is called *Noether's condition* at p. That a global identity is equivalent to a finite list of local ones makes this a *local-to-global* theorem, and it is the reason the corollaries below are as easy as they are: each is a way of certifying the local condition cheaply.

***Proof*:**
One direction is immediate: if $h = af + bg$, then dehomogenizing at any p gives $h_* = a_* f_* + b_* g_*$, so h_* lies in $(f_*, g_*)\mathcal{O}_p(\mathbb{P}^2_k)$.

For the converse, change coordinates so that $\mathcal{Z}(f) \cap \mathcal{Z}(g) \cap \mathcal{Z}(z) = \emptyset$, which is possible because the intersection is finite, and dehomogenize in the chart $z = 1$. Noether's condition says the residue of h_* in $\mathcal{O}_p(\mathbb{A}^2_k)/(f_*, g_*)$ vanishes for every $p \in \mathcal{Z}(f_*, g_*)$. By lemma 42.2.5 the ring $k[x, y]/(f_*, g_*)$ is the product of those local quotients, so the residue of h_* there vanishes too:

$$h_* = \alpha f_* + \beta g_* \qquad \alpha, \beta \in k[x, y]$$

Homogenizing and clearing the powers of z introduced gives $r \geq 0$ and forms A, B with

$$z^r h = Af + Bg$$

Multiplication by z on $\Gamma = k[x, y, z]/(f, g)$ is injective, as established inside the proof of theorem 43.1.1, so cancelling z one factor at a time from $\overline{z^r h} = \overline{0}$ leaves $\overline{h} = \overline{0}$, that is $h = a' f + b' g$ for some forms a', b', not necessarily homogeneous.

Finally, extract the right graded pieces. Write $a' = \sum_i a'_i$ and $b' = \sum_i b'_i$ with a'_i, b'_i homogeneous of degree i. Comparing homogeneous components of degree $\deg h$ in $h = a' f + b' g$, and using that h is itself homogeneous, gives

$$h = a'_s f + b'_t g \qquad s = \deg(h) - \deg(f), \quad t = \deg(h) - \deg(g)$$

since those are the only pieces contributing in that degree. Taking $a = a'_s$ and $b = b'_t$ completes the proof.

Verifying Noether's condition directly is unpleasant. The following criteria cover every case that arises in practice.

Proposition 43.3.3: Noether's Criterion

Let f, g, h be projective plane curves and $p \in \mathcal{Z}(f) \cap \mathcal{Z}(g)$. Each of the following implies Noether's condition at p:

1. f and g meet transversally at p, and $p \in \mathcal{Z}(h)$;
2. p is a nonsingular point of f, and $I(p, h \cap f) \geq I(p, g \cap f)$;
3. f and g have no tangent line in common at p, and $m_p(h) \geq m_p(f) + m_p(g) - 1$.

***Proof*:**
(2). Since p is a nonsingular point of f, property (9) of corollary 42.4.2 converts both intersection numbers into orders, so the hypothesis reads $\operatorname{ord}_p^f(h_*) \geq \operatorname{ord}_p^f(g_*)$. In the discrete valuation ring $\mathcal{O}_p(f)$ that says

$$\overline{h}_* \in (\overline{g}_*) \subseteq \mathcal{O}_p(f)$$

Now $\mathcal{O}_p(f) \cong \mathcal{O}_p(\mathbb{A}^2_k)/(f_*)$ by the third exercise of exercise set 42.4.1, so $\mathcal{O}_p(f)/(\overline{g}_*) \cong \mathcal{O}_p(\mathbb{A}^2_k)/(f_*, g_*)$ and the residue of h_* there is zero, which is Noether's condition.

(3). Take $p = [0 : 0 : 1]$ and write $I = (x, y)$, $m = m_p(f)$, $n = m_p(g)$. The hypothesis $m_p(h) \geq m + n - 1$ says $h_* \in I^{m+n-1}$, and lemma 42.3.2(1) says $I^t \subseteq (f_*, g_*)\mathcal{O}_p(\mathbb{A}^2_k)$ for every $t \geq m + n - 1$ precisely because f and g have no common tangent. Hence $h_* \in (f_*, g_*)\mathcal{O}_p(\mathbb{A}^2_k)$.

(1). Transversality makes $m_p(f) = m_p(g) = 1$ with distinct tangents, so (3) applies with the requirement $m_p(h) \geq 1 + 1 - 1 = 1$, which is exactly $p \in \mathcal{Z}(h)$, completing the proof.

Corollary 43.3.4: Sufficient Condition For Max Noether's Theorem

Let f, g, h be projective plane curves with f and g having no common component, and suppose either

1. $\mathcal{Z}(f)$ and $\mathcal{Z}(g)$ meet in $\deg(f)\deg(g)$ distinct points and h passes through all of them, or
2. every point of $\mathcal{Z}(f) \cap \mathcal{Z}(g)$ is a nonsingular point of f, and $h \bullet f \geq g \bullet f$.

Then there is a curve b of degree $\deg(h) - \deg(g)$ with

$$b \bullet f = h \bullet f - g \bullet f$$

***Proof*:**
In case (1), corollary 43.2.2 says the $\deg(f)\deg(g)$ points are transversal intersections, so proposition 43.3.3(1) supplies Noether's condition at each. In case (2), the hypothesis $h \bullet f \geq g \bullet f$ is exactly $I(p, h \cap f) \geq I(p, g \cap f)$ at every p, so proposition 43.3.3(2) applies. Either way theorem 43.3.2 produces $h = af + bg$ with b of degree $\deg(h) - \deg(g)$, and the computation preceding that theorem turns the identity into the stated equation of cycles, completing the proof.

43.4 Application: Pascal's and Pappus's Theorems

Max Noether's theorem is a statement about ideals, and its geometric consequences are about incidence. Two of them are theorems of classical projective geometry, one from the fourth century and one from the seventeenth, and both come out of the same three-line computation: a cubic that splits into three lines, a conic, and the observation that Noether's condition costs nothing at a transversal intersection.

The shared setup is this. Let Q be a conic and let $p_1, \dots, p_6$ be six distinct points on $\mathcal{Z}(Q)$, thought of as the vertices of a hexagon in that cyclic order. Its six sides split into two alternating triples,

$$L_1 = \overline{p_1p_2}, \quad L_2 = \overline{p_3p_4}, \quad L_3 = \overline{p_5p_6} \qquad M_1 = \overline{p_2p_3}, \quad M_2 = \overline{p_4p_5}, \quad M_3 = \overline{p_6p_1}$$

and the three pairs of *opposite* sides are (L_1, M_2), (M_1, L_3) and (L_2, M_3). Write $C = L_1L_2L_3$ and $C' = M_1M_2M_3$, both cubics.

Lemma 43.4.1: The Hexagon Identity

With the notation above, suppose that no side of the hexagon meets $\mathcal{Z}(Q)$ outside the two vertices it joins. Then there are a constant $\lambda \in k$ and a linear form ℓ, not identically zero, with

$$M_1M_2M_3 = \lambda\, L_1L_2L_3 + \ell\, Q$$

***Proof*:**
Apply theorem 43.3.2 to $f = C$, $g = Q$ and $h = C'$. The curves C and Q have no common component, since each L_i meets $\mathcal{Z}(Q)$ in the two points p_{2i-1}, p_{2i} and so is not contained in it. By hypothesis $\mathcal{Z}(C) \cap \mathcal{Z}(Q)$ is exactly $\{p_1, \dots, p_6\}$, which is $\deg(C)\deg(Q) = 3 \cdot 2 = 6$ distinct points, so corollary 43.2.2 makes every one of them a transversal intersection. Each p_i also lies on C': the vertex p_j lies on M_1, M_2 or M_3 according to its index. So proposition 43.3.3(1) supplies Noether's condition at all six points, and theorem 43.3.2 gives

$$C' = aC + bQ$$

with $\deg a = 3 - 3 = 0$ and $\deg b = 3 - 2 = 1$; write $\lambda = a$ and $\ell = b$.

It remains to rule out $\ell = 0$, which would force $M_1M_2M_3 = \lambda L_1L_2L_3$ and hence, by unique factorization, make each M_i proportional to some L_j. That cannot happen: L_j meets $\mathcal{Z}(Q)$ in $\{p_{2j-1}, p_{2j}\}$ and M_i meets it in the corresponding pair for M_i, and the three pairs $\{p_1, p_2\}, \{p_3, p_4\}, \{p_5, p_6\}$ are disjoint from the three pairs $\{p_2, p_3\}, \{p_4, p_5\}, \{p_6, p_1\}$ as unordered pairs, the six vertices being distinct, as we sought to show.

Theorem 43.4.2: Pascal's Theorem

Let a hexagon with distinct vertices be inscribed in an irreducible conic. Then the three points in which the pairs of opposite sides meet are collinear.

***Proof*:**
Let Q be the conic and adopt the notation above. The hypothesis of lemma 43.4.1 holds: a line meets the irreducible conic $\mathcal{Z}(Q)$ in at most two points by theorem 43.1.1, since it is not a component of it, so each side meets $\mathcal{Z}(Q)$ exactly in its two vertices. Let λ and ℓ be as in that lemma.

Let r_1 be the point $L_1 \cap M_2$, the meeting of a pair of opposite sides, and define r_2 and r_3 from the pairs (M_1, L_3) and (L_2, M_3). Evaluating the identity of lemma 43.4.1 at r_1: the left side vanishes because $M_2(r_1) = 0$, and the term $\lambda L_1 L_2 L_3$ vanishes because $L_1(r_1) = 0$. Hence

$$\ell(r_1)\, Q(r_1) = 0$$

Now $Q(r_1) \neq 0$. For r_1 lies on L_1, whose only points on $\mathcal{Z}(Q)$ are p_1 and p_2, and on M_2, whose only points on $\mathcal{Z}(Q)$ are p_4 and p_5; were r_1 on $\mathcal{Z}(Q)$ it would belong to both pairs, which are disjoint. Therefore $\ell(r_1) = 0$, and the same computation gives $\ell(r_2) = \ell(r_3) = 0$. As ℓ is a nonzero linear form, $\mathcal{Z}(\ell)$ is a line containing all three points, as we sought to show.

Pappus's theorem is the case in which the conic degenerates into a pair of lines. The hexagon then has its vertices alternating between the two lines, and the argument runs unchanged.

Theorem 43.4.3: Pappus's Theorem

Let L and L' be distinct lines, and let p_1, p_2, p_3 be distinct points of $\mathcal{Z}(L)$ and q_1, q_2, q_3 distinct points of $\mathcal{Z}(L')$, none of the six equal to the point $\mathcal{Z}(L) \cap \mathcal{Z}(L')$. Put

$$r_1 = \overline{p_1 q_2} \cap \overline{q_1 p_2}, \qquad r_2 = \overline{q_2 p_3} \cap \overline{p_2 q_3}, \qquad r_3 = \overline{p_3 q_1} \cap \overline{q_3 p_1}$$

Then r_1, r_2, r_3 are collinear.

***Proof*:**
Take $Q = LL'$, a conic, and the hexagon with vertices $p_1, q_2, p_3, q_1, p_2, q_3$ in that cyclic order, all six lying on $\mathcal{Z}(Q)$ and all distinct. Its alternating side-triples are

$$\overline{p_1 q_2},\ \overline{p_3 q_1},\ \overline{p_2 q_3} \qquad \text{and} \qquad \overline{q_2 p_3},\ \overline{q_1 p_2},\ \overline{q_3 p_1}$$

and the three r_i are the intersections of the opposite pairs.

The hypothesis of lemma 43.4.1 holds. A side such as $\overline{p_1 q_2}$ joins a point of $\mathcal{Z}(L)$ to a point of $\mathcal{Z}(L')$, and it is equal to neither line, since $q_2 \notin \mathcal{Z}(L)$ and $p_1 \notin \mathcal{Z}(L')$ by the hypothesis on the six points. So it meets $\mathcal{Z}(L)$ only at p_1 and $\mathcal{Z}(L')$ only at q_2, and therefore meets $\mathcal{Z}(Q)$ exactly in its two vertices. Let λ and ℓ be as in the lemma.

Evaluating at r_1 exactly as in theorem 43.4.2 gives $\ell(r_1)Q(r_1) = 0$, so it remains to check $Q(r_1) \neq 0$, that is $r_1 \notin \mathcal{Z}(L) \cup \mathcal{Z}(L')$. Suppose $r_1 \in \mathcal{Z}(L)$. Then r_1 lies on $\overline{p_1 q_2}$, which meets $\mathcal{Z}(L)$ only at p_1, so $r_1 = p_1$; and r_1 lies on $\overline{q_1 p_2}$, which meets $\mathcal{Z}(L)$ only at p_2, so $r_1 = p_2$. These contradict $p_1 \neq p_2$. The case $r_1 \in \mathcal{Z}(L')$ is symmetric, using $q_2 \neq q_1$. Hence $\ell(r_1) = 0$, likewise for r_2 and r_3, and $\mathcal{Z}(\ell)$ is the required line, as we sought to show.

43.5 The Dual Curve and Plücker's Formulas

A nonsingular point of a plane curve has a tangent line, and a line in $\mathbb{P}^2_k$ is a point of the dual projective space. So a curve determines a second curve, and the numerical relations between the two are the oldest quantitative statements in the subject.

Definition 43.5.1: Dual Space and Dual Curve

The *dual projective space* $(\mathbb{P}^2_k)^\vee$ is the set of lines in $\mathbb{P}^2_k$, itself a $\mathbb{P}^2_k$ by sending $\mathcal{Z}(a_0x_0 + a_1x_1 + a_2x_2)$ to $[a_0 : a_1 : a_2]$. For an irreducible plane curve C, the *dual curve* $C^\vee \subseteq (\mathbb{P}^2_k)^\vee$ is the closure of the set of tangent lines to C at its nonsingular points. The *class* of C is $\deg C^\vee$.

By corollary 43.2.4 the nonsingular points of C are all but finitely many, so $C^\vee$ is the closure of the image of a map defined on a dense open set: the *Gauss map*

$$\gamma\colon C \dashrightarrow (\mathbb{P}^2_k)^\vee \qquad p \mapsto \big[\partial_0 F(p) : \partial_1 F(p) : \partial_2 F(p)\big]$$

whose coordinates are the partials of the defining form, by the tangent-line formula of definition 42.1.6. It is a rational map of curves, so $C^\vee$ is an irreducible curve by lemma 42.2.8 applied to a nonsingular model.

Proposition 43.5.2: The Class of a Nonsingular Curve

Let C be a nonsingular plane curve of degree $d \geq 2$ with $\operatorname{char} k = 0$. Then

$$\deg C^\vee = d(d-1)$$

***Proof*:**
A line of $(\mathbb{P}^2_k)^\vee$ is the set of lines of $\mathbb{P}^2_k$ through a fixed point q, so by theorem 41.5.1 the degree of $C^\vee$ is the number of points in which $C^\vee$ meets such a line for general q, counted through the Gauss map. In characteristic zero that map is birational onto its image for a nonsingular plane curve, so the count of points of $C^\vee$ equals the count of tangent lines to C through q; it is here, and only here, that the characteristic hypothesis is used.

A point $p \in C$ has its tangent line through $q = [q_0 : q_1 : q_2]$ exactly when

$$P_q(p) \;=\; q_0\,\partial_0 F(p) + q_1\,\partial_1 F(p) + q_2\,\partial_2 F(p) \;=\; 0$$

The form P_q has degree $d-1$ and is the *polar* of C with respect to q. It is not the zero form for general q: the partials $\partial_i F$ are not all zero, since $\operatorname{char} k = 0$ and F is nonconstant, and a general linear combination of forms that are not all zero is nonzero. And F does not divide P_q, because $\deg P_q = d-1 < d$ while F is irreducible. So C and $\mathcal{Z}(P_q)$ have no common component.

Theorem 43.1.1 therefore counts the intersection as $d(d-1)$ with multiplicity. For general q the intersections are transversal, so there are $d(d-1)$ distinct points and as many tangent lines through q, as we sought to show.

Example 43.5.3: Classes of Small Curves

A nonsingular conic has $d = 2$ and class 2: through a general point of the plane there pass exactly two tangent lines to a conic, and the dual of a conic is again a conic.

A nonsingular cubic has $d = 3$ and class 6. That number is the reason the dual of a smooth cubic is a sextic and not a cubic: dualizing does not preserve degree, and $(C^\vee)^\vee = C$ only because the two operations are inverse, not because the degrees match.

Singular points reduce the class, because a singular point has no well-defined tangent and the Gauss map is undefined there. The bookkeeping is Plücker's, and it is stated here rather than proved: the corrections require the genus and the behaviour of δ-invariants under duality.

43.5.4 Note: Plücker's Formulas Let C be an irreducible plane curve of degree d over a field of characteristic zero, with δ ordinary double points and κ ordinary cusps and no other singularities, and let $d^\vee$ be its class. Then

$$d^\vee = d(d-1) - 2\delta - 3\kappa$$

and dually, writing $\delta^\vee$ and $\kappa^\vee$ for the bitangents and inflections of C,

$$d = d^\vee(d^\vee - 1) - 2\delta^\vee - 3\kappa^\vee$$

The genus is common to both and is given by

$$g = \frac{(d-1)(d-2)}{2} - \delta - \kappa$$

consistently with the genus drop recorded in section 44.4, a node and a cusp each costing 1.
For a nonsingular cubic, $\delta = \kappa = 0$ gives $d^\vee = 6$, and the second formula reads $3 = 30 - 2\delta^\vee - 3\kappa^\vee$; with $\delta^\vee = 0$, since a smooth cubic has no bitangent, this gives $\kappa^\vee = 9$. Those nine are the inflection points, recovering by a completely different route the count obtained in exercise set 45.3.1 from the Hessian and theorem 45.2.2.
A proof needs the resolution of chapter 47 together with the genus, and is in [54, chapter 9] and in [29] analytically.

Exercise 43.5.1

1. Let X be an irreducible curve. Show that $k[X] = \bigcap_{p \in X} \mathcal{O}_p(X)$, the intersection being taken inside $k(X)$.

2. Show that a line and an irreducible conic are nonsingular curves, either directly from definition 42.1.5 or from one of the corollaries of section 43.2.

3. Let C and C' be cubics with $C \cdot C' = \sum_{i=1}^{9} p_i$ for nine distinct points, and let Q be a conic with $Q \cdot C = \sum_{i=1}^{6} p_i$. Assuming $p_1, \dots, p_6$ are nonsingular points of C, show that p_7, p_8, p_9 lie on a line. (Run the argument of lemma 43.4.1 with Q in place of the conic there.)

4. Show that the bound of corollary 43.2.5 fails for reducible curves by exhibiting a reducible curve of degree n violating it.

5. Verify that theorem 43.4.3 really is theorem 43.4.2 for a degenerate conic, by checking that the two proofs differ only in the verification that $r_i \notin \mathcal{Z}(Q)$.

6. Two conics meet in at most four points unless they share a component. Deduce that five points in general position determine a unique conic, and say what "general position" has to mean.

44

Divisors on Curves

The intersection cycles of section 43.3 are formal sums of points on a curve, and such sums form a group under addition. Not every formal sum is cut out by an equation, and the failure is measured by quotienting out the sums that arise from rational functions. What remains is the divisor class group, an invariant of the curve alone.

This chapter builds that group. Its degree-zero part is what chapter 45 identifies with the classical chord-tangent law on a cubic, and one book later it becomes the Jacobian. Its structure also detects rationality: a nonsingular plane curve is a copy of $\mathbb{P}^1$ exactly when distinct points on it are linearly equivalent, and that happens only in degrees 1 and 2. The invariant separating the cases is the genus, and the chapter closes by giving the genus-degree formula of section 38.5 that job.

44.1 Divisors and Their Degree

Throughout, C is an irreducible projective curve over the algebraically closed field k, and C is *nonsingular* unless said otherwise. Every local ring $\mathcal{O}_p(C)$ is then a discrete valuation ring by proposition 35.5.2, so every point carries an order function ord_p as in definition 42.2.4.

Section 37.5 already defined Weil divisors on any normal variety. A nonsingular projective curve is normal by corollary 35.5.3, and its prime divisors are its points, every point having codimension one. So the following is definition 37.5.1 specialized, restated here because the curve case is the one the rest of this Part uses.

Definition 44.1.1: Divisor on a Curve

A *divisor* on C is a formal sum

$$D = \sum_{p \in C} n_p\, p \qquad n_p \in \mathbb{Z}$$

with $n_p = 0$ for all but finitely many p. The divisors form an abelian group $\mathrm{Div}(C)$ under coefficientwise addition. The *degree* of D is $\deg D = \sum_p n_p$, and D is *effective*, written $D \geq 0$, if every $n_p \geq 0$. Write $D \geq D'$ for $D - D' \geq 0$.

A divisor is the same kind of object as a zero-cycle (definition 43.3.1), with the points confined to C. The intersection cycle of section 43.3 is the first source of divisors: if C is a nonsingular plane curve and G is a plane curve with no component in common, then $G \bullet C$ is an effective divisor on C, of degree $\deg(G)\deg(C)$ by theorem 43.1.1.

The second source is rational functions, and it is the one that matters.

Definition 44.1.2: Divisor of a Rational Function

Let $f \in k(C)^*$ be a nonzero rational function. Its *divisor* is

$$\mathrm{div}(f) = \sum_{p \in C} \mathrm{ord}_p(f)\, p$$

The divisor of zeros is $\mathrm{div}_0(f) = \sum_{\mathrm{ord}_p(f)>0} \mathrm{ord}_p(f)\, p$ and the divisor of poles is $\mathrm{div}_\infty(f) = -\sum_{\mathrm{ord}_p(f)<0} \mathrm{ord}_p(f)\, p$, so that $\mathrm{div}(f) = \mathrm{div}_0(f) - \mathrm{div}_\infty(f)$ with both parts effective.

The definition needs justification: the sum must be finite.

Proposition 44.1.3: A Rational Function Has Finitely Many Zeros and Poles

Let $f \in k(C)^*$. Then $\mathrm{ord}_p(f) = 0$ for all but finitely many $p \in C$, so $\mathrm{div}(f)$ is a divisor.

***Proof*:**
The set where $\mathrm{ord}_p(f) > 0$ is where f vanishes. Writing $f = g/h$ with g, h regular on some affine open $U \subseteq C$ and h not identically zero, the zeros of f in U lie in $\mathcal{Z}(g) \cap U$, a proper closed subset of the irreducible curve C, hence finite by proposition 34.3.5. The same argument applied to $1/f$ handles the poles, and $C \setminus U$ is finite for the same reason. So only finitely many points contribute, as we sought to show.

Example 44.1.4: Divisors on the Projective Line

Take $C = \mathbb{P}^1_k$ with coordinate x on the standard chart and ∞ the point at infinity.

1. *A function with a zero and a pole.* $\mathrm{div}(x) = 0 - \infty$, written $(0) - (\infty)$: the function x vanishes to order 1 at the origin and has a simple pole at infinity, since $1/x$ is a uniformizer there. Its degree is 0, as theorem 44.2.2 requires.

2. *Higher order.* $\operatorname{div}(x^n) = n(0) - n(\infty)$ for $n \in \mathbb{Z}$, negative n interchanging the roles. So every divisor supported on $\{0, \infty\}$ of degree 0 is principal.

3. *A general ratio.* For $f = (x-a)/(x-b)$ with $a \neq b$,

$$\operatorname{div}(f) = (a) - (b)$$

with no contribution at infinity, the numerator and denominator having equal degree. This is the computation behind proposition 44.2.4: every degree-zero divisor on the line is a combination of such differences.

4. *A divisor that is not principal.* The single point (0) has degree $1 \neq 0$, so by theorem 44.2.2 it is not $\operatorname{div}(f)$ for any f. On $\mathbb{P}^1_k$ the degree is the only obstruction, by proposition 44.2.4; on a curve of positive genus it is not, which is what theorem 44.2.5 shows.

The two sources are compatible in the case that matters, and the computation is worth doing once.

Proposition 44.1.5: Divisors from Ratios of Forms

Let $C \subseteq \mathbb{P}^2_k$ be a nonsingular plane curve and let G, H be forms of the same degree e, neither divisible by C. Then G/H defines a rational function on C and

$$\operatorname{div}\left(\frac{G}{H}\right) = G \bullet C - H \bullet C$$

***Proof*:**
The ratio G/H is a quotient of two forms of equal degree, so it is a well defined element of $k(C)$, nonzero because H does not divide G modulo C.

Fix $p \in C$. Property (9) of corollary 42.4.2 says that at a nonsingular point of C the intersection number is an order: $I(p, C \cap G) = \operatorname{ord}_p(G_*)$, where G_* is the dehomogenization of G in a chart containing p, and likewise for H. Choosing the same chart for both, $\operatorname{ord}_p(G_*/H_*) = \operatorname{ord}_p(G_*) - \operatorname{ord}_p(H_*)$ because ord_p is a valuation. The coefficient of p in $G \bullet C - H \bullet C$ is exactly that difference, and the chart cancels because G and H have the same degree, as we sought to show.

44.2 Principal Divisors and Linear Equivalence

Definition 44.2.1: Principal Divisor and Linear Equivalence

This is definition 37.5.3 for a curve. A divisor of the form $\operatorname{div}(f)$ for some $f \in k(C)^*$ is *principal*. The principal divisors form a subgroup $\operatorname{Prin}(C) \subseteq \operatorname{Div}(C)$, since $\operatorname{div}(fg) = \operatorname{div}(f) + \operatorname{div}(g)$. Two divisors D and D' are *linearly equivalent*, written $D \sim D'$, if $D - D'$ is principal.

The first structural fact is that the degree cannot see the difference between linearly equivalent divisors.

Theorem 44.2.2: Principal Divisors Have Degree Zero

Let C be a nonsingular projective plane curve and $f \in k(C)^*$. Then $\deg \operatorname{div}(f) = 0$. Consequently $D \sim D'$ implies $\deg D = \deg D'$.

***Proof*:**
Write $f = G/H$ with G, H forms of the same degree e, neither divisible by C; this is possible because $k(C)$ consists of exactly such ratios. By proposition 44.1.5, $\operatorname{div}(f) = G \bullet C - H \bullet C$. Both intersection cycles have degree $e \deg(C)$ by theorem 43.1.1, so the difference has degree 0. The consequence is immediate from additivity of the degree, completing the proof.

That Bézout's theorem is what makes this work is worth pausing on. The statement $\deg \operatorname{div}(f) = 0$ says a rational function on a projective curve has as many zeros as poles, and its analytic counterpart is the argument principle. Projectivity is essential: on $\mathbb{A}^1_k$ the function x has one zero and no poles.

The converse question is when a degree-zero divisor is principal, and the first thing to settle is which functions have no divisor at all.

Proposition 44.2.3: Functions with Trivial Divisor

Let C be a nonsingular projective curve and $f \in k(C)^*$ with $\operatorname{div}(f) = 0$. Then f is constant.

***Proof*:**
If $\operatorname{div}(f) = 0$ then $\operatorname{ord}_p(f) \geq 0$ at every p, so f lies in every local ring $\mathcal{O}_p(C)$ and is therefore a regular function on all of C. A regular function on a projective variety is constant by corollary 40.2.4, completing the proof.

On the simplest curve the converse of theorem 44.2.2 holds outright, and the computation is the model for everything later.

Proposition 44.2.4: Divisors on the Projective Line

Every divisor of degree 0 on $\mathbb{P}^1_k$ is principal. In particular any two points of $\mathbb{P}^1_k$ are linearly equivalent.

***Proof*:**
Let $D = \sum_i n_i p_i$ have degree 0, and write $p_i = [a_i : b_i]$ with $L_i = b_i x - a_i y$ the linear form vanishing exactly at p_i. Fix an index j with p_j distinct from the others. For $i \neq j$ the ratio L_i/L_j is a rational function on $\mathbb{P}^1_k$, and in the affine chart containing p_i the form L_i generates the maximal ideal at p_i while L_j is a unit there, so $\operatorname{ord}_{p_i}(L_i/L_j) = 1$; symmetrically $\operatorname{ord}_{p_j}(L_i/L_j) = -1$, and the order is 0 elsewhere. Hence $\operatorname{div}(L_i/L_j) = p_i - p_j$. Set

$$f = \prod_i \left(\frac{L_i}{L_j}\right)^{n_i}$$

a legitimate rational function since the exponents are integers. Then $\operatorname{div}(f) = \sum_i n_i(p_i - p_j) = D - (\deg D)\, p_j = D$, as we sought to show.

For curves of higher degree the answer is different, and the difference is the whole subject. The following theorem is the engine: on a plane curve of degree at least three, distinct points are never linearly equivalent. Its proof is a single application of Max Noether's theorem.

Theorem 44.2.5: Distinct Points Are Not Equivalent

Let C be a nonsingular projective plane curve of degree $d \geq 3$, and let $p, q \in C$ satisfy $p \sim q$. Then $p = q$.

***Proof*:**
Suppose $\operatorname{div}(f) = p - q$ and write $f = G/H$ with G, H forms of the same degree e, neither divisible by C. By proposition 44.1.5 this reads $G \bullet C - H \bullet C = p - q$, that is

$$G \bullet C + q = H \bullet C + p$$

an equality of effective divisors.

Choose a line L through p and write $L \bullet C = p + E$, so $E \geq 0$ has degree $d - 1 \geq 2$ by theorem 43.1.1. Then

$$(LH) \bullet C = L \bullet C + H \bullet C = p + E + H \bullet C = E + q + G \bullet C \;\geq\; G \bullet C$$

Every point of C is nonsingular, so corollary 43.3.4(2) applies to the curve C, the curve G and the curve LH, and produces a curve of degree $\deg(LH) - \deg(G) = (e + 1) - e = 1$, that is a line L', with

$$L' \bullet C = (LH) \bullet C - G \bullet C = E + q$$

So L and L' both cut E out of C, one with p left over and the other with q. Now E is effective of degree $d - 1 \geq 2$, and there are two cases. If its support contains two distinct points, then L and L' share those two points and hence coincide. Otherwise $E = (d - 1)r$ for a single point r, and since $d - 1 \geq 2$ both lines meet C at r with multiplicity at least 2, making each of them the tangent line to C at r, which is unique by definition 42.1.6; again they coincide.

With $L = L'$, comparing $L \bullet C = p + E$ against $L' \bullet C = q + E$ gives $p = q$, as we sought to show.

The hypothesis $d \geq 3$ is not an artefact. For $d = 1$ the curve is a line and proposition 44.2.4 says all its points are equivalent; for $d = 2$ the leftover divisor E has degree 1, a single point, which does not determine a line, and indeed a nonsingular conic is isomorphic to $\mathbb{P}^1_k$ by the computation in example 39.4.4. The theorem is the first place where a plane curve of degree three behaves differently from every curve seen so far.

44.3 The Picard Group

Definition 44.3.1: Picard Group

The *Picard group* of a nonsingular projective curve C, which is its class group $\mathrm{Cl}(C)$ in the sense of definition 37.5.3, is

$$\mathrm{Pic}(C) = \frac{\mathrm{Div}(C)}{\mathrm{Prin}(C)}$$

The class of a divisor D is written $[D]$. The subgroup of classes of degree zero is written $\mathrm{Pic}^0(C)$.

By theorem 44.2.2 the degree descends to a homomorphism $\deg\colon \mathrm{Pic}(C) \to \mathbb{Z}$, and it is surjective for a plane curve, since a hyperplane section has degree $d \neq 0$ and any class of degree n can be built from points. Its kernel is $\mathrm{Pic}^0(C)$, so there is a short exact sequence

$$0 \to \mathrm{Pic}^0(C) \to \mathrm{Pic}(C) \xrightarrow{\deg} \mathbb{Z} \to 0$$

All the geometry is in Pic^0.

Example 44.3.2: The Picard Group of the Line

For $C = \mathbb{P}^1_k$, proposition 44.2.4 says every degree-zero divisor is principal, so $\mathrm{Pic}^0(\mathbb{P}^1_k) = 0$ and the degree map is an isomorphism $\mathrm{Pic}(\mathbb{P}^1_k) \cong \mathbb{Z}$. The Picard group is as small as it can be, and this is exactly the statement that no formal sum of points on the line carries information beyond how many points it has.

The contrast with a curve of higher degree is total. On a nonsingular plane cubic, Pic^0 turns out to be in bijection with the points of the curve itself, and the bijection carries the chord-tangent operation of section 45.1 to addition of divisor classes. That is section 45.2, and the one general fact it needs is recorded here.

Lemma 44.3.3: Hyperplane Sections Are All Equivalent

Let C be a nonsingular plane curve and L, M lines, neither a component of C. Then $L \cdot C \sim M \cdot C$.

***Proof*:**
The ratio L/M is a quotient of forms of degree 1, so proposition 44.1.5 gives $\mathrm{div}(L/M) = L \cdot C - M \cdot C$, which is therefore principal, completing the proof.

More generally the same argument shows $G \cdot C \sim G' \cdot C$ for any two curves G, G' of equal degree meeting C properly, so the class of a plane section depends only on the degree. This is the statement that a plane curve carries a distinguished element of $\mathrm{Pic}(C)$ in each degree, and everything computed below is measured against it.

44.4 The Genus of a Plane Curve

Section 38.5 computed the arithmetic genus of a nonsingular plane curve of degree d from its Hilbert polynomial and found

$$p_a = \frac{(d-1)(d-2)}{2}$$

That computation was about the embedding. This section gives the number a job.

Definition 44.4.1: Genus of a Nonsingular Plane Curve

The *genus* of a nonsingular projective plane curve C of degree d is

$$g(C) = \frac{(d-1)(d-2)}{2}$$

which is its arithmetic genus in the sense of definition 38.5.3.

So a line and a conic have genus 0, a cubic has genus 1, a quartic genus 3, and no plane curve has genus 2: the sequence $0, 0, 1, 3, 6, 10, \ldots$ skips it. Curves of genus 2 exist, but none of them embeds in $\mathbb{P}^2_k$ as a nonsingular curve.

The genus was introduced as a number attached to an embedding, and the following theorem is the first evidence that it is measuring the curve itself.

Theorem 44.4.2: Genus Zero Means Rational

Let C be a nonsingular projective plane curve of degree d. The following are equivalent:

1. $g(C) = 0$;
2. $d \leq 2$;
3. $C \cong \mathbb{P}^1_k$;
4. some two distinct points of C are linearly equivalent.

***Proof*:**
(1) $\Leftrightarrow$ (2) is arithmetic: $(d-1)(d-2)/2 = 0$ exactly when $d = 1$ or $d = 2$.

(2) $\Rightarrow$ (3): a line is $\mathbb{P}^1_k$. For a nonsingular conic C, fix $p \in C$ and project from p onto any line not through it. A line through p meets C in one further point by theorem 43.1.1, the tangent at p being the case where that point is p itself, so the projection is a bijection $C \to \mathbb{P}^1_k$; it is regular away from p, and regular at p by lemma 42.2.8, with a regular inverse for the same reason. Example 39.4.4(3) carries the computation out explicitly for $\mathcal{Z}(x^2 + y^2 - z^2)$.

(3) $\Rightarrow$ (4): an isomorphism carries rational functions to rational functions and preserves orders, hence carries principal divisors to principal divisors and linear equivalence to linear equivalence. Any two points of $\mathbb{P}^1_k$ are linearly equivalent by proposition 44.2.4, and a curve has more than one point, so the same holds on C.

(4) $\Rightarrow$ (2): this is theorem 44.2.5 in contrapositive form, which says $d \geq 3$ forces distinct points to be inequivalent, completing the proof.

Corollary 44.4.3: Nonsingular Plane Cubics Are Not Rational

A nonsingular projective plane cubic has genus 1 and is not isomorphic to $\mathbb{P}^1_k$. In particular it is not a rational curve.

***Proof*:**
Its genus is $(3-1)(3-2)/2 = 1 \neq 0$, so theorem 44.4.2 rules out $C \cong \mathbb{P}^1_k$. A rational curve is birational to $\mathbb{P}^1_k$, and a birational map between nonsingular projective curves is an isomorphism by lemma 42.2.8 applied in both directions, completing the proof.

This settles a claim made in passing in chapter 33, that the classification of elliptic curves up to birational equivalence needs the genus: the cubics are exactly the plane curves the genus first distinguishes from $\mathbb{P}^1_k$, and theorem 45.2.2 says what replaces the vanishing Picard group when it does.

Singular curves are handled by passing to a nonsingular model, which is what chapter 37 was built for, and the genus drops in a way controlled by the singularities.

44.4.4 Note: The Genus of a Singular Plane Curve Let C be an irreducible plane curve of degree d whose singular points are all *ordinary*, meaning m_p distinct tangent lines at a point of multiplicity m_p (definition 42.1.6), and let $\tilde{C}$ be its normalization (chapter 37), a nonsingular curve birational to C. Then

$$g(\tilde{C}) = \frac{(d-1)(d-2)}{2} - \sum_p \frac{m_p(m_p-1)}{2}$$

each singular point costing exactly $\binom{m_p}{2}$. The formula is proved in theorem 47.4.1, by counting adjoint curves of degree $d-3$ rather than by any computation on a blow-up.
That the right side is non-negative is corollary 43.2.5, proved in chapter 43 by a dimension count on curves of degree $d-1$, which now reads as the statement that a genus cannot be negative. The extremal curve $\mathcal{Z}(x^d + y^{d-1}z)$ of section 43.2 attains the bound and is rational, as section 47.4 exhibits explicitly.

Exercise 44.4.1

1. Show that $\operatorname{div}(fg) = \operatorname{div}(f) + \operatorname{div}(g)$ and $\operatorname{div}(1/f) = -\operatorname{div}(f)$, so that $\operatorname{Prin}(C)$ is a subgroup of $\operatorname{Div}(C)$ and $f \mapsto \operatorname{div}(f)$ is a homomorphism $k(C)^* \to \operatorname{Div}(C)$.
2. Deduce from proposition 44.2.3 that the kernel of that homomorphism is k^*, so that $\operatorname{Prin}(C) \cong k(C)^*/k^*$.
3. Let C be a nonsingular plane curve of degree d and H a line. Show that the class $[H \cdot C]$ generates the image of deg in $\mathbb{Z}$ if and only if $d = 1$, and describe the image in general.
4. Show that on a nonsingular plane cubic C with base point O, a point p satisfies $p \oplus p \oplus p = \varphi(O, O)$ if and only if p is an inflection point. Deduce, using theorem 45.2.2, that the inflection points form a subgroup of $E_k(C, O)$ when O is itself an inflection point.

5. Show that a divisor D on a nonsingular projective curve satisfies $D \sim 0$ and $D \geq 0$ only if $D = 0$.
6. Give an example of two divisors on a nonsingular plane cubic that have the same degree but are not linearly equivalent, and prove they are not.

45

The Group Law on Cubic Curves

A line meets a nonsingular cubic in three points, and that fact alone produces a group. The construction is elementary, its verification is not: associativity is a statement about the nine intersection points of two cubics, and the proof runs through Max Noether's theorem.

The chapter then explains where the group came from. Under the divisor theory of chapter 44 the chord-tangent law is addition in $\operatorname{Pic}^0(C)$, transported to the curve by $p \mapsto [p - O]$, and the hard-won associativity becomes the associativity of a quotient group. That description also settles the one loose end of the construction: it needed a base point, and nothing distinguishes one choice from another, but the target $\operatorname{Pic}^0(C)$ mentions no base point at all. The group obtained is the object that *Elliptic Curves* [12] takes as its subject.

45.1 The Chord-Tangent Construction

Let C be a nonsingular projective plane cubic. It is irreducible: were $C = C_1C_2$ a proper factorization, theorem 43.1.1 would give $\mathcal{Z}(C_1)$ and $\mathcal{Z}(C_2)$ a common point, and proposition 42.1.7 makes any such point singular on C. So no line is a component of C, and theorem 43.1.1 says every line meets it in exactly three points counted with multiplicity. Given $p, q \in \mathcal{Z}(C)$, not necessarily distinct, let L be the line through them, taken to be the tangent line at p when $p = q$. Then

$$L \cdot C = p + q + r$$

for a unique third point r, again with multiplicity. This defines a map

$$\varphi\colon \mathcal{Z}(C) \times \mathcal{Z}(C) \to \mathcal{Z}(C) \qquad \varphi(p, q) = r$$

which is visibly symmetric, and which satisfies $\varphi(p, \varphi(p, q)) = q$, since the line realizing the left side is the same L.

Figure 45.1 shows the two cases.

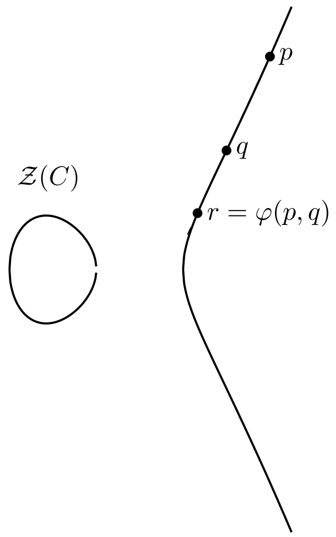

Figure 45.1: The chord through p and q meets the cubic in a third point. When $p = q$ the chord is replaced by the tangent line at p.

The map φ is a symmetric binary operation, but it is not a group law: there is no identity, since $\varphi(p, q) = q$ would force p to lie on the tangent at q for every q. The repair is to compose with φ once more against a chosen base point. Fix any $O \in \mathcal{Z}(C)$ and define

$$p \oplus q = \varphi\big(O, \varphi(p, q)\big)$$

Lemma 45.1.1: The Base Point Is an Identity

For every $p \in \mathcal{Z}(C)$, $O \oplus p = p \oplus O = p$.

***Proof*:**
Symmetry of φ gives $O \oplus p = p \oplus O$, so it is enough to compute one. Setting $q = \varphi(O, p)$, the involution property gives

$$O \oplus p = \varphi\big(O, \varphi(O, p)\big) = \varphi(O, q) = p$$

as we sought to show.

Before the group law can be proved, one point needs care. The natural guess for the inverse of p is $\varphi(p, O)$, and the natural guess for collinearity is that three collinear points sum to O. Both are false for a general base point, and the reason is that $\varphi(O, O)$, the third point on the tangent at O, need not be O itself. A point p with $\varphi(p, p) = p$ is one where the tangent line meets C triply, that is an *inflection point*, and a nonsingular cubic has only finitely many of them.

Lemma 45.1.2: Collinearity and the Sum

Let $p, q, r \in \mathcal{Z}(C)$. Then p, q, r are collinear, in the sense that $L \bullet C = p + q + r$ for some line L, if and only if

$$p \oplus q \oplus r = \varphi(O, O)$$

In particular, if the base point O is an inflection point then $\varphi(O, O) = O$ and three collinear points sum to the identity.

***Proof*:**
Suppose p, q, r are collinear, so $r = \varphi(p, q)$. Then $p \oplus q = \varphi(O, r)$, and

$$(p \oplus q) \oplus r = \varphi\Big(O, \varphi\big(\varphi(O, r), r\big)\Big)$$

The points O, r and $\varphi(O, r)$ are collinear by definition of φ, so $\varphi(\varphi(O, r), r) = O$, and the right side is $\varphi(O, O)$.

Conversely, suppose $p \oplus q \oplus r = \varphi(O, O)$, and let $r' = \varphi(p, q)$, so that p, q, r' are collinear. By the first part $p \oplus q \oplus r' = \varphi(O, O)$ as well, so r and r' have the same image under the map $x \mapsto (p \oplus q) \oplus x$. That map is injective once $\oplus$ is known to be a group law. Proposition 45.1.4 establishes this using only the involution property of φ and lemma 45.1.3, never the present converse, so there is no circularity. Hence $r = r'$ and p, q, r are collinear, as we sought to show.

The associativity of $\oplus$ is the hard point, and it rests on the following consequence of Max Noether's theorem: two cubics that agree with C in eight of their nine intersection points agree in the ninth as well.

Lemma 45.1.3: Cubic Point Counting

Let C be an irreducible cubic and C', C'' cubics with no component in common with C. Suppose

$$C' \bullet C = \sum_{i=1}^{9} p_i \qquad C'' \bullet C = \sum_{i=1}^{8} p_i + q$$

where the p_i are nonsingular points of C, not necessarily distinct. Then $q = p_9$.

***Proof*:**
Suppose $q \neq p_9$ and choose a line L through p_9 not passing through q, possible because the lines through p_9 sweep out the plane and only one of them contains q. Write $L \bullet C = p_9 + r + s$.

The quartic LC'' satisfies

$$(LC'') \bullet C = L \bullet C + C'' \bullet C = \sum_{i=1}^{9} p_i + q + r + s \ \geq\ C' \bullet C$$

Every point of $\mathcal{Z}(C') \cap \mathcal{Z}(C)$ is a nonsingular point of C by hypothesis, so corollary 43.3.4(2) applies to the triple (C, C', LC'') and produces a curve of degree $\deg(LC'') - \deg(C') = 4 - 3 = 1$, that is a line L', with

$$L' \bullet C = (LC'') \bullet C - C' \bullet C = q + r + s$$

Now L and L' coincide. If $r \neq s$, both contain the two distinct points r and s, and two distinct points determine a line. If $r = s$, then $L \bullet C \geq 2r$ and $L' \bullet C \geq 2r$, so both are tangent to C at the nonsingular point r, and the tangent line there is unique by definition 42.1.6.

But $L' = L$ forces q to lie on L, contradicting the choice of L. Hence $q = p_9$, as we sought to show.

Proposition 45.1.4: Group Law For Cubics

Let C be a nonsingular projective plane cubic and $O \in \mathcal{Z}(C)$ a base point. Then $\mathcal{Z}(C)$ with the operation $\oplus$ is an abelian group with identity O, in which the inverse of p is

$$\ominus p = \varphi\big(p, \varphi(O,O)\big)$$

Write $E_k(C,O)$ for this group.

***Proof*:**
Commutativity is the symmetry of φ, and O is an identity by lemma 45.1.1.

Inverses. Let $t = \varphi(O,O)$ and $\ominus p = \varphi(p,t)$. Only the involution property is needed: by definition of $\oplus$,

$$p \oplus \ominus p = \varphi\big(O, \varphi(p, \ominus p)\big) = \varphi\big(O, \varphi(p, \varphi(p,t))\big) = \varphi(O,t) = \varphi\big(O, \varphi(O,O)\big) = O$$

the third equality applying $\varphi(p, \varphi(p,-)) = \mathrm{id}$ and the last applying $\varphi(O, \varphi(O,-)) = \mathrm{id}$.

Associativity. Let $p, q, r \in \mathcal{Z}(C)$ and introduce six lines by

$$\begin{array}{lll} L_1 \bullet C = p + q + s' & M_1 \bullet C = O + s' + s & L_2 \bullet C = s + r + t' \\ M_2 \bullet C = q + r + u' & L_3 \bullet C = O + u' + u & M_3 \bullet C = p + u + t'' \end{array}$$

so that $s = \varphi(O,s') = p \oplus q$ and $u = \varphi(O,u') = q \oplus r$. Then

$$(p \oplus q) \oplus r = \varphi(O, \varphi(s,r)) = \varphi(O,t') \qquad p \oplus (q \oplus r) = \varphi(O, \varphi(p,u)) = \varphi(O,t'')$$

so it suffices to prove $t' = t''$. Put $C' = L_1L_2L_3$ and $C'' = M_1M_2M_3$, both cubics with no component in common with the irreducible C, since a line meets C in three points and so is not a component. Adding the three displayed cycles in each row,

$$C' \bullet C = p + q + s' + s + r + t' + O + u' + u \qquad C'' \bullet C = O + s' + s + q + r + u' + p + u + t''$$

The two agree in the eight points O, p, q, r, s, s', u, u', and every point of $\mathcal{Z}(C)$ is nonsingular, so lemma 45.1.3 gives $t' = t''$.

Thus $\oplus$ is an abelian group law, completing the proof.

The group depends on the base point only up to isomorphism, and the isomorphism is explicit. Given a second base point O', set $Q = \varphi(O,O')$ and

$$\alpha\colon E_k(C,O) \to E_k(C,O') \qquad \alpha(p) = \varphi(Q,p)$$

This sends O to O', since the line through Q and O is the line through O, O' and Q. That α is a group isomorphism is proved in section 45.3, once section 45.2 has identified $E_k(C,O)$ with a group of divisor classes and made the computation one line rather than a chain of collinearity arguments.

45.2 The Group Law via the Picard Group

The chord-tangent law was constructed by hand, and its associativity cost a nine-point argument through Max Noether. This section explains where the group comes from: it is $\operatorname{Pic}^0(C)$, transported to the curve.

Throughout, C is a nonsingular projective plane cubic with base point O, and φ, $\oplus$ are as in section 45.1. The bridge is a single linear equivalence.

Proposition 45.2.1: The Chord-Tangent Law Is Addition of Classes

For all $p, q \in C$,

$$p + q \;\sim\; (p \oplus q) + O$$

Consequently the map

$$\theta\colon E_k(C,O) \to \operatorname{Pic}^0(C) \qquad \theta(p) = [\,p - O\,]$$

is a group homomorphism.

***Proof*:**
Let $r = \varphi(p,q)$ and $s = \varphi(O,r) = p \oplus q$, and let L and M be the lines realizing them, so that

$$L \cdot C = p + q + r \qquad M \cdot C = O + r + s$$

By lemma 44.3.3 these are linearly equivalent, and subtracting the common r gives $p + q \sim O + s$, which is the display.

For the consequence, θ lands in Pic^0 because $\deg(p - O) = 0$, and

$$\theta(p) + \theta(q) = [\,p + q - 2O\,] = [\,(p \oplus q) + O - 2O\,] = [\,(p \oplus q) - O\,] = \theta(p \oplus q)$$

using the display in the middle step, as we sought to show.

Theorem 45.2.2: The Group Law Is the Picard Group

Let C be a nonsingular projective plane cubic with base point O. Then

$$\theta\colon E_k(C,O) \longrightarrow \operatorname{Pic}^0(C) \qquad \theta(p) = [\,p - O\,]$$

is an isomorphism of abelian groups.

***Proof*:**
It is a homomorphism by proposition 45.2.1.

Injective. If $\theta(p) = \theta(q)$ then $p - O \sim q - O$, so $p \sim q$, and theorem 44.2.5 gives $p = q$, the cubic having degree 3.

Surjective. Let D have degree 0 and write $D = \sum_{i=1}^{n} p_i - \sum_{j=1}^{n} q_j$, the two counts being equal because $\deg D = 0$; points may repeat, and $n = 0$ gives $D = 0 = \theta(O)$. First,

$$\sum_{i=1}^{n} p_i \;\sim\; (p_1 \oplus \cdots \oplus p_n) + (n-1)O$$

by induction on n. The case $n = 1$ is trivial. Given the statement for n, add p_{n+1} to both sides and apply proposition 45.2.1 to the pair $(p_1 \oplus \cdots \oplus p_n,\ p_{n+1})$, which replaces their sum by $(p_1 \oplus \cdots \oplus p_{n+1}) + O$; that is the statement for $n + 1$.

Writing $P = p_1 \oplus \cdots \oplus p_n$ and $Q = q_1 \oplus \cdots \oplus q_n$ and subtracting the two instances, the $(n-1)O$ terms cancel and $D \sim P - Q$. Finally

$$[P - Q] = [P - O] - [Q - O] = \theta(P) - \theta(Q) = \theta(P \ominus Q)$$

so D lies in the image, as we sought to show.

Associativity of $\oplus$, which proposition 45.1.4 obtained from lemma 45.1.3 and so ultimately from Max Noether's theorem, is now visible as the associativity of addition in a quotient group. The two proofs are not independent: theorem 44.2.5 itself runs through Max Noether. What changes is where the difficulty sits. In section 45.1 it sits in a configuration of six lines; here it sits in the statement that a rational function on a cubic cannot have a single simple pole.

45.2.3 Note: Which Facts Are Doing the Work Two theorems carry theorem 45.2.2, and they pull in opposite directions. Lemma 44.3.3 says linear equivalence is coarse enough that all line sections agree, which is what makes θ additive. Theorem 44.2.5 says it is fine enough that points stay apart, which is what makes θ injective. On a conic the second fails and Pic^0 collapses to zero; on a line there is nothing to say at all. Degree three is the smallest case where both hold, which is the precise sense in which the group law is a phenomenon of cubics.

45.3 Independence of the Base Point

The construction of $\oplus$ required choosing O, and nothing recommends one point over another. Theorem 45.2.2 settles the matter at once, because its target does not mention O.

Theorem 45.3.1: Independence of the Base Point

Let C be a nonsingular projective plane cubic and $O, O' \in C$. Then

$$E_k(C,O) \;\cong\; E_k(C,O')$$

both being isomorphic to $\operatorname{Pic}^0(C)$, which is defined without reference to a base point.

***Proof*:**
Write θ_O and $\theta_{O'}$ for the two maps of theorem 45.2.2, each an isomorphism onto $\operatorname{Pic}^0(C)$. Then $\theta_{O'}^{-1} \circ \theta_O$ is an isomorphism $E_k(C,O) \to E_k(C,O')$, completing the proof.

The explicit map promised in section 45.1 is almost that one, differing by an inversion.

Proposition 45.3.2: The Explicit Isomorphism

Let $Q = \varphi(O,O')$ and $\alpha(p) = \varphi(Q,p)$. Then $\alpha\colon E_k(C,O) \to E_k(C,O')$ is a group isomorphism, and

$$\theta_{O'}\big(\alpha(p)\big) = -\,\theta_O(p)$$

***Proof*:**
The points Q, p and $\alpha(p)$ are collinear by definition of φ, and so are O, O' and Q. By lemma 44.3.3 the two line sections are linearly equivalent:

$$Q + p + \alpha(p) \;\sim\; O + O' + Q$$

Cancelling Q and rearranging gives $\alpha(p) - O' \sim O - p$, that is

$$\theta_{O'}\big(\alpha(p)\big) = [\,\alpha(p) - O'\,] = [\,O - p\,] = -[\,p - O\,] = -\theta_O(p)$$

So $\alpha = \theta_{O'}^{-1} \circ (-\mathrm{id}) \circ \theta_O$. Inversion is an automorphism of an abelian group, and θ_O, $\theta_{O'}$ are isomorphisms, so α is one too, as we sought to show.

That the natural explicit map inverts is not a defect of the choice; no map defined by a single application of φ can avoid it, since φ itself reverses the sign. Composing twice, $p \mapsto \varphi(O', \varphi(Q,p))$ is the base-point-free isomorphism $\theta_{O'}^{-1}\theta_O$ on the nose.

45.3.3 Note: What the Group Does and Does Not Depend On The *group* $E_k(C,O)$ depends on O only up to isomorphism, and the isomorphism class is that of $\operatorname{Pic}^0(C)$. What does depend on O is the identification of points of C with group elements: which point is the identity, and hence which triples sum to zero. Choosing O to be an inflection point makes lemma 45.1.2 read in its familiar form, three collinear points summing to the identity, and this is why the literature almost always makes that choice for a curve given in Weierstrass form, where the point at infinity is an inflection.

Exercise 45.3.1

1. Show that a nonsingular *projective* plane curve must be irreducible, and give a nonsingular *affine* plane curve that is not.
2. Let C be a nonsingular plane cubic with base point O. Show that $\varphi(O, O) = O$ if and only if O is an inflection point, and that in that case the inverse of proposition 45.1.4 takes the familiar form $\ominus p = \varphi(p, O)$.
3. With O an inflection point, show that the inflection points of C are exactly the elements of order dividing 3 in $E_k(C, O)$, and bound their number using theorem 43.1.1 and the Hessian.
4. Show that a nonsingular plane cubic has no point p with $\varphi(p, p) = p$ other than its inflection points.
5. Let C be a nonsingular plane cubic and $p, q \in C$ with $p \sim q$ as divisors. Show $p = q$, and explain precisely which step of the argument fails on a nonsingular conic.
6. Compare the labour of verifying associativity of $\oplus$ directly on $y^2 = x^3 + 1$ with $O = [0 : 1 : 0]$, for three points of your choosing, against the one-line argument of theorem 45.2.2.

46

Differential Forms and the Canonical Class

Every invariant of a curve met so far has been extrinsic: the degree depends on an embedding, the multiplicity on a choice of coordinates, the divisor class group on nothing at all but says little by itself. This chapter constructs the invariant that governs the rest, the canonical class, and it does so from the one piece of machinery not yet used, differentiation.

Derivations, the module $\Omega_{B/A}$ and its universal property, and the two fundamental exact sequences are commutative algebra, developed in section 21.3; this chapter takes them as given and does the geometry. What comes out is a divisor class attached to a curve with no choices at all, whose degree is $2g-2$, and which chapter 48⋆ shows to be the error term in Riemann's inequality.

46.1 Differential Forms on a Variety

Definition 46.1.1: Differentials on a Variety

Let X be an affine variety over k. The *module of differentials* of X is $\Omega_X = \Omega_{k[X]/k}$, the module of relative differential forms of definition 21.3.2, together with the universal k-derivation $d\colon k[X] \to \Omega_X$. Its elements are the *differential forms* on X.
For $p \in X$ the *forms at* p are $\Omega_{X,p} = \Omega_X \otimes_{k[X]} \mathcal{O}_p(X)$, and for an irreducible X the *rational differential forms* are $\Omega_{k(X)/k}$, a vector space over $k(X)$.

Example 46.1.2: Modules of Differentials

1. *Affine space.* $\Omega_{\mathbb{A}^n_k}$ is free of rank n over $k[x_1, \dots, x_n]$ with basis $dx_1, \dots, dx_n$, since a k-derivation is determined by arbitrary choices of the dx_i. This is the first exercise of exercise set 46.2.1.

2. *A nonsingular plane curve.* On $C = \mathcal{Z}(y - x^2)$ the relation $dy = 2x\,dx$ holds, so Ω_C is generated by dx alone and is free of rank $1 = \dim C$, as proposition 46.1.3 predicts.

3. *The cuspidal cubic.* On $C = \mathcal{Z}(y^2 - x^3)$ the relation is $2y\,dy = 3x^2\,dx$. At the origin both coefficients vanish, so the relation imposes nothing there and $\Omega_{C,0} \otimes k$ has dimension 2, while $\dim C = 1$. By proposition 46.1.3 the origin is singular, which is the fifth exercise of exercise set 46.2.1. Away from the origin the relation is nontrivial and Ω is free of rank 1.

4. *A form with a pole.* On $\mathbb{P}^1_k$ the form dx has $\operatorname{div}(dx) = -2(\infty)$, computed in the second exercise of exercise set 46.2.1. Its degree -2 is $2g - 2$ with $g = 0$, which is theorem 46.2.4 in the smallest case.

Two facts do all the work, and both are transported from the algebra.

Proposition 46.1.3: Differentials Detect Smoothness

Let X be a variety of dimension n and $p \in X$. Then

$$\dim_k \Omega_{X,p} \otimes_{\mathcal{O}_p(X)} k \;=\; \dim_k \mathfrak{m}_p/\mathfrak{m}_p^2$$

so p is a nonsingular point if and only if that dimension is n. If X is nonsingular then $\Omega_{X,p}$ is a free $\mathcal{O}_p(X)$-module of rank n.

***Proof*:**
Apply the second fundamental exact sequence (proposition 21.3.7) to $k[X] \to \mathcal{O}_p(X) \to k$ with $I = \mathfrak{m}_p$. Since $\Omega_{k/k} = 0$, it reads

$$\mathfrak{m}_p/\mathfrak{m}_p^2 \xrightarrow{\delta} \Omega_{X,p} \otimes k \to 0$$

and δ is injective because a k-linear functional on $\mathfrak{m}_p/\mathfrak{m}_p^2$ extends to a k-derivation of $\mathcal{O}_p(X)$, by sending f to the class of $f - f(p)$; so δ has a left inverse. That gives the displayed equality, and corollary 35.1.1 identifies the right side with n exactly at the nonsingular points.

For freeness, $\Omega_{X,p}$ is a finitely generated module over the Noetherian local ring $\mathcal{O}_p(X)$ by corollary 21.3.8, whose fibre has dimension n; a finitely generated module over a regular local ring whose fibre dimension equals the generic rank is free, which is lemma 21.3.12, completing the proof.

Corollary 46.1.4: Rational Differentials on a Curve

Let C be a nonsingular projective curve. Then $\Omega_{k(C)/k}$ is a one-dimensional vector space over $k(C)$. If t is a uniformizer at a point p, then dt is a basis, and every rational differential form is $f\,dt$ for a unique $f \in k(C)$.

***Proof*:**
By proposition 46.1.3 the module $\Omega_{C,p}$ is free of rank 1 over $\mathcal{O}_p(C)$, so tensoring up to the fraction field gives $\dim_{k(C)} \Omega_{k(C)/k} = 1$.

For the basis, $\mathcal{O}_p(C)$ is a discrete valuation ring with uniformizer t and $\mathfrak{m}_p/\mathfrak{m}_p^2$ is spanned by the class of t, so dt generates $\Omega_{C,p} \otimes k$ under the isomorphism of proposition 46.1.3. Nakayama's lemma then makes dt a generator of the free rank-one module $\Omega_{C,p}$, hence a basis after tensoring with $k(C)$, completing the proof.

46.2 The Canonical Class

A nonzero rational differential form on a curve has zeros and poles, exactly as a rational function does, and they assemble into a divisor. The point of the section is that the divisor class does not depend on the form.

Definition 46.2.1: The Divisor of a Differential Form

Let C be a nonsingular projective curve and $\omega \in \Omega_{k(C)/k}$ nonzero. For $p \in C$ with uniformizer t, write $\omega = f\,dt$ with $f \in k(C)$ as in corollary 46.1.4, and set $\operatorname{ord}_p(\omega) = \operatorname{ord}_p(f)$. The *divisor* of ω is

$$\operatorname{div}(\omega) = \sum_{p \in C} \operatorname{ord}_p(\omega)\, p$$

Proposition 46.2.2: The Divisor of a Form Is Well Defined

$\operatorname{ord}_p(\omega)$ does not depend on the choice of uniformizer, and $\operatorname{ord}_p(\omega) = 0$ for all but finitely many p, so $\operatorname{div}(\omega)$ is a divisor.

***Proof*:**
Let s be another uniformizer at p, so $s = ut$ with u a unit of $\mathcal{O}_p(C)$. Then $ds = u\,dt + t\,du$, and writing $du = u'\,dt$ with $u' \in \mathcal{O}_p(C)$ gives $ds = (u + tu')\,dt$. The coefficient $u + tu'$ is a unit, being u modulo $\mathfrak{m}_p$, so $\omega = f\,dt = f(u+tu')^{-1}ds$ and the order of the coefficient is unchanged.

For finiteness, cover C by finitely many affine opens; on each, $\omega = f\,dg$ for some $f, g \in k[U]$, and $\operatorname{ord}_p(\omega) \neq 0$ only where f or dg degenerates, a proper closed subset, hence finite by proposition 34.3.5, completing the proof.

Theorem 46.2.3: The Canonical Class

Let C be a nonsingular projective curve. Any two nonzero rational differential forms on C have linearly equivalent divisors, so their common class

$$K_C = [\mathrm{div}(\omega)] \;\in\; \mathrm{Pic}\,(C)$$

is an invariant of C, the *canonical class*. A divisor in that class is a *canonical divisor*.

***Proof*:**
Let ω, ω' be nonzero. By corollary 46.1.4 the space $\Omega_{k(C)/k}$ is one-dimensional over $k(C)$, so $\omega' = f\omega$ for a unique $f \in k(C)^*$. At each p, writing $\omega = g\,dt$, gives $\omega' = fg\,dt$ and hence $\mathrm{ord}_p(\omega') = \mathrm{ord}_p(f) + \mathrm{ord}_p(\omega)$. Summing,

$$\mathrm{div}(\omega') = \mathrm{div}(f) + \mathrm{div}(\omega)$$

so the two divisors differ by a principal one and are linearly equivalent by definition 44.2.1, completing the proof.

That one line is the whole point of introducing differentials: a curve carries a distinguished divisor class, obtained without choosing an embedding, a point, or a coordinate. Its degree is the genus in disguise.

Theorem 46.2.4: The Degree of the Canonical Class

Let C be a nonsingular projective plane curve of degree d, with genus $g = \binom{d-1}{2}$ as in definition 44.4.1. Then

$$K_C = (d-3)\,H \cdot C \qquad \text{and} \qquad \deg K_C = 2g - 2$$

where H is a line.

***Proof*:**
Work in the affine chart $z = 1$ with $C = \mathcal{Z}(f)$, $f = F(x, y, 1)$, and consider the rational form

$$\omega = \frac{dx}{\partial f/\partial y}$$

On C one has $f = 0$, so $0 = df = \partial_x f\,dx + \partial_y f\,dy$ and therefore $\omega = -\,dy/\partial_x f$ as well. At a point where $\partial_y f \neq 0$ the function x is a uniformizer, since $\mathcal{O}_p(C)$ is a discrete valuation ring and dx generates $\Omega_{C,p}$ by proposition 46.1.3; there ω has neither zero nor pole. Where $\partial_y f = 0$ the second expression applies and $\partial_x f \neq 0$, again giving neither zero nor pole, since C is nonsingular and the two partials cannot both vanish. So ω has no zeros and no poles in the affine chart.

It remains to compute the behaviour on the line at infinity. Homogenizing, $x = X/Z$ and $\partial f/\partial y$ has degree $d-1$ as a form, so ω is a ratio in which the numerator contributes -2 and the denominator $-(d-1)$ in the variable Z; collecting, ω acquires a zero of order $d-3$ along each point of C at infinity. Since the points at infinity are $H \cdot C$ for the line $H = \mathcal{Z}(Z)$, this reads

$$\mathrm{div}(\omega) = (d-3)\,H \cdot C$$

Taking degrees, $\deg K_C = (d-3)\cdot d$ by theorem 43.1.1, and

$$d(d-3) = (d-1)(d-2) - 2 = 2g - 2$$

as we sought to show.

This settles what chapter 48⋆ previously had to cite Fulton for: the identification $K = (d-3)H \bullet C$ and the degree $2g-2$ are now proved, and Riemann-Roch may quote them.

Example 46.2.5: Canonical Classes of Small Curves

1. *A line*, $d = 1$: $K_C = -2H \bullet C$ of degree $-2 = 2\cdot 0 - 2$. On $\mathbb{P}^1_k$ the form dx has a double pole at infinity and no zeros, which is the whole story.
2. *A conic*, $d = 2$: $K_C = -H \bullet C$ of degree -2, consistent with a conic being isomorphic to $\mathbb{P}^1_k$ by theorem 44.4.2.
3. *A cubic*, $d = 3$: $K_C = 0$, so the canonical class is trivial and $\deg K_C = 0 = 2g-2$ with $g = 1$. A smooth cubic carries a nowhere-zero, nowhere-polar differential form, which is the invariant differential of the group law of chapter 45 and the reason theorem 48.4.4 could take $K \sim 0$.
4. *A quartic*, $d = 4$: $K_C = H \bullet C$ of degree $4 = 2\cdot 3 - 2$, so the canonical class is the hyperplane class and the canonical map is the original embedding, as exercise set 48.4.1 observes.

Exercise 46.2.1

1. Show that $\Omega_{\mathbb{A}^n_k}$ is free of rank n over $k[x_1, \dots, x_n]$ with basis $dx_1, \dots, dx_n$, directly from the universal property.
2. Compute $\operatorname{div}(dx)$ on $\mathbb{P}^1_k$ and verify $\deg K = -2$.
3. Let C be the nonsingular cubic $\mathcal{Z}(y^2z - x^3 - axz^2 - bz^3)$. Show that $\omega = dx/y$ is regular and nowhere zero on C, so that $K_C = 0$ directly.
4. Show that a nonsingular plane curve of degree $d \geq 4$ has $\deg K_C > 0$, and deduce that it admits no nonconstant map to $\mathbb{P}^1_k$ of degree 1.
5. Use proposition 46.1.3 to give a second proof that the cuspidal cubic $\mathcal{Z}(y^2 - x^3)$ is singular at the origin, by computing Ω there.
6. Show that $\operatorname{div}(\omega)$ for ω a nonzero rational form depends on ω only up to linear equivalence, and that every divisor in the class K_C arises as $\operatorname{div}(\omega)$ for some ω.

47

Blowing Up and Resolution of Curve Singularities

Chapter 37 already resolved the singularities of a curve: corollary 37.4.2 says the normalization of any curve is smooth. That proof is an existence statement obtained by taking an integral closure, and it says nothing about what the smooth model looks like or how singular the original was.

This chapter gives the geometric construction. Blowing up replaces a point by the set of directions through it, separating branches that were tangled together, and it is explicit enough to compute with: the multiplicity of a curve at a point is visible as the multiplicity with which the exceptional divisor appears in the total transform, and the tangent lines of definition 42.1.6 reappear as the points where the strict transform crosses it. The construction also survives into dimensions where normalization is not enough, which is why it, and not the integral closure, is what resolution of singularities means in general.

47.1 The Blow-Up of the Plane at a Point

A point of $\mathbb{P}^1_k$ is a direction through the origin of $\mathbb{A}^2_k$. The blow-up is the variety obtained by attaching all of those directions to the plane at once, in such a way that a curve through the origin remembers which direction it arrived from.

Definition 47.1.1: Blow-Up of the Plane at the Origin

Let $0 = (0,0) \in \mathbb{A}^2_k$ and give $\mathbb{P}^1_k$ homogeneous coordinates $[s:t]$. The *blow-up* of $\mathbb{A}^2_k$ at the origin is

$$\mathrm{Bl}_0\mathbb{A}^2_k = \big\{ \big((x,y),[s:t]\big) \in \mathbb{A}^2_k \times \mathbb{P}^1_k \;\big|\; xt = ys \big\}$$

with $\pi\colon \mathrm{Bl}_0\mathbb{A}^2_k \to \mathbb{A}^2_k$ the first projection. The *exceptional divisor* is $E = \pi^{-1}(0)$.

The defining equation says that the vector (x,y), when nonzero, points in the direction $[s:t]$. So away from the origin the second coordinate is determined by the first, and over the origin it is unconstrained.

Proposition 47.1.2: Basic Properties of the Blow-Up

Let $B = \mathrm{Bl}_0\mathbb{A}^2_k$. Then:

1. B is closed in $\mathbb{A}^2_k \times \mathbb{P}^1_k$, and is covered by two open sets each isomorphic to $\mathbb{A}^2_k$;
2. B is an irreducible quasi-projective variety of dimension 2;
3. π restricts to an isomorphism $B \setminus E \to \mathbb{A}^2_k \setminus \{0\}$;
4. $E = \{0\} \times \mathbb{P}^1_k \cong \mathbb{P}^1_k$, and π is not an isomorphism at any point of E.

***Proof*:**
(1). The equation $xt = ys$ is homogeneous of degree 1 in $[s:t]$, so its vanishing is well defined on $\mathbb{A}^2_k \times \mathbb{P}^1_k$, and being closed is a local condition on the cover by $\{s \neq 0\}$ and $\{t \neq 0\}$. On $\{s \neq 0\} \cong \mathbb{A}^2_k \times \mathbb{A}^1_k$, with $v = t/s$ and coordinates (x,y,v), the equation reads $y = xv$, whose zero set is the graph of $(x,v) \mapsto xv$ and so is closed and isomorphic to $\mathbb{A}^2_k$ with coordinates (x,v). Call this chart U_s; then

$$\pi|_{U_s}(x,v) = (x,xv)$$

Symmetrically the chart U_t where $t \neq 0$ is $\mathbb{A}^2_k$ with coordinates (u,y), where $u = s/t$ and $x = uy$, and $\pi|_{U_t}(u,y) = (uy,y)$. The two charts cover B, which is therefore closed.

(2). Each U_s, U_t is irreducible of dimension 2, being isomorphic to $\mathbb{A}^2_k$, and they meet, since the point $((1,1),[1:1])$ lies in both. Lemma 40.1.5 makes B irreducible, and corollary 34.3.3 reads its dimension off either chart as 2.

(3). For $(x,y) \neq (0,0)$ the equation $xt = ys$ determines $[s:t]$ uniquely, namely $[x:y]$, so π is bijective there with inverse $(x,y) \mapsto ((x,y),[x:y])$, which is regular because x and y do not vanish simultaneously.

(4). Setting $x = y = 0$ leaves $[s:t]$ free, so $E = \{0\} \times \mathbb{P}^1_k$. Any nonempty open neighbourhood of a point of E meets E in an infinite set, since $E \cong \mathbb{P}^1_k$ is irreducible, and π sends all of it to the origin. So π is not injective on any such neighbourhood, completing the proof.

The chart map $\pi|_{U_s}(x,v) = (x,xv)$ has been seen before. It is the map of example 40.5.2, whose fibre over the origin jumped from a point to a line, and that jump is now identified: the fibre is the exceptional divisor, and the jump is the whole point of the construction rather than a pathology.

What E records is direction, and the following makes that precise.

Proposition 47.1.3: The Exceptional Divisor Parameterizes Directions

Let $L = \mathcal{Z}(bx - ay) \subseteq \mathbb{A}^2_k$ be a line through the origin, with $[a : b] \in \mathbb{P}^1_k$. Then the closure in B of $\pi^{-1}(L \setminus \{0\})$ is a curve meeting E in the single point $(0, [a : b])$, and distinct lines meet E in distinct points.

***Proof*:**
Parameterize $L \setminus \{0\}$ by $\lambda \mapsto (\lambda a, \lambda b)$ with $\lambda \neq 0$. Its preimage under the isomorphism of proposition 47.1.2(3) is $\big((\lambda a, \lambda b), [\lambda a : \lambda b]\big) = \big((\lambda a, \lambda b), [a : b]\big)$, so the preimage lies in $\mathbb{A}^2_k \times \{[a : b]\}$, a closed set. Its closure therefore also lies there, and adding the limit $\lambda \to 0$ gives the point $(0, [a : b])$. Distinct lines through the origin have distinct $[a : b]$, completing the proof.

So two lines through the origin, which meet in the plane, become disjoint after blowing up: they are pulled apart by exactly the amount needed to record that they arrived along different directions. That is the mechanism by which a node will be resolved in section 47.3.

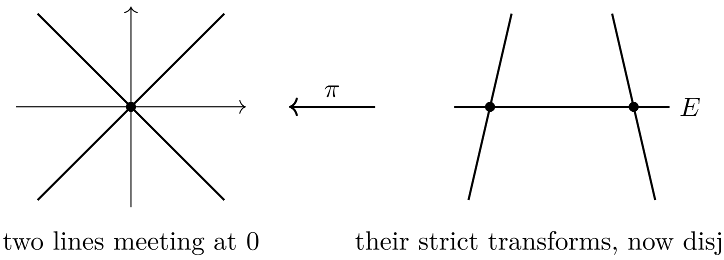

Figure 47.1: Blowing up separates the branches of a node. The exceptional divisor E records the direction along which each branch approaches the origin.

47.2 Blowing Up a Variety Along a Subvariety

Nothing in definition 47.1.1 was special to dimension two.

Definition 47.2.1: Blow-Up of Affine Space at the Origin

Give $\mathbb{P}^{n-1}_k$ homogeneous coordinates $[\ell_1 : \cdots : \ell_n]$. The blow-up of $\mathbb{A}^n_k$ at the origin is

$$\mathrm{Bl}_0\mathbb{A}^n_k = \big\{(x, [\ell]) \in \mathbb{A}^n_k \times \mathbb{P}^{n-1}_k \;\big|\; x_i \ell_j = x_j \ell_i \text{ for all } i, j\big\}$$

with π the first projection and $E = \pi^{-1}(0) \cong \mathbb{P}^{n-1}_k$.

The equations are exactly those saying the matrix with rows x and ℓ has rank at most one, which is the 2×2 minor condition of proposition 40.1.3. The proof of proposition 47.1.2 carries over verbatim with n charts in place of two: on the chart $\ell_i \neq 0$, setting $v_j = \ell_j/\ell_i$ gives $x_j = x_i v_j$ for $j \neq i$, so the chart is $\mathbb{A}^n_k$ with coordinates $(x_i, v_j)_{j \neq i}$ and

$$\pi(x_i, v) = (x_i v_1, \ldots, x_i, \ldots, x_i v_n)$$

Hence $\mathrm{Bl}_0\mathbb{A}^n_k$ is an irreducible quasi-projective variety of dimension n, isomorphic to $\mathbb{A}^n_k$ away from E, and E is a $\mathbb{P}^{n-1}_k$ parameterizing the lines through the origin.

Blowing up a subvariety rather than a point is the same construction with the point replaced by a linear subspace, at least locally.

Definition 47.2.2: Blow-Up Along a Coordinate Subspace

Let $Z = \mathcal{Z}(x_1, \ldots, x_r) \subseteq \mathbb{A}^n_k$ be a coordinate subspace, $0 < r \leq n$. The blow-up of $\mathbb{A}^n_k$ along Z is

$$\mathrm{Bl}_Z\mathbb{A}^n_k = \left\{(x, [\ell]) \in \mathbb{A}^n_k \times \mathbb{P}^{r-1}_k \;\middle|\; x_i\ell_j = x_j\ell_i,\ 1 \leq i, j \leq r\right\}$$

with π the first projection. Its exceptional locus $\pi^{-1}(Z)$ is $Z \times \mathbb{P}^{r-1}_k$.

The last $n - r$ coordinates are carried along untouched, so $\mathrm{Bl}_Z\mathbb{A}^n_k \cong \mathrm{Bl}_0\mathbb{A}^r_k \times \mathbb{A}^{n-r}_k$; the construction is the point case in the transverse directions, applied uniformly along Z. The general blow-up along an arbitrary closed subvariety is not this concrete: it is defined as the Proj of the Rees algebra $\bigoplus_{d\geq 0} I^d$ of the ideal I of the subvariety, a construction that needs the language of [5]. Everything in this chapter happens at a point of a curve, where definition 47.2.1 suffices.

What is blown up is the ambient space; what one wants is the effect on a subvariety sitting inside it.

Definition 47.2.3: Strict and Total Transform

Let $X \subseteq \mathbb{A}^n_k$ be a closed subvariety and $\pi\colon \mathrm{Bl}_0\mathbb{A}^n_k \to \mathbb{A}^n_k$ the blow-up at a point $p \in X$. The *total transform* of X is $\pi^{-1}(X)$. The *strict transform* is

$$\tilde{X} = \overline{\pi^{-1}\big(X \setminus \{p\}\big)}$$

the closure being taken in $\mathrm{Bl}_0\mathbb{A}^n_k$.

The total transform always contains the whole exceptional divisor, which carries no information about X. The strict transform discards it and keeps only what is approached from X itself. By proposition 47.1.2(3) the map $\tilde{X} \to X$ is an isomorphism away from p, so $\tilde{X}$ is birational to X; and $\tilde{X}$ is irreducible whenever X is, being the closure of a set isomorphic to the irreducible $X \setminus \{p\}$.

47.3 Resolving Plane Curve Singularities

Now specialize to a plane curve. Everything reduces to one computation, carried out in the chart $\pi(x, v) = (x, xv)$.

Theorem 47.3.1: The Blow-Up of a Plane Curve at a Point

Let $f \in k[x,y]$ be an affine plane curve with $m = m_0(f) \geq 1$, and write $f = f_m + f_{m+1} + \cdots$ for its homogeneous decomposition, so that the tangent cone is $f_m = \prod_i L_i^{r_i}$ with $\sum_i r_i = m$. Then in the chart U_s with coordinates (x,v),

$$f(x,xv) = x^m \tilde{f}(x,v) \qquad \tilde{f}(x,v) = f_m(1,v) + x\, f_{m+1}(1,v) + x^2 f_{m+2}(1,v) + \cdots$$

and $\mathcal{Z}(\tilde{f})$ is the strict transform $\tilde{C}$. Moreover:

1. the exceptional divisor occurs in the total transform with multiplicity exactly m;
2. $\tilde{C}$ meets E exactly at the points corresponding, under proposition 47.1.3, to the tangent lines $\mathcal{Z}(L_i)$, and the intersection multiplicity there is r_i; in particular $\tilde{C} \bullet E$ has degree m;
3. at the point $q_i \in E$ corresponding to L_i, the multiplicity satisfies $m_{q_i}(\tilde{C}) \leq r_i \leq m$.

***Proof*:**
Each f_j is homogeneous of degree j, so $f_j(x,xv) = x^j f_j(1,v)$, and summing over $j \geq m$ gives the displayed factorization with $\tilde{f}$ as stated. Since E is cut out by $x = 0$ in this chart, the factor x^m is the exceptional divisor with multiplicity m, which is (1). The remaining factor $\tilde{f}$ does not vanish identically on E: writing $f_m = \sum_j c_j x^{m-j} y^j$ gives $\tilde{f}(0,v) = f_m(1,v) = \sum_j c_j v^j$, which is the zero polynomial only if every $c_j = 0$, that is only if $f_m = 0$. So $\mathcal{Z}(\tilde{f})$ contains no component of E, and away from E it agrees with $\pi^{-1}(C)$; hence $\mathcal{Z}(\tilde{f})$ is the closure of $\pi^{-1}(C \setminus \{0\})$, which is $\tilde{C}$.

(2). On E the equation of $\tilde{C}$ is $f_m(1,v) = 0$. Writing $L_i = b_i x - a_i y$, so that $\mathcal{Z}(L_i)$ is the line through the origin in direction $[a_i : b_i]$, gives $f_m(1,v) = \prod_i (b_i - a_i v)^{r_i}$ up to a scalar, whose roots are $v = b_i/a_i$ when $a_i \neq 0$. Under proposition 47.1.3 the point $v = b_i/a_i$ of E is the direction $[a_i : b_i]$, that is the tangent line $\mathcal{Z}(L_i)$; the roots with $a_i = 0$ are the tangent line $\mathcal{Z}(x)$ and appear in the chart U_t. The multiplicity of the root is r_i, and $\sum_i r_i = m$.

(3). Translate so that q_i is the origin of the chart, replacing v by $v_i + w$. Then

$$\tilde{f} = f_m(1, v_i + w) + x\, f_{m+1}(1, v_i + w) + \cdots$$

The first summand has order exactly r_i in w, by (2). Every later summand is divisible by x, hence has order at least 1. So the lowest-degree part of $\tilde{f}$ has degree at most r_i, which is (3), as we sought to show.

Part (3) is the statement that blowing up never makes things worse, and for the singularities named in definition 42.1.6 it makes them disappear outright.

Corollary 47.3.2: One Blow-Up Resolves an Ordinary Singularity

Let p be an ordinary singular point of multiplicity m on a plane curve C, so that C has m distinct tangent lines at p. Then $\tilde{C}$ meets E in m distinct points, each a nonsingular point of $\tilde{C}$, and each intersection is transversal.

***Proof*:**
Ordinariness says every $r_i = 1$ and there are m of them, so theorem 47.3.1(2) gives m distinct intersection points, each with intersection multiplicity 1, which is transversality. Theorem 47.3.1(3) bounds $m_{q_i}(\tilde{C}) \leq r_i = 1$, and a multiplicity is at least 1 at a point of the curve, so each q_i is nonsingular, completing the proof.

Example 47.3.3: Resolving a Node, a Cusp, and a Higher Cusp
All three computations use theorem 47.3.1 in the chart (x, v), where $y = xv$.

1. *The node* $f = y^2 - x^2 - x^3$. Here $f_2 = y^2 - x^2 = (y - x)(y + x)$, two distinct tangents, so the point is an ordinary double point. Substituting,
$$f(x, xv) = x^2v^2 - x^2 - x^3 = x^2\big(v^2 - 1 - x\big)$$
so $\tilde{f} = v^2 - 1 - x$, whose partial derivative in x is -1, nowhere zero: the strict transform is nonsingular. It meets $E = \mathcal{Z}(x)$ at $v = \pm 1$, the two tangent directions, as corollary 47.3.2 predicts.

2. *The cusp* $f = y^2 - x^3$. Here $f_2 = y^2$, a single tangent with $r_1 = 2$, so the point is *not* ordinary. Nonetheless
$$f(x, xv) = x^2v^2 - x^3 = x^2\big(v^2 - x\big)$$
and $\tilde{f} = v^2 - x$ is nonsingular. One blow-up suffices here too, though corollary 47.3.2 does not apply; the strict transform meets E at the single point $v = 0$, with intersection multiplicity 2.

3. *A higher cusp* $f = y^2 - x^5$. Again $f_2 = y^2$, and
$$f(x, xv) = x^2v^2 - x^5 = x^2\big(v^2 - x^3\big)$$
so $\tilde{f} = v^2 - x^3$: the blow-up has replaced the singularity by an ordinary cusp, not by a nonsingular point. Blowing up once more, by (2), resolves it. Two blow-ups are needed, and no fewer.

Item (3) is the general situation: one blow-up reduces a singularity but need not remove it, and the content of the resolution theorem is that the process stops.

Theorem 47.3.4: Resolution of Plane Curve Singularities

Let C be an irreducible plane curve. Then after finitely many blow-ups at points, the strict transform is a nonsingular curve birational to C.

***Proof*:**
Each blow-up is an isomorphism away from the point blown up by proposition 47.1.2(3), so the strict transform stays birational to C throughout, and C has only finitely many singular points by corollary 43.2.4, so they may be treated one at a time. Theorem 47.3.1(3) says the multiplicity at every point above the one blown up is at most the multiplicity below, so blowing up never makes a singularity worse, and corollary 47.3.2 removes an ordinary point in a single

step.

What those facts leave open is whether the multiplicity must eventually reach 1, rather than stabilizing forever at some $m \geq 2$. The input needed is that each singular point p carries a non-negative integer δ_p, the drop in arithmetic genus recorded in section 44.4, which strictly decreases at every blow-up above p; a strictly decreasing sequence of non-negative integers is finite, so the process stops. That δ_p behaves this way is a comparison of the local rings of C and of its strict transform, the same computation section 44.4 deferred, and it is carried out in [54, chapter 7]; the cohomological account is in [5]. Granting it, the process terminates and the final strict transform is nonsingular and birational to C, as we sought to show.

The theorem is not new information: corollary 37.4.2 already produced a smooth model, and section 37.3 showed it is unique in its birational class. So the smooth curve reached by blowing up is the normalization, arrived at by a different road. What blowing up adds is that the road is explicit and that each step is measured, which is the subject of the last section.

47.4 Multiplicity, Genus, and the Effect of Blowing Up

Blowing up trades a singular point for an intersection with the exceptional divisor, and theorem 47.3.1 says the trade is exact: a point of multiplicity m becomes m points of intersection with E, counted properly. That bookkeeping is what turns resolution into a computation of the genus.

Recall from section 44.4 that a nonsingular plane curve of degree d has genus $\binom{d-1}{2}$, and that for a singular curve the genus of the smooth model drops by $\binom{m_p}{2}$ at each ordinary singular point. Blowing up is where that number comes from.

Theorem 47.4.1: The Genus Drop at an Ordinary Singularity

Let C be an irreducible plane curve of degree d whose singular points $p_1, \ldots, p_s$ are all ordinary, of multiplicities $m_1, \ldots, m_s$, and let $\tilde{C}$ be its nonsingular model. Then

$$g(\tilde{C}) \;=\; \frac{(d-1)(d-2)}{2} \;-\; \sum_{i=1}^{s} \binom{m_i}{2}$$

***Proof*:**
The genus is computed by the space of regular differential forms, whose dimension is g by theorem 48.3.2, and on a plane curve those forms are described by *adjoints*. Say a curve G of degree e is an *adjoint* of C if $m_{p_i}(G) \geq m_i - 1$ at every singular point.

Adjoints of degree $d-3$ give the regular differentials. By theorem 46.2.4 a canonical divisor on a nonsingular plane curve of degree d is cut by a curve of degree $d-3$. For a curve with ordinary singularities the same computation applies on $\tilde{C}$, with the correction that a form $G/\partial_y f$ is regular at the points of $\tilde{C}$ over p_i exactly when G vanishes to order at least $m_i - 1$ at p_i: the denominator $\partial_y f$ vanishes to order $m_i - 1$ along each of the m_i branches, and $\tilde{C}$ separates the branches by corollary 47.3.2. So the regular differential forms on $\tilde{C}$ correspond to the adjoint curves of degree $d-3$, modulo those divisible by f.

Counting them. The curves of degree $d-3$ form a space of dimension $\binom{d-1}{2}$, since $\binom{d-3+2}{2} =$

$\binom{d-1}{2}$. Requiring $m_{p_i}(G) \geq m_i - 1$ imposes $\binom{m_i}{2}$ linear conditions, being the vanishing of all partial derivatives of order less than $m_i - 1$, and for ordinary singularities in distinct positions these conditions are independent, by the same argument that established independence in corollary 43.2.5. Nothing of degree $d - 3 < d$ is divisible by f. Hence

$$g(\tilde{C}) = \binom{d-1}{2} - \sum_{i=1}^{s} \binom{m_i}{2}$$

as we sought to show.

The formula was quoted in section 44.4 and used in corollaries 47.4.3 and 47.4.4; it is now proved, and those two corollaries are unconditional.

47.4.2 Note: Two Routes to the Same Number The proof above counts conditions on adjoint curves and never mentions the blow-up. There is a second route, standard in the literature, which computes the arithmetic genus of the strict transform on the blown-up surface: the total transform is $\tilde{C} + mE$, and the correction $\frac{1}{2}m(m-1)$ falls out of the self-intersection $E \cdot E = -1$ together with $\tilde{C} \cdot E = m$ from theorem 47.3.1(2).
That route was not taken here, deliberately. It requires an intersection pairing for divisors on a surface, which this book does not build and which [5] develops as its first genuine intersection product, with the general theory in [16]. The adjoint count needs only linear systems and the canonical class, both of which are now in hand, so the hub proves what it needs without borrowing from downstream.

Two consequences can be read off without that ingredient, because they only use the non-negativity of a genus.

Corollary 47.4.3: Blowing Up Terminates for Ordinary Singularities

Let C be an irreducible plane curve of degree d all of whose singular points are ordinary. Then one blow-up at each removes them all, the total drop in arithmetic genus is $\sum_p \binom{m_p}{2}$, and the number of blow-ups is at most

$$\frac{(d-1)(d-2)}{2}$$

***Proof*:**
A blow-up at an ordinary point of multiplicity m removes that point by corollary 47.3.2, and by theorem 47.4.1 it drops the arithmetic genus by $\binom{m}{2}$, which is at least 1 because a singular point has $m \geq 2$. Summing over the singular points, finite in number by corollary 43.2.4, gives the total drop.

The arithmetic genus starts at $\binom{d-1}{2}$ by definition 44.4.1 and ends at the genus of a smooth curve, which is non-negative, so the total drop is at most $\binom{d-1}{2}$. Since each blow-up contributes at least 1 to that drop, there are at most $\binom{d-1}{2}$ of them, completing the proof.

Corollary 47.4.4: The Multiplicity Bound, Read Geometrically

For an irreducible plane curve of degree d with ordinary singularities,

$$\sum_p \binom{m_p}{2} \leq \frac{(d-1)(d-2)}{2}$$

with equality exactly when the smooth model has genus 0.

***Proof*:**
This is corollary 47.4.3 restated: the total drop is bounded by the starting genus, with equality exactly when the final genus is 0, completing the proof.

The equality case is a rationality statement, though not by way of theorem 44.4.2, which was about plane curves and the smooth model of a singular plane curve is generally not one. That a smooth projective curve of genus 0 is isomorphic to $\mathbb{P}^1_k$ is true and is one of the payoffs of chapter 48$\star$. For the extremal curve it can be seen by hand: on $\mathcal{Z}(x^d + y^{d-1}z)$ one may solve $z = -x^d/y^{d-1}$, so

$$\mathbb{P}^1_k \to \mathcal{Z}(x^d + y^{d-1}z) \qquad [x:y] \mapsto [\,xy^{d-1} : y^d : -x^d\,]$$

parameterizes it.

That inequality was already proved in chapter 43, as corollary 43.2.5, by an entirely different argument: a dimension count on the curves of degree $d-1$ passing through the singular points with prescribed multiplicity. The two proofs agree, and the agreement is informative. The Bézout argument says the bound holds because there are not enough curves of degree $d-1$ to impose more conditions; the blow-up argument says it holds because a genus cannot be negative. The extremal curve $\mathcal{Z}(x^d+y^{d-1}z)$ of section 43.2 attains the bound, and corollary 47.4.4 now explains why it is rational.

47.5 Cubic Surfaces and the Twenty-Seven Lines

Theorem 41.4.3 showed that a general cubic surface carries finitely many lines, by a dimension count that never produced a number. The number is 27, and the route to it is the blow-up: a smooth cubic surface is $\mathbb{P}^2_k$ blown up at six points, and under that description the lines can simply be listed.

Throughout, $\operatorname{char} k \neq 2$ and the six points $p_1, \ldots, p_6 \in \mathbb{P}^2_k$ are in *general position*, meaning no three collinear and not all six on a conic.

Proposition 47.5.1: The Blow-Up of Six Points Is a Cubic Surface

Let $p_1, \ldots, p_6 \in \mathbb{P}^2_k$ be in general position and let S be the blow-up of $\mathbb{P}^2_k$ at the six points. The cubics through the six points form a linear system of projective dimension 3, and the map it defines embeds S as a cubic surface in $\mathbb{P}^3_k$.

***Proof*:**
Cubic forms in three variables constitute a space of dimension $\binom{5}{3} = 10$, so the cubics of $\mathbb{P}^2_k$ form a $\mathbb{P}^9_k$. Passing through a point is one linear condition, and for six points in general position the six conditions are independent: were they dependent, some p_i would lie on every cubic through the other five, which fails because the union of a conic through five of them and a line missing the sixth, or of three lines pairing them up, gives cubics through five and not the sixth. So the system has projective dimension $9 - 6 = 3$.

Let $\varphi\colon S \to \mathbb{P}^3_k$ be the map defined by that system, which is a morphism on S because blowing up the six points resolves the base locus. Its image is a surface, and the degree of the image is the number of points in which two general members of the system meet away from the p_i: two cubics meet in 9 points by theorem 43.1.1, of which six are the base points, leaving 3. So the image is a cubic surface, and φ is birational onto it since a general pair of members separates points of $\mathbb{P}^2_k$ away from the base locus.

That φ is an embedding, rather than merely birational, is the statement that the system separates points and tangent vectors on S; it does so exactly because no three of the p_i are collinear and the six do not lie on a conic, which are the configurations making two members of the system agree to first order somewhere. See [31, chapter V.4] for the verification, as we sought to show.

With the description in hand the lines can be counted, and the count is a matter of listing three families.

Theorem 47.5.2: The Twenty-Seven Lines

Let $S \subseteq \mathbb{P}^3_k$ be a smooth cubic surface, realized as the blow-up of $\mathbb{P}^2_k$ at six points $p_1, \ldots, p_6$ in general position. Then S contains exactly 27 lines, namely

1. the six exceptional curves $E_1, \ldots, E_6$ over the six points;
2. the $\binom{6}{2} = 15$ strict transforms of the lines $\overline{p_i p_j}$;
3. the six strict transforms of the conics through five of the six points.

In total $6 + 15 + 6 = 27$.

***Proof*:**
These are lines. A curve on S is a line exactly when the linear system of proposition 47.5.1 cuts it in a single point, that is when its image under φ has degree 1. The system consists of cubics through the six points, so its degree on a curve $D \subseteq \mathbb{P}^2_k$ is $3 \deg D$ less one for each base point on D, counted with multiplicity.

For an exceptional curve E_i the system restricts to the pencil of cubics through p_i with varying tangent direction, cutting E_i once, so $\varphi(E_i)$ is a line. For the line $\overline{p_i p_j}$ we get $3 \cdot 1 - 1 - 1 = 1$. For a conic Q through five of the six, $3 \cdot 2 - 5 = 1$. So all 27 are lines.

There are no others. Let $L \subseteq S$ be a line and let $D \subseteq \mathbb{P}^2_k$ be its image, of degree $e \geq 0$, passing through p_i with multiplicity m_i. The degree computation above reads

$$3e - \sum_{i=1}^{6} m_i = 1$$

and a second constraint comes from the genus: $L \cong \mathbb{P}^1_k$ has genus 0, while by section 44.4 the normalization of a plane curve of degree e with multiplicities m_i has genus

$$\frac{(e-1)(e-2)}{2} - \sum_{i=1}^{6} \binom{m_i}{2} = 0$$

So $\sum_i m_i = 3e - 1$ and $\sum_i \binom{m_i}{2} = \binom{e-1}{2}$. The case $e = 0$ is an exceptional curve. For $e \geq 1$ these two equations already bound e. The function $m \mapsto \binom{m}{2}$ is convex, so by Jensen's inequality applied to the six values m_i, whose mean is $(3e-1)/6$,

$$\binom{e-1}{2} = \sum_{i=1}^{6} \binom{m_i}{2} \geq 6\binom{(3e-1)/6}{2} = \frac{(3e-1)(3e-7)}{12}$$

Multiplying by 12 gives $6(e-1)(e-2) \geq (3e-1)(3e-7)$, that is $3e^2 - 6e - 5 \leq 0$, so $e \leq 2$.

It remains to check $e = 1$ and $e = 2$. For $e = 1$ the genus equation reads $\sum \binom{m_i}{2} = 0$, so every $m_i \leq 1$, and $\sum m_i = 2$ picks out two of the six points: a line through p_i and p_j. For $e = 2$ again every $m_i \leq 1$, and $\sum m_i = 5$ picks out five: a conic through five of the six. Counting the choices gives 6, $\binom{6}{2} = 15$ and $\binom{6}{5} = 6$, as we sought to show.

47.5.3 Note: What the Count Is Really About Three features of the argument deserve separating.

The number 27 does not depend on the six points. Every smooth cubic surface arises as such a blow-up, so the count is intrinsic, and the configuration of the 27 lines is the same for all of them: each line meets exactly 10 others, and the whole configuration has a symmetry group of order 51840, the Weyl group of the root system E_6. That is the beginning of a story this book does not tell; see [31] and, for the representation theory, [26].

The dimension count of section 41.4 and the present listing answer different questions. The first shows finiteness for a *general* cubic without exhibiting a single line; the second exhibits all of them for a *smooth* one. Neither subsumes the other, and the first is what guarantees the second is not vacuous.

The general-position hypothesis is doing real work. If three of the six points are collinear, the strict transform of that line has $3 \cdot 1 - 3 = 0$ and is contracted rather than embedded, and the image acquires a singular point. Cubic surfaces with singularities have fewer lines: the surface $\mathcal{Z}(x_0x_1x_2 - x_3^3)$ of lemma 41.4.2 has three.

Exercise 47.5.1

1. Show that $\mathrm{Bl}_0\mathbb{A}^2_k$ is not isomorphic to $\mathbb{A}^2_k$. Suggestion: $E \cong \mathbb{P}^1_k$ is a complete curve sitting inside it, whereas a curve inside $\mathbb{A}^2_k$ carries nonconstant regular functions, which corollary 40.2.4 forbids on a projective variety.
2. Compute the strict transform of the curve $y^2 = x^4 + x^5$ under one blow-up at the origin, identify its singularities, and say how many further blow-ups are needed.
3. Show that the blow-up of $\mathbb{A}^2_k$ at the origin, restricted to the chart U_t, is the map $(u, y) \mapsto (uy, y)$, and redo example 47.3.3(2) in that chart. Explain why the answer looks different and why

the two are consistent.

4. Let C be a plane curve with an ordinary point of multiplicity m at the origin. Show that the strict transform meets E transversally in m points, and deduce that $\tilde{C} \cdot E$ has degree m whether or not the point is ordinary.

5. Show that $\mathrm{Bl}_Z \mathbb{A}^n_k \cong \mathrm{Bl}_0 \mathbb{A}^r_k \times \mathbb{A}^{n-r}_k$ for Z a coordinate subspace of codimension r, as claimed after definition 47.2.2.

6. A curve of degree 4 can have at most three double points. Prove this from corollary 47.4.4, and exhibit a quartic attaining the bound.

48⋆

Riemann-Roch for Plane Curves

⋆ *Optional. This chapter is an aside; nothing later in the book depends on it.*

Every question this book has asked about a curve reduces, sooner or later, to the same one: given a divisor D, which rational functions have poles no worse than D allows? Chapter 44 met the question in the special case $D = 0$, where proposition 44.2.3 answered it, and again in theorem 45.2.2, where the answer for $D = p - q$ decided injectivity. The Riemann-Roch theorem answers it in general, up to a correction term that vanishes once D is large.

Nothing earlier in the book depends on this chapter, and the theorem is proved in full elsewhere in the series: analytically in *Complex Analysis* [40], cohomologically in *Algebraic Geometry* [5]. What is offered here is the plane-curve account, where the statement can be made concrete and the consequences are immediate. Section 48.1 builds the vector spaces and proves what can be proved directly; sections 48.2 and 48.3 state Riemann's theorem and Riemann-Roch and say how the proof goes; section 48.4 spends the theorem, including on two debts left open in chapters 44 and 47.

Throughout, C is a nonsingular projective curve over the algebraically closed field k, and divisors are as in chapter 44.

48.1 The Space of Functions with Prescribed Poles

Definition 48.1.1: The Space $L(D)$

Let D be a divisor on C. The *Riemann-Roch space* of D is

$$L(D) = \{f \in k(C)^* \mid \operatorname{div}(f) + D \geq 0\} \cup \{0\}$$

and $\ell(D) = \dim_k L(D)$.

Writing $D = \sum_p n_p\, p$, the condition $\operatorname{div}(f) + D \geq 0$ says $\operatorname{ord}_p(f) \geq -n_p$ at every p: where $n_p > 0$ the function may have a pole of order at most n_p, and where $n_p < 0$ it is required to vanish to order at least $-n_p$. So $L(D)$ is the space of functions whose poles are bounded by D and whose zeros are forced by it.

Proposition 48.1.2: Basic Properties of $L(D)$

Let D and D' be divisors on C. Then:

1. $L(D)$ is a k-vector space;
2. $L(0) = k$, so $\ell(0) = 1$;
3. if $\deg D < 0$ then $L(D) = 0$;
4. if $D \leq D'$ then $L(D) \subseteq L(D')$ and $\ell(D') - \ell(D) \leq \deg D' - \deg D$;
5. $\ell(D) \leq \deg D + 1$ whenever $\deg D \geq 0$;
6. if $D \sim D'$ then $\ell(D) = \ell(D')$, so ℓ is a function on $\operatorname{Pic}(C)$.

***Proof*:**
(1). For nonzero $f, g \in L(D)$ and $\lambda \in k^*$, the valuation inequality $\operatorname{ord}_p(f+g) \geq \min(\operatorname{ord}_p(f), \operatorname{ord}_p(g))$ holds at every p, and $\operatorname{ord}_p(\lambda f) = \operatorname{ord}_p(f)$, so $L(D)$ is closed under addition and scaling.

(2). $L(0)$ consists of the f with $\operatorname{div}(f) \geq 0$, that is with $\operatorname{ord}_p(f) \geq 0$ at every p. Such an f lies in every local ring $\mathcal{O}_p(C)$ and so is regular on all of C, hence constant by corollary 40.2.4. Conversely every constant lies in $L(0)$.

(3). If $f \in L(D)$ is nonzero then $\operatorname{div}(f) + D \geq 0$, so $\deg \operatorname{div}(f) + \deg D \geq 0$; but $\deg \operatorname{div}(f) = 0$ by theorem 44.2.2, so $\deg D \geq 0$.

(4). The inclusion is immediate from the definition. For the inequality it suffices, by induction on $\deg D' - \deg D$, to treat $D' = D + p$ for a single point p, and to show $\ell(D+p) \leq \ell(D) + 1$. Let n be the coefficient of p in D and let t be a uniformizer at p. The map

$$L(D+p) \to k \qquad f \mapsto \left(t^{n+1} f\right)(p)$$

is well defined, since $f \in L(D+p)$ has $\operatorname{ord}_p(f) \geq -n-1$ so $t^{n+1} f$ lies in $\mathcal{O}_p(C)$, and it is k-linear. Its kernel is exactly $L(D)$, because $\left(t^{n+1} f\right)(p) = 0$ says $\operatorname{ord}_p(f) \geq -n$. So $L(D+p)/L(D)$ embeds in k and the codimension is at most 1.

(6). Suppose $D' = D + \operatorname{div}(h)$ for some $h \in k(C)^*$, and consider $f \mapsto f/h$. For $f \in L(D)$,

$$\operatorname{div}(f/h) + D' = \operatorname{div}(f) - \operatorname{div}(h) + D + \operatorname{div}(h) = \operatorname{div}(f) + D \;\geq\; 0$$

so $f/h \in L(D')$. The map is k-linear and multiplication by h inverts it, so $L(D) \cong L(D')$ and $\ell(D) = \ell(D')$.

(5). If $L(D) = 0$ then $\ell(D) = 0 \leq \deg D + 1$. Otherwise choose a nonzero $f \in L(D)$ and put $D_0 = \operatorname{div}(f) + D$, which is effective by the definition of $L(D)$ and satisfies $D_0 \sim D$, hence $\deg D_0 = \deg D$ and $\ell(D_0) = \ell(D)$ by (6). Now $0 \leq D_0$, so (4) applied to the pair $(0, D_0)$ gives

$$\ell(D_0) - \ell(0) \;\leq\; \deg D_0 - 0 = \deg D$$

and $\ell(0) = 1$ by (2), so $\ell(D) = \ell(D_0) \leq \deg D + 1$, as we sought to show.

Item (5) already shows the size of $L(D)$ is controlled by $\deg D$ from above. Riemann's theorem is the statement that it is controlled from below as well, by the same quantity shifted by an invariant of the curve.

Example 48.1.3: The Spaces $L(D)$ on the Projective Line

Take $C = \mathbb{P}^1_k$ and $D = n\,\infty$ for $n \geq 0$, where $\infty = [1:0]$. A rational function with poles only at ∞, of order at most n, is a polynomial in the affine coordinate x of degree at most n. So

$$L(n\infty) = \{a_0 + a_1 x + \cdots + a_n x^n \mid a_i \in k\} \qquad \ell(n\infty) = n + 1$$

The bound of proposition 48.1.2(5) is attained for every $n \geq 0$. Since every divisor of degree n on $\mathbb{P}^1_k$ is linearly equivalent to $n\infty$ by proposition 44.2.4, item (6) gives $\ell(D) = \deg D + 1$ for every divisor of non-negative degree on the line. The line is the curve on which $L(D)$ is as large as it can possibly be.

48.2 Riemann's Theorem

On $\mathbb{P}^1_k$ the inequality $\ell(D) \leq \deg D + 1$ is an equality. On any other curve it is not, and the deficiency is bounded.

Theorem 48.2.1: Riemann's Theorem

Let C be a nonsingular projective curve. There is a smallest integer $g \geq 0$, the *genus* of C, such that

$$\ell(D) \;\geq\; \deg D + 1 - g$$

for every divisor D on C. Moreover equality holds for all D of sufficiently large degree.

Two things are worth extracting before saying where the proof comes from. First, taking $D = 0$ gives $\ell(0) = 1 \geq 1 - g$, so $g \geq 0$ automatically; and $g = 0$ forces $\ell(D) \geq \deg D + 1$, which combined with proposition 48.1.2(5) makes it an equality, the situation of example 48.1.3. Second, the genus so defined is an invariant of C as an abstract curve, since $L(D)$ and $\deg D$ are defined from $k(C)$ and the valuations alone. That is what section 44.4 could not say about $\binom{d-1}{2}$, which was read off an embedding.

48.2.2 Note: Where the Proof Comes From For a plane curve the proof is a counting argument built on machinery this book already has. Let C be a nonsingular plane curve of degree d and H a line, so $H \cdot C$ is a divisor of degree d. One computes $\ell(mH \cdot C)$ for large m by identifying $L(mH \cdot C)$ with the space of curves of degree m modulo those containing C, and the identification is exactly the local-to-global statement of theorem 43.3.2: a form of degree m cuts out a divisor $\geq$ a given one precisely when Noether's condition holds at each point. The dimension of the space of forms of degree m in three variables is $\binom{m+2}{2}$, and subtracting the forms divisible by C, of which there are $\binom{m-d+2}{2}$, leaves

$$\binom{m+2}{2} - \binom{m-d+2}{2} = md - \frac{d(d-3)}{2} = \deg(mH \cdot C) + 1 - \frac{(d-1)(d-2)}{2}$$

which is Riemann's bound with $g = \binom{d-1}{2}$, the number definition 44.4.1 already called the genus. Extending from the divisors $mH \cdot C$ to arbitrary D is proposition 48.1.2(4) together with the fact that every divisor is dominated by some $mH \cdot C$. The details, in particular the surjectivity of the map from forms to $L(mH \cdot C)$, are in [54, chapter 8].

The computation in that box is worth pausing on, because it is the same arithmetic as example 38.5.4(3): $md - d(d-3)/2$ is the Hilbert polynomial of a plane curve of degree d. The Hilbert polynomial counts forms of degree m modulo those vanishing on C, and Riemann's theorem counts functions with poles bounded by $mH \cdot C$; Max Noether's theorem is what identifies the two counts.

Corollary 48.2.3: Genus of a Nonsingular Plane Curve

The genus of theorem 48.2.1 agrees, for a nonsingular plane curve of degree d, with the genus of definition 44.4.1:

$$g(C) = \frac{(d-1)(d-2)}{2}$$

***Proof*:**
The computation of box 48.2.2 produces the bound of theorem 48.2.1 with $g = \binom{d-1}{2}$, so the genus is at most that. It is not smaller: were the bound to hold with some $g' < g$, then taking $D = mH \cdot C$ for large m would give $\ell(D) \geq \deg D + 1 - g' > \deg D + 1 - g$, contradicting that the same computation evaluates $\ell(D)$ exactly as $\deg D + 1 - g$ for large m, completing the proof.

This is the statement section 44.4 could only assert: the number computed from the embedding is the intrinsic invariant. It is also what makes theorem 44.4.2 more than a coincidence of small degrees.

48.3 The Canonical Divisor and Riemann-Roch

Riemann's theorem leaves an inequality, and the error term has a name. It is measured by a divisor class attached to the curve itself.

Definition 48.3.1: Canonical Divisor

A *canonical divisor* on C is a divisor K with the property that

$$\ell(D) - \ell(K - D) = \deg D + 1 - g$$

for every divisor D. Its class in $\mathrm{Pic}\,(C)$ is the *canonical class.*

Stated this way the definition presumes what has to be proved, namely that such a K exists. Theorem 46.2.3 has already constructed the class: it is the divisor class of any nonzero rational differential form, and theorem 46.2.4 computes it for a plane curve. What is still unproved at this point is that the class so constructed satisfies the displayed identity, which is the content of theorem 48.3.2.

Theorem 48.3.2: Riemann-Roch

Let C be a nonsingular projective curve of genus g. Then a canonical divisor K exists, and for every divisor D,

$$\ell(D) - \ell(K - D) = \deg D + 1 - g$$

Moreover $\deg K = 2g - 2$ and $\ell(K) = g$.

The last two assertions are consequences of the first. Taking $D = 0$ gives $1 - \ell(K) = 1 - g$, so $\ell(K) = g$; taking $D = K$ gives $\ell(K) - 1 = \deg K + 1 - g$, and substituting $\ell(K) = g$ leaves $\deg K = 2g - 2$. Riemann's theorem follows too: $\ell(K - D) \geq 0$ always, so $\ell(D) \geq \deg D + 1 - g$, and once $\deg D > 2g - 2$ the divisor $K - D$ has negative degree, so $\ell(K - D) = 0$ by proposition 48.1.2(3) and the inequality becomes an equality. That is the precise form of "sufficiently large degree" in theorem 48.2.1.

Proposition 48.3.3: The Canonical Divisor of a Plane Curve

Let C be a nonsingular plane curve of degree d and H a line. Then the canonical class of C is

$$K = (d - 3)\, H \bullet C$$

***Proof*:**
This is theorem 46.2.4, proved in chapter 46 by exhibiting the form $\omega = dx/\partial_y f$ and computing its divisor: it has neither zeros nor poles in the affine chart, because C is nonsingular and its two partials cannot vanish together, and it acquires a zero of order $d - 3$ at each point of C at infinity.

The degrees are consistent with theorem 48.3.2, as they must be: $H \bullet C$ has degree d by theorem 43.1.1, so the right side has degree $d(d - 3)$, while $\deg K = 2g - 2$ with $g = \binom{d-1}{2}$ by corollary 48.2.3 gives

$$2g - 2 = (d - 1)(d - 2) - 2 = d^2 - 3d = d(d - 3)$$

completing the proof.

The degree check alone would not have sufficed: a divisor class is not determined by its degree,

$\operatorname{Pic}^0(C)$ being generally nonzero, and on a cubic theorem 45.2.2 makes it as large as the curve. It is the explicit form ω that identifies the class.

The formula explains the numerology of low-degree plane curves at a glance. For $d = 1$ and $d = 2$ the canonical class has negative degree, for $d = 3$ it is zero, and for $d \geq 4$ it is positive. Those three regimes are the trichotomy that organizes the classification of curves, and the next section is the case analysis.

48.4 Application: Curves of Low Genus

Riemann-Roch is used the same way every time: choose D so that $\ell(K - D)$ vanishes for degree reasons, read off $\ell(D)$, and interpret a function in $L(D)$ geometrically. One input is needed from outside, and it is the only one.

48.4.1 Note: The Degree of a Map to the Line Let $f \in k(C)$ be nonconstant. By lemma 42.2.8 it defines a morphism $F\colon C \to \mathbb{P}^1_k$, and the fact used below is that

$$\deg \operatorname{div}_\infty(f) = \big[\, k(C) : k(f) \,\big]$$

so that a function with a single simple pole generates the whole function field. Both sides count the fibre of F, one geometrically and one algebraically; the proof is in [54, chapter 8].

Theorem 48.4.2: Genus Zero Curves Are Rational

Let C be a nonsingular projective curve of genus 0. Then $C \cong \mathbb{P}^1_k$.

***Proof*:**
Pick any $p \in C$ and apply theorem 48.3.2 with $D = p$. Then $\deg(K - p) = -2 < 0$, so $\ell(K - p) = 0$ by proposition 48.1.2(3), and

$$\ell(p) = \deg(p) + 1 - 0 = 2$$

Since $L(0) = k$ has dimension 1 by proposition 48.1.2(2), there is a nonconstant $f \in L(p)$. Its only possible pole is a simple one at p, and it must occur, since otherwise $\operatorname{div}(f) \geq 0$ would make f constant. So $\operatorname{div}_\infty(f) = p$ has degree 1, and box 48.4.1 gives $k(C) = k(f)$, that is C is birational to $\mathbb{P}^1_k$. A birational map between nonsingular projective curves is an isomorphism by lemma 42.2.8 applied in both directions, completing the proof.

Example 48.4.3: Genus Zero, Worked
Take $C = \mathcal{Z}(x^2 + y^2 - z^2) \subseteq \mathbb{P}^2_k$, a nonsingular conic, so $d = 2$ and $g = \binom{1}{2} = 0$ by definition 44.4.1.

Follow the proof of theorem 48.4.2 with $p = [1 : 0 : 1]$. Riemann-Roch gives $\ell(p) = 2$, so there is a nonconstant f with at most a simple pole at p and no other pole. Concretely, in the affine chart $z = 1$ the function

$$f = \frac{y}{1 - x}$$

does it. Substituting the parameterization $x = (t^2 - 1)/(t^2 + 1)$, $y = 2t/(t^2 + 1)$ gives $f = t$ identically, and that parameterization sends $t = 0$ to $[-1 : 0 : 1]$ and $t = \infty$ to p. So

$$\operatorname{div}(f) = \big([-1 : 0 : 1]\big) - \big([1 : 0 : 1]\big)$$

a single simple zero and a single simple pole. Hence $\deg \operatorname{div}_\infty(f) = 1$ and box 48.4.1 gives $k(C) = k(f)$.

So the abstract argument and the explicit parameterization of example 33.3.2(1) are the same map, and the genus is what guaranteed in advance that one exists.

This settles the debt left in section 47.4: the smooth model of a plane curve attaining the bound of corollary 43.2.5 has genus 0 and is therefore rational, so the extremal curves are exactly the rational ones.

Theorem 48.4.4: Genus One Curves Are Plane Cubics

Let C be a nonsingular projective curve of genus 1 and $O \in C$. Then C is isomorphic to a nonsingular plane cubic, embedded by $L(3O)$, and O maps to an inflection point.

***Proof*:**
Here $\deg K = 2g - 2 = 0$ and $\ell(K) = g = 1$, so $L(K)$ contains a nonzero f with $\operatorname{div}(f) + K \geq 0$ of degree 0, hence $\operatorname{div}(f) + K = 0$ and $K \sim 0$. So for any D of positive degree, $\deg(K - D) < 0$ and theorem 48.3.2 reads

$$\ell(D) = \deg D$$

Applying this to O, $2O$ and $3O$ gives dimensions $1, 2, 3$. Choose $x \in L(2O) \setminus L(O)$ and $y \in L(3O) \setminus L(2O)$, so that x has a double pole at O and y a triple one.

Now count in $L(6O)$, of dimension 6. The seven functions

$$1,\ x,\ y,\ x^2,\ xy,\ x^3,\ y^2$$

all lie in $L(6O)$, their pole orders at O being $0, 2, 3, 4, 5, 6, 6$. Seven vectors in a six-dimensional space are dependent, and any dependence must involve both x^3 and y^2, since they are the only two with a pole of order exactly 6 and every other listed function has a distinct pole order. Normalizing their coefficients gives a relation

$$y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6$$

which is a plane cubic W in Weierstrass form.

The map $p \mapsto [x(p) : y(p) : 1]$, defined on $C \setminus \{O\}$ and regular everywhere by lemma 42.2.8, has image in W. It is birational onto W: the subfield $k(x, y) \subseteq k(C)$ satisfies $[k(C) : k(x)] = 2$ and $[k(C) : k(y)] = 3$ by box 48.4.1, since $\deg \operatorname{div}_\infty(x) = 2$ and $\deg \operatorname{div}_\infty(y) = 3$, so $[k(C) : k(x, y)]$ divides both 2 and 3 and is therefore 1.

Hence W is birational to C, and W is not rational: a rational W would make C birational to $\mathbb{P}^1_k$ and so isomorphic to it by lemma 42.2.8, giving C genus 0 rather than 1.

But a singular irreducible plane cubic *is* rational. If q is a singular point of such a cubic W', then $m_q(W') \geq 2$, so every line L through q has $I(q, W' \cap L) \geq 2$ by property (6) of the intersection number, and $\deg W' \deg L = 3$, so theorem 43.1.1 leaves exactly one further intersection point, counted with multiplicity. Sending L to that point is a birational map $\mathbb{P}^1_k \dashrightarrow W'$, the lines through q forming a $\mathbb{P}^1_k$. So W is nonsingular, and a birational map between nonsingular projective curves is an isomorphism by lemma 42.2.8 applied in both directions.

Finally, homogenizing the Weierstrass equation as $y^2z+a_1xyz+a_3yz^2 = x^3+a_2x^2z+a_4xz^2+a_6z^3$ and intersecting with the line $z=0$ leaves $x^3=0$, so that line meets W only at $[0:1:0]$ and with multiplicity 3. That point is the image of O, since x and y both blow up there with y of higher order. So O is an inflection point in the sense of definition 42.1.6, completing the proof.

That last sentence closes the loop with chapter 45. Lemma 45.1.2 took its simplest form when the base point was an inflection point, and the Weierstrass embedding produces one for free: any point of a genus-one curve can be made the inflection at infinity. So the classical picture, in which three collinear points on a cubic sum to zero, is available for every choice of base point after re-embedding.

48.4.5 Note: The Genus Trichotomy The three cases are governed by the sign of $\deg K = 2g-2$.

- $g=0$: $\deg K = -2$. The curve is $\mathbb{P}^1_k$ by theorem 48.4.2, there is exactly one such curve, and its group Pic^0 is trivial by example 44.3.2.
- $g=1$: $\deg K = 0$. The curve is a plane cubic by theorem 48.4.4, there is a one-parameter family of them, and $\operatorname{Pic}^0(C) \cong C$ by theorem 45.2.2.
- $g \geq 2$: $\deg K = 2g-2 > 0$. The canonical class itself embeds the curve for $g \geq 3$ non-hyperelliptic, the curves form a $(3g-3)$-dimensional family, and Pic^0 is an abelian variety of dimension g, the Jacobian.

Only the first two rows are proved here. The third is the beginning of the theory of moduli and of abelian varieties, and it is where this book stops.

Exercise 48.4.1

1. Show that $\ell(D)=0$ when $\deg D = 0$ and $D \not\sim 0$, and $\ell(D)=1$ when $D\sim 0$.
2. Let C have genus g and let D be effective of degree $\deg D > 2g-2$. Show $\ell(D) = \deg D + 1 - g$ exactly, and deduce $\ell(K) = g$ without using theorem 48.3.2 twice.
3. Compute $\ell(nO)$ for all $n \geq 0$ on a nonsingular plane cubic, and check the answer against example 48.1.3 to see where the two curves first differ.
4. A curve of genus 2 has $\deg K = 2$ and $\ell(K)=2$. Deduce that it admits a degree-two map to $\mathbb{P}^1_k$, so that every genus-two curve is hyperelliptic.
5. Show that a nonsingular plane quartic has genus 3 and that its canonical class is $H \bullet C$, so that the canonical map is the original embedding. Conclude that no nonsingular plane quartic is hyperelliptic.
6. Use theorem 48.4.4 to show that the group $E_k(C,O)$ of chapter 45 is defined for any nonsingular projective curve of genus 1, not just for those presented as plane cubics.

49

What Next?

This book has worked over a fixed algebraically closed field, with varieties as sets of points and rings of functions on them. That framework is what makes the subject concrete, and every one of its limitations points at a successor theory.

Three Things This Book Could Not Say

Three separate difficulties have surfaced, and it is worth collecting them, because each is resolved by a different extension.

Multiplicity is not carried by the points. Chapter 42 had to define a plane curve as a polynomial up to scalar rather than as its zero set, precisely because $\mathcal{Z}(f)$ and $\mathcal{Z}(f^2)$ are the same set of points while the two curves ought to be different. Every intersection number in chapter 43 was then computed from the ideal, not from the set, and the book never had an object whose points and whose multiplicities were carried together.

The field is fixed and algebraically closed. The Nullstellensatz (theorem 32.4.4) is the foundation of the whole algebra-geometry dictionary, and it fails without algebraic closure. So nothing here applies to the geometry of equations over $\mathbb{Q}$ or over a finite field, and those are exactly the cases number theory treats.

Nilpotents are invisible. Chapter 32 matched varieties with *radical* ideals, discarding everything else. A family of varieties degenerating to a limit, say two points colliding or a smooth conic degenerating to a double line, has a limit whose natural equation is not radical, and the theory built here cannot see the difference between that limit and the reduced set underneath it.

Schemes

All three difficulties have one resolution: stop insisting that the geometric object be a set of points with a ring of functions on it, and let an arbitrary commutative ring define a space directly. The points of $\operatorname{Spec} R$ are the prime ideals of R, the structure sheaf is built from localizations, and the Nullstellensatz is no longer needed because the dictionary is definitional rather than a theorem.

That move recovers everything above as a special case. A variety over k becomes a scheme whose ring is a finitely generated reduced k-algebra, and dropping either adjective is what gives the three resolutions: dropping "reduced" makes $\operatorname{Spec} k[x,y]/(f^2)$ a genuinely different object from $\operatorname{Spec} k[x,y]/(f)$, and dropping "over an algebraically closed k" allows $\operatorname{Spec} \mathbb{Z}$ and its relatives. Chevalley's theorem (theorem 41.3.4) survives verbatim, the Picard group of section 44.3 becomes a functor, and Riemann-Roch becomes a statement about the cohomology of a sheaf.

This is *Algebraic Geometry* [5], which is the direct continuation of this book and the one to read next. Its prerequisite is exactly what has been developed here: the reason to endure the machinery of schemes is that one already knows what it is supposed to do.

Four Directions

Schemes are the trunk. Four branches lead off from the material of this book in particular.

The analytic theory. Over $\mathbb{C}$ a nonsingular projective curve is a compact Riemann surface, and the genus of chapter 48⋆ is its topological genus, the number of handles. The Riemann-Roch theorem is then a statement about holomorphic differentials, proved by analysis rather than by Max Noether's theorem, and the group law of chapter 45 becomes the quotient $\mathbb{C}/\Lambda$ by a lattice. *Complex Analysis* [40] develops this. The two theories give the same answers because the analytic and algebraic categories agree for projective varieties, which is a theorem and not merely a correspondence of vocabulary.

Intersection theory. Chapter 43 counted intersections of plane curves, and section 41.4 counted lines on a cubic surface, but both counts were run by hand. The general machinery replaces the intersection cycle of section 43.3 by the Chow ring, in which classes of subvarieties multiply and the answer to an enumerative question is a coefficient. The self-intersection self-intersection $E \bullet E = -1$, which box 47.4.2 explains this book does not need but which any surface theory must supply, is among its first computations. This is *Intersection Theory* [16].

Toric varieties. Sections 40.1 and 41.1 constructed embeddings by writing down monomials, and the varieties so obtained are governed entirely by the combinatorics of which monomials appear. Toric geometry makes that systematic: a fan of cones determines a variety, and its geometry (its singularities, its divisors, its cohomology) is read off the combinatorics. It is the best available source of examples that are complicated enough to be interesting and explicit enough to compute with. This is *Toric Geometry* [24].

Abelian varieties. Theorem 45.2.2 identified a cubic curve with its own Pic^0. For a curve of genus $g \geq 2$ that fails, and Pic^0 becomes a g-dimensional projective variety with a group law, the Jacobian. Abelian varieties are the projective group varieties, and they are where the group law of chapter 45 generalizes. This is *Abelian Varieties* [4]; the arithmetic of the genus-one case is *Elliptic Curves* [12].

Two Books to Read Alongside

Two external texts have been cited throughout and are worth naming as companions rather than as references.

Fulton's *Algebraic Curves* [54] is the source for chapters 42 and 43 and for the parts of chapter 48⋆ that were stated rather than proved. It is short, entirely classical, and available freely; a reader who wants the adjoint-curve proof of Riemann-Roch should go there first.

Shafarevich's *Basic Algebraic Geometry* [46] covers the varieties half of this book at greater length and with more examples, and its second volume treats schemes and complex manifolds side by side. Where this book has compressed, Shafarevich has room. Hartshorne [31] remains the standard reference for the scheme-theoretic account, but its first chapter is a compressed version of what has been done here, and it is easier read second.

50

Relating Algebra to Number Theory

A central object of study in mathematics is, naturally, the natural numbers $\mathbb{N}$ and, if the negatives are included, the integers $\mathbb{Z}$. So far, it is arguable to say that these objects have played a relatively minor algebraic role in this book: we know $\mathbb{N}$ (resp. $\mathbb{Z}$) is the initial abelian monoid (resp. ring) in their respective categories, that they are free objects, and that from $\mathbb{N}$ we may construct $\mathbb{Z}$, then $\mathbb{Q}$, and from there is any other field of characteristic 0. One aspect of $\mathbb{N}$ and $\mathbb{Z}$ we have barely touched on are their *primes* (recall the Fundamental Theorem of Arithmetic's, corollary 10.1.34). Exercise ref:HERE showed that there are infinitely many primes, and since $\mathbb{Z}$ is a PID we have that being irreducible is equivalent to being prime. However, we have explored little the nature of primes, and more generally have explored little of functions with integer solutions (elements of $f \in \mathbb{Z}[x_1, ..., x_n]$ are called *Diophantine equations*).

Unlike fields, it is in general much harder to ascertain whether an algebraic equation has solutions over the integers (or even integral extensions of the integers). Perhaps the most famous number theory problem demonstrating this difficulty is the following:

Show that for $n \geq 3$, the equation $x^n + y^n = z^n$ has no integer solutions

This problem is known as *Fermat's Last Theorem*. This is trivial if $n = 1$ (ex. $1 + 2 = 3$). It is more interesting to see the case of $n = 2$, that is we want to find all $(a, b, c) \in \mathbb{Z}^3$ ($\gcd(a, b, c) = 1$) such that $x^2 + y^2 = z^2$. Such a triple is called a *Pythagorean triple* and there are infinitely many. However, for $n \geq 3$, it is incredibly more difficult to find whether solutions exist or not, partly due to the fact that many rings that naturally arise in solving this case are *not* unique factorization domains, and partly because there turn out to be some "bad number" that make many of the number theory strategies fail. This particular problem has spurred a lot of the development of modern algebraic and analytic number theory, and shall be touched on later due to some interesting general theory that came from it. In this section we shall cover the mathematics that build built-up in solving Diophantine equations, including some special cases of Fermat's last theorem, and prepare the reader for Class Field theory which shall definitively answer the question of factoring integer-polynomials mod primes[1].

One final intuition that shall become more evident is that the theory of prime factorization in field extensions tie into solving irreducible polynomials mod some prime ideals. This theory extends results from the classical results of solutions or lack thereof for an irreducible polynomial over $\mathbb{Q}$ when considering it mod p for all primes $p \in \mathbb{Z}$. Recall that factorization and irreducibility of monic polynomials over $\mathbb{Q}$, more generally a finite extension $K/\mathbb{Q}$ is exactly reflected to the factorization and irreducibility of monic polynomials over $\mathbb{Z}$ (which will have a ring $\mathcal{O}_K$ that shall be the equivalent[2]) by Gauss's lemma (proposition 11.2.1). This was the historical origin of number theory, as it is much easier to work with polynomials finite fields (recall proposition 11.3.8 and example 11.3.9).

Material Overview

In this chapter, we shall start by exploring when do $\mathbb{Z}$-polynomials solutions over a field k. The space of solutions shall naturally be a subset of the field k. It shall be labeled as $\mathcal{O}_K$ and called *rings of integers*, and will have many important properties to determine. Similarly to how we extended fields to find solutions to polynomials over fields, rings of integers shall be extended (in parallel to a field extension) to find more solutions. Some key functionals such as the trace, norm, and discriminant shall become important tools to find properties of elements of $\mathcal{O}_K$ and the structure of $\mathcal{O}_K$ itself. As we classify $\mathcal{O}_K$, we shall see that we may consider $\mathcal{O}_K$ as a *lattice* when embedded in $\mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$ for appropriate $r_1, r_1 \in \mathbb{N}$. This geometric interpretation of $\mathcal{O}_K$ shall add some important new perspectives onto the elements of $\mathcal{O}_K$[3], and will allow us to define some important inequalities.

After having done a sweep over the structure of $\mathcal{O}_K$, we shall tackle some of it's algebraic structure. Namely, we shall see that they form a new type of ring called a *Dedekind domain*. Dedekind domains are very important types of rings; for those who are keen on algebraic geometry, Dedekind domains are the algebraic counter-part to 1-dimensional smooth curves (or schemes). In fact, we have seen Dedekind domains before in the previous chapter (for example, $\mathbb{Q}[x, y]/(x - y^2)$). Hence, Dedekind domains will be studied in their own right. They shall have a very rich structure: for example, many $\mathcal{O}_K$ will *not* be unique factorization domain (a fact that led to many wrong proofs of Fermat's last theorem), however we shall be able to define an abelian group structure on the ideals of $\mathcal{O}_K$ which *will* have a unique factorization (in the case where $\mathcal{O}_K$ is a PID, we shall see the ideal group I_K is isomorphic to $\mathbb{Q}^\times$, exactly mirroring the structure of Frac($\mathbb{N}$), however in general it may be much more complicated[4]). The discussion on Dedekind domains shall finish with a discussion of the unit's in Dedekind rings, which shall be important for finding the factorization of ideals.

After we realise we ought to be focusing on the *prime ideals* of $\mathcal{O}_K$ rather than the irreducible elements of $\mathcal{O}_K$ (for they are not necessarily prime), we shall start exploring how prime may further decompose as we extend to larger rings of integers. This helps in finding solutions to $\mathbb{Z}$-polynomials for the prime ideals in larger rings will have very rigid structure that can be taken advantage of. We have already seen this before: It shall turn out that $\mathcal{O}_{\mathbb{Q}(i)} = \mathbb{Z}[i]$ (the Gaussian integers). In the

[1] In particular, the *Artin Reciprocity Law* shall give the over-arching result showing how to factorize Diophantine equations

[2] See definition 50.1.3

[3] and of the norm

[4] which is measured by the *class group*, as we shall see

Gaussian integers, we saw that 2 is not prime, for

$$2 = (1+i)(1-i) = 1^2 - i^2 = 1 + 1$$

or in terms of ideals, we shall have $(2) = (1+i)(1-i)$. Hence, 2 has further factored into new primes. In section 10.3, this was used to prove Fermat's Theorem for sums of squares. More generally, we shall see that any prime ideal $\mathfrak{p} \subseteq \mathcal{O}_K$ may factor:

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_k^{e_k} \tag{50.1}$$

Though it may currently seem unrelated, the study of the factorization of primes *almost* mirrors that of the factorization of irreducible polynomials mod $\mathfrak{p}$ after extending fields. In fact, it shall turn out to be the case that *all but finitely many primes* shall factor exactly like how a polynomial factors, the "bad primes" essentially being primes for which an exponent in equation (50.1) is greater than 1, ≥ 2. This sort of exploration leads to a lot of very interesting theory that have applications beyond classical number theory, for example we shall be able to fully classify all abelian extensions of $\mathbb{Q}$.

For those who get motivation through algebraic geometry, algebraic number theory naturally ties into it; it may help to think of the main object of study of this chapter (rings of integers) as further expanding the dictionary between commutative algebra and geometry, namely they shall be important for *normal schemes* which links to the notion of a smooth curve[5]

At the end of this chapter, we shall briefly touch on some analytic number theory, for it's study is central to modern number theory and the author of this books considers that anyone that has reached this stage of the book would find it enlightening to see how the Riemann-zeta function play an important role in number theory.

50.0.1 Warning Some elementary analysis will be assumed in this section, including some properties of the real numbers.

50.1 Ring of Integers

In this chapter, whenever the notation $L/K/\mathbb{Q}$ is used for some letter's L, K, it is implied that L/K are both finite extensions of $\mathbb{Q}$, and L is an extension of K. Unless otherwise specified, the characteristic of any field is implicitly assumed to be 0. We start by defining our terms.

Definition 50.1.1: Algebraic Number Fields

Let K be a field. If $K/\mathbb{Q}$ is a finite extension of $\mathbb{Q}$, then K is called an *algebraic number field* or *number field* if unambiguous.

Example 50.1.2: Number Fields

1. Let $\zeta_n = e^{2\pi/n}$ be a root of unity. Then $\mathbb{Q}(\zeta_n)$ is a number field, called the *Cyclotomic field.*
2. Let $m \in \mathbb{Z}$ be not-a-square. Then Fields of the form $\mathbb{Q}(\sqrt{m})$ is called a *quadratic field.* Such fields always have degree 2. Notice that we can consider any $m \in \mathbb{Z}$, however we get many

[5] See a textbook in algebraic geometry for further details

equality of fields, for example $\mathbb{Q}(\sqrt{12}) = \mathbb{Q}(\sqrt{3})$. The field $\mathbb{Q}(i)$ is both a quadratic field and a Cyclotomic field since $i = \zeta_4$. As an exercise, show that $\mathbb{Q}(\sqrt{-3})$ is a Cyclotomic field.

3. The field $\mathbb{Q}(\sqrt{n}, \sqrt{m})$ is called a *biquadratic* field where n, m are both not-a-square.
4. The field $\mathbb{R}$ and $\mathbb{C}$ are *not* algebraic number fields, are they are not algebraic extensions of $\mathbb{Q}$ (they both contain transcendental elements).
5. Similarly, $k(x)$ for any field k is not an algebraic number field (it is an [algebraic] function field). However, in many ways this field is very similar to algebraic number fields, and shall be given some more attention in section 50.2.

Of key interest to this chapter the study of integer polynomials with solutions fields:

Definition 50.1.3: Ring of Integers (of Number Fields)

Let K be a field of characteristic 0 and identify $\mathbb{Z} \subseteq K$ via the (unique) map $\mathbb{Z} \hookrightarrow K$. Then the *ring of integers* of K is the integral closure of $\mathbb{Z}$ over K (definition 26.1.3):

$$\mathcal{O}_K := \overline{\mathbb{Z}}^K = \{a \in K \mid f(a) = 0,\ f(x) \in \mathbb{Z}[x]\}$$

As all fields in consideration shall be number fields $K/\mathbb{Q}$, there is already $\mathbb{Z} \subseteq K$ identified; the generality in the definition is to show that the ring of integers is defined over any field of characteristic 0. Note that there is an equivalent definition for fields of positive characteristic, however as $\operatorname{im}(\mathbb{Z}) \cong \mathbb{Z}/p\mathbb{Z}$ any integral closure of $\mathbb{Z}/p\mathbb{Z}$, $\overline{\mathbb{Z}/p\mathbb{Z}}^K$, is a field extension by proposition 26.1.8 and so there is no notion of prime ideals which essentially erases the key extra information that is studied. Instead, $\mathbb{F}_p[t]$ becomes the new $\mathbb{Z}$ and a parallel theory of finite extension $K/\mathbb{F}_p(t)$ is studied; these are called *algebraic function fields* and the corresponding $\overline{\mathbb{F}_p[t]}^K$ is the *ring of integers of function fields.*. The two theories have many parallels, but exploring these is beyond the scope of this book, see [39] for more details.

Although, once this chapter becomes it's own book, it may be a good idea to dedicate a section or chapter to this.

By corollary 26.1.6, $\mathcal{O}_K \subseteq K$ is a ring. Since we will often work over $\mathbb{Z}$, it is useful to know that instead of taking all roots of polynomials, it is equivalent to take all the roots of *irreducible polynomials*; by using Gauss's lemma, if $f = gh$, $f \in \mathbb{Z}[x]$ and $g, h \in \mathbb{Q}[x]$, then in fact $g, h \in \mathbb{Z}[x]$. Hence, the smallest degree polynomial for which α is a root will be irreducible. An important ring of integer that is worth isolating is the following:

Definition 50.1.4: Algebraic Integers [of Number Fields]

The collection of elements

$$\mathcal{O}_{\overline{\mathbb{Q}}} = \mathcal{O}_{\mathbb{C}} := \overline{\mathbb{Z}}^{\mathbb{C}}$$

are called the *algebraic integers*, and is sometimes denoted $\mathbb{A}$[a].

[a] this notation comes from the theory of *idele rings* that is an important tool in class field theory, see [39]

Just like for fields, there may be multiple "integral closures", and they are all isomorphic which motivates saying they are *the* algebraic integers.

Lemma 50.1.5: Equivalence Definition

Let $K/\mathbb{Q}$ be a finite extension and let $\mathcal{O}_\mathbb{C}$ be the algebraic integers. Then:

$$\mathcal{O}_\mathbb{C} \cap K = \mathcal{O}_K$$

***Proof*:**
exercise.

Example 50.1.6: Ring of Integers

1. $\mathcal{O}_\mathbb{Q} = \mathbb{Z}$. For this reason, the integers in algebraic number theory are sometimes called the rational integers

2. $\mathcal{O}_{\mathbb{Q}(i)} = \mathbb{Z}[i]$. To see this, let $\alpha = a + bi$, $a, b \in \mathbb{Q}$. Then for $\alpha \in \mathcal{O}_{\mathbb{Q}(i)}$, we need to show that the minimal polynomial of α:

$$\alpha^2 - 2a\alpha + (a^2 + b^2) = 0$$

has integer coefficients, that is $-2a$ and $a^2 + b^2$ are integers. First, if $c, d \in \mathbb{Z}$, $c + di \in \mathcal{O}_{\mathbb{Q}(i)}$. Since $\mathcal{O}_{\mathbb{Q}(i)}$ is a ring, if $a + bi \in \mathcal{O}_{\mathbb{Q}(i)}$, then so is $a + bi - c - di = a' + b'i$ for $c, d \in \mathbb{Z}$ where $a', b' \leq 1$. But then from $(a')^2 + (b')^2 = k \in \mathbb{Z}$, we get $a', b' \in \{-1, 0, 1\}$. Then that implies $a, b \in \mathbb{Z}$, showing that $\mathcal{O}_{\mathbb{Q}(i)} = \mathbb{Z}[i]$.

3. In general, it is difficult to find the ring of integers. The difficulty of finding the ring of integers can even show up for quadratic extensions. Consider $F = \mathbb{Q}(\sqrt{-3})$. Then we might be tempted to say that $\mathcal{O}_F = \mathbb{Z}[\sqrt{-3}]$. However, this is not the case, take:

$$\omega = \frac{-1 + \sqrt{-3}}{2} \in \mathbb{Q}(\sqrt{-3})$$

Then $\omega^2 + \omega + 1 = 0$, however $\omega \notin \mathbb{Z}[\sqrt{-3}]$.

4. In general, we will need more tools to find $\mathcal{O}_k$, but in the quadratic case, since the polynomial are relatively simple to work with, we may find all rings of integers. Let $k = \mathbb{Q}(\sqrt{m})$. Then:

$$\mathcal{O}_k = \mathbb{Z}[\sqrt{m}] \qquad m \equiv 2, 3 \bmod 4$$
$$\mathcal{O}_k = \mathbb{Z}\left[\frac{1 + \sqrt{m}}{2}\right] \qquad m \equiv 1 \bmod 4$$

To see this, let $\alpha = r + s\sqrt{m}$, $r, s \in \mathbb{Q}$. If $s = 0$, we've done, hence if $s \neq 0$ we get the monic irreducible polynomial:

$$x^2 - 2rx + r^2 - ms^2$$

Hence, α is algebraic if and only if $2r$ and $r^2 - ms^2$ are integers. Since $2r \in \mathbb{Z}$, $r \in \frac{1}{2}\mathbb{Z}$. Considering now $r^2 - ms^2 \in \mathbb{Z}$, if $r = \alpha/2$ for $\alpha \in \mathbb{Z}$, then subtracting both sides by $(\alpha^2 - 1)/4$ we get that $1/4 - ms^2 \in \mathbb{Z}$ or $m^2 = \mathbb{Z} + 1/4$. Now, this equality holds true if $s = \beta/2$ and $m \equiv 1 \bmod 4$ or $s = \beta$ and $m \equiv 2, 3 \bmod 4$. This now gives our restrictions on our coefficients.

The ring of integers $\mathcal{O}_K/\mathbb{Z}$ hold the core information of $K/\mathbb{Q}$. In particular, if $\mathbf{Fld}_0^{\text{fin}}$ is the category whose objects are finite extensions of $\mathbb{Q}$ and morphisms are field morphisms and $\mathbf{AlgInt}_0^{\text{fin}}$ is the category whose objects are the rings of integers $\mathcal{O}_K$ of finite extensions $K/\mathbb{Q}$ and whose morphisms are ring homomorphisms, these two categories are *isomorphic*. From here onto section 50.1.1 this correspondence is proven. Some of the key facts will require results that are proved later in this section (ex. that all non-trivial ring homomorphism $\mathcal{O}_K \to \mathcal{O}_L$ are injective), however knowing this correspondence is valuable enough that it is worth introducing this result early.

First, if $\varphi : F \to L$ be a field homomorphism (not necessarily a k-homomorphism), then $\varphi|_{\mathcal{O}_F} : \mathcal{O}_F \to \mathcal{O}_L$ is certainly well defined since if $\alpha \in \mathcal{O}_F$, then:

$$a_0 + a_1\alpha + \cdots + a_{n-1}\alpha^{n-1} + \alpha^n = 0 \qquad a_i \in \mathbb{Z}$$

Then $\varphi(a_i\alpha^i) = a_i\varphi(\alpha)^i$, since $a_i \in \mathbb{Z}$. Hence $\varphi(\alpha) \in \mathcal{O}_L$. From this, define $\mathcal{O}_- : \mathbf{Fld}_0^{\text{fin}} \to \mathbf{AlgInt}_0^{\text{fin}}$ which gives the commutative diagram:

$$\begin{tikzcd} F \arrow[r, hook, "\varphi"] \arrow[d, "\mathcal{O}_-"] & L \arrow[d, "\mathcal{O}_-"] \\ \mathcal{O}_F \arrow[r, "\varphi|_{\mathcal{O}_F}"] & \mathcal{O}_L \end{tikzcd}$$

Now given a map $\psi : \mathcal{O}_F \to \mathcal{O}_K$, can we find a map $\Psi : F \to K$ which is furthermore an inverse to the above functor? Yes; to find this functor, we first find how to retrieve the field from the ring of integers:

Proposition 50.1.7: Field of Fraction of Integral Closures of Extensions

Let R be an integral domain, $K = K(R)$ its field of fraction, and $S = \overline{R}^L$ where L/K is an algebraic extension. Then $L = K(S)$. Equivalently, $L = \langle S \rangle_{K(R)}$.

If $R = \mathbb{Z}$ and $K(R) = \mathbb{Q}$ so that $S = \overline{\mathbb{Z}}^L = \mathcal{O}_L$, then $L = K(\mathcal{O}_L)$.

***Proof*:**
Let R, K, S and L be defined as in the question. We shall first show that if $\alpha \in L$ is algebraic over K, then there exists a $d \in R$ such that $d\alpha$ is integral over R. Since α is algebraic over K,

$$\alpha^m + a_1\alpha^{m-1} + \cdots + a_m = 0 \qquad a_i \in K$$

Let d be the least common multiple of the denominators of a_i so that $da_i \in R$ for all i. Then multiplying the above equation by d^m, we get:

$$d^m\alpha^m + d^m a_1\alpha^{m-1} + \cdots + d^m a_m = 0 \qquad a_i \in K$$

re-writing:

$$(d\alpha)^m + da_1(d\alpha)^{m-1} + \cdots + d^m a_m = 0 \qquad a_i \in K,$$

where each $a_i d, ..., a_m d^m \in R$, hence $d\alpha$ is integral over R. Note that this immediately gives the equivalence $L = \langle S \rangle_{K(S)}$.

With that, to see that $L = K(S)$, notice that every $\alpha \in L$ can be written as $\alpha = b/d$ for $d \in R$, hence $L \subseteq K(S)$. Conversely, if $a/b \in K(S)$, where $a, b \in S$ and each satisfy an R-polynomial, then they are certainly satisfy a K-polynomial, and furthermore S is all elements of L that satisfy an R-polynomial, hence $a/b \in L$, giving equality.

Corollary 50.1.8: Basis For Number Field

Let $F/\mathbb{Q}$ be a finite extension of degree n and $(\alpha_1, \alpha_2, ..., \alpha_n)$ an $\mathbb{Q}$-basis for F. Then there exists an $m_i \in \mathbb{Z}$ such that $m_1\alpha_1, m_2\alpha_2, ..., m_n\alpha_n \in \mathcal{O}_F$

***Proof*:**
let $R = \mathbb{Z}$ in proposition 50.1.7.

Theorem 50.1.9: Isomorphic Categories: Fields and Rings of Integers

Let $K/\mathbb{Q}$ be a number field and $\mathcal{O}_K$ the ring of integers of K. Then:

1. If L/K, then $\mathcal{O}_L \cap K = \mathcal{O}_K$. In particular $\mathcal{O}_K \cap \mathbb{Q} = \mathbb{Z}$.
2. $\mathcal{O}_K \otimes_{\mathbb{Z}} \mathbb{Q} \cong K$. Namely, $\mathcal{O}_{-} \otimes_{\mathbb{Z}} \mathbb{Q} : \mathbf{AlgInt}_0^{\text{fin}} \to \mathbf{Fld}_0^{\text{fin}}$ is a functor.

Giving us a correspondence that is covariant under inclusion:

$$\left\{ \begin{matrix} \varphi : F \to K \\ \text{char}(F) = \text{char}(K) = 0 \end{matrix} \right\} \underset{(-)\otimes_{\mathbb{Z}}\mathbb{Q}}{\overset{\overline{\mathbb{Z}}^{(-)}}{\rightleftarrows}} \left\{ \begin{matrix} \varphi : \mathcal{O}_F \to \mathcal{O}_K \\ K(\mathcal{O}_F) = F, \ K(\mathcal{O}_K) = K \end{matrix} \right\}$$

which gives a bijection on Hom's:

$$\text{Hom}_{\mathbf{Fld}_0^{\text{fin}}}(L_1, L_2) \xrightarrow{\sim} \text{Hom}_{\mathbf{AlgInt}_0^{\text{fin}}}(B_1, B_2)$$

And hence there is an isomorphism of categories that preserves the lattice structure (meets and joins):

$$\mathbf{Fld}_0^{\text{fin}} \cong \mathbf{AlgInt}_0^{\text{fin}}$$

***Proof*:**
For the first two points:

1. This is essentially by definition: $\mathcal{O}_k = \overline{\mathbb{Z}}^k$ are all integral elements over $\mathbb{Z}$ that belonging k. Hence,$\mathcal{O}_k \cap \mathbb{Q}$ must be integral over k and also rational. But the only integral elements that are rational are the integers, hence we have equality. Similarly, $\mathcal{O}_L \cap k$ are all integral elements over $\mathbb{Z}$ that also belong to k, which by definition is $\mathcal{O}_k$
2. This comes from proposition 23.4.10 and its corollary.

To show the hom's are bijective, we would have to show that a non-trivial ring homomorphism $\varphi : \mathcal{O}_K \to \mathcal{O}_L$ for some two fields K, L is injective and that $L/K/\mathbb{Q}$ is a finite extension: both of these are a direct consequence of the proof of theorem 50.2.6. The lattice structure is preserved as $- \cap K$ and $- \otimes \mathbb{Q}$ preserves the lattice structures. Finally, composing these two functors certainly give the identity on $\mathbf{Fld}_0^{\text{fin}}$ and $\mathbf{AlgInt}_0^{\text{fin}}$, showing they are isomorphic (not just equivalent!) as we sought to show.

Note that finiteness is important: it shall be shown that $\mathcal{O}_K$ for $K/\mathbb{Q}$ a finite extension is a domain with factorization (or atomic domain, recall definition 10.1.9), however $\mathcal{O}_{\mathbb{C}}$ is *not* an atomic domain as shown in example 10.1.8 which is certainly desirable as we are generalizing the factorization of primes.

This shows how to relate $\mathcal{O}_K$ with K and a bit about how to move down the lattice, but we have not said much about the structure of $\mathcal{O}_K$. We know it is a ring, but is it a PID? A UFD? Every ring is a $\mathbb{Z}$-module; it is a finitely generated $\mathbb{Z}$-module? Noetherian $\mathbb{Z}$-module? Projective? The strategy in example 50.1.6 to find the structure of $\mathcal{O}_K$ gets much harder for more complicated roots of irreducible, even once we have degree 3, and especially beyond degree 4. Our first goal is to establish the structure of $\mathcal{O}_K$. To find the structure, we will require some tools for detecting elements of $\mathcal{O}_K$: we shall find numerical values for the elements of K to determine whether they are elements of $\mathcal{O}_K$, i.e. we shall find functionals. We shall see that $\mathcal{O}_K$ will be a free $\mathbb{Z}$-module of finite rank, in fact it shall be a particular $\mathbb{Z}$-module known as a *complete* lattice, as shall be demonstrated in section 50.1.4.

50.1.1 Functionals: Field Trace and Field Norms

(this link is useful: here)

Let M/k be a finite extension, and take $\alpha \in M$. We shall define two invariances on α that will detect whether α is algebraic over k or not, detect when it is an algebraic integer, and eventually help us find the structure of $\mathcal{O}_M$ as well as the factorization of elements of $\mathcal{O}_M$.

Define $L_\alpha : M \to M$ by $m \mapsto \alpha m$. This is a k-linear transformation, since:

$$L_\alpha(a + kb) = \alpha(a + kb) = \alpha a + k\alpha b = L_\alpha(a) + kL_\alpha(b)$$

Thus, we can represent this linear transformation in a matrix form (usually with basis given by α). Since the trace and determinant are basis independent calculations, it is meaningful to ponder what the trace/determinant of this transformation and what information it may provide us:

Definition 50.1.10: Trace And Norm

Let M/k be a finite extension, $L_\alpha : M \to M$ be a linear transformation defined by multiplication Then we call the trace of this linear transformation the *trace* of α and the determinant of this linear transformation the *norm* of α.

Example 50.1.11: Trace And Norm

1. Let $\mathbb{C}/\mathbb{R}$ be the extension and $\alpha = x + iy$. Pick basis $\{1, i\}$. Then multiplication is:

$$\begin{pmatrix} x & y \\ -y & x \end{pmatrix}$$

and so the trace is $2x = 2\text{Re}\alpha$ and the norm is $x^2 + y^2 = \|\alpha\|^2$. If you know some complex analysis, then we see that the norm does indeed match with our usual understanding of the norm, and the trace can be thought of as a generalization of taking the real part of the complex number (up to a factor).

2. Let $\alpha = a + b \cdot \left(\frac{1+\sqrt{-7}}{2}\right) \in \mathbb{Z}\left[\frac{1+\sqrt{-7}}{2}\right]$. Then:

$$\text{Nm}_{\mathbb{Q}(\sqrt{-7})/\mathbb{Q}}(\alpha) = \alpha^2 + \alpha\beta + 2\beta^2$$

3. Let $M = k(\alpha)$ be a finite extension, and let

$$m_{\alpha,k}(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0$$

be the minimal polynomial. Then this is the same as the characteristic polynomial (since plugging in L_α into the minimal polynomial produces the zero transformation by Cayley Hamilton [a]). Then the trace of α is $-a_{n-1}$ and the norm is $\pm a_0$ depending on whether $m_{\alpha,k}(x)$ is even or odd.

[a]Alternatively, choose basis $1, \alpha, ..., \alpha^{n-1}$ and compute

Naturally, if F/k, $a_1, a_2 \in F$ and $b \in k$:

$$\mathrm{tr}_{F/k}(a_1 + a_2) = \mathrm{tr}_{F/k}(a_1) + \mathrm{tr}_{F/k}(a_2) \quad \mathrm{tr}_{F/k}(ba_1) = b\mathrm{tr}_{F/k}(a_1) \quad \mathrm{tr}_{F/k}(a) = na$$

and:

$$\mathrm{Nm}_{F/k}(a_1 a_2) = \mathrm{Nm}_{F/k}(a_1)\mathrm{Nm}_{F/k}(a_2) \quad \mathrm{Nm}_{F/k}(ba_1) = b^n \mathrm{Nm}_{F/k}(a_1) \quad \mathrm{Nm}_{F/k}(b) = b^n$$

Most of the properties of the trace and norm come from linear algebra, and furthermore since every finite separable extension has a primitive element generating the entire field, the norm and trace always show up in the minimal polynomial. In section 20.2.3, we saw another way of characterizing the trace and norm, which will be emphasized here due to its importance:

Proposition 50.1.12: Trace and Norm via Galois Conjugates

Let M/k be a finite extension where $[M : k] = n$ and let $\alpha \in M$ be algebraic over k. Then:

$$\mathrm{tr}_{M/k}(\alpha) = [M : k(\alpha)] \cdot \sum_{\substack{r \\ \text{root of } m_{\alpha,k}}} r \qquad \mathrm{Nm}_{M/k}(\alpha) = \left(\prod_{\substack{r \\ \text{root of } m_{\alpha,k}}} r \right)^{[M:k(\alpha)]}$$

Proof:

Let $\sigma_i(\alpha) \in \overline{k}$ be the roots of $m_{\alpha,k}(x)$ where $\sigma_i : M \to \overline{k}$ are the embeddings of M into the algebraic closure of k. Suppose first that $M = k(\alpha)$ and is a separable extension. Pick a basis $1, \alpha, ..., \alpha^{n-1}$. Then concretely computing the trace, we get the $n-1$th coefficient of

$$\alpha^n - a_{n-1}\alpha^{n-1} - \cdots - a_1\alpha - a_0 = 0$$

which, if we factor out the above polynomial in a normal closure and collect the terms of the roots as we've done in section 20.2.3, we see that

$$\alpha_{n-1} = \sum_i \sigma_i(\alpha)$$

that is, it is the sum of the roots. Similarly, we get that $\mathrm{Nm}_{F/k}(\alpha) = a_0 = \prod_i \sigma_i(\alpha)$, giving us both results.

For the general finite extension case, we may use induction and transitivity. The inseparable case is left as an exercise.

Corollary 50.1.13: Trace and Norm Via Embeddings

Let L/k be a separable extension of degree n, an $\sigma_1, \sigma_2, ..., \sigma_n$ the embedding of L into it's Galois closure or $\overline{k}$. Then for $\alpha \in L$:

$$\mathrm{tr}_{L/k}(\alpha) = \sum_i^n \sigma_i(\alpha) \qquad \mathrm{Nm}_{L/k}(\alpha) = \prod_i^n \sigma_i(\alpha)$$

***Proof*:**
this is just a re-phrasing of the previous result. Note that there may be $\sigma_i(\alpha)$ that repeat since σ_i may be fixed in $k(\alpha)$.

This immediately shows us that for algebraic elements, $\mathrm{tr}_{M/k}(\alpha), \mathrm{Nm}_{M/k}(\alpha) \in k$, since $\pm a_{n-1}, a_0 \in k$. An easy way to remember that that the trace gives a_{n-1} and Norm gives a_0 is that it is not possible that a minimal polynomial have 0 constant term since

$$x^n + a_{n-1}x^{n-1} + \cdots + a_1 x$$

is reducible. Hence, $\mathrm{Nm}_{M/k}(\alpha) = a_1$ while $\mathrm{tr}_{M/k}(\alpha) = a_{n-1}$. To relate this back to our goal of understanding $\mathcal{O}_M$, we would like to identify when $\alpha \in M$ belongs in $\mathcal{O}_M$ using tr and Nm. This is exactly when the coefficients are integers, that is $\mathrm{tr}_{M/k}(\alpha), \mathrm{Nm}_{M/k}(\alpha) \in \mathbb{Z}$. We've in fact proved something slightly more general that is important to point out for when we are working with intermediary extensions:

Corollary 50.1.14: Trace and Norm on Rings of Integers

Let R be an integrally closed integral domain ($\overline{R}^K = R$), and let $F/K(R)$ be a finite field extension of the field of fraction of R. Then if $\alpha \in F$ is integral over R,

$$\mathrm{tr}_{F/K(R)}(\alpha) \in R \qquad \mathrm{Nm}_{F/K(R)}(\alpha) \in R$$

A particular consequence of this is $\mathrm{tr}_{L/k}(\mathcal{O}_L) \subseteq \mathcal{O}_k$

***Proof*:**
If α is integral, then certainly so are all its Galois conjugates. But then adding and multiplying all the Galois conjugates remains integral, meaning the coefficients of the corresponding polynomials remains in R, hence the trace and norm of α is in R.

In particular, if $\alpha \in \mathcal{O}_L = \overline{\mathbb{Z}}^L \subseteq \overline{k}^L$, $\mathrm{tr}_{L/k}(\alpha) \in \mathcal{O}_L \cap k = \mathcal{O}_k$ by theorem 50.1.9.

If $R = \mathbb{Z}$ and $F/\mathbb{Q}$ is a finite extension, we get can detect potential integral elements using the trace and norm! Since we may be working with intermediate fields $M/L/k$, it is useful to know how to compute the trace and norm given information about the trace and norm of the intermediate fields:

Proposition 50.1.15: Trace and Norm w.r.t. Towers

Let $M/L/K$ be finite extensions. Then:

$$\mathrm{tr}_{M/K}(\alpha) = \mathrm{tr}_{L/K}(\mathrm{tr}_{M/L}(\alpha)) \qquad \mathrm{Nm}_{M/K}(\alpha) = \mathrm{Nm}_{L/K}(\mathrm{Nm}_{M/L}(\alpha))$$

***Proof*:**
Let $\sigma_1, \sigma_2, ..., \sigma_n$ be the embeddings of L in $\mathbb{C}$ which fix K pointwise and let $\tau_1, \tau_2, ..., \tau_m$ be the embeddings in $\mathbb{C}$ fixing L pointwise. We will want to compose σ_i with the τ_j, so we will extend our embeddings as follows: Let N/M be the normal closure of M so that all σ_i, τ_j can be extended to automorphisms of N; relabel our extensions σ_i, τ_j (i.e. keep the same labeling). Then:

$$\mathrm{tr}_{L/k}(\mathrm{tr}_{M/L}(\alpha) = \sum_i^n \sigma_i \left(\sum_j^m \tau_j(\alpha) \right) = \sum_{i,j} \sigma_i \tau_j(\alpha)$$

$$\mathrm{Nm}_{L/k}(\mathrm{Nm}_{M/L}(\alpha) = \prod_i^n \sigma_i \left(\prod_j^m \tau_j(\alpha) \right) = \prod_{i,j} \sigma_i \tau_j(\alpha)$$

It only remains to show that the mappings $\sigma_i \tau_j$ when restricted to M give the embeddings of M in $\mathbb{C}$ fixing k pointwise. Certainly they fix k pointwise and there is the right number of them, so this follows by showing they are all distinct (TBD).

Note that it is not necessarily sufficient that the trace and norm is integral:

Example 50.1.16: Trace And Norm Insufficient To Detect Integral Elements
Let $L = \mathbb{Q}(\alpha)$ where $\alpha^4 + 2\alpha^3 + 1/2\alpha^2 + 1/2\alpha + 2\alpha = 0$. Note that $x^4 + 2x^3 + 1/2x^2 + 1/2x + 3$ is irreducible, hence this is a degree 4 extension. Furthermore,

$$\mathrm{tr}_{L/k}(\alpha) = 2 \qquad \mathrm{tr}_{L/K}(\alpha) = 3$$

But certainly $\alpha \notin \mathcal{O}_L$.

A notable exception to this is for quadratic extensions, since any extension of degree 2 is quadratic, giving only 2 possible coefficients:

Example 50.1.17: Rings of Integers of Quadratic Extensions
Let $K = \mathbb{Q}(\sqrt{n})$ where n is square free, and consider $\alpha = a + b\sqrt{n} \in \mathcal{O}_K$ where a, b are square free. Then:

$$\mathrm{tr}_{K/\mathbb{Q}}(\alpha) = 2a \in \mathbb{Z} \qquad \mathrm{Nm}_{K/\mathbb{Q}}(\alpha) = (a + b\sqrt{n})(a - b\sqrt{n}) = a^2 - nb^2 \in \mathbb{Z}$$

We may ask when $2a \in \mathbb{Z}$, that is when is it possible that $a = 1/2$? Let's say it was, so that

$$\left(\frac{1}{2}\right)^2 - nb^2 \in \mathbb{Z} \qquad \Leftrightarrow \qquad \frac{b^2 n}{4} \in \mathbb{Z} + \frac{1}{4}$$

hence, $4b^2 n \in \mathbb{Z}$. Since n is square-free, $n \neq m^2$ implying that we cannot have $b^2 = p^2/m^2 \cdot m^2$, so $2b \in \mathbb{Z}$. Thus, if $a = 1/2$, it must be that $b = 1/2$. Similarly, if b is an integer, a has to be an integer.

Now, is $\alpha = \frac{1}{2} + \frac{1}{2}\sqrt{n}$ an algebraic integer? For this to be the case, it would have to solve the equation:

$$\alpha^2 - \alpha + \frac{1-n}{4} = 0$$

or equivalently, $\mathrm{Nm}(\alpha) = \frac{1-n}{4}$. Hence, we need $n \equiv 1 \bmod 4$. Thus, we have

$$\mathcal{O}_{\mathbb{Q}(\sqrt{d})} = \begin{cases} \mathbb{Z}[\sqrt{d}] & d \not\equiv 1 \bmod 4 \\ \mathbb{Z}\left[\frac{1+\sqrt{n}}{2}\right] & d \equiv 1 \bmod 4 \end{cases}$$

A final result in this section is to find the group of units of $\mathcal{O}_K$. Note that in general, if $\alpha \in \mathcal{O}_K$, then $1/\alpha \notin \mathcal{O}_K$; for example $2 \in \mathcal{O}_{\mathbb{Q}}$, but certainly $1/2 \notin \mathcal{O}_{\mathbb{Q}}$. In fact, the only units in $\mathcal{O}_{\mathbb{Q}}$ are ± 1. If $\mathcal{O}_K$ contains roots of unity, then certainly their inverse is in $\mathcal{O}_K$ (for if $\alpha = \zeta_n$ $1/\zeta = \zeta_n^{n-1}$). There are in general more units in $\mathcal{O}_K$, and the group of units of a ring of integers shall be fully characterized in section 50.2.4. With the norm, we have a way of detecting units:

Proposition 50.1.18: Norm And Units

Let L/K be a finite field extension. Then

$$\alpha \in \mathcal{O}_L^* \qquad \Leftrightarrow \qquad \mathrm{Nm}_{L/K}(\alpha) \in \mathcal{O}_K^*$$

In the space case where $K = \mathbb{Q}$, then $\alpha \in \mathcal{O}_L^*$ if and only if $\mathrm{Nm}_{L/\mathbb{Q}}(\alpha) = \pm 1$.

***Proof*:**
Let $\alpha \in \mathcal{O}_L^*$ so that $\mathrm{Nm}_{L/K}(\alpha) \in \mathcal{O}_K$. If α is a unit in $\mathcal{O}_L$, then $1/\alpha \in \mathcal{O}_L$ exists. Then:

$$1 = \mathrm{Nm}_{L/K}(1) = \mathrm{Nm}_{L/K}(\alpha \cdot 1/\alpha) = \mathrm{Nm}_{L/K}(\alpha)\mathrm{Nm}_{L/K}(1/\alpha)$$

hence, $\mathrm{Nm}_{L/K}(\alpha), \mathrm{Nm}_{L/K}(1/\alpha) \in \mathcal{O}_K^\times$. Conversely, if $\mathrm{Nm}_{L/K}(\alpha) \in \mathcal{O}_K$, then there exists a β such that

$$\beta\mathrm{Nm}_{L/K}(\alpha) = 1$$

Then by definition of the norm:

$$1 = \beta\mathrm{Nm}_{L/K}(\alpha) = \beta\prod_{\sigma}\sigma(\alpha) = \alpha\left(\beta\prod_{\sigma\neq\mathrm{id}}\sigma(\alpha)\right) = \alpha y$$

where $y \in \mathcal{O}_L$ since each $\sigma(\alpha) \in \mathcal{O}_L$, which gives the result.

Proposition 50.1.19: Norm And Irreducible

Let $L/\mathbb{Q}$ be a finite extension and $\alpha \in \mathcal{O}_L$. Then if p is prime:

$$\mathrm{Nm}_{L/\mathbb{Q}}(\alpha) = p \implies \alpha \text{ is irreducible}$$

***Proof*:**
Suppose α where reducible so that $\alpha = \beta\gamma$ where β, γ or not units, hence have norm greater than 1. Then:

$$\begin{aligned}\mathrm{Nm}_{L/\mathbb{Q}}(\alpha) &= \mathrm{Nm}_{L/\mathbb{Q}}(\beta\gamma)\\ &= \mathrm{Nm}_{L/\mathbb{Q}}(\beta)\mathrm{Nm}_{L/\mathbb{Q}}(\gamma)\\ &= p\end{aligned}$$

a contradiction.

Note that the converse is not true

Example 50.1.20: Prime, But Norm Not Prime
Let $K = \mathbb{Q}(\sqrt{2})$ so that $\mathcal{O}_K = \mathbb{Z}[\sqrt{2}]$. Then $\mathrm{Nm}_{K/\mathbb{Q}}(5) = 5^2 = 25$, which is certainly not prime, however 5 is prime in $\mathbb{Z}[\sqrt{2}]$. This is at this stage a tedious calculation: assume that it factors $5 = \alpha\beta$ where $\alpha, \beta \in \mathbb{Z}[\sqrt{2}]$, $\alpha = a + bi$, $\beta = c + di$, and:

$$\mathrm{Nm}_{K/\mathbb{Q}}(\alpha) = a - 2b = 5 = c - 2d = \mathrm{Nm}_{K/\mathbb{Q}}(\beta)$$

but no such a, b, c, d exist. Later, we shall be able to deduce this almost immediately using Dedekind-Kummer's Theorem (see theorem 50.4.7).

In lemma 50.2.27, we shall give a partial converse which shall as a corollary imply:

$$\alpha \text{ prime} \implies \mathrm{Nm}_{K/\mathbb{Q}}(\alpha) = p^n$$

for appropriate n. Note how α must be prime, which is *stronger* than irreducible. However, we will often be working over rings where we have few prime elements but many irreducible elements. In section 50.2 we shall show how to "fix" this problem to make the norm more useful.

50.1.2 Functionals: Discriminant

As we saw, if $\alpha \in F/\mathbb{Q}$ is integral, then $\mathrm{tr}(\alpha), \mathrm{Nm}(\alpha) \in \mathbb{Z}$. However, the converse is not necessarily true as we saw in example 50.1.16. We will require a more powerful result, one that will verify that an element is an element of a ring of integers. For this, we shall bring in some multilinear algebra and define a new tool that shall become invaluable finding a *basis* for $\mathcal{O}_K$ (recall that it was mentioned that $\mathcal{O}_K$ shall be proven to be a finitely generated free $\mathbb{Z}$-module). Given a basis can be found, then an element can be determined to be integral using the basis. The tool that shall be used to detect a basis for $\mathcal{O}_K$ is called the *field discriminant*. The norm and the trace shall both be used in the definition of the field discriminant.

Some Multi-Linear Algebra

Recall from section 13.3.4 that multi-linear forms have matrix representations and so the determinant of multi-linear maps is well-defined:

Definition 50.1.21: [General] Discriminant

Let $\varphi : V \times V \to k$ be a symmetric k-bilinear map ($\varphi(x, y) = \varphi(y, x)$). Then given a basis $v_1, v_2, ..., v_n$, the *discriminant* of φ is:

$$\operatorname{disc}(\varphi) = \det \begin{pmatrix} \varphi(v_1, v_1) & \varphi(v_1, v_2) & \cdots & \varphi(v_1, v_n) \\ \varphi(v_2, v_1) & \varphi(v_2, v_2) & \cdots & \varphi(v_2, v_n) \\ \vdots & & \ddots & \vdots \\ \varphi(v_n, v_1) & \varphi(v_n, v_2) & \cdots & \varphi(v_n, v_n) \end{pmatrix}$$

and is denoted $\operatorname{disc}(\varphi)$.

Let $\{\beta_1, \beta_2, ..., \beta_n\}$ be a basis for V and $\{v_1, v_2, ..., v_n\}$ be some collection of elements so that

$$v_i = \sum_i a_i \beta_i$$

Then:

$$\varphi(v_k, v_l) = \sum_{i,j} \varphi(a_{ki}\beta_i, a_{lj}\beta_j) = a_{ki}\varphi(\beta_i, \beta_j)a_{kl}$$

hence, as matrices, we have the (component-wise) equality:

$$(\varphi(v_k, v_l)) = A \cdot (\varphi(e_i, e_j)) \cdot A^{\mathrm{tr}}$$

where $A = (a_{ij})$. Then if we have a change of basis, we have the determinant of the matrix is:

$$\det((\varphi(f_i, f_j)) = \det(A)^2 \cdot \det((\varphi(\beta_i, \beta_j))) \tag{50.2}$$

Since $A \in \mathrm{GL}(k)$, we see that the discriminant is defined up to the square of a unit. Hence, if $\operatorname{disc}(\varphi) \neq 0$, $\operatorname{disc}(\varphi)$ is well-defined in $k^\times/(k^\times)^2$ If $K = \mathbb{Q}$, then $(\mathbb{Q}^\times)^2 = 1$, hence the discriminant is well-defined in $\mathbb{Q}^\times$.

Invertible matrices allowed us to define an isomorphism between V and $V^\vee$ when V is finite dimensional. We shall require this same property for bilinear forms. For this, the notion of non-generate form needs to be upgraded for bilinear forms:

Definition 50.1.22: Non-degenerate Form

let φ be a bilinear form. Then φ is *non-generate* if φ has a non-zero discriminant

Proposition 50.1.23: Non-degenerate Form Equivalences

let φ be a bilinear form. Then φ is *non-generate* if any of the following equivalent conditions hold:

1. φ has a non-zero discriminant
2. the left kernel is zero: $\{v \in V \mid \varphi(v, x) = 0, \ \forall x \in V\}$
3. the right kernel is zero: $\{v \in V \mid \varphi(x, v) = 0, \ \forall x \in V\}$

***Proof*:**
exercise

If φ is non-degenerate, it always induces an isomorphism

$$V \mapsto V^\vee \qquad v \mapsto (x \mapsto \varphi(v,x))$$

Showing that non-degenerate maps φ give a "representation" of the hom-dual. The particular symmetric k-bilinear form that will be useful in finding the rank of the ring of integers is the one built from the trace, definition 19.6.30; in this chapter we call it the *trace pairing* and write it with the lower-case tr used throughout,

$$\mathrm{tr}_{F/k} : F \times F \to k \qquad (\alpha, \beta) \mapsto \mathrm{tr}_{F/k}(\alpha\beta)$$

Its nondegeneracy is a statement about *separability*, not about F alone: if F/k is separable then the trace pairing is nondegenerate (proposition 19.6.31). The hypothesis is not decorative. Over $k = \mathbb{F}_p(t)$ the extension $F = k(t^{1/p})$ has $\mathrm{tr}_{F/k} \equiv 0$, so the pairing vanishes identically. Nor can separability be dodged by arguing that $\mathrm{tr}_{F/k}(\alpha\alpha^{-1}) = \mathrm{tr}_{F/k}(1) = [F:k] \neq 0$ for $\alpha \neq 0$: that degree is computed *in* k, and it dies whenever $\mathrm{char} k \big| [F:k]$ — already for $\mathbb{F}_4/\mathbb{F}_2$, which is separable and whose trace pairing is nondegenerate all the same.

Every extension we pair below is separable, so by proposition 50.1.23 the left kernel is trivial and we have an isomorphism

$$F \xrightarrow{\cong} \mathrm{Hom}_k(F,k) = F^* \qquad x \mapsto (y \mapsto \mathrm{tr}_{F/k}(xy))$$

The submodule of F that this isomorphism carries onto a prescribed integrality condition is the *integral trace dual*, defined in definition 50.1.35 once we have the ring of integers in hand to state it for.

Field Discriminant

With a general overview of discriminants, we return to detecting algebraic integers more precisely using the discriminant. First the determinant, det, is an alternating n-form, meaning $(\det)^2$ is a symmetric n-form. Note that this is the same discriminant introduced in section 19.6.3; the equivalence shall soon be shown.

Definition 50.1.24: [Field] Discriminant

Let L/k be a finite extension of degree n, and let $\sigma_1, \sigma_2, ..., \sigma_n \in \mathrm{Emb}_k(L)$ be the k-embeddings of L in $\mathbb{C}$. Then for any n-tuple of elements $\alpha_1, \alpha_2, ..., \alpha_n \in L$, define the *discriminant* of $\alpha_1, \alpha_2, ..., \alpha_n$ to be:

$$\mathrm{disc}_{L/k}(\alpha_1, \alpha_2, ..., \alpha_n) = \det \begin{pmatrix} \sigma_1(\alpha_1) & \cdots & \sigma_1(\alpha_n) \\ \vdots & \ddots & \vdots \\ \sigma_n(\alpha_1) & \cdots & \sigma_n(\alpha_n) \end{pmatrix}^2 = \det((\sigma_i(\alpha_j))_{ij})^2$$

Notice that the square makes the discriminant independent of the ordering of the σ_i and α_j. If we chose a different set of elements $(\beta_1, \beta_2, ..., \beta_n)$ that differ from $(\alpha_1, \alpha_2, ..., \alpha_n)$ by a change of basis, that is $\vec{\alpha} = A\vec{\beta}$, then as we observed in equation 50.2, we get

$$\mathrm{disc}_{L/k}(\beta_1, \beta_2, ..., \beta_n) = \det(A)^2 \cdot \mathrm{disc}_{L/k}(\alpha_1, \alpha_2, ..., \alpha_n)$$

meaning the discriminant is not quite basis independent, meaning it is properly defined for operators in $L^\times / L^{\times 2}$ (where $L^\times$ are the units of L, since det maps invertible matrices to units, see proposition 13.4.10).

Example 50.1.25: Field Discriminant

1. Let $K = \mathbb{Q}(\sqrt{m})$ where m is square free. Then K has a basis $A = \{1, \sqrt{m}\}$ and $B = \left\{1, \frac{1+\sqrt{m}}{2}\right\}$. If $m \equiv 2, 3 \bmod 4$, then the former is a basis for $\mathcal{O}_K$ and if $m \equiv 1 \bmod 4$, then then the latter is a basis for $\mathcal{O}_K$. Computing both, we get:

$$\mathrm{disc}_{K/\mathbb{Q}}(A) = \det \begin{pmatrix} 1 & \sqrt{m} \\ 1 & -\sqrt{m} \end{pmatrix}^2 = (-\sqrt{m} - \sqrt{m})^2 = 4m$$
$$\mathrm{disc}_{K/\mathbb{Q}}(B) = \det \begin{pmatrix} 1 & \frac{1+\sqrt{m}}{2} \\ 1 & \frac{1-\sqrt{m}}{2} \end{pmatrix}^2 = \left(\frac{-2\sqrt{m}}{2}\right)^2 = m$$

Yet another basis for $\mathbb{Q}(\sqrt{m})$ is $C = \{1, \sqrt{m}/10\}$. In that case:

$$\mathrm{disc}_{K/\mathbb{Q}}(C) = \det \begin{pmatrix} 1 & \frac{\sqrt{m}}{10} \\ 1 & -\frac{\sqrt{m}}{10} \end{pmatrix} = \left(\frac{-\sqrt{m}}{5}\right)^2 = \frac{m}{25}$$

However, C is not a basis for $\mathcal{O}_K$, namely since the denominator is too big. Notice that the first two discriminant integers, while the third one is not.

2. Let $K = \mathbb{Q}(\sqrt[3]{2})$. Then $A = \{1, \sqrt[3]{2}, \sqrt[3]{3}\}$ is a basis for K, and:

$$\mathrm{disc}_{K/\mathbb{Q}}(A) = \begin{pmatrix} 1 & \sqrt[3]{2} & \sqrt[3]{4} \\ 1 & \sqrt[3]{2}\zeta_3 & \sqrt[3]{3}\zeta_3^2 \\ 1 & \sqrt[3]{2}\zeta_3^2 & \sqrt[3]{3}\zeta_3 \end{pmatrix}^2 = -108 = -2^2 \cdot 3^3$$

showing that the discriminant can be negative. We shall come back to seeing how this is useful for finding whether $\mathcal{O}_K = \mathbb{Z}[\sqrt[3]{2}]$.

The following alternative form is useful for an alternate way of computing the discriminant as well as important for deducing some theoretical properties of the elements inputted into the discriminant:

Proposition 50.1.26: Discriminant Via Trace-Pairing

$$\mathrm{disc}_{L/k}(\alpha_1, \alpha_2, ..., \alpha_n) = \det(\mathrm{tr}_{L/k}(\alpha_i \alpha_j))$$

***Proof*:**
This follows immediately from the matrix equation. If $[\sigma_i(\alpha_j)]$ represents the matrix:

$$[\sigma_j(\alpha_i)][\sigma_i(\alpha_j)] = [\sigma_1(\alpha_i\alpha_j) + \cdots + \sigma_n(\alpha_i\alpha_j)] = [\mathrm{tr}_{L/k}(\alpha_i\alpha_j)]$$

Using the fact that the determinant is multiplicative and invariant under transposes, we get our result.

In particular, the above form allows for the detection of sets of algebraic integers:

Corollary 50.1.27: Detecting Algebraic Integers using Discriminant

Let K be a number field and $\alpha_1, \alpha_2, ..., \alpha_n$ a $\mathbb{Q}$-basis. Then $\text{disc}_{K/\mathbb{Q}}(\alpha_1, ..., \alpha_n) \in \mathbb{Q}$, and if all $\alpha_1, \alpha_2, ..., \alpha_n$ are algebraic integers, then $\text{disc}(\alpha_1, \alpha_2, ..., \alpha_n) \in \mathbb{Z}$.

***Proof*:**
we know that $\text{tr}_{K/\mathbb{Q}}(\alpha_i\alpha_j) \in \mathbb{Q}$ by proposition 50.1.12 and are integers via corollary 50.1.14, hence $\text{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) \in \mathbb{Q}$, and if they are all algebraic integers then $\text{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) \in \mathbb{Z}$.

Corollary 50.1.28: Discriminant And Linear Independence

$\text{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) = 0$ if and only if $\alpha_1, \alpha_2, ..., \alpha_n$ are $\mathbb{Q}$-linearly dependent.

***Proof*:**
If the $\alpha_1, \alpha_2, ..., \alpha_n$ are $\mathbb{Q}$-linearly dependent, then two of the columns would be linearly dependent, hence $\text{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) = 0$. Conversely, assuming $\text{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) = 0$, then the rows of the matrix $[T(\alpha_i\alpha_j)]$ are linearly dependent; let's label them R_i so that for some $a_1, a_2, ..., a_n$ which are not all zero:

$$a_1 R_1 + \cdots + a_n R_n = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}$$

For the sake of contradiction, let's say that the $\alpha_1, \alpha_2, ..., \alpha_n$ are $\mathbb{Q}$-linearly independent. Then they form a $\mathbb{Q}$-basis for K^n. Consider:

$$\alpha = a_1\alpha_n 1 + \cdots + a_n\alpha_n$$

where $\alpha \neq 0$ since some $a_i \neq 0$ and $(\alpha_1, \alpha_2, ..., \alpha_n)$ is linearly independent. Then $(\alpha\alpha_1, ..., \alpha\alpha_n)$ also forms a $\mathbb{Q}$-basis for K. By the linear dependence of the row space, we have that for each j

$$\text{tr}_{K/\mathbb{Q}}(\alpha\alpha_j) = \sum_i a_i \text{tr}_{K/\mathbb{Q}}(\alpha_i\alpha_j) = 0$$

But not for any $t \in K$, $t = \sum b_i\alpha\alpha_j$, and by our above observation that implies that $\text{tr}_{K/\mathbb{Q}}(t) = 0$, however that is a contradiction since we know that $\text{tr}_{K/\mathbb{Q}}(1) = n$. Hence, it must be that $(\alpha_1, \alpha_2, ..., \alpha_n)$ are linearly independent, completing the proof.

The corollary can be thought of as motivation for the name discriminant: If $K/\mathbb{Q}$ is a number field of dimension n, the discriminant will "discriminate" sets that are bases for $K/\mathbb{Q}$.

Since number fields are finite separable extensions, we always find a primitive element for a separable algebraic extension, the following theorem gives another important interpretation of the discriminant:

Proposition 50.1.29: Discriminant via Primitive Element

Let L/K be a finite separable field extension, with α a primitive element and $m_{\alpha,k}(x) \in K[x]$ the minimal polynomial with roots $\alpha_1, ..., \alpha_n$ in the splitting field of L. Then the *[field] discriminant* of L[a] is:

$$\Delta_K^2 = \left(\prod_{1 \leq i < j \leq n} (\alpha_i - \alpha_j) \right)^2 = \mathrm{Nm}_{L/K}(m'_{\alpha,k}(\alpha))$$

where $m'_{\alpha,k}(x)$ is the derivative of the minimal polynomial. If unambiguous the discriminant is often denoted

$$\mathrm{disc}_{L/K}(\alpha)$$

[a]In section 20.3, we called this the discriminant of $m_{\alpha,k}(x)$

***Proof*:**
Take as basis $1, \alpha, \alpha^2, ..., \alpha^{n-1}$. This comes down to noticing that $(\mathrm{tr}_{B/A}(\alpha^i \alpha^j))$ form the matrix:

$$\begin{pmatrix} 1 & \mathrm{tr}(\alpha) & \mathrm{tr}(\alpha^2) & \cdots & \mathrm{tr}(\alpha^{n-1}) \\ \mathrm{tr}(\alpha) & \mathrm{tr}(\alpha^2) & \mathrm{tr}(\alpha^3) & \cdots & \mathrm{tr}(\alpha^n) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathrm{tr}(\alpha^{n-1}) & \mathrm{tr}(\alpha^n) & \mathrm{tr}(\alpha^{n+1}) & \cdots & \mathrm{tr}(\alpha^{2n-2}) \end{pmatrix}$$

gives us:

$$\begin{pmatrix} \sum_i \alpha_i^0 & \sum_i \alpha_i^1 & \sum_i \alpha_i^2 & \cdots & \sum_i \alpha_i^{n-1} \\ \sum_i \alpha_i^1 \alpha & \sum_i \alpha_i^2 & \sum_i \alpha_i^3 & \cdots & \sum_i \alpha_i^n \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sum_i \alpha_i^{n-1} & \sum_i \alpha^n & \sum_i \alpha_i^2 & \cdots & \sum_i \alpha_i^{2n-2} \end{pmatrix}$$

This matrix can be split into:

$$\begin{pmatrix} 1 & 1 & \cdots \\ \alpha_1 & \alpha_2 & \cdots \\ \alpha_1^2 & \alpha_2^2 & \cdots \\ \vdots & \vdots & \ddots \end{pmatrix} \begin{pmatrix} 1 & \alpha_1 & \alpha_1^2 & \cdots \\ 1 & \alpha_2 & \alpha_2^2 & \cdots \\ \vdots & \vdots & \ddots & \end{pmatrix}$$

which are the Vandermonde matrices we saw when dealing with the symmetric group. Then by simple computation we get:

$$\det(\mathrm{tr}_{B/A}(\alpha_i \alpha_j)) = \prod_{1 \leq i < j \leq n} (x_i - x_j)$$

For the final equality, notice that:

$$\mathrm{Nm}_{L/K}(m_{\alpha,k}(\alpha)) = \prod_{r=1}^{n} \sigma_r(m'_{\alpha,k}(\alpha)) = \prod_{r=1}^{n} m'_{\alpha,k}(\alpha_r) \stackrel{!}{=} \prod_{s \neq r} (\alpha_r - \alpha_s)$$

where $\stackrel{!}{=}$ comes from differentiating $m_{\alpha,k}(x)$ and plugging in α_r, completing the proof.

If $L = K[\alpha]$, then we shall often write $\text{disc}_{L/K}(\alpha)$ instead of $\text{disc}_{L/K}(\alpha, \alpha_2, .., \alpha_n)$. Note that this theorem shows that the discriminant cannot detect a basis on a non-separable extension:

Corollary 50.1.30: Discriminant And Separability

Let F/k be a finite extension. Then $\text{disc}_{F/k}$ is a nonzero function if and only if F is separable

If you recall that the resultant is zero if a two polynomials share a root, then this shows how the discriminant is also related to the resultant.

***Proof*:**
By proposition 50.1.29, we have the discriminant is the product of the differences of roots. If all the roots are distinct, the discriminant is nonzero, and similarly if the extension is inseparable so that there are repeated roots, the discriminant is zero.

Example 50.1.31: Discriminant On Cyclotomic extension
Let ζ_n be an pth primitive root of unity and consider $K = \mathbb{Q}[\zeta_p]$. Then recall from section 19.7.1 that it's minimal polynomial is:

$$f(x) = 1 + x + x^2 + \cdots + x^{p-1}$$

Then to compute $f'(\zeta_n)$, recall that

$$x^p - 1 = (x-1)f(x) \implies px^{p-1} = f(x) + (x-1)f'(x) \implies f'(\zeta_n) = \frac{p}{\zeta_p(\zeta_p - 1)}$$

Taking the norm, we get:

$$\text{Nm}_{K/\mathbb{Q}}(f'(\zeta_p)) = \frac{\text{Nm}_{K/\mathbb{Q}}(p)}{\text{Nm}_{K/\mathbb{Q}}(\zeta_p)\text{Nm}_{K/\mathbb{Q}}(\zeta_p) - 1} = \frac{p^{p-1}}{1 \cdot p}$$

where $\text{Nm}_{K/\mathbb{Q}}(\zeta_p - 1) = p$ is left as an exercise. Hence:

$$\text{disc}_{K/\mathbb{Q}}(\zeta_p) = \text{Nm}_{K/\mathbb{Q}}(f'(\zeta_p)) = p^{p-2}$$

The precise value of $\text{disc}(\zeta_n)$ shall be covered in lemma 50.4.65, however it is relatively easy to see that for arbitrary n, $\text{disc}(\zeta_n)\big|n^{\varphi(n)}$ where φ is the Euler totient. If f is the [monic] irreducible polynomial for ζ_n over $\mathbb{Q}$ for arbitrary $n \in \mathbb{N}$, we get that

$$x^n - 1 = f(x)g(x) \qquad g(x) \in \mathbb{Z}[x]$$

Differentiating and evaluating at ζ_n, we get $n = \zeta_n f'(\zeta_n)g(\zeta_n)$. Taking the norm, we get:

$$n^{\varphi(n)} = \pm\text{disc}(\zeta_n)\text{Nm}(\zeta_n g(\zeta_n))$$

which since $\text{Nm}(\zeta_n g(\zeta_n)) \in \mathbb{Z}$, we get that $\text{disc}(\zeta_n)\big|n^{\varphi(n)}$.

Exercise 50.1.1

1. Give a second proof of proposition 19.6.31, independent of the Vandermonde argument used there: show that if F/K is finite and separable, then $\mathrm{tr}_{F/K}(a)$ cannot be 0 for all $a \in F$ (Hint: use Dedekind's lemma, corollary 20.1.40). Deduce that the bilinear form $(x, y) \mapsto \mathrm{tr}_{F/K}(xy)$ is non-degenerate.

2. (series of question for Stickelberger's theorem, that $d_K \equiv 0, 1 \bmod 4$)

50.1.3 Abelian Group Structure

We now prove that $\mathcal{O}_K$ is a free $\mathbb{Z}$-module of finite rank. From the above discussion, we can start seeing how this is useful in finding elements of $\mathcal{O}_K$: given it is finitely generated and we know the rank, we can look for generating linearly independent sets, i.e. a basis, for $\mathcal{O}_K$ (since $\mathcal{O}_K$ is a module over a PID).

We in fact can prove something slightly stronger that shall be useful later in this chapter:

Proposition 50.1.32: Generation of Ring of Integers

Let R be a normal integral domain, ($\overline{R}^{K(R)} = R$), $K = K(R)$ the field of fraction of R, F/K a separable extension of degree n, and let $S = \overline{R}^F$ where F/K. Then there exists free R-submodules M' of F such that if $M = R^n$,

$$M \subseteq S \subseteq M'$$

Hence, S is a finitely generated R-module if R is Noetherian, and it is free of rank n if R is a Principal Ideal Domain.

Hence, the integral closure over a larger field that is a finite extension shall only extend the integral closure by a relatively controlled manner; the more condition on R the better the control.

We are usually considering $\mathcal{O}_F$ for some number field $F/\mathbb{Q}$, the generality is to work over the cases that are less nice (as shall be done in algebraic geometry[6], see [12]). To see this result more concretely, it is worth stating the following immediate corollary:

Corollary 50.1.33: $\mathcal{O}_K$ is a Free $\mathbb{Z}$-Module

Let $F/\mathbb{Q}$ be a number field of degree n. Then $\mathcal{O}_F$ is a free $\mathbb{Z}$-module of degree n.

***Proof*:**
Of proposition 50.1.32
Let $K = K(R)$ and let $B = \{\beta_1, \beta_2, ..., \beta_n\}$ be a basis for F over K. We shall use this basis to squish S between two finitely generated R-modules (note that S is an R-module since S/R is an integral extension)

To define the R-module M, as we saw in the proof of proposition 50.1.7, there exists a nonzero $d \in R$ such that $d\beta_i \in S$. Clearly $dB = \{d\beta_1, d\beta_2, ..., d\beta_n\}$ is still a K-basis for F. Now, consider

$$\langle d\beta_1, d\beta_2, ..., d\beta_n\rangle_R = M$$

[6] The integral points of curves shall often have more nuanced behaviour

Since S is naturally an R-module and $d\beta_i \in S$, we have that $M \subseteq S$. Without loss of generality, we may now assume that $\beta_i \in S$ for all $1 \leq i \leq n$, that is $B \subseteq S$ and is a K-basis for F.

For the second R-module, define: the *integral trace dual*

$$^*M = M^{\mathrm{tr}\vee} = \left\{ b \in F \mid \forall \ell \in M, \mathrm{tr}_{F/K}(b\ell) \in R \right\}$$

The extension F/K is separable by hypothesis, so the trace pairing is nondegenerate (proposition 19.6.31) and there is a dual K-basis $B' = \{\beta_1', ..., \beta_n'\}$ of F given by $\mathrm{tr}(\beta_i\beta_j') = \delta_{ij}$. Both modules are free of rank n over R, so in particular $M \cong_R M^{\mathrm{tr}\vee}$. This $M^{\mathrm{tr}\vee}$ is the module called M' in the statement.

The key result we shall prove is:

$$M = R\beta_1 + R\beta_2 + \cdots + R\beta_n \subseteq S \subseteq R\beta_1' + R\beta_2' + \cdots + R\beta_n' = M^{\mathrm{tr}\vee} \tag{50.3}$$

The first inclusion has already been proved, hence we show the second inclusion. Let $b \in S$ be arbitrary. Since $S \subseteq F$ and B' is a basis for F, we may write b as

$$b = \sum_i b_i \beta_i' \qquad b_i \in K$$

If we show that each $b_i \in R$, we are done. First, Since $\beta_i, b \in S$, their product is in S since S is a ring, $b\beta_i \in S$, hence $\mathrm{tr}_{F/K}(b\beta_i) \in R$ for each i since S is integral over R. Computing, we get:

$$\mathrm{tr}(b\beta_i) = \mathrm{tr}(\sum_j b_j\beta_j'\beta_i) = \sum_j b_j \mathrm{tr}(\beta_j'\beta_i) = \sum_j b_j\delta_{ij} = b_i$$

Hence, $b_i \in R$, showing equation (50.3). If R is Noetherian, then $M^{\mathrm{tr}\vee}$ is a Noetherian R-module, and hence S would be finitely generated. If furthermore R is a Principal Ideal Domain, then any submodule of a free module (over a PID) is free, and S is free of rank less than or equal to n. Since it contains a free R-module of rank n, it has to be free rank greater than or equal to n, and so it has rank n as an R-module, completing the proof.

Note that this implies that if $\mathcal{O}_K$ is a PID and L/K a separable extension where $K = K(\mathcal{O}_K)$, then *every* nonzero finitely generated $\mathcal{O}_L$-module is a free $\mathcal{O}_K$-module of rank $[L : K]$.

Corollary 50.1.34: Maximality of Ring Of Integers for Number Fields

The ring of integers of a number field L is the largest subring that is finitely generated as a $\mathbb{Z}$-module.

***Proof*:**
By the above proposition, $\mathcal{O}_L$ is finitely generated as a $\mathbb{Z}$-module If $B \subseteq L$ is a subring that is also a finitely generated $\mathbb{Z}$-submodule, then every element of B is integral over $\mathbb{Z}$ (proposition 26.1.4(3)). Hence, $B \subseteq \mathcal{O}_L$.

With 50.1.32, we now have an "upper bound" on how far away a ring of integers is form simply being $\mathbb{Z}[\alpha]$ where $K = \mathbb{Q}(\alpha)$.

Definition 50.1.35: Integral Trace Dual

Let R be a normal integral domain, $K = K(R)$, L/K a finite separable extension, $S = \overline{R}^L$. Then the *integral trace dual* of S is

$$^*S = \left\{ b \in L \;\middle|\; \forall \ell \in S, \mathrm{tr}_{L/K}(b\ell) \in R \right\}$$

Example 50.1.36: Finding Integral Trace Dual

Let $K = \mathbb{Q}(\sqrt{5})$ considered as an extension $K/\mathbb{Q}$ so that $R = \mathbb{Z}$. Then we know that $L = \langle 1, \sqrt{5} \rangle \subseteq \mathcal{O}_K$. Let's try to bound by above the elements of $\mathcal{O}_K$. Let $b = r + s\sqrt{5} \in \mathbb{Q}(\sqrt{5})$ be an arbitrary element. Then:

$$\mathrm{tr}(b \cdot 1) = 2r \qquad r(b\sqrt{5}) = 10s$$

Hence, if $2r \in \mathbb{Z}$ and $10s \in \mathbb{Z}$, we get:

$$^*\mathcal{O}_K = \left\langle \frac{1}{2}, \frac{\sqrt{5}}{10} \right\rangle_{\mathbb{Z}}$$

Note that $^*\mathcal{O}_K$ is bigger than $\mathcal{O}_K$, for example $1/2 \notin \mathcal{O}_K$. By similar reasoning, we can check that $\frac{1}{\sqrt{5}} \in {}^*\mathcal{O}_K$, but it can be verified that it is not in $\mathcal{O}_K$, and so $\mathcal{O}_K^\vee \neq \mathcal{O}_K$. This does not contradict corollary 50.1.34 as $^*\mathcal{O}_K$ is *not* a subring (note that $1/2 \cdot 1/2 \notin {}^*\mathcal{O}_K$). Note however that they are both still rank 2.

Note that separability is a necessary hypothesis to insure the non-degeneracy of the trace-pairing, meaning this result works at least over over number fields, function fields, and perfect fields[7]. Naturally, if R is not a Principal Ideal Domain, then S need not be a free R-module. For now, we shall always let $R = \mathbb{Z}$ so that $K = \mathbb{Q}$ and $F/\mathbb{Q}$ is a number field. Note that we are only working with the addition structure of $\mathcal{O}_K$, while $\mathcal{O}_K$ is a ring. Thus, when talking about generators as a $\mathbb{Z}$-module, it must not be confounded with a set of generators for the ring. For example $(\alpha) \subseteq \mathcal{O}_K$ is a principal ideal and hence generated by a single element, but it may be generated by many elements as a $\mathbb{Z}$-module.

Definition 50.1.37: Integral Basis

Let $K/\mathbb{Q}$ be a number field. Then a $\mathbb{Z}$-basis for $\mathcal{O}_K$ is called an *integral basis* for K.

The previous proposition also gives more motivation for squaring the determinant in the definition of the discriminant. By corollary 50.1.27, if $(\alpha_1, \alpha_2, ..., \alpha_n)$ is a $\mathbb{Z}$-basis for $\mathcal{O}_F$, then $\mathrm{disc}_{F/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n) \in \mathbb{Z}$ and any change of basis A must map to a unit, hence $\det(A) \in \mathbb{Z}^\times = \{-1, 1\}$. Squaring thus guarantees that the discriminant is basis independent for rings of integers. Now that we have explicitly found that $\mathcal{O}_K$ is a finitely generated $\mathbb{Z}$-module in the case of K being a number field, the term *field discriminant*, or just *discriminant* for short, shall imply that the input is an integral basis for $\mathcal{O}_K$, unless explicitly stated otherwise:

[7] fields of positive characteristic may require some extra work

Definition 50.1.38: Discriminant For Ring of Integers

Let $K/\mathbb{Q}$ be a number field. Then if $A = \{\alpha_1, \alpha_2, ..., \alpha_n\}$ is an integral basis for $\mathcal{O}_K$, then:

$$d_K := \text{disc}(\mathcal{O}_K) := \text{disc}_{K/\mathbb{Q}}(A) = \text{disc}(\mathcal{O}_K)$$

is the *field discriminant* of K. It is sometimes also denoted $\text{disc}(K)$ if clear from context.

The discriminant can be thought of as capturing some information on how far $\mathcal{O}_K$ is from being Thus, in example 50.1.25 where $K = \mathbb{Q}(\sqrt{m})$, we have:

$$d_K = \begin{cases} 4m & m \equiv 2, 3 \text{ mod } 4 \\ m & m \equiv 1 \text{ mod } 4 \end{cases}$$

As we saw, we may have many bases for K, not all of them necessarily basis for $\mathcal{O}_K$. Given $K/\mathbb{Q}$ of dimension n, we may have many $M \subseteq B$ of rank n. Since M is of rank n, then if $\mathcal{O}_K \subseteq M$, $\mathcal{O}_K/M$ is of rank 0, and if $M \subseteq \mathcal{O}_K$, then $M/\mathcal{O}_K$ is also of rank 0 (some elementary group theory can be used to prove this, see exercise ref:HERE (fund thm of fin gen ab grp)). This naturally leads to asking how the discriminants of such $\mathbb{Z}$-modules compare:

Proposition 50.1.39: Discriminant And Comparing Basis

Let $B/\mathbb{Z}$ be a free $\mathbb{Z}$-module of rank n, and let $A \subseteq B$ be a $\mathbb{Z}$-submodule of finite index (i.e. $[B : A] < \infty$). Then if $\text{disc}_{B/\mathbb{Z}}(\gamma_1, \gamma_2, ..., \gamma_n) \neq 0$, then:

$$\text{disc}(A) = [B : A]^2 \text{disc}(B)$$

***Proof*:**
Let $\beta_1, \beta_2, ..., \beta_n$ is a basis for B. By the previous corollary, if $N \subseteq B$ is of finite index, then it must be a free module of rank n and so the discriminant is nonzero, and similarly the other way around.

Then there exists a change of basis matrix A, and we get $\text{disc}(N) = \det(A)^2 \text{disc}(B)$. It is not hard to see that $\det(A) = [B : N]$ (it will be easier to visualize after finishing section 50.1.4), which complete the proof.

Corollary 50.1.40: Subset And Same Discriminant, Then Equal

Let $F/\mathbb{Q}$ be number field, Let $A, B \subseteq F$ be free $\mathbb{Z}$-modules, $B \subseteq A$ and $\text{disc}(A) = \text{disc}(B)$. Then $B = A$. Hence, we may use discriminants to identify free $\mathbb{Z}$-modules of finite rank.

***Proof*:**
Since the discriminants match and

$$\text{disc}(B) = [B : A]^2 \text{disc}(N)$$

we have $[B : A] = 1$, meaning $B = N$.

Corollary 50.1.41: Isomorphism Check Of Number Fields

Let $\mathbb{Q}(\alpha), \mathbb{Q}(\beta)$ be two number fields. Then if the discriminant is different, the number fields are not isomorphic

***Proof*:**
If the rings of integers were the same, their index would be 1, but since their discriminant is not equal this is not the case.

Note that it is possible that there are multiple fields with the same discriminant:

Example 50.1.42: Same Discriminant, Different Fields
Take $\mathbb{Q}(\alpha), \mathbb{Q}(\beta), \mathbb{Q}(\gamma)$ where

$$a^3 - 18\alpha - 6 = 0 \qquad \beta^3 - 36\beta - 78 = 0 \qquad \gamma^3 - 58\gamma - 150 = 0$$

Then each has discriminant 22356, but these fields are not isomorphic (as shall be shown in example 50.4.20)

It should be noted that there are only finitely many fields for each discriminant value, however we shall not prove this fact[8]

The next couple of theorems give some computational tools on finding the ring of integers:

Proposition 50.1.43: Computation Of Dual For Ring Of Integers

Let K be a number field with basis $(\alpha_1, \alpha_2, ..., \alpha_n)$ of algebraic integers and let $d = \mathrm{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n)$. Then every $\alpha \in \mathcal{O}_k$ can be expressed as:

$$\frac{m_1\alpha_1}{d} + \cdots + \frac{m_k\alpha_k}{d}$$

where $m_i \in \mathbb{Z}$ and each m_i^2 is divisible by d ($d \big| m_i^2$)

***Proof*:**
First, $d \neq 0$ since $\alpha_1, \alpha_2, ..., \alpha_n$ forms a basis for K and $d \in \mathbb{Z}$ since the α_i are algebraic integers (which exists by corollary 50.1.8).

Let $\alpha = x_1\alpha_1 + \cdots + x_n\alpha_n$ for some $x_i \in \mathbb{Q}$. Letting $\sigma_1, \sigma_2, ..., \sigma_n$ denote the embeddings of K into $\mathbb{C}$, we get

$$\sigma_i(\alpha) = x_1\sigma(\alpha_1) + \cdots + x_n\sigma(\alpha_n)$$

for each $1 \leq i \leq n$. We can solve for the x_j's using Cramers rule, namely

$$x_j = y_j/\delta$$

where $\delta = \det(\sigma_i(\alpha_j))$ and y_j is obtained by replacing the jth column of the previous determinant by $\sigma_i(\alpha)$. Clearly y_j and δ are algebraic integers, and furthermore $\delta^2 = \mathrm{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n)$.

[8] For those interested, it is the *Hermite-Minkowski's Theorem*

Hence, letting $d = \mathrm{disc}_{K/\mathbb{Q}}(\alpha_1, \alpha_2, ..., \alpha_n)$ we have

$$dx_j = \delta y_j$$

showing that the rational number dx_j is an algebraic integer, and so $dx_j \in \mathbb{Z}$. Let $m_i = dx_j$. What's left to show is that $m_j^2/d \in \mathbb{Z}$, so it suffices to show that it is an algebraic integer. But $m_j^2/d = y_j^2$, which completes the proof.

Hence, for any $\mathcal{O}_K$, if $\alpha_1, \alpha_2, ..., \alpha_n$ is a basis for $K/\mathbb{Q}$

$$\bigoplus \alpha_i \mathbb{Z} \subseteq \mathcal{O}_K \subseteq \bigoplus \frac{\alpha_i}{d}\mathbb{Z}$$

And if $K = \mathbb{Q}(\alpha)$ so that $1, \alpha, ..., \alpha^{n-1}$ is a basis for K, then by proposition 50.1.29 $d = \left(\prod_{i \neq j}(\alpha_i - \alpha_j)\right)^2$ and:

$$\mathbb{Z}[\alpha] \subseteq \mathcal{O}_K \subseteq \mathbb{Z}\left[\frac{\alpha}{d}\right]$$

Note that in general, $\mathbb{Z}[\alpha] \neq \mathcal{O}_K$; a counter-example shall be given in example 50.4.29. In the special case where $\mathbb{Z}[\alpha] = \mathcal{O}_K$, we give such a number ring a name:

Definition 50.1.44: Monogenic Number Ring

Let $K/\mathbb{Q}$ be a number field, $\mathcal{O}_K$ be the associated number ring, and α the primitive element so that $K = \mathbb{Q}(\alpha)$. Then if

$$\mathbb{Z}[\alpha] = \mathcal{O}_K$$

Then $\mathcal{O}_K$ is called *monogenic* and is said to be a *monogenic number ring*.

Since all number fields are monogenic, that is $K = \mathbb{Q}(\alpha)$ for some appropriate α, it is reasonable to ask if $\mathcal{O}_K$ can be expressed using α. The following theorem gives this structure:

Theorem 50.1.45: Basis For Ring Of Integers

Let $\alpha \in \mathcal{O}_k$ and suppose α has degree n over $\mathbb{Q}$. Then there exists $d_1, d_2, ..., d_{n-1} \in \mathbb{Z}$, and monic polynomial $f_i \in \mathbb{Z}[x]$ of degree i for $1 \leq i \leq n-1$ such that

$$\mathcal{O}_K = \mathbb{Z} \oplus \frac{f_1(\alpha)}{d_1}\mathbb{Z} \oplus \cdots \oplus \frac{f_{n-1}(\alpha)}{d_{n-1}}\mathbb{Z}$$

is an integral basis where

$$d_1 \big| d_2 \big| \cdots \big| d_{n-1}$$

and the d_i's are unique.

***Proof*:**
Marcus p.26

Example 50.1.46: Ring Of Integers Of Cubic Extension

Let $K = \mathbb{Q}(\sqrt[3]{2})$ and $\alpha = \sqrt[3]{2}$. We want to find $\mathcal{O}_K$. First rank $\mathcal{O}_K = 3$ since $[K : \mathbb{Q}] = 3$, and $L = \mathbb{Z}[\sqrt[3]{2}] \subseteq \mathcal{O}_K$. If A is the change of basis from L to $\mathcal{O}_K$, then $\det(A) = [\mathcal{O}_K : \mathbb{Z}[\alpha]]$[a]. Thus, by doing a change of basis from $\mathbb{Z}[\alpha]$ to $\mathcal{O}_K$ by A, we get that:

$$\operatorname{disc}(\mathbb{Z}[\alpha]) = [\mathcal{O}_K : \mathbb{Z}[\alpha]]^2 \operatorname{disc}(\mathcal{O}_K)$$

Thus, computing the discriminant of the left hand side we get:

$$\operatorname{disc}(\mathbb{Z}[\alpha]) = \det \begin{pmatrix} 3 & 0 & 0 \\ 0 & 0 & 6 \\ 0 & 6 & 0 \end{pmatrix} = -3 \cdot 36 = -(2^2 \cdot 3^2) \cdot 3 = -108$$

giving us that $[\mathcal{O}_K : \mathbb{Z}[\alpha]]^2 \big| 108 \Rightarrow [\mathcal{O}_K : \mathbb{Z}[\alpha]] \big| 2 \cdot 3 = 6$. If we show the index is 1, the proof is done. We shall prove the contradiction for the case of $[\mathcal{O}_K : \mathbb{Z}[\alpha]] = 3$, the proof for $[\mathcal{O}_K : \mathbb{Z}[\alpha]] = 2$ is similar, and from that we can also conclude that $[\mathcal{O}_K : \mathbb{Z}[\alpha]] \nmid 6$.

Let's say $[\mathcal{O}_K : \mathbb{Z}[\alpha]] = 3$. Then $\mathcal{O}_K/\mathbb{Z}[\alpha] \cong \mathbb{Z}/3\mathbb{Z}$. Any element $\beta \in \mathcal{O}_K$ lands in one of the cosets of $\mathcal{O}_K/\mathbb{Z}[\alpha]$ which implies that $a, b, c \in \frac{1}{3}\mathbb{Z}$. We want to show that a, b, c must be integers (lands in the zero coset). Since the ring of integers is closed under subtraction, we may without loss of generality subtract the non-fractional part of any element β we choose so that $a, b, c \in \{-1, 0, 1\}$[b]. Hence we take the norm of $\beta = (a/3) + (b/3)\alpha + (c/3)\alpha^2$

$$N(\beta) = \det \begin{pmatrix} a/3 & 2c/3 & 2b/3 \\ b/3 & a/3 & 2c/3 \\ c/3 & b/3 & a/3 \end{pmatrix} = \frac{1}{27}(a^3 + 2b^2 + 4c^3 - 6abc)$$

Since β is algebraic, $N(\beta) \in \mathbb{Z}$ meaning $27 \big| (a^3 + 2b^2 + 4c^3 - 6abc)$. But, unless $a = b = c = 0$:

$$|a^3 + 2b^2 + 4c^3 - 6abc| \leq 15$$

showing that no such combination of a, b, c exist, meaning β is an algebraic integer if $a, b, c \in \mathbb{Z}$. A similar argument can be made in the case of $[\mathcal{O}_K : \mathbb{Z}[\alpha]] = 2$, hence we have that $\mathcal{O}_K = \mathbb{Z}[\alpha]$, completing the proof.

[a] since the index is finite, a basis for $\mathbb{Z}[\alpha]$ may be scaled to form a basis for $\mathcal{O}_K$, which translates to the determinant result

[b] Equivalently, any coset can be chosen to have such representatives

In some special cases, the ring of integers of more composite fields may be found given ring of integers of each respective field:

Theorem 50.1.47: Ring of Integers of Composites

Let $K_1/K, K_2/K$ be Galois with degree n and m and with coprime discriminants $d_{K_1} = d$ and $d_{K_2} = d'$ respectively. Let $L = K_1K_2$ and $K_1 \cap K_2 = K$. Let $\omega_1, \omega_2, ..., \omega_n$ and $\omega'_1, \omega'_2, ..., \omega'_m$ be an integral basis for K_1/K and K_2/K. Then $\omega_i\omega'_j$ is an integral basis for K_1K_2 with discriminant $(d_{K_1})^m(d_{K_2})^n = d^m(d')^n$, namely

$$\mathcal{O}_L = \mathcal{O}_{K_1}\mathcal{O}_{K_2}$$

***Proof*:**
Since $K_1 \cap K_2 = K$, $[K_1K_2 : K] = nm$, so the nm products $\omega_i\omega'_j$ form a basis of K_1K_2/K. Now, let α be an integral element of K_1K_2 over K, and write:

$$\alpha = \sum_{i,j} a_{ij}\omega_i\omega'_j \qquad a_{ij} \in K$$

We must show that $a_{ij} \in \mathcal{O}_K$. Let

$$\beta_j = \sum_i a_{ij}\omega_i$$
$$\mathrm{Gal}_{K_2}(L) = \{\sigma_1, \sigma_2, ..., \sigma_n\}$$
$$\mathrm{Gal}_{K_1}(L) = \{\tau_1, \tau_2, ..., \tau_m\}$$

Then since $[L : K] = nm$, by proposition 20.1.32$\mathrm{Gal}_K(L) = \{\sigma_k\tau_\ell \mid 1 \leq k \leq n\ 1 \leq \ell \leq m\}$. Furthermore, let:

$$T = \tau_\ell(\omega'_j) \qquad a = (\tau_1(\alpha), ..., \tau_m(\alpha))^t \qquad b = (\beta_1, ..., \beta_m)^t$$

Then by definition we have $\det(T)^2 = d'$ and $a = Tb$. If T^* is the adjoint of T, then some linear algebra manipulation gives:

$$\det(T)b = T^*a$$

Now, since T^* and a have integral entries (in L), $d'b$ has integral entries in K_1< i.e.

$$d'\beta_j = \sum_k d/a_{ij}\omega_i$$

Hence, $d'a_{ij} \in \mathcal{O}_K$. Now, changing (ω_i) and $\omega'_j)$, we get that $da_{ij} \in A$, hence since the discriminants are relatively prime, we get for appropriate x, x':

$$a_{ij}xda_{ij} + x'd'a_{ij} \in \mathcal{O}_K$$

Hence, $\omega_i\omega'_j$ form an integral basis for L/K, completing the first part of the proof.

We next find the discriminant the ring of integers of L/K. Since we have the Galois group of L over K, take the $(nm \times m)$ matrix

$$M = (\sigma_k\tau_\ell(\omega_i\omega'_j)) = (\sigma_k(\omega_i)\tau_\ell(\omega'_j))$$

Note that M can be interpreted as an $(m \times m)$-matrix with entries being $(n \times n)$-matrices where each (ℓ, j)-entry is the matrix $Q\tau_\ell\omega'_j$ where $Q = (\sigma_k\omega_i)$:

$$M = \begin{pmatrix} Q & & 0 \\ & \ddots & \\ 0 & & Q \end{pmatrix} \begin{pmatrix} E\tau_1\omega'_1 & \cdots & E\tau_m(\omega'_1) \\ \vdots & \ddots & \vdots \\ E\tau_1(\omega'_m) & \cdots & E\tau_m(\omega'_m) \end{pmatrix}$$

where E is an $(n \times n)$-unit matrix. Now, changing indices to compare the two representations of M, we get:

$$\mathrm{disc}(\mathcal{O}_L) = \det(M)^2 = \det(Q)^{2m} = \det\left((\tau_\ell(\omega'_j))\right)^{2n} = d^m(d')^n$$

as we sought to show.

Note that for the general separable case, we need to replace our assumption with

$$K_1 \cap K_1 = K \qquad K_1,\ K_2 \text{ are linearly disjoint}$$

If the discriminants are not relatively prime, then there is a partial generalization in the case where $K = \mathbb{Q}$:

Corollary 50.1.48: Ring of Integers of Composite, Partial Generalization

Let $K_1/\mathbb{Q}$ and $K_2/\mathbb{Q}$ be finite separable extensions, $d_1 = \text{disc}(\mathcal{O}_{K_1})$ and $d_2 = \text{disc}(\mathcal{O}_{K_2})$. Then if $L = K_1K_2$:

$$\mathcal{O}_L \subseteq \frac{1}{\gcd(d_1, d_2)}\mathcal{O}_{K_1}\mathcal{O}_{K_2}$$

***Proof*:**
Marcus p.25

Example: Ring of Integers of Cyclotomic Field

Let's use the above results to show that if $K = \mathbb{Q}(\zeta_n)$ then $\mathcal{O}_K = \mathbb{Z}[\zeta_n]$, that is the ring of integers of K is monogenic. Besides quadratic extensions, this is so far the only other ring of integers we have classified (in particular since they are rather difficult to classify). We first require some lemmas:

Lemma 50.1.49: Cyclotomic Field Lemmas

Let $n = p^r$ where $n \geq 3$. Then:

1. $\mathbb{Z}[\zeta_n] = \mathbb{Z}[1 - \zeta_n]$ and $\text{disc}(\zeta_n) = \text{disc}(1 - \zeta_n)$
2. $\prod_k (1 - \zeta_n^k) = p$

***Proof*:**

1. Certainly $\mathbb{Z}[\zeta_n] = \mathbb{Z}[1 - \zeta_n]$ since $\zeta_n = 1 - (1 - \zeta_n)$, implying the discriminants are equal. Similarly, by proposition 50.1.29

$$\text{disc}(\zeta_n) = \prod_{r<s}(\alpha_r - \alpha_s)^2 = \prod_{r<s}((1 - \alpha_r) - (1 - \alpha_s))^2 = \text{disc}(1 - \zeta_n)$$

2. Let

$$f(x) = \frac{x^{p^r - 1}}{x^{p^{r-1}} - 1} = 1 + x^{p^{r-1}} + x^{2p^{r-1}} + \cdots x^{(p-1)p^{r-1}}$$

Then for $p \nmid k$, ζ_n^k are the roofs of f, since they are roots of $x^{p^r} - 1$, but not of $x^{p^{r-1}} - 1$. Thus:

$$f(x) = \prod_{p \nmid k}(x - \zeta_n^k)$$

Since there is exactly $\varphi(p^r) = (p-1)p^{r-1}$ where φ is the Euler totient. Thus, setting $x = 1$ gives us the desired result.

Proposition 50.1.50: Ring Of Integers Of Prime-Power Cyclotomic Field

Let $n = p^r$ and $K = \mathbb{Q}(\zeta_n)$. Then:

$$\mathcal{O}_K = \mathbb{Z}[\zeta_n]$$

***Proof*:**
We shall show that $\mathcal{O}_K = \mathbb{Z}[1-\zeta_n]$. By theorem 50.1.45, any $\alpha \in \mathcal{O}_K$ can be written as:

$$\alpha = \frac{n_1 + n_2(1-\zeta_n) + \cdots + n_m(1-\zeta_n)^{m-1}}{\mathrm{disc}(1-\zeta_n)}$$

where $m = \varphi(p^r)$, $n_i \in \mathbb{Z}$, and $\mathrm{disc}(1-\zeta_n) = \mathrm{disc}(\zeta_n)$. As we saw in example 50.1.31, if $n = p$ is a prime, $\mathrm{disc}(\zeta_n) = p^{p-2}$. Since $n = p^r$, by example 50.1.31, d is a power of p.

Let's now assume for the sake of contradiction that $\mathcal{O}_K \neq \mathbb{Z}[1-\zeta_n]$, so that there must exist some $\alpha \in \mathcal{O}_K$ such that not all n_i are divisible by d, namely $\mathcal{O}_K$ contains an element of the form:

$$\beta = \frac{n_i(1-\zeta_n)^{i-1} + n_{i+1}(1-\zeta_n)^i + \cdots + n_m(1-\zeta_n)^{m-1}}{p}$$

where $i \leq n$, $n_i \in \mathbb{Z}$, not all n_i are divisible by p. Now, by lemma 50.1.49 since $(1-\zeta_n)\big|(1-\zeta_n)^k$ in $\mathbb{Z}[\zeta_n]$,

$$\frac{p}{(1-\zeta_n)^m} \in \mathbb{Z}[\zeta_n] \implies \frac{p}{(1-\zeta_n)^i} \in \mathbb{Z}[\zeta_n] \implies \frac{\beta p}{(1-\zeta_n)^i} \in \mathcal{O}_K$$

Subtracting the terms that are in $\mathcal{O}_K$ (by closure of multiplication) we get

$$\frac{n_i}{1-\zeta_n} \in \mathcal{O}_K \implies \mathrm{Nm}_{K/\mathbb{Q}}\left(\frac{n_i}{1-\zeta_n}\right) \in \mathbb{Z} \implies \mathrm{Nm}_{K/\mathbb{Q}}(1-\zeta_n)\big|\mathrm{Nm}_{K/\mathbb{Q}}(n_i)$$

However, this is a contradiction since $\mathrm{Nm}_{K/\mathbb{Q}}(n_i) = n_i^m$, but by lemma 50.1.49 $\mathrm{Nm}_{K/\mathbb{Q}}(1-\zeta_n) = p$, Hence

$$\mathcal{O}_K = \mathbb{Z}[\zeta_n]$$

as we sought to show.

We now look to generalize to any cyclotomic field. The key idea is that the ring of integers of cyclotomic fields will be the composite of simpler ring of integers

Proposition 50.1.51: Ring of Integers of Cyclotomic Field

Let $K = \mathbb{Q}(\zeta_n)$ for any $n \in \mathbb{N}$. Then:

$$\mathcal{O}_K \cong \mathbb{Z}[\zeta_n]$$

***Proof*:**
We shall do a form of induction. This was proven if n is a prime power, so let's assume it's not so that we may write $n = n_1 n_2$ for relatively prime $n_1, n_2 > 1$. We shall work by induction on

n_1, n_2. The base case was proposition 50.1.50, hence set:

$$\begin{aligned} \omega_1 &= \zeta_{n_1} & \omega_2 &= \zeta_{n_2} \\ K_1 &= \mathbb{Q}(\omega_1) & K_2 &= \mathbb{Q}(\omega_2) \\ \mathcal{O}_{K_1} &= \mathbb{Z}[\omega_1] & \mathcal{O}_{K_2} &= \mathbb{Z}[\omega_2] \end{aligned}$$

First, it is clear that

$$\zeta_n^{n_1} = \omega_2 \qquad \zeta_n^{n_2} = \omega_1 \implies \zeta_n = \omega_1^r \omega_2^s,\ r, s \in \mathbb{Z}$$

Thus, $L = K_1 K_2$. Next, as we saw in example 50.1.31,

$$\operatorname{disc}(\omega_1)\big|n_1 \qquad \operatorname{disc}(\omega_2)\big|n_2$$

since $\gcd(n_1, n_2) = 1$, we see the discriminants are relatively prime. Since $\varphi(n) = \varphi(n_1)\varphi(n_2)$, we by theorem 50.1.47 that

$$\mathcal{O}_K = \mathcal{O}_{K_1}\mathcal{O}_{K_2} = \mathbb{Z}[\omega_1]\mathbb{Z}[\omega_2] = \mathbb{Z}[\zeta_n]$$

as we sought to show.

Exercise 50.1.2

1. Generalize proposition 50.1.39 for modules over $\mathcal{O}_K$.
2. Give a counter-example where $\mathcal{O}_{KL} = \mathcal{O}_K\mathcal{O}_L$?

50.1.4 Lattice Structure: Geometry of Number Rings

An important word of warning must be given about free $\mathbb{Z}$-modules due to the existence of non-invertible elements. It is possible that A, B are two free $\mathbb{Z}$-module of rank 2, one contains the basis of the other, however $A \subsetneq B$! This is in contract to the case of modules over fields where if A, B are two k-vector-spaces of the same dimension and $A \subseteq B$, then $A = B$[9]. Even more behavior can happen: consider $\mathbb{Q} \otimes_{\mathbb{Z}} A$. Then this is a vector-space with a finite dimension. However, the dimension need not match the rank of A:

Example 50.1.52: Behavior of $\mathbb{Z}$-modules

1. Let $A = \langle (1,0), (0,1) \rangle_{\mathbb{Z}}$ and $B = \langle (1/2, 0), (0, 1/2) \rangle_{\mathbb{Z}}$. Then by construction they are both isomorphic as abelian groups to $\mathbb{Z}^2$, however $A \subsetneq B$.
2. Let A be a free $\mathbb{Z}$-module of rank 2. Then we may extend scalar to make A into a free $\mathbb{R}$-module; either take $\mathbb{R} \otimes_{\mathbb{Z}} A$ or consider $\langle a_1, a_1 \rangle_{\mathbb{R}}$ for some free generating set $\{a_1, a_2\}$. Then $\mathbb{R} \otimes_{\mathbb{Z}} A$ *need not be dimension 2*. For example, take
$$A = \langle (1,1), (\sqrt{2}, \sqrt{2}) \rangle_{\mathbb{Z}}$$
Then $\mathbb{R} \otimes_{\mathbb{Z}} A$ is one dimensional

[9] $b \in B$ can be appropriately shrunk to a nonzero size so that its in A (since the dimensions are the same), and then we use closure of scalar multiplication

3. By construction of $\mathcal{O}_k$, if $\langle \alpha_1, \alpha_2, ..., \alpha_n \rangle_{\mathbb{Z}} = \mathcal{O}_k$, then $\langle \alpha_1, \alpha_2, ..., \alpha_n \rangle_{\mathbb{Q}} = k$, Thus $\mathcal{O}_k$ is a little more than just a $\mathbb{Z}$-module. We shall explore this in this section.

The third example shows that the rank of the ring of integers more coincides with the dimension of the natural vector-space when extending the actions to a field. As was explored in chapter 13, [finite dimensional] vector spaces have easy visualizations using orthonormal bases. In chapter 10, this was used implicitly when it was intuited that $\mathbb{Z}[i]$ forms a nice square lattice in $\mathbb{Q}^2$. More generally, ring of integer $\mathcal{O}_K$ will form a lattice when embedded into an appropriate vector-space. To better visualize this lattice, it is easer to see it embedded into a direct sum of $\mathbb{R}$ and $\mathbb{C}$[10]. This has the extra advantage that these spaces have a well-defined notion of *measure* that gives us an area. We shall take advantage of tools from analysis to further enlighten the structure of rings of integers, however as a consequence an elementary level of topology and analysis will be assumed.

Let $n = [K : \mathbb{Q}]$ so that $\mathrm{Hom}_{\mathbb{Q}}(K, \mathbb{C}) = n$. Then every embedding of K into $\mathbb{C}$ is either embeds into $\mathbb{R}$ or does not (that is, either $K \cap (\mathbb{C} \setminus \mathbb{R}) = \emptyset$ or $\neq 0$); let's call the former *real embeddings* and the latter *complex embeddings*. For a complex embedding $\tau \in \mathrm{Hom}_{\mathbb{Q}}(K, \mathbb{C})$, we may always find another embedding $\overline{\tau}$ since for any α where $p(\alpha) = 0$ for appropriate $p(x) \in \mathbb{Q}[x]$

$$0 = \overline{\tau}(0) = \overline{\tau}(p(\alpha)) = \tau(\overline{p(\alpha)}) = \tau(p(\overline{\alpha}))$$

showing that $\overline{\tau}$ maps roots to roots. Hence the degree n may be split into $n = r_1 + 2r_2$ where r_1 represents the amount of embeddings where the image σ_i is real:

$$\alpha_1, \alpha_2, ..., \alpha_{r_1}$$

while r_2 represents the embeddings that embedded into $\mathbb{C}$ is not strictly in $\mathbb{R}$, giving us a total list of embeddings:

$$\sigma_1, \sigma_2, ..., \sigma_{r_1}, \tau_1, \tau_2, ..., \tau_{r_2}, \overline{\tau_1}, ..., \overline{\tau_{r_2}}$$

Definition 50.1.53: Archimedean Embedding

Let $K/\mathbb{Q}$ be a number field. Then its *Archimedean embedding* is defined as

$$\begin{aligned} \sigma : &K \hookrightarrow \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2} \\ &\alpha \mapsto (\sigma_1(\alpha), ..., \tau_{r_2}(\alpha)) \end{aligned}$$

The space $\mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$ is called the *Minkowski space*, and will be labeled $K_{\mathbb{R}}$.

Example 50.1.54: Archimedean Embedding

1. Trivially, $\mathbb{Q}_{\mathbb{R}} = \mathbb{R}$, and $\mathbb{C}_{\mathbb{R}}$ is not defined since $\mathbb{C}/\mathbb{Q}$ is not a finite extension.

2. Take $K = \mathbb{Q}(i)$ so that $\mathcal{O}_K = \mathbb{Z}[i]$. Then $\mathrm{Gal}_{\mathbb{Q}}(\mathbb{Q}(i)) = \{\mathrm{id}, c\}$ where c is the conjugate. Then K is simply the embedding of K into $\mathbb{C}$

$$\sigma : K \hookrightarrow \mathbb{C}^1 \qquad k \mapsto k$$

[10] For those who may prefer $\overline{\mathbb{Q}}$ over $\mathbb{R}$ or $\mathbb{C}$, I would stipulate $\mathbb{R}$ and $\mathbb{C}$ are is a very natural object in this context: $\mathbb{R}$ is perhaps the only "natural" object for which a finite extension is an algebraic closure, this will have algebraic and geometric consequence when counting the number of embeddings of a field into the algebraically closed field $\mathbb{C}$

Notice the gaussian integers form the usual grid in $\mathbb{C}$.

3. Take $K = \mathbb{Q}(\sqrt{2}, \sqrt{3})$ Then $\mathrm{Gal}_{\mathbb{Q}}(K) \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ corresponds to the conjugating each root separately. Then

$$\begin{gathered}\sigma : K \mapsto \mathbb{R}^4 \\ (a + b\sqrt{2} + c\sqrt{3} + d\sqrt{6}) \\ \mapsto \\ (a + b\sqrt{2} + c\sqrt{3} + d\sqrt{6}, a - b\sqrt{2} + c\sqrt{3} + d\sqrt{6}, \\ a + b\sqrt{2} - c\sqrt{3} + d\sqrt{6}, a - b\sqrt{2} - c\sqrt{3} + d\sqrt{6})\end{gathered}$$

Our goal is to show that $\sigma(\mathcal{O}_K)$ behaves like the just like $\mathbb{Z}[i]$ when embedded in $\mathbb{C}$. To characterize a lattice in higher dimensions, we define it in the following way:

Definition 50.1.55: [Integral] Lattice

Let V be a finite dimensional vector space over$\mathbb{R}$. Then a *lattice* in V is a $\mathbb{Z}$-submodule satisfying any two of the following 3 properties;

1. Λ spans V as a k-vector space ($\langle\Lambda\rangle_{\mathbb{R}} = V$)
2. Λ is discrete in the topological space V (there is an open ball near the origin that intersects only the origin) and the rank of the lattice is the dimension of V[a]
3. Λ is a free $\mathbb{R}$-module on n generators

[a] some authors call lattices where $n = m$ *complete lattices*, and if $n < m$ a *lattices*

Lemma 50.1.56: Equivalence Of Conditions

Any two of these conditions implies the third

***Proof*:**
Let $L \cong_{\mathbf{Ab}} \mathbb{Z}^n$. We'll show that (2) $\Leftrightarrow$ (3). For (2) $\Rightarrow$ (1), namely

(2) L is discrete

(3) $\langle L\rangle_{\mathbb{R}} = \mathbb{R}^n$

let $\ell_1, \ell_2, ..., \ell_n$ be a $\mathbb{Z}$-basis for L. Then there exists an invertible matrix $A \in \mathrm{GL}_n(\mathbb{R})$ such that $A = (a_{ij})$ where for each e_i of the standard basis for $\mathbb{R}^n$,

$$e_i = \sum_j a_{ij}\ell_j$$

Let $v = (v_1, v_2, ..., v_n) \in \mathbb{Z}^n$. Then

$$\sum_i^n v_i\ell_i = \sum_i^n w_ie_i$$

where $w = A^{-1}v$. We have now converted our number into one in the standard basis, hence we have a notion of size we may borrow. In particular, we have that if $v = Aw$, then

$$\|w\| \geq \frac{\|v\|}{n\|A\|}$$

where we can choose our favourite matrix norm, say the max norm on entries. hence, as v grows, w get's further from 0.

Conversely, we'll do the contrapositive, so suppose $\langle \ell_1, \ell_2, ..., \ell_n \rangle_{\mathbb{R}} \neq \mathbb{R}^n$. Then for some $a_i \in \mathbb{R}$ not all zero

$$\sum_i^n a_i \ell_i = 0$$

By the Pigeon hole Principle[a] (also known as Dirichlet's box principle), there exists $N \in \mathbb{N}, N > 0$ such that $|Na_i - [Na_i]| < \epsilon$ where $[Na_i]$ is the closest integer. Thus

$$0 = \sum Na_i \ell_i = \underbrace{\sum [Na_i]\ell_i}_{\in L} + \underbrace{\sum \{Na_i\}\ell_i}_{\in B_\epsilon(0)}$$

where $\{Na_i\}$ denote the fractional part, completing the proof.

[a] see section 0.1.3

The discrete condition need only be checked at the origin due to linearity[11]. An example of a free $\mathbb{Z}$-module in $\mathbb{R}^2$ that is not discrete is the one elaborated in example 50.1.52

$$\langle (1,1), (\sqrt{2}, \sqrt{2}) \rangle \subseteq \mathbb{R}^2$$

In particular, we may get as close as we want to $(0,0)$ by adding integer-multiples these two elements.

Proposition 50.1.57: Archimedean Embedding of $\mathcal{O}_K$ is Lattice

Let $K/\mathbb{Q}$ be a number field and σ the Archimedean embedding. Then $\sigma(\mathcal{O}_k)$ is a lattice in $\mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$, namely

$$\langle \sigma(\mathcal{O}_K) \rangle_{\mathbb{R}} = \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$$

***Proof*:**
We may prove this result in using any of the equivalent definitions.

1. Let's show $\sigma(\mathcal{O}_K)$ is discrete. Let $\alpha \in K$ so that

$$\mathrm{Nm}_{K/\mathbb{Q}}(\alpha) = \prod_i^{r_1} \sigma_i(\alpha) \cdot \prod_j^{r_2} \|\tau_j(\alpha)\|^2 \in \mathbb{Q}$$

Then if $\alpha \in \mathcal{O}_K$, $\mathrm{Nm}_{K/\mathbb{Q}}(\alpha) \in \mathbb{Z}$. Therefore, if $\alpha \in \mathcal{O}_K \setminus \{0\}$, we have $|\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)| \geq 1$. But then $|\sigma(\alpha)| \geq 1$. Thus, taking $B \subseteq \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$,

$$B = \{\alpha \mid |\alpha_i| < 1,\ 1 \leq i \leq r_1 + r_2\}$$

[11] This is reminiscent to how many conditions for topological groups need only be checked at the origin, including many proofs in real and complex analysis

Then $\sigma(\mathcal{O}_K) \cap B = \{0\}$

2. Let's show that the $\mathbb{R}$-span of $\sigma(\mathcal{O}_K)$ is our entire space. Since $\mathcal{O}_K$ is $\mathbb{Z}$-finitely generated we have

$$\langle \alpha_1, \alpha_2, ..., \alpha_n \rangle_{\mathbb{Z}} = \mathcal{O}_K$$

We want to show that

$$\mathrm{span}_{\mathbb{R}}(\sigma_1(\alpha_i), ..., \sigma_{r_1}(\alpha_i), .., \tau_{r_2}(\alpha_i))_{i \in \{1,...,n\}} = \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$$

Then the determinant of these values would be nonzero:

$$0 \neq \det \begin{pmatrix} \sigma_1(\alpha_1) & \cdots & \sigma_{r_1}(\alpha_1) & \mathrm{Re}\tau_1(\alpha_1) & \mathrm{Im}(\tau_1(\alpha_1)) & \cdots & \mathrm{Im}\tau_{r_2}(\alpha_1) \\ \sigma_1(\alpha_2) & \cdots & \sigma_{r_1}(\alpha_2) & \mathrm{Re}\tau_2(\alpha_2) & \mathrm{Im}(\tau_2(\alpha_2)) & \cdots & \mathrm{Im}\tau_{r_2}(\alpha_2) \\ & & & \vdots & & & \\ & & & \vdots & & & \\ & & & \vdots & & & \end{pmatrix}$$

By doing some elementary operations, we get the matrix to be of the form:

$$0 \neq \det \begin{pmatrix} \sigma_1(\alpha_1) & \cdots & \sigma_{r_1}(\alpha_1) & \tau_1(\alpha_1) & \overline{\tau_1(\alpha_1)} & \cdots & \overline{\tau_{r_2}(\alpha_1)} \\ \sigma_1(\alpha_2) & \cdots & \sigma_{r_1}(\alpha_2) & \tau_2(\alpha_2) & \overline{\tau_2(\alpha_2)} & \cdots & \overline{\tau_{r_2}(\alpha_2)} \\ & & & \vdots & & & \\ & & & \vdots & & & \\ & & & \vdots & & & \end{pmatrix}$$

Now, choose a primitive element $\alpha \in K$ so that $K = Q(\alpha)$. Then we know that $\mathbb{Z}[\alpha] = \langle 1, \alpha, ..., \alpha^{n-1} \rangle_{\mathbb{Z}} \subseteq \mathcal{O}_K$. We know this is of finite index. Letting $\alpha_i = \alpha^{i-1}$, we get a Vandermonde matrix. If M is the above matrix:

$$\det(M) = \prod_{\substack{\sigma \neq \sigma' \\ \sigma, \sigma' \in \mathrm{Emb}_K(\mathbb{C})}} (\sigma(\alpha) - \sigma'(\alpha)) \neq 0$$

But then this implies that the volume of $\sigma(\mathcal{O}_K)$ is non-zero, as we sought to show.

Corollary 50.1.58: Sign Of Discriminant

Let $K/\mathbb{Q}$ be a number field, $\mathcal{O}_K$ its ring of integers, its discriminant. Then:

$$\mathrm{sign}(d_K) = (-1)^{r_2}$$

***Proof*:**
Simply keep track of the elementary operations when transitioning between both matrices in

proposition 50.1.57

$$\det\begin{pmatrix} \sigma_1(\alpha_1) & \cdots & \sigma_{r_1}(\alpha_1) & \tau_1(\alpha_1) & \overline{\tau_1(\alpha_1)} & \cdots & \overline{\tau_{r_2}(\alpha_1)} \\ \sigma_1(\alpha_2) & \cdots & \sigma_{r_1}(\alpha_2) & \tau_2(\alpha_2) & \overline{\tau_2(\alpha_2)} & \cdots & \overline{\tau_{r_2}(\alpha_2)} \\ & & & \vdots & & & \\ & & & \vdots & & & \\ & & & \vdots & & & \end{pmatrix}$$

$$= \frac{1}{(2i)^{r_2}}\det\begin{pmatrix} \sigma_1(\alpha_1) & \cdots & \sigma_{r_1}(\alpha_1) & \mathrm{Re}\tau_1(\alpha_1) & \mathrm{Im}(\tau_1(\alpha_1)) & \cdots & \mathrm{Im}\tau_{r_2}(\alpha_1) \\ \sigma_1(\alpha_2) & \cdots & \sigma_{r_1}(\alpha_2) & \mathrm{Re}\tau_2(\alpha_2) & \mathrm{Im}(\tau_2(\alpha_2)) & \cdots & \mathrm{Im}\tau_{r_2}(\alpha_2) \\ & & & \vdots & & & \\ & & & \vdots & & & \\ & & & \vdots & & & \end{pmatrix}$$

completing the proof.

Hence, any ring of integers $\mathcal{O}_K$ forms a lattice in $K_{\mathbb{R}}$, and any ideal $\mathfrak{a} \subseteq \mathcal{O}_K$ will also form a lattice in $K_{\mathbb{R}}$. Since $K_{\mathbb{R}}$ is an inner product and a lattice is discrete, it is meaningful to define the volume of a lattice:

Definition 50.1.59: Volume of Lattice

let $\mathcal{O}_K$ be a ring of integers. Then if $\Gamma = (v_1, v_2, ..., v_n)$ is an integral basis for $\mathcal{O}_K$, then the *volume* of $\mathcal{O}_K$ is defined to be

$$\mathrm{vol}(\mathcal{O}_K) := \mathrm{vol}(K_{\mathbb{R}}/\Gamma) = \mathrm{coVol}(\Gamma) = |\det(\langle v_i, v_j\rangle)|^{1/2} =$$

where $\frac{1}{2^{r_2}}$ comes from the extra complex embeddings, as seen in the proof of corollary 50.1.58.

If you know some differential geometry, we may equivalently take the canonical differential form on $\mathbb{R}^n \cong \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$:

$$\omega = dx_1 \wedge \cdots \wedge dx_n$$

and write:

$$\mathrm{vol}(\mathcal{O}_K) = \mathrm{coVol}(K_{\mathbb{R}}/\mathcal{O}_K) = \frac{1}{2^{r_2}}\left|\int_{K_{\mathbb{R}}/\mathcal{O}_K}\omega\right| = \frac{1}{2^{r_2}}\left|\int_P \omega\right|$$

where the $1/2^{r_2}$ comes from eliminating the extra complex dimension, and:

$$P = \left\{\sum a_i v_i \;\middle|\; 0 \leq a_i \leq 1\right\}$$

This also motivates the vocabulary of covolume. Note that any different choice of a basis will produce the same result since the change of basis matrix B will have determinant ± 1 which in the absolute value becomes 1, and hence it is well-defined. Note that every ideal $\alpha \subseteq \mathcal{O}_K$ will also produce a lattice, since it's a sublattice of $\mathcal{O}_K$, and hence we may find the volume of any sublattice. The way we shall find the volume of the lattice is by taking advantage of the discriminant and the index of the ideal:

Proposition 50.1.60: Volume of Ideal Lattice

Let $0 \neq \mathfrak{a} \subseteq \mathcal{O}_K$ be an ideal. Then $\Gamma_{\mathfrak{a}} = \sigma(\mathfrak{a})$ is a [complete] lattice in K_R and its fundamental mesh has volume

$$\operatorname{vol}(\Gamma_{\mathfrak{a}}) = \frac{1}{2^{r_2}}\sqrt{|\operatorname{disc}(K)}[\mathcal{O}_K : \mathfrak{a}]$$

As a consequence:

$$\operatorname{vol}(\mathcal{O}_K) = \frac{1}{2^{r_2}}\sqrt{|\operatorname{disc}(\mathcal{O}_K)}$$

Thus, the discriminant provides volume information for the lattice given by the ring of integers.

The theorem can equivalently be stated as:

$$\operatorname{vol}(\Gamma_{\mathfrak{a}}) = \left| \int_{\mathbb{R}^{r_1} \oplus \mathbb{R}^{r_2}/\Gamma_{\mathfrak{a}}} \omega \right|$$

***Proof*:**
Let $\alpha_1, \alpha_2, ..., \alpha_n$ be a $\mathbb{Z}$-basis of $\mathfrak{a}$ so that $\Gamma_{\mathfrak{a}} = \mathbb{Z}\sigma(\alpha_1) + \cdots + \mathbb{Z}\sigma(\alpha_n)$ is a lattice. Numbering the embeddings $\tau K \to \mathbb{C}$ as $\tau_1, \tau_2, ..., \tau_n$, define the matrix $A = (\tau_\ell \alpha_i)$ so that we get by proposition 50.1.39,

$$\operatorname{disc}(\mathfrak{a}) = \operatorname{disc}(\alpha_1, \alpha_2, ..., \alpha_n) = \det(A)^2 = [\mathcal{O}_K : \mathfrak{a}]^2 \operatorname{disc}(\mathcal{O}_K) = [\mathcal{O}_K : \mathfrak{a}]^2 d_K$$

On the other hand, we have:

$$\left(\langle \sigma(\alpha_i), \sigma(\alpha_j) \rangle\right)_{ij} = \left(\sum_{\ell=1}^{n} \tau_\ell(\alpha_i) \overline{\tau}_\ell \alpha_j \right) = A\overline{A}^t$$

Thus:

$$\operatorname{vol}(\Gamma_{\mathfrak{a}}) = \left| \det\left(\langle \sigma(\alpha_i), \sigma(\alpha_j) \rangle\right)_{ij} \right|^{1/2} = |\det(A)| = \sqrt{|d_K|}[\mathcal{O}_k : \mathfrak{a}]$$

as we sought to show.

Thus, if $K = \mathbb{Q}(\sqrt{m})$ where m is square-free:

$$\operatorname{vol}(\mathcal{O}_K) = \begin{cases} \sqrt{m} & m \equiv 1 \bmod 4 \\ 2\sqrt{m} & m \equiv 2, 3 \bmod 4 \end{cases}$$

Absolute Norm and Geometric Inequalities

Besides introducing a geometric intuition for number rings and their ideals, the key reason to introduce volumes is that they will allow us make many bounding arguments on ideals using the lattice structure of $\mathcal{O}_K$. To do this, we introduce a new "norm" on the ideals of $\mathcal{O}_K$ that shall represent the size of the ideal with respect to the lattice. This will be helpful in many algebraic arguments, but also in upgrading many clasical results about primes (such as their distribution[12], see [39]).

[12] the number of primes p where $|p| \leq X$ tends asymptotically to $\frac{X}{\log(X)}$

Definition 50.1.61: Absolute Norm

Let $0 \neq \mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal of $\mathcal{O}_K$. Then the *absolute norm* of $\mathfrak{a}$ is given by

$$\mathfrak{N}_K(\mathfrak{a}) := [\mathcal{O}_K : \mathfrak{a}]$$

If unambiguous, the notation $\mathfrak{N}(\mathfrak{a})$ is also used.

The absolute norm is inspired by the fact that ideals of $\mathcal{O}_K$, when thought of as representing a sublattice of a certain sparsity as compared to the lattice of $\mathcal{O}_K$. The norm of an ideal is always finite by proposition 50.1.39. Note that the notation $\mathfrak{N}_{K/\mathbb{Q}}$ should not be used, for it shall have a different meaning than $\mathfrak{N}$[13]

Lemma 50.1.62: Norm Of Principal Ideal

Let $(\alpha) \subseteq \mathcal{O}_K$ be a principal ideal. Then:

$$\mathfrak{N}((\alpha)) = \left|N_{K/\mathbb{Q}}(\alpha)\right|$$

***Proof*:**
Let $\beta_1, \beta_2, ..., \beta_n$ be a $\mathbb{Z}$-basis for $\mathcal{O}_K$. Then $\alpha\beta_1, \alpha\beta_2, ..., \alpha\beta_n$ is a $\mathbb{Z}$-basis for $(\alpha) = \alpha\mathcal{O}_K$. Then if $A = (a_{ij})$ is the change of basis formula so

$$\alpha w_i = \sum_j a_{ij}\omega_j$$

by proposition 50.1.39 $|\det(A)| = [\mathcal{O}_K : \alpha]$. But by definition of the basis of A, namely it is left multiplication, we get the definition of the norm:

$$|\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)| = \det(A)$$

giving us equality, as we sought to show.

Lemma 50.1.63: Ideal Divides Absolute Norm

Let $I \subseteq \mathcal{O}_K$ be an ideal. Then:

$$I \big| (\mathfrak{N}(I))$$

***Proof*:**
If we show $\mathfrak{N}(I) = [\mathcal{O}_K : I] \in I$, then $(\mathfrak{N}(I)) \subseteq I$, which by corollary 50.2.19 implies we're done. But this is simply some ring theory: Take $1 \in \mathcal{O}_K$. Then

$$\overline{n} = \underbrace{\overline{1 + \cdots + 1}}_{n \text{ times}} \in \mathcal{O}_K/I$$

Since $|\mathcal{O}_K/I| = n$, it must be that $\overline{n} = \overline{0}$, in particular $n \in I$. Since $n = [\mathcal{O}_K : I]$, we have the desired result.

[13] see definition 50.3.13

Lemma 50.1.64: Volume Form Reformulation

Let $I \subseteq R$ be an ideal of a number field K. Then:

$$\text{vol}(I) = \mathfrak{N}(I)\text{vol}(\mathcal{O}_K)$$

***Proof*:**
This is just reformulating proposition 50.1.60.

Theorem 50.1.65: Bounding Ideals

Let $K/\mathbb{Q}$ be a number field and $\mathcal{O}_K$ its number ring. Then there exists $\lambda \in \mathbb{R}_{>0}$ such that for every $0 \neq I \subseteq \mathcal{O}_K$, there exists a $\alpha \in I$ such that

$$|\text{Nm}_{K/\mathbb{Q}}(\alpha)| \leq \lambda\mathfrak{N}(I)$$

***Proof*:**
Let $\alpha_1, \alpha_2, ..., \alpha_n$ be an integral basis for R, and let $\sigma_1, \sigma_2, ..., \sigma_n$ denote the embeddings of K into $\mathbb{C}$. I claim that:

$$\lambda = \prod_{i=1}^{n}\left(\sum_{j=1}^{n}|\sigma_i(\alpha_j)\right)$$

Let I be any ideal, and m the unique positive integer satisfying:

$$m^n \leq \mathfrak{N}(I) < (m+10^n$$

Consider the $(m+1)^n$ elements of $\mathcal{O}_K$ where:

$$\sum_{j=1}^{n} m_j\alpha_j \qquad m_j \in \mathbb{Z} \qquad 0 \leq m_j \leq m$$

Then two of these *must* be congruent $\mod I$ since there are more than $\mathfrak{N}(I)$ of them. Taking the difference of these two elements, we get a nonzero member of I of the form:

$$\alpha = \sum_{j=1}^{n} m_j\alpha_j \qquad m_j \in \mathbb{Z} \qquad |m_j| \leq m$$

Hence:

$$\left|\text{Nm}_{K/\mathbb{Q}}(\alpha)\right| \leq \prod_{i=1}^{n}|\sigma_i(\alpha)| \leq \prod -i = 1^n\left(\sum_{j=1}^{n} m_j|\sigma_i(\alpha_j)|\right) \leq m^n\lambda \leq \mathfrak{N}(I)\lambda$$

as we sought to show.

Proposition 50.1.66: Image Of Norm Is Finite Up To Units

Let K be a field, $\mathcal{O}_K$ its ring of integers, and $a \in \mathbb{Z}_{>0}$. Then up to multiplication by units, there are only finitely many element $\alpha \in \mathcal{O}_K$ such that

$$\mathrm{Nm}_{K/\mathbb{Q}}(\alpha) = a$$

***Proof*:**
Let $a \in \mathbb{Z}_{>0}$. Recall that $\mathcal{O}_K/a\mathcal{O}_K$ is finite. I claim that, up to multiplication by units, there is at most one element α in each coset such that $|\mathfrak{N}(\alpha)| = |\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)| = a$. For, if $\beta = \alpha + a\gamma$ where $\gamma \in \mathcal{O}_K$, then since $N(\beta) = a$, we can write $\beta = \alpha + N(\beta)\gamma$. Dividing both sides by β then re-arranging we get:

$$\frac{\alpha}{\beta} = 1 \pm \frac{\mathrm{Nm}_{K/\mathbb{Q}}(\beta)}{\beta}\gamma$$

since $\mathrm{Nm}_{K/\mathbb{Q}}(\beta) = \beta \prod_{\tau \neq \mathrm{id}} \tau(\beta)$, we have that $\alpha/\beta \in \mathcal{O}_K$. By diving by α, rearranging, and substituting $a = N(\alpha)$, we also get:

$$\frac{\beta}{\alpha} = 1 \pm \frac{\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)}{\alpha}\gamma \in \mathcal{O}_K$$

hence, α and β are associates. Thus, up to multiplication by units, there is at most $[\mathcal{O}_K : a\mathcal{O}_K]$ elements of norm $\pm a$.

For computational purposes, we add a tighter bound on the norms of ideals. We start with the following lemma:

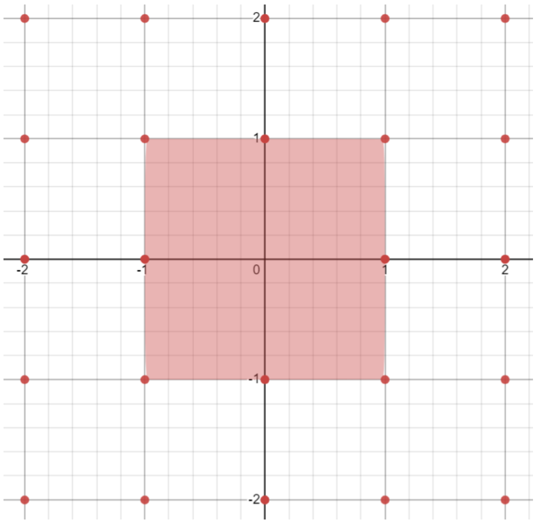
Lemma 50.1.67: Minkowski's Lattice Point Theorem

Let Γ be a discrete complete lattice in the Euclidean vector space V of dimension n and let X be a centrally symmetric convex subset of V. Then if

$$\mathrm{vol}(X) > 2^n \mathrm{vol}(\Gamma)$$

then X contains at least one nonzero lattice point $\gamma \in \Gamma$

Before proving this result, consider $\sigma(\mathbb{Z}[i])$. The smallest centrally symmetric set would



it is clear this square have volume arbitrarily close to 2^2, any large and it would intersect $\sigma(\mathbb{Z}[i])$. Similarly, if there was a long stretched area that tried to avoid the points of $\sigma(\mathbb{Z}[i])$, do to the size constraint, it will necessarily be to large to avoid intersecting the lattice:

***Proof*:**
It suffice to show that there exists two distinct lattice points $\gamma_1, \gamma_2 \in \Gamma$ such that

$$\left(\frac{1}{2}X + \gamma_1\right) \cap \left(\frac{1}{2}X + \gamma_2\right) \neq \emptyset$$

To show this, let's first say there exists such a point so that

$$\frac{1}{2}x_1 + \gamma_1 + \frac{1}{2}x_2 + \gamma_2$$

Then we may re-write to obtain:

$$\gamma = \gamma_1 - \gamma_2 = \frac{1}{2}x_1 - \frac{1}{2}x_2$$

Notice that this is in the center o the line segment joining $-x_1$ and x_2, and hence belongs in $X \cap \Gamma$.

Now, if the set $\frac{1}{2}X + \gamma$, $\gamma \in \Gamma$ were all pairwise disjoint, then the same is the case for the intersections $\Phi \cap (\frac{1}{2}X\gamma)$ for fundamental mesh Φ of Γ, hence we would have

$$\mathrm{vol}(\Phi) \geq \sum_{\gamma \in \Gamma} \mathrm{vol}\left(\Phi \cap \left(\frac{1}{2}X + \gamma\right)\right)$$

However, translation so $\Phi \cap (\frac{1}{2}X + \gamma)$ by $-\gamma$ creates the set $(\Phi - \gamma) \cap \frac{1}{2}X$ of equal volume, implying $\Phi - \gamma$ covers all of V, and hence $\frac{1}{2}X$ It follows from our assumption that

$$\mathrm{vol}(\Phi) \geq \sum)\gamma \in \Gamma \mathrm{vol}\left((\varphi - \gamma) \cap \frac{1}{2}X\right) = \mathrm{vol}(\frac{1}{2}X) = \frac{1}{2^n}X$$

contradicting the hypothesis.

Theorem 50.1.68: Minkowski's Bound

Let $[\mathfrak{a}] \in Cl(K)$ be an ideal class of degree n. Then there exists an integral ideal $\mathfrak{a}$ such that

$$\mathfrak{N}(\mathfrak{a}) \leq \frac{n!}{n^n}\left(\frac{4}{\pi}\right)^{r_2}\sqrt{|d_K|}$$

***Proof*:**
Let $\mathbb{R}^N \cong_{\mathbb{R}} \mathbb{R}^{r_1} \oplus \mathbb{R}^{r_2}$. Define the following norm on $\mathbb{R}^n$:

$$N(x) = x_1 \cdots x_r(x_{r_1+1}^2 + x_{r_1+2}^2) \cdots (x_{n-1}^2 + x_n^2)$$

(actually, type this up later, Marcus p.95)

Notice that is we re-arrange, we get:

$$\frac{n^n}{n!}\left(\frac{\pi}{4}\right)^{r_2} \leq \sqrt{|d_K}$$

Thus, we get a result that may seem obvious, but is in general rather difficult to prove:

Corollary 50.1.69: Discriminant Nonzero

Let $\mathcal{O}_K \neq \mathbb{Z}$. Then:

$$|d_K| > 1$$

***Proof*:**
immediate consequence of above since $n > 1$

50.2 Ring Structure and Dedekind Domains

So far, we have shown that rings of integers are lattices whose rank corresponds to the dimension of their corresponding field extension. Since they are rings, we may naturally ask what type of ring are they. Using example 50.1.17, we can look at the particular example of $\mathcal{O}_{\mathbb{Q}(\sqrt{-5})} = \mathbb{Z}[\sqrt{-5}]$. Is this ring a Euclidean Domain, Principal Ideal Domain, or Unique Factorization Domain? It is certainly Noetherian, being a finitely generated $\mathbb{Z}$-module (where $\mathbb{Z}$ is Noetherian). However, not all irreducible elements are prime, for example:

$$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$$

showing that 2 is not prime. This may seem troubling since we may have to keep track of multiple factorizations showing there is more structure or tools that would need to be added/used to keep track of this information. Fortunately, there is a way to recover factorization. The goal of this section is to define a new type of ring for which the notion of Unique factorization is recovered, and show that all rings of integers are this type of ring. First, we may use the norm to see that a factorization into irreducible is always certainly possible in $\mathcal{O}_k$. For, if $\alpha = \beta\gamma$, then if β, γ are non-units:

$$1 < |N_{K/\mathbb{Q}}(\beta)| < |N_{K/\mathbb{Q}}(\alpha)| \qquad 1 < |N_{K/\mathbb{Q}}(\gamma)| < |N_{K/\mathbb{Q}}(\alpha)|$$

showing that it is a factorization domain. However this factorization need not be unique as we have demonstrated with $\mathcal{O}_{\mathbb{Q}(\sqrt{-5})} = \mathbb{Z}[\sqrt{-5}]$, another example being $21 = 3 \cdot 7 = (1+2\sqrt{-5})(1-2\sqrt{-5})$. We may see these are irreducible elements by using the norm. Doing the case of 3, if $3 = \alpha\beta$ for non-units α, β, then $9 = N_{K/\mathbb{Q}}(\alpha)N_{K/\mathbb{Q}}(\beta)$ would give us that $N_{K/\mathbb{Q}}(\alpha) = \pm 3$. Given $\alpha = a + b\sqrt{-5}$ we get

$$N_{K/\mathbb{Q}}(a+b\sqrt{-5}) = a^2 + 5b^2 = \pm 3$$

But this certainly has no solutions in $\mathbb{Z}$, and hence 3 is irreducible in $\mathcal{O}_K$. A similar argument can be made for $7, 1 \pm 2\sqrt{-5}$. Furthermore, the numbers 3 and 5 are not associated to $1 \pm 2\sqrt{-5}$, for we would require that

$$\frac{1 \pm 2\sqrt{-5}}{3}, \frac{1 \pm 2\sqrt{-5}}{7} \in \mathcal{O}_K$$

both of which we can check are not using the norm. Hence, we certainly have different factorizations.

The failure of unique factorization has lead Eduard Kummer to try to embed the ring of integers of K into a bigger domain of "ideal numbers" where unique factorization into "ideal prime numbers" would hold (which was inspired by the discovery of complex numbers somehow being "ideal" for roots polynomial roots). As an example, our original decomposition in $\mathbb{Z}[\sqrt{-5}]$

$$21 = 3 \cdot 7 = (1+2\sqrt{-5})(1-2\sqrt{-5})$$

would factor into ideal prime numbers $\mathfrak{p}_1, \mathfrak{p}_2, \mathfrak{p}_3, \mathfrak{p}_4$ with the relations

$$3 = \mathfrak{p}_1\mathfrak{p}_2 \qquad 7 = \mathfrak{p}_3\mathfrak{p}_4 \qquad 1+2\sqrt{-5} = \mathfrak{p}_1\mathfrak{p}_3 \qquad 1-2\sqrt{-5} = \mathfrak{p}_2\mathfrak{p}_4$$

Then we would have fixed non-uniqueness since we would get the factorization:

$$21 = (\mathfrak{p}_1\mathfrak{p}_2)(\mathfrak{p}_3\mathfrak{p}_4) = (\mathfrak{p}_1\mathfrak{p}_3)(\mathfrak{p}_2\mathfrak{p}_4)$$

Some key properties that these ideals numbers should have is that for $a, b, \lambda \in \mathcal{O}_K$, an ideal number $\mathfrak{a}$ should satisfy the following natural divisibility restrictions:

$$\mathfrak{a}\big|a \text{ and } \mathfrak{a}\big|b \Rightarrow \mathfrak{a}\big|a \pm b \qquad a\mathfrak{a}\big|a \Rightarrow \mathfrak{a}\big|\lambda a$$

An furthermore an ideal number $\mathfrak{a}$ ought to be determinable by the set of its divisors in $\mathcal{O}_K$, that is

$$\underline{\mathfrak{a}} = \left\{a \in \mathcal{O}_K \;\middle|\; \mathfrak{a}\big|a\right\}$$

But given these rules, this set is simply an ideal of $\mathcal{O}_K$ as we know the notion of ideal. It was Richard Dedekind that took the notion of ideal numbers that Kummer invented and invented the notion of *ideals* of $\mathcal{O}_K$ giving the modern definition of ideals. Then division $\mathfrak{a}\big|a$ is replaced by belonging $a \in \mathfrak{a}$, and divisibility $\mathfrak{a}\big|\mathfrak{b}$ is replaced by containment $\mathfrak{b} \subseteq \mathfrak{a}$.

Hence, we shall seek a unique factorization of *ideals* into *prime ideals* in $\mathcal{O}_K$. The 3 key properties of $\mathcal{O}_K$ that require this factorization was singled out by Dedekind and form a class of rings larger than rings of integers and are worth taking a look at on their own:

Definition 50.2.1: Dedekind Domain

Let R be an integral domain. Then if:

1. R is a Noetherian ring
2. every nonzero prime ideal of R is maximal
3. R is normal ($\overline{R}^{K(R)} = R$)

then R is called a *Dedekind Domain*

The Noetherian condition can be thought of as a natural eliminator of any infinites lurking around, while the prime implies maximal condition can be thought of as making sure that there can be a prime ideal that further contains prime ideals. In particular, we shall see that $(a) \subseteq (b)$ if and only if $b|a$, which doesn't make sense if we allow for prime ideals being contained in larger prime ideals.

50.2.2 Foreshadowing in Algebraic Geometry Notice that we have already seen a ring with these conditions before, namely if V is a smooth 1-dimensional variety, then the associated k-algebra is Noetherian, 1 [Krull] dimensional and is normal (normal implies smoothness[a]). In Algebraic Geometry, Dedekind domains can be thought of as representing 1-dimensional smooth schemes (in particular, 1-dimensional smooth $\mathbb{Z}$-curves)

[a] But only necessarily in 1 dimension; in higher dimension normalness need not imply smoothness, see [5]

Lemma 50.2.3: PID's, UFD's, and Dedekind Domain

Let R be a ring. Then:

1. If R is a PID, R is a Dedekind Domain
2. If R is a UFD, R need not be a Dedekind Domain
3. If R is a Dedekind domain and a UFD, it is a PID

The following image demonstrates the realation:

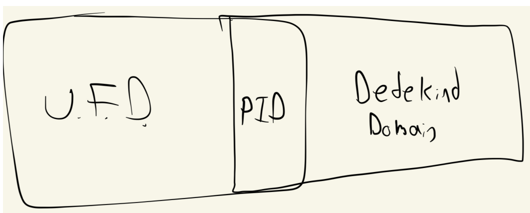


Figure 50.1: Venn diagram

***Proof*:**
R is trivially Noetherian and all prime ideals are maximal. For normalness, since R is a Unique Factorization Domain, $\overline{R}^{K(R)} = R$, hence R is a Dedekind Domain.

For the counter-example, take $\mathbb{Z}[\sqrt{-13}]$ and find two ways of decomposing 14. The last is an exercise.

For algebro-geometric purposes, the following characterizes Dedekind domains locally:

Lemma 50.2.4: Dedekind Domain As DVR

Let R be commutative ring. Then R is a Dedekind domain if and only if for each prime P, R_P is a DVR. Thus, Dedekind domains are local DVR's.

***Proof*:**
exercise.

Lemma 50.2.5: Dedekind Domains And Localization

Let R be a Dedekind domain and $S \subseteq R \setminus \{0\}$ is a multiplicative subset. Then $S^{-1}R$ is also a Dedekind Domain.

***Proof*:**
The localization of Noetherian rings is Noetherian, and by the correspondence of ideals in localizations, we have that prime implies maximal in $S^{-1}R$. Finally, $S^{-1}R$ is integrally closed since if $x \in K = K(R)$ satisfies:

$$x^n + \frac{a_1}{s_1}x^{n-1} + \cdots + \frac{a_n}{s_n} = 0 \qquad \frac{a_i}{s_i} \in S^{-1}R$$

Then multiplying with the nth power of $s_1 \cdots s_n$ gives that sx is integral over R, hence $sx \in R$, and so $x \in S^{-1}R$, as we sought to show.

Importantly for number theory, all rings of integers are Dedekind domains:

Theorem 50.2.6: Ring Of Integers Are Dedekind Domains

Let $\mathcal{O}_K$ be a ring of integers. Then it is a Dedekind domain.

***Proof*:**
By proposition 50.1.32, $\mathcal{O}_K$ is Noetherian, and by definition $\mathcal{O}_K$ is normal, namely $\mathcal{O}_K = \overline{\mathbb{Z}}^K$ meaning by corollary 26.1.6:

$$\overline{\mathcal{O}_K}^K = \overline{\overline{\mathbb{Z}}^K}^K = \overline{\mathbb{Z}}^K$$

What's left to show is that every prime ideal is maximal, which is equivalent to showing $\mathcal{O}_K/\mathfrak{p}$ is a field. In particular, since $\mathcal{O}_K/\mathfrak{p}$ is always an integral domain, if we show that it is finite then by corollary 9.1.25 we shall have that it's a field. The key intuition comes from the fact that $\mathcal{O}_K$ and its ideals form a lattice, meaning when we quotient we necessarily get a finite ring.

Furthermore, the volume of the ideal is determined by the discriminant and the index, which will determine the cardinality of the quotient ring[a]

Let $0 \neq \alpha \in \mathfrak{p}$. Then $(p) = \mathfrak{p} \cap \mathbb{Z}$ is also a prime ideal. Since $\mathfrak{p} \subseteq \mathcal{O}_K$, we know α is associated to a minimal polynomial $m_{\alpha,\mathbb{Z}}(x)$ where

$$m_{\alpha,\mathbb{Z}}(\alpha) = \alpha^n + a_{n-1}\alpha^{n-1} + \cdots + a_1\alpha + a_0 = 0 \qquad a_i \in \mathbb{Z}$$

Then $a_0 = -(\alpha^n + a_{n-1}\alpha^{n-1} + \cdots + a_1\alpha) \in \mathfrak{p} \subseteq \mathcal{O}_K$, and since $m_{\alpha,\mathbb{Q}}(x)$ is irreducible with integer coefficients, $a_0 \neq 0$ and $a_0 \in (p) = p\mathbb{Z}$. From here, we shall give two proofs: first, we may directly appeal to the fact that

$$(\mathcal{O}_K/\mathfrak{p})/(\mathbb{Z}/p\mathbb{Z})$$

is an integral extension (see example 26.1.9) where the base ring is a field, hence $\mathcal{O}_K/\mathfrak{p}$ is a field by proposition 26.1.8. Another is the following: we have a non-trivial ideal with chains of inclusions $(a_0) \subseteq \mathfrak{p} \subseteq \mathcal{O}_K$ implying

$$|\mathcal{O}_K/\mathfrak{p}| \leq |\mathcal{O}_K/(a_0)| = |\mathcal{O}_K/a_0\mathcal{O}_K|$$

Now, since we are quotienting ideals, this is a $\mathbb{Z}$-module quotient, and since we are quotienting n-rank free $\mathbb{Z}$-modules, we get that

$$|\mathcal{O}_K/(a_0)| = p^n$$

But then $\mathcal{O}_K/\mathfrak{p}$ is finite (even better, its order divides $|a_0|^n$). Thus, $\mathfrak{p}$ must be maximal, and since $\mathfrak{p}$ was arbitrary every prime ideal is maximal, completing the proof.

[a] We shall soon see that the index can be thought of as the "norm" of a general ideal; this will mean the constant term of a minimal polynomial represent the "size", sheading some light on the proof

Since in general $\mathcal{O}_K$ is not a Unique Factorization Domain, rings of integers represent a class of rings where prime implies maximal, but factorization is not unique. In this way, we see that the integral closure of $\mathbb{Z}$ with respect to K may be far from having the nice element-wise properties we are used to in PIDs, but this shall be salvaged through having an understandable ideal structure and a way to measure how far away our ring is from being a PID.

Another important example of a Dedekind domain that is not a number ring is the ring is $k[x]$ (since it's a PID). We shall later see that integral extensions of Dedekind domains are Dedekind domains, an so these types of rings will form a basis for another large class of Dedekind domains that are not number rings.

50.2.1 Fractional Ideals in Rings

Following from the idea that ideals are the generalisation of numbers, we may define the following divisibility notions usually used for the [algebraic] lattice of integers induced by divisibility. These concepts shall be defined for general commutative rings:

Definition 50.2.7: GCD, LCM, Divisibility Of Ideals

let R be a commutative ring, $\mathfrak{a}, \mathfrak{b} \subseteq R$ ideals of R. Then:

$$\gcd(\mathfrak{a}, \mathfrak{b}) = (\mathfrak{a}, \mathfrak{b}) = \mathfrak{a} + \mathfrak{b} \qquad \operatorname{lcm}(\mathfrak{a}, \mathfrak{b}) = \mathfrak{a}\mathfrak{b}$$

And we can say that $\mathfrak{a}, \mathfrak{b}$ are relatively prime when $\gcd(\mathfrak{a}, \mathfrak{b}) = (1)$. Divisibility $\mathfrak{a}\big|\mathfrak{b}$ is defined as $\mathfrak{b} \subseteq \mathfrak{a}$, and hence we have an order and the ideals similar to that given by divisibility.

As we've seen in chapter 10, gcd and lcm are usually well-behaved in special classes of rings, usually UFDs. We shall show they are well-behaved in Dedekind domains since the ideals shall have unique factorizations. Let's now prove some lemmas for this result.

One finiteness fact is needed throughout, and it is the reason the Noetherian hypothesis appears in the definition of a Dedekind domain at all: in a Noetherian domain every nonzero proper ideal *contains* a product of nonzero prime ideals, each of which contains it (corollary 23.1.6). An ideal need not factor into primes — that is the theorem we are working toward, and it needs the full strength of a Dedekind domain — but it always contains such a product, and that much is available from the Noetherian condition alone.

For the following lemmas, we bring back the notion of fractional ideal that was defined in chapter 23. These ideals were at the time a way of extending ideals into the ring of fractions, and were shown to work well with localization. Due to all the properties of Dedekind domains, the product of ideals can be made into a *group*, even an *abelian group*. Since the fractional ideal structure will have such a strong restriction, this will produce incredible results on the relations between ideals. To begin, the following lemma shows that no prime ideal acts like the identity:

Lemma 50.2.8: Fractional Ideals

Let $P \subseteq R$ be a prime ideal of the Dedekind domain R, $K = K(R)$. Define

$$(R :_K P) = P^{-1} = \{x \in K \mid xP \subseteq R\}$$

Then

$$AP^{-1} = \left\{ \sum_i a_i x_i \;\middle|\; a_i \in A,\ x_i \in P^{-1} \right\} \neq A$$

for every ideal $0 \neq A \subseteq R$

Note that by definition $R \subseteq P^{-1}$ and so P^{-1} is not in general an ideal. The simplest "fractional ideal" would be those of $\mathbb{Z}$, namely $(n)^{-1} = \frac{1}{n}\mathbb{Z}$.

***Proof*:**
Note that when we work with the inverse of elements, we are considering them as being part of $K(R)$.

We shall first show the special case of $P^{-1} \neq R$. Let $a \in P$ with $a \neq 0$. The ideal (a) is nonzero and proper, so it contains a product of nonzero primes by the fact recalled above (corollary 23.1.6); consider such a product $P_1 P_2 \cdots P_r \subseteq (a) \subseteq P$ with r minimal. Then one of the P_i, is containing in P, without loss of generality say $P_1 = P$ (since P_l is maximal). Indeed, if non of the P_i were contained in P, then for every i there would exist $a_i \in P_i \setminus P$ such that

$a_1 \cdots a_r \in P$, but P is maximal. Next, by minimality $P_2 \cdots P_r \not\subseteq (a)$, so there exists $b \in P_2 \cdots P_r$ such that $b \notin (a) = aR$, that is $a^{-1}b \notin R$. On the other hand, since $P = P_1$, $P_1 b \in P_1 P_2 \cdots P_n r$, hence we have $bP \subseteq (a) = aR$ that is $a^{-1}bP \subseteq R$, and so $a^{-1}b \in P^{-1}$. It follows that $P^{-1} \neq R$, namely $P^{-1} \supsetneq R$.

Next, let $0 \neq A \subseteq R$ be an ideal. Since R is Noetherian, let

$$A = (\alpha_1, \alpha_2, ..., \alpha_n)$$

For the sake of contradiction, say $AP^{-1} = A$. Then for every $x \in P^{-1}$

$$xa_i = \sum_j a_{ij}\alpha_j \qquad a_{ij} \in R$$

Letting M be the matrix $(x\delta_{ij} - a_{ij})$, we get $M(\alpha_1, \alpha_2, ..., \alpha_n)^t = 0$. By Cramers rule, if $d = \det(M)$, then $d\alpha_1 = \cdots = d\alpha_n = 0$, and so $d = 0$. Then x is integral over R, since its' the zero of the monic polynomial

$$f(X) = \det(X\delta_{ij} - a_{ij}) \in R[x]$$

Thus, since R is integrally closed $x \in R$. But then $P^{-1} = R$; a contradiction to your first part, as we sought to show.

Definition 50.2.9: Fractional Ideal and Quotient ideal

Let R be an integral domain and $K = K(R)$. Then a *fractional ideal* J of K is a finitely generated non-trivial R-submodule of K where there exists a $r \in R$ such that $rJ \subseteq R$ is an ideal.

If $I, J \subseteq R$ are ideals, then the *quotient ideal* of I with respect to J is:

$$(I : J) = \{x \in R \mid xJ \subseteq I\}$$

If $I = R$,then $(R : J)$ is denoted J^{-1}

Fractional ideals are multiplied in the similar way ideals are multiplied (treat them as sub-algebra multiplication). Since all ideals of R are rank 1 submodules of R, they are all fractional ideals. For those who are motivated by algebraic geometry, fractional ideals shall be shown to form line bundles over the smooth $\mathbb{Z}$-curves $\mathcal{O}_K$ [14].

Quotient ideals have a lot of interesting theory, for example to motivate their name if J is principle and $I \subseteq J$, then $I = J \cdot (I : J)$. There is no room in this chapter to explore these in detail, hence they are left as exercises 50.2.1(50.2.1 (6)).

Fractional ideals that are ideals are given a name:

[14]See section 50.7 to see how to interpret rings of integers as smooth $\mathbb{Z}$-curves, and ref:HERE for interpreting fractional ideals as line bundles

Definition 50.2.10: Integral Ideals

Let R be an integral domain and $K = K(R)$. Then a fractional ideal $I \subseteq K$ that is of rank 1 is called an *integral ideal*, and $I \subseteq R$.

Example 50.2.11: Fractional Ideal

1. Since $\mathbb{Z}$ is a Principal Ideal Domain, every ideal is of the form $a\mathbb{Z}$ for $a \in \mathbb{Z}$. Then $(a)^{-1} = a^{-1}\mathbb{Z}$. Hence, the fractional ideals are in bijective correspondence with $\mathbb{Q}^{\times}_{>0}$. Naturally, all ideals of $\mathbb{Z}$ are fractional ideals, in particular they are integral ideals.

2. More generally, if $a \in K^{\times}$, then we get fractional principal ideals $(a) = aR$, and we have a bijective correspondence between the fractional ideals and $K^{\times}/R^{\times}$.

The condition that there must exist an $r \in R$ such that $rJ \subseteq R$ is superfluous in Noetherian domains:

Corollary 50.2.12: Fractional Ideal Representative

Let R be a Noetherian Domain, $K = K(R)$, and $\mathfrak{a} \subseteq K$ a fractional ideal. Then there exists a $r \in R \setminus \{0\}$ and ideal $I \subseteq R$ such that

$$\mathfrak{a} = r^{-1}I$$

Stated differently, $\mathfrak{a} \cong_R I$

If $R = \mathcal{O}_K$, we may take $r \in \mathbb{Z}$. Furthermore, the above is an if and only if statement.

***Proof*:**
Use the fact that R is Noetherian. Let $\mathfrak{a} = (\alpha_1, \alpha_2, ..., \alpha_n)$. In particular, since $\mathfrak{a}$ is a finitely generated $\mathbb{Z}$-module:

$$\mathfrak{a} = \sum R\alpha_i \qquad\qquad \alpha_i \in K(R)$$

by definition, $\alpha_i = a_i/b_i$ for $a_i, b_i \in R$. Taking $b = b_1 b_2 \cdots b_n$, we get

$$b\mathfrak{a} \subseteq R$$

Hence, $b\mathfrak{a}$ is an ideal, say $b\mathfrak{a} = I$ Then $\mathfrak{a} \subseteq b^{-1}I$.

This immediately implies that $\mathfrak{a} \cong_R I$, for if $\mathfrak{a} = (\alpha_1, \alpha_2, ..., \alpha_n)$ so that $I = (r^{-1}\alpha_1, ..., r^{-1}\alpha_n)$, then define $\varphi(\alpha_i) = r^{-1}\alpha_i$ is an R-module isomorphism.

Notice that this generalizes the definition of ideals, if R is a Dedekind ring over itself, then the ideals of R are the finitely generated sub-modules. Then if $K = \mathrm{Frac}(R)$, the fractional ideals are the finitely generated K-modules.

Corollary 50.2.13: Inverse of Prime Ideals

Let R be a Dedekind domain and $\mathfrak{p} \subseteq R$ be a prime ideal. Then:

$$\mathfrak{p}\mathfrak{p}^{-1} = (1)$$

***Proof*:**
If $x \in \mathfrak{p}\mathfrak{p}^{-1}$, then $x = \sum p_i k_i$ for $p_i \in \mathfrak{p}$ and $k_i \in \mathfrak{p}^{-1}$. But by definition of $\mathfrak{p}^{-1}$, we have that $p_i k_i \in R$, hence x element is in R, and so $\mathfrak{p}\mathfrak{p}^{-1} \subseteq R$. Next, certainly $\mathfrak{p} \subseteq \mathfrak{p}\mathfrak{p}^{-1} \subseteq R$. Since $\mathfrak{p}$ is maximal, either $\mathfrak{p}\mathfrak{p}^{-1} = \mathfrak{p}$ or $\mathfrak{p}\mathfrak{p}^{-1} = R$. The former is a contradiction by lemma 50.2.8, and hence $\mathfrak{p}\mathfrak{p}^{-1} = (1)$, completing the proof.

Lemma 50.2.14: Invariance Number Ring Multiplication

Let $t \in K$, $\mathfrak{a} \subseteq K$ a fractional ideal. If $tI = I$, then $t \in R$

***Proof*:**
Since I is a finitely generated R module, there exists a surjective R-module homomorphism $\varphi : R^n \to I$. Next, since $tI = I$, there exists an R-module homomorphism $t : I \to I$ sending $i \mapsto ti$. Then $t \in \mathrm{Hom}_R(I, I)$. Since R^n is free, if we consider the following lift:

$$\begin{tikzcd}
R^n \arrow[r, two heads] & I \\
R^n \arrow[u, dashed, "\text{lift}"] \arrow[r, two heads, "\varphi"] \arrow[ur, two heads] & I \arrow[u, "t"']
\end{tikzcd}$$

Then $xt \in \mathrm{Hom}_R(R^n, I)$. Taking $\alpha \in \mathrm{Hom}_R(R^n, R^n)$:

$$\det(xI - \alpha)(\alpha) = 0 \Rightarrow \det(xI - \alpha)(t) = 0$$

now using that R is a Dedekind domain, namely that it's integrally closed, we get that $t \in R$, completing the proof.

50.2.2 Prime Decomposition in Dedekind Domain

With these properties, we may show the factorization of prime ideals in Dedekind domains.

Theorem 50.2.15: Unique Factorization Of Ideals In Dedekind Domains

Let R be a Dedekind Domain and $\mathfrak{a} \subseteq R$ a non-trivial proper ideal. Then there exists unique $\mathfrak{p}_1, \mathfrak{p}_2, ..., \mathfrak{p}_n$ such that

$$\mathfrak{a} = \mathfrak{p}_1\mathfrak{p}_2 \cdots \mathfrak{p}_n$$

***Proof*:**
We start with the existence of such a factorization. Let $\mathfrak{M}$ be the set of all non-trivial proper ideals which do not admit a prime ideal decomposition. If $\mathfrak{M}$ is non-empty, then since R is Noetherian there exists a maximal element, say $\mathfrak{m}$. Then this ideal is contained in some maximal ideal $\mathfrak{p}$. Since $R \subseteq \mathfrak{p}^{-1}$, we get the following chain of inclusions:

$$\mathfrak{m} \subseteq \mathfrak{m}\mathfrak{p}^{-1} \subseteq \mathfrak{p}\mathfrak{p}^{-1} \subseteq R$$

by lemma 50.2.8, we have $\mathfrak{m} \subsetneq \mathfrak{m}\mathfrak{p}^{-1}$ and $\mathfrak{p} \subsetneq \mathfrak{p}\mathfrak{p}^{-1} \subseteq R$. By maximality of $\mathfrak{p}$, $\mathfrak{p}\mathfrak{p}^{-1} = R$, and by maximality of $\mathfrak{m}$ in $\mathfrak{M}$, $\mathfrak{m}\mathfrak{p}^{-1}$ admits a prime ideal decomposition, say

$$\mathfrak{m}\mathfrak{p}^{-1} = \mathfrak{p}_1 \cdots \mathfrak{p}_r$$

But then, since $\mathfrak{p}\mathfrak{p}^{-1} = R$, $\mathfrak{m}R = \mathfrak{m}$ and so

$$\mathfrak{m} = \mathfrak{m}\mathfrak{p}^{-1}\mathfrak{p} = \mathfrak{p}_1 \cdots \mathfrak{p}_r\mathfrak{p}$$

contradicting the definition of $\mathfrak{m}$. Hence $\mathfrak{M}$ is an empty-set

For uniqueness, let

$$\mathfrak{a} = \mathfrak{p}_1\mathfrak{p}_2 \cdots \mathfrak{p}_r = \mathfrak{q}_1\mathfrak{q}_2 \cdots \mathfrak{q}_s$$

be two prime ideal factorizations of $\mathfrak{a}$. Then by the repeated application of property of prime ideals ($\mathfrak{a}\mathfrak{b} \subseteq P \Rightarrow \mathfrak{a} \subseteq P$ or $\mathfrak{b} \subseteq P$), we have that $\mathfrak{p}_1$ divides a factor of the right hand side, say $\mathfrak{q}_1$, and by maximality is thus equal to $\mathfrak{q}_1$. Then we can multiply both sides by $\mathfrak{p}_1^{-1}$ and since $\mathfrak{p}_1 \neq \mathfrak{p}_1\mathfrak{p}_1^{-1} = R$ we get

$$\mathfrak{p}_2 \cdots \mathfrak{p}_r = \mathfrak{q}_2 \cdots \mathfrak{q}_s$$

Then proceeding inductively, we will get that $r = s$ and $\mathfrak{p}_i = \mathfrak{q}_i$, up to renumbering, completing the proof.

50.2.16 Note It is in fact equivalent to define a Dedekind domain as ring in which each ideal factors uniquely, showing that this theorem characterizes Dedekind domains, see exercise ref:HERE.

From now on, we shall group the prime ideals to write

$$\mathfrak{a} = \mathfrak{p}_1^{n_1} \cdots \mathfrak{p}_r^{n_r} \qquad n_i > 0$$

If $\mathfrak{a} = (a)$ is a principal ideal, we shall use the slight abuse of notation and write

$$a = \mathfrak{p}_1^{n_1} \cdots \mathfrak{p}_r^{n_r} \qquad n_i > 0$$

Similarly, we shall often write $\mathfrak{a}\big|a$ instead of $\mathfrak{a}\big|(a)$. An important result worth emphasizing is the structure of R/I for an ideal $I \subseteq R$. First, note that if $\mathfrak{p}_i + \mathfrak{p}_j = (1)$, then $\mathfrak{p}_i^{n_i} + \mathfrak{p}_j^{n_j} = (1)$ (this was exercise ref:HERE (in CRT section)); the trick is to consider $1 = 1^{n_i+n_j+1} = (ax+by)^{n_i+n_j+1}$, use the binomial theorem, and group appropriate elements. Then by the Chinese Remainder Theorem:

$$R/I = \bigoplus_i R/P_i^{n_i}$$

By the 4th isomorphism theorem, $\overline{I} \subseteq R/P_i^{n_i}$ if and only if $P_i^{n_i} \subseteq I$, that is $I\big|P_i^{n_i}$. But by unique factorization, that means that $I = P_i^k$ for $1 \leq k \leq n_i$. Hence, every quotient has only finitely many ideals, each ideal I corresponding to a set of prime power of the decomposition of I via the isomorphism given by the CRT. This matches with the result that $R/(a)$ is a finite ring, showing there can only be finitely many ideals, and the prime factorization theorem for ideals gives us the structure of the ideals of $R/(a)$ through the correspondence given by the 4th isomorphism theorem. This also immediately shows that R/I is *Artinian*[15].

Using the fact that ideals factor and "behave" like the positive rational numbers ($-\mathfrak{p} = \mathfrak{p}$ since -1 is a unit), we can conclude some powerful results. We have shown that every ideal has a unique inverse. This immediately shows that:

$$\mathfrak{a}\mathfrak{b} = \mathfrak{a}\mathfrak{c} \quad \Longrightarrow \quad \mathfrak{b} = \mathfrak{c}$$

by the Cancellation law. Next, it is easy to see is that we may generalize the notion of finding GCD and LCM of UFD's to Dedekind domains:

Corollary 50.2.17: GCD, LCM, and Divisibility In Dedekind Domains

Let $\mathfrak{a}, \mathfrak{b} \subseteq R$ be ideals in a Dedekind domain R. Then

1. $\operatorname{lcm}(\mathfrak{a}, \mathfrak{b}) = P_1^{\max(a_1, b_1)} \cdots P_k^{\max(a_k, b_k)}$
2. $\gcd(\mathfrak{a}, \mathfrak{b}) = P_1^{\min(a_1, b_1)} \cdots P_k^{\min(a_k, b_k)}$
3. $\mathfrak{a} \big| \mathfrak{b}$ if and only if there exists a $\mathfrak{c}$ such that $\mathfrak{a}\mathfrak{c} = \mathfrak{b}$

***Proof*:**
For the first two, work with the factorization and property of ideals.

For 3, if $\mathfrak{a} \big| \mathfrak{b}$, we have that $\mathfrak{b} \subseteq \mathfrak{a}$. In a Dedekind domain, multiplying by $\mathfrak{a}^{-1}$, we get $\mathfrak{a}\mathfrak{a}^{-1} = (1)$ by extending lemma 50.2.8 with the above theorem. Hence:

$$\mathfrak{b}\mathfrak{a}^{-1} \subseteq \mathfrak{a}\mathfrak{a}^{-1} \subseteq R$$

showing that $\mathfrak{b}\mathfrak{a}^{-1} = \mathfrak{c} \subseteq R$ is an ideal, and $\mathfrak{b} = \mathfrak{c}\mathfrak{a}$, which properly generalizes the notion factorizing elements to the level of ideals.

We know that every ideal has an inverse. However, that inverse is a fractional ideal. Fortunately, there always exists an integral ideal that is "almost" the inverse, in that the product is a principal ideal[16]:

Corollary 50.2.18: Exists J such that IJ is Principal

Let R be a Dedekind Domain and $I \subseteq R$ an ideal. Then there exists an ideal $J \subseteq R$ such that $IJ = (a)$ for some element $a \in I$. In other words, there exists an ideal J such that the product IJ is principal.

[15] Equivalently, $\operatorname{kdim}(R/I) = 0$, and hence it is Artinian

[16] this almost inverse can be made into a concrete inverse when we show the principal ideals form a normal subgroup formed by the group of fractional ideals

***Proof*:**
Let $I = P_1^{n_1} \cdots P_k^{n_k}$. For each i, choose a nonzero element $r_i \in P_i^{n_i} \setminus P_i^{n_i+1}$. By the Chinese Remainder Theorem, there exists an $a \in R$ such that

$$a \equiv r_i \bmod P_i^{n_i+1} \qquad 1 \leq i \leq k$$

Thus, $a \in P_i^{n_i} \setminus P_i^{n_i+1}$ for each i, and so since $a \in P_i^{n_i}$, the power of P_i in the factorization is n_i. Now, taking the prime factorization of (a), we get:

$$(a) = P_1^{n_1} \cdots P_k^{n_k} P_{n+1}^{n_{k+1}} \cdots P_m^{n_m}$$

Letting $J = P_{n+1}^{n_{k+1}} \cdots P_m^{n_m}$ gives us

$$(a) = IJ$$

This same process can be repeated for fractional ideals; for any fractional ideal I, take $r \in R$ such that $rI = J \subseteq R$. Then proceed with the proof above, giving us an ideal L such that $(a) = JL = rIL$. Then $(r^{-1}a) = IL$, completing the proof.

In section 50.3.1, we shall find a more systematic way of finding the prime ideals that multiply to get a principal ideal using Galois groups. As seen with rings of integers, not all Dedekind domains are PIDs since they are not all UFDs. With the factorization theorem, we get that they are the next best thing:

Corollary 50.2.19: PIR, and Generation Of Ideals In Dedekind Domains

Let R be a Dedekind domain and $I \subseteq R$ an ideal. Then R/I is a Principal Ideal Ring, and I is generated by *at most* 2 elements.

***Proof*:**
For any ideal $I \subseteq R$, by the Chinese remainder theorem and prime factorization of I:

$$R/I = \bigoplus_i R/P_i^{n_i}$$

We shall show that each $R/P_i^{n_i}$ is a principal ideal ring, from which we may conclude by the isomorphism that R/I is a principal ideal ring. This shall give the desired result, for if $I \subseteq R$, then for any $J \subseteq I$ we may take R/J where $\overline{I} \subseteq R/(\alpha)$. Then since all ideals of $R/(\alpha)$ are principal, $\overline{I} = (\overline{\beta})$, that is $I = J + (\beta) = (\alpha, \beta)$. If we take $\alpha \in I$, then we would get $(\alpha) \subseteq I$ and $R/(\alpha)$, and so $I = (\alpha) + (\beta) = (\alpha, \beta)$, showing each ideal is generated by at most 2 elements.

Hence, we prove $R/P_i^{n_i}$ is a Principal ideal ring (PIR). If $\overline{J} \subseteq R/(P_i^{n_i})$, then $P_i^{n_i} \subseteq J \subseteq R$, meaning $J | P_i^{n_i}$, and so by unique factorization it must be that $J = P_i^k$ for some $1 \leq k \leq n_i$, which has image $\overline{P_i^k}$ (i.e., there are finitely many ideals).

Now, if $\overline{P_i} = \overline{P_i^2}$, then $\overline{P_i} = \overline{P_i^n} = \overline{0}$, and so $P_i = P_i^n$ implying that $R/P_i^{n_i}$ is a field, and it then automatically a PIR. If $\overline{P_i} \neq \overline{P_i^2}$, take $\alpha \in \overline{P_i} \setminus \overline{P_i^2}$. Then $\overline{\alpha} \notin \overline{P_i^2} \supseteq \overline{P_i^3} \supseteq \cdots$. Thus it must be that

$$\overline{P_i} \big| (\overline{\alpha})$$

But since the only ideals of $R/P_i^{n_i}$ are $\overline{P_i}, ..., \overline{P_i^{n_i-1}}$, it must follow that $(\overline{\alpha}) = \overline{P_i}$. From that it follows that $(\overline{\alpha}^k) = \overline{P_i^k}$, showing that $R/P_i^{n_i}$ is a PIR. But then R/I is a PIR since the isomorphism maps principal ideals to principal ideals, which then as we saw completes the proof.

As a consequence of this, if $\mathfrak{p}\big|(p)$ for some $p \in \mathbb{Z}$, then by using the construction of the proof above, we may always find an element $\alpha \in \mathfrak{p}$ such that $\mathfrak{p} = (p, \alpha)$. Hence, factorization of a prime $p \in \mathbb{Z}$ can always by recovered by adding an appropriate element to (p). More generally, if $I \subseteq J$, then $J = I + (a)$ (can you think of any conditions a needs to satisfy?). Our final result shows all pairs of ideals are, up to a multiple of $K(R)$, relatively prime. This mirrors the property that if $\gcd(a, b) = c$, we can divide a by c to get $\gcd(a/c, b) = 1$:

Corollary 50.2.20: Always Almost Relatively Prime

Let A, B be fractional ideals of the Dedekind Domain R. Then there exists elements $x, y \in K$ such that xA and yB are relative prime.

***Proof*:**
By multiplying A, B by appropriate scalars, we may assume they are integral ideal. We shall find an element c such that $cA + B = R$. First, let $a \in A$, and I be the ideal such that $AI = (a)$. Then since $BI \subseteq I$, consider:

$$\overline{I} \subseteq R/BI$$

Then since R/BI is principal, $I = BI + (b)$ for some $b \in R$. Multiplying by A, dividing by a, and letting $c = b/a$, we get

$$cA + B = R$$

as we sought to show.

With the division of ideals defined and mirroring the structure of $K^\times/R^\times$ ($\mathbb{Q}^\times_{>0}$ when working with $\mathbb{Z}$), it is tempting to say that they form a group structure, and this is indeed the case and is the focus in the remainder of this section.

One of the main metrics to measure is how many more "ideal numbers" need to be added to recover unique factorization into primes. If $\mathfrak{p}$ and $\mathfrak{q}$ are added, then if for some $t \in K$, $t\mathfrak{p} = \mathfrak{q}$, then $\mathfrak{p}$ and $\mathfrak{q}$ don't actually differ much in structure: it can be shown that $I = aJ$ ($a \in K(R)$) if and only if $I \cong_{\mathcal{O}_K} J$). Hence, we may classify "different" classes of ideals up to multiplication by a principal ideal. The more classes there are, the more a ring R fails to be a unique factorization domain. When R is a number ring, we shall show that there are only finitely many such classes.

The first result to prove is that the collection of fractional ideals of a Dedekind domain does indeed form a group:

Theorem 50.2.21: Ideal Group

Let R be a Dedekind domain, $K = K(R)$, and let J_K be the collection of fractional ideals. Then $(J_K, \cdot)$ has an abelian group structure via fractional ideal multiplication, and is called the *ideal group* of K

***Proof*:**
The operation is certainly well-defined (the product of fractional ideals is a fractional ideal), associativity and commutativity come for free, and the identity is $R = (1)$ since for any $\mathfrak{a} \in J_K$

$$\mathfrak{a}(1) = (1)\mathfrak{a} = \mathfrak{a}$$

What's left to check for is the existence of an inverse. For prime ideals, we have that $\mathfrak{p} \subsetneq \mathfrak{p}\mathfrak{p}^{-1}$, an hence by maximality we have $\mathfrak{p}\mathfrak{p}^{-1} = (1)$. For an integral ideal, if $\mathfrak{a} = \mathfrak{p}_1\mathfrak{p}_2 \cdots \mathfrak{p}_r$, then its inverse is

$$\mathfrak{b} = \mathfrak{p}_1^{-1} \cdots \mathfrak{p}_r^{-1}$$

We want to show that $\mathfrak{b} = \mathfrak{a}^{-1}$. Since $\mathfrak{b}\mathfrak{a} = (1)$, then by definition of fractional ideals $\mathfrak{b} \subseteq \mathfrak{a}^{-1}$. Conversely, to show $\mathfrak{a}^{-1} \subseteq \mathfrak{b}$, if $x\mathfrak{a} \subseteq (1)$, then $x\mathfrak{a}\mathfrak{b} \subseteq \mathfrak{b}$. Since $\mathfrak{a}\mathfrak{b} = R$, we have $aR \subseteq \mathfrak{b}$, that is $(a) \subseteq \mathfrak{b}$, and so $x \in \mathfrak{b}$. Hence, we have $\mathfrak{b} = \mathfrak{a}^{-1}$. Finally, if $\mathfrak{a}$ is an arbitrary fractional ideal and $0 \neq c \in R$ such that $c\mathfrak{a} \subseteq R$, then $(c\mathfrak{a})^{-1} = c^{-1}\mathfrak{a}^{-1}$ is the inverse of $c\mathfrak{a}$, so then $\mathfrak{a}\mathfrak{a}^{-1} = R$, completing the proof.

Corollary 50.2.22: Fractional Ideal Prime Decomposition

Every fractional ideal $\mathfrak{a}$ admits a unique representation as the product

$$\mathfrak{a} = \prod_{\mathfrak{p}} \mathfrak{p}^{n_\mathfrak{p}}$$

where $n_p \in \mathbb{Z}$ and $n_p = 0$ for almost all $\mathfrak{p}$. Thus, J_K is the free abelian group generated by the set of nonzero prime ideals $\mathfrak{p}$ of R

***Proof*:**
Notice that every fractional ideal $\mathfrak{a}$ is the quotient of two integral ideals,

$$\mathfrak{a} = \mathfrak{b}/\mathfrak{c}$$

which both have a prime decomposition. Thus, $\mathfrak{a}$ has a prime decomposition as stated in the corollary. Uniqueness follows the same argument as for integral ideals.

Definition 50.2.23: Ideal Group

Let R be a Dedekind Domain. Then J_R denotes the *ideal group* given by ideal multiplication.

We shall often write J_R interchangeably with J_K

Example 50.2.24: Ideal Group

1. The canonical example would be $J_\mathbb{Z} \cong \mathbb{Q}_+^\times$ with the bijection

   $$q\mathbb{Z} = (q) \mapsto q$$

   Note that it is important to think of the multiplicative structure of $\mathbb{Q}$, $(\mathbb{Q}, +)$ is not a free abelian group, having no two distinct elements be linearly dependent and not being cyclic.

2. More generally, let R be a Principal Ideal Domain. Then:

$$J_R \cong K^\times / R^\times$$

This isomorphism does not work in general, namely since not all ideals of R are principal.

A natural subgroup of J_K is formed by the principal ideal (a) where $a \in K^\times$. This subgroup can be thought of as representing our usual notion of factorization into elements instead of ideals As some foreshadowing, notice that the principal ideal The quotient of J_K by the subgroup of principle ideals can be thought of as measuring how far away the ideal group is from being a PID:

Definition 50.2.25: Ideal Class Group

Let J_K be the class group of K. Then

$$Cl(K) = J_K / P_K$$

is called the *ideal class group*, *class group*, or *Picard group* of K.

50.2.26 Note on Nomenclature The term Picard group shall not be used in this book, as the nomenclature is more so associated within algebraic geometry. It is pointed out here that some call the class group the Picard group as the class group is a special case of the Picard group.

These naturally fit in the following exact sequence:

$$1 \to R^\times \to K^\times \to J_K \to Cl(K) \to 1$$

where $K^\times \to J_K$ is the map $a \mapsto (a)$. Hence, we may think of the class group $Cl(K)$ as a measure of the expansion that happens when we pass from numbers to ideals, where the unit group $R^\times$ measure the contraction of the same process. Thus, we may want to understand the groups $R^\times$ and $Cl(K)$ more thoroughly. In general, these can be arbitrary abelian groups[17], but for rings of integers $\mathcal{O}_K$ of number fields K, we get that the size of the class group is always finite and that $\mathcal{O}_K^\times$ is a free $\mathbb{Z}$-module along with roots of unity contained in K, as will soon be shown.

50.2.3 Class Group of Ring of Integer

Recall that ideals $\mathfrak{a} \subseteq \mathcal{O}_K$ form a sub-lattice of $\mathcal{O}_K$ in the Archimedean embedding. The following theorem is key bound on the covolume of lattice. Using theorem 50.1.65, we may rather easily show that the class group is finite. The way we shall find the size of the class group is by showing that every element in a class group will have absolute norm less than a bound (say M), and that only finitely many ideals can have norm equal to $m < M$. Then, by considering the principal ideals that have norm less than M, we shall be able to find all prime ideals that compose these principal ideals, which shall give us an estimate on the size of the group.

[17]There are "enough" 1-dimensional smooth schemes to make arbitrary class groups on Dedekind domains

Lemma 50.2.27: Absolute Norm of Prime

Let $0 \neq \mathfrak{p} \subseteq \mathcal{O}_K$ be a prime ideal of $\mathcal{O}_K$ and let $\mathcal{O}_K$ be rank n. Then

$$\mathfrak{N}(\mathfrak{p}) = p^n$$

***Proof*:**
By theorem 26.3.2, $\mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$. Since $\mathcal{O}_K/\mathbb{Z}$ is an integral extension, $\mathcal{O}_K/\mathfrak{p}$ is a finite field extension of $\mathbb{Z}/p\mathbb{Z}$ of degree n by example 26.1.9(3). Hence:

$$\mathfrak{N}(\mathfrak{p}) = p^n$$

Proposition 50.2.28: Absolute Norm for Ring of Integers Is Multiplicative

Let $\mathfrak{a} = \mathfrak{p}_1^{n_1} \cdots \mathfrak{p}_k^{n_s}$ be the prime Factorization of the nonzero ideal $\mathfrak{a}$. Then:

$$\mathfrak{N}(\mathfrak{a}) = \mathfrak{N}(\mathfrak{p}_1)^{n_1} \cdots \mathfrak{N}(\mathfrak{p}_k)^{n_s}$$

From this, we may conclude that

$$\mathfrak{N}(\mathfrak{a}\mathfrak{b}) = \mathfrak{N}(\mathfrak{a})\mathfrak{N}(\mathfrak{b})$$

***Proof*:**
By the Chinese remainder theorem:

$$\mathcal{O}_K/\mathfrak{a} \cong \mathcal{O}_K/\mathfrak{p}_1^{n_1} \oplus \cdots \oplus \mathcal{O}_K/\mathfrak{p}_s^{n_s}$$

Hence, we see that the index $[\mathcal{O}_K : \mathfrak{a}]$ is the product of the indexes $[\mathcal{O}_K : \mathfrak{p}_k^{n_i}]$. To find this, notice that the chain

$$\mathfrak{p}^n \subseteq \mathfrak{p}^{n-1} \subseteq \cdots \mathfrak{p} \subseteq \mathcal{O}_K$$

is a sequence of integral extensions[a], so we may use the fact that the index is multiplicative, namely:

$$[\mathcal{O}_K : \mathfrak{p}^n] = [\mathcal{O}_K : \mathfrak{p}][\mathfrak{p}^2 : \mathfrak{p}] \cdots [\mathfrak{p}^n : \mathfrak{p}^{n-1}]$$

We must now show each index has the same size. We shall take advantage of the fact that $\mathcal{O}/\mathfrak{p}$ is finite, and show that each $\mathfrak{p}^i/\mathfrak{p}^{i+1}$ is isomorphic to $\mathcal{O}/\mathfrak{p}$ (meaning they are all of the same size, hence the same index). I claim that $\mathfrak{p}^i/\mathfrak{p}^{i+1}$ is an $(\mathcal{O}_K/\mathfrak{p})$-vector space of dimension 1 with the natural left-multiplication action; this will come down to the multiplicative structure of J_K. To see this, let $a \in \mathfrak{p}^i \setminus \mathfrak{p}^{i+1}$ and take $\mathfrak{b} = (a) + \mathfrak{p}^{i+1} = \gcd((a), \mathfrak{p}^{i+1})$ so that $\overline{\mathfrak{b}}_{\mathfrak{p}^{i+1}} = \overline{(a)}_{\mathfrak{p}^{i+1}}$. Then by construction

$$\mathfrak{p}^{i+1} \subsetneq \mathfrak{b} \subseteq \mathfrak{p}^i$$

From this, we must conclude that $\mathfrak{p}^i = \mathfrak{b}$; this can be seen immediately by realising that $\mathfrak{b} = \gcd((a), \mathfrak{p}^{i+1}) = \mathfrak{p}^i$ by definition of (a). Therefore $\overline{\mathfrak{b}} = a \bmod \mathfrak{p}^{i+1}$ is a basis for the $\mathcal{O}_K/\mathfrak{p}$-vector-space $\mathfrak{p}^i/\mathfrak{p}^{i+1}$, hence $\mathfrak{p}^i/\mathfrak{p}^{i+1} \cong \mathcal{O}_K/\mathfrak{p}$. This can also be demonstrated by taking

$$\mathcal{O} \to \mathfrak{p}^i/\mathfrak{p}^{i+1} \qquad \alpha \mapsto \overline{\alpha a}$$

and seeing the map is surjective since $\mathfrak{p}^i = \gcd(\mathfrak{b}, \mathfrak{p}^{i+1})$ and has kernel $\mathfrak{p}$. Since this is true for all i, $1 \leq i \leq n$:

$$\mathfrak{N}(\mathfrak{p}^n) = [\mathcal{O}_K : \mathfrak{p}^n] = [\mathcal{O}_K : \mathfrak{p}][\mathfrak{p} : \mathfrak{p}^2] \cdots [\mathfrak{p}^{n-1} : \mathfrak{p}^n] = \mathfrak{N}(\mathfrak{p})^n$$

Thus more generally:

$$\mathfrak{N}(\mathfrak{a}\mathfrak{b}) = \mathfrak{N}(\mathfrak{a})\mathfrak{N}(\mathfrak{b})$$

as we sought to show.

[a]This is a *rng* integral extension. Show every $x \in \mathfrak{p}^i$ is a solution to a $\mathfrak{p}^{i+1}$ polynomial

You may ask what is the absolute norm of a prime $\mathfrak{p}$? If $\mathfrak{p}$ were principal, we know it is p^f for appropriate f. For the non-principal case, in corollary 50.3.16, we shall show that if $\mathfrak{p}_k$ lies over p, then $\mathfrak{N}(\mathfrak{p}_k) = p^f$ for an appropriate number f that we shall determine later.

Since the absolute norm is multiplicative and the index is always positive, and fractional ideals also form lattices, we may extend it to be defined on fractional ideals and get a group homomorphism:

$$\mathfrak{N} : J_K \to \mathbb{R}^\times_{>0} \qquad \mathfrak{a} \mapsto \mathfrak{N}(\mathfrak{a})$$

where $\mathfrak{a} = \prod_{\mathfrak{p}} \mathfrak{p}^{n_\mathfrak{p}}$ with $n_\mathfrak{p} \in \mathbb{Z}$.

Corollary 50.2.29: Volume Form Reformulation

Let $I \subseteq K$ be a fractional ideal of a number field K. Then:

$$\mathrm{vol}(I) = \mathfrak{N}(I)\mathrm{vol}(\mathcal{O}_K)$$

***Proof*:**
This is just reformulating proposition 50.1.60 or lemma 50.1.64

Perhaps include the proof in MIT p.18?

Theorem 50.2.30: Class Number

Let K be a number field and let $Cl(K) = J_K/P_k$ be the class group of K. Then $Cl(K)$ is finite.

***Proof*:**

Let $0 \neq \mathfrak{p} \subseteq \mathcal{O}_K$ be a prime ideal of $\mathcal{O}_K$. By lemma 50.2.27,$\mathfrak{N}(\mathfrak{p}) = p^n$, where $n = [\mathcal{O}_K/\mathfrak{p} : \mathbb{Z}/p\mathbb{Z}]$. Given p, there are only finitely many prime ideals $\mathfrak{p}$ such that $\mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$ by proposition 50.1.66 (equivalently, because $p\mathcal{O}_K$ must have a number of terms in it's factorization and $\mathfrak{p}\big|p\mathcal{O}_K$). Thus, there are only finitely many prime ideal of bounded absolute norm. Since every integral ideal factors into prime ideals, we have

$$\mathfrak{N}(\mathfrak{a}) = \mathfrak{N}(\mathfrak{p}_1)^{n_1} \cdots \mathfrak{N}(\mathfrak{p}_k)^{n_k}$$

It follows that there are only a finite number ideals $\mathfrak{a}$ of $\mathcal{O}_K$ with bounded absolute norm $\mathfrak{N}(\mathfrak{a}) \leq M$.

Thus, it suffices to show that each class $[\mathfrak{a}] \in Cl(K)$ contains an integral ideal $\mathfrak{a}_1$ satisfying

$$\mathfrak{N}(\mathfrak{a}_1) \leq \lambda$$

for if there were infinitely many classes, then there would be infinitely many distinct ideals with absolute norm less than λ, contradicting our earlier discussion. By theorem 50.1.65, for any ideal $I \in [\mathfrak{a}]^{-1}$, pick $\alpha \in \mathfrak{a}$ such that

$$|\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)| \leq \lambda \mathfrak{N}(I)$$

By corollary 50.2.18 there exists a J such that $(\alpha) = IJ$. By definition, $J \in [\mathfrak{a}]$. Then:

$$\mathfrak{N}(I)\mathfrak{N}(J) = \mathfrak{N}(\alpha) = |\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)| \leq \lambda \mathfrak{N}(I) \implies \mathfrak{N}(J) \leq \lambda$$

but this now gives that there are only finitely many classes, and hence the class group is finite, as we sought to show.

Definition 50.2.31: Class Number

Let $Cl(K)/ = J_K/P_k$ be the class group of K. Then $h_K = [J_K : P_K]$ is called the *class number* of $Cl(K)$ or K.

A consequence of there being a finite class number is that for every ideal $I \subseteq \mathcal{O}_K$, there exists a minimal number n such that $I^n = (\alpha)$ for some $\alpha \in \mathcal{O}_K$. There is also a minimal number n' such that for *any* ideal of $\mathcal{O}_K$, the ideal to the power of n' is principal. This may encourage thoughts of converting the problem on ideals into one on principal ideals, given there is a way of going back to the original ideals. We shall see that this shall sometimes be the case.

Example 50.2.32: Class Groups

1. Naturally, $|Cl(\mathbb{Q})| = 1$ since $\mathbb{Z}$ is a PID
2. Similarly, $|Cl(\mathbb{Q}(i)| = |Cl(\mathbb{Q}(\sqrt{-3})| = 1$ since $\mathbb{Z}[i]$ and $\mathbb{Z}\left[\frac{1+\sqrt{-3}}{2}\right]$ are PID.
3. Every DVR has ideals of the form (π^n) for appropriate uniformizer π. Thus, the ideal group is isomorphic to $\mathbb{Z}$, and the class group is trivial.
4. Consider $Cl(\mathbb{Q}(\sqrt{-5})$. Since $\mathbb{Z}[\sqrt{-5}]$ is not a Unique Factorization Domain (hence Principal Ideal Domain), we will get a non-trivial class group. Let $K = \mathbb{Q}(\sqrt{-5})$. Choose an integral basis

$$\mathcal{O}_K = \langle 1, \sqrt{-5} \rangle_{\mathbb{Z}}$$

so that $D_k = -20$. Hence, the Minkowski bound gives us:

$$M_k = \sqrt{20}\frac{2}{2^2}\frac{4}{\pi} < 4$$

In fact, we have < 3, but we shall purposefully miss-guess the bound to show how to determine when two ideals belong in the same class group. Consider the ideal $(2), (3)$. Assume that $\mathfrak{p}_2 \big| (2)$. Then we know $\mathfrak{N}(\mathfrak{p}_2) \big| \mathfrak{N}((2)) = 4$. To find $\mathfrak{p}_2 \subseteq \mathcal{O}_K$ consider the map $\varphi : \mathcal{O}_K \to \mathcal{O}_K/(2)$. Since $\mathcal{O}_K/(2)$ is finite the pre-image of a prime ideal of a surjective map is prime, we may find prime ideals of $\mathcal{O}_K/(2)$. By the 4th isomorphism theorem, if $\overline{I} \subseteq \mathcal{O}_K/(2)$ if and only if $(2) \subseteq I$, that is $I\big|(2)$, and hence any prime ideal corresponding to prime ideal of $\mathcal{O}_K/(2)$ divides (2); thus we look for $\varphi^{-1}(P) = \mathfrak{p}_2$. To find such a $\mathfrak{p}_2$, think of $\mathcal{O}_K$ as $\mathcal{O}_K \cong \mathbb{Z}[x]/(x^2+5)$[a] so that we can take:

$$\mathcal{O}_K/(2) \cong \mathbb{Z}[x]/(x^2+5,2) \cong \mathbb{F}_2[x]/(x^2-1) = \mathbb{F}_2[x]/(x+1)^2)$$

Recall that the prime ideals of a ring are in corresponding with the prime ideals of the ring quotiented by the nilradical (see section 32.2). But then we immediately see that the only prime ideal in $\mathcal{O}_K/(2)$ is $(1+x)$. Hence

$$\mathfrak{p}_2 = (1+\sqrt{-5}, 2)$$

Since $\mathfrak{N}(\mathfrak{p}_2)\big|4$, the only possibility is that $\mathfrak{p}^2 = 2$, and indeed:

$$\mathfrak{p}_2^2 = (4, 2+2\sqrt{-5}, -4+2\sqrt{-5}) = (2)$$

Is $\mathfrak{p}_2$ principal? If it was, then $\mathfrak{p}_2 = (a+b\sqrt{-5})$. Then:

$$2 = \mathfrak{N}(\mathfrak{p}_2) = |\mathrm{Nm}_{K/\mathbb{Q}}(a+b\sqrt{-5})| = a^2+5b^2$$

but it's evident this is not possible, hence it is not principal! Similarly with (3), we get:

$$\mathcal{O}_K/(3) \cong \mathbb{Z}[x]/(x^2+5,3) = \mathbb{F}_3[x]/(x^2-1) = \mathbb{F}_2 \oplus \mathbb{F}_3$$

From this, we can see that $3 = \mathfrak{p}_3\mathfrak{p}_3'$ where

$$\mathfrak{p}_3 = (3, 1+\sqrt{-5}) \qquad \mathfrak{p}_3' = (3, 1-\sqrt{-5})$$

Finally, notice that $[\mathfrak{p}_2] = [\mathfrak{p}_3]$. To see this, notice their product is in fact principal:

$$\mathfrak{p}_2\mathfrak{p}_3 = (2, 1+\sqrt{-5})(3, 1+\sqrt{-5}) = (6, 1+\sqrt{-5}, (1+\sqrt{-5})^2) = (1+\sqrt{-5})$$

Hence, $\mathfrak{p}_3 = (1+\sqrt{-5})^{-1}\mathfrak{p}_2$. Evidently, $\mathfrak{p}_3, \mathfrak{p}_3'$ are in the same class. Since there are only two elements, it must be that $Cl(K) \cong \mathbb{Z}/2\mathbb{Z}$.

5. Let $K = \mathbb{Q}(\sqrt{-23})$. Choose $\mathcal{O}_K = \langle 1, \frac{1+\sqrt{-23}}{2}\rangle_{\mathbb{Z}}$ so that it's discriminant is $d_k = -23$ and the Minkowski bound is $M_K = \sqrt{23}\frac{4}{\pi}\frac{1}{2} < 4$. Hence, we again check the prime ideals (2) and (3), noting that the minimal polynomial of the generator is $x^2 - x + 6$:

$$\mathcal{O}_K/(2) \cong \mathbb{F}_2[x]/(t^2 - t)$$

Thus, if $t = \frac{1+\sqrt{-23}}{2}$:

$$(2) = (2, t-1)(2, t)$$

and similarly

$$(3) = (3, t-1)(3, t)$$

Certainly, each prime multiple of (2) and (3) are in the same equivalence class. Is $[(2,t)] = [(3, t-1)]$? Choosing good representatives and multiplying, we get

$$(3,t)(2,t) = (6,t) = (t)$$

hence, we again get that $Cl(K) = \mathbb{Z}/2\mathbb{Z}$.

6. Let $K = \mathbb{Q}(\sqrt{15})$ and $\mathcal{O}_K = \langle 1, \sqrt{15}\rangle_{\mathbb{Z}}$. Then doing the same procedure, we get:

$$(3, \sqrt{15})^2 = (3)$$

How do we know that $(3, \sqrt{15})$ is principal or not? We can see that $a^2 - 15b^2 = 3$ has no solutions using modular arithmetic's, but it will not always be feasible to use this method, so we introduce another. Let's say $(3, \sqrt{15}) = (\alpha)$. Then

$$(\alpha^2) = (3)$$

meaning they are associate, hence $\alpha^2 = 3u$ for $u \in \mathcal{O}_K^\times$. Does there exist such a unit? In section 50.2.4, we shall find this structure. For now, it can be taken for granted that $\mathcal{O}_K^\times = \pm\langle 4 + \sqrt{15}\rangle$ (notice the norm of all such numbers is 1). Then from this we see that no such unit exist, hence $(3, \sqrt{15})$ is not principal.

Notice that all of these examples are for quadratic extensions. It is much more difficult to find prime-factorization for non-quadratic extension since the ring of integers is not easy to find. In the next section, we shall see how we may get some information on the factorization of primes when $\mathcal{O}_K$ is not available

[a]Note how this relied on knowing the structure of $\mathcal{O}_K$! See comment at the end of this example

In general, we have $h_K > 1$. If $h_K = 1$ then we can think of the prime factorization of ideals being the same as the prime factorization of elements as is already well-understood. If $K = \mathbb{Q}(\sqrt{d})$ where d is square-free and negative, then the quadradic extensions in which the class number is 1 is

$$-1, -2, -3, -7, -11, -19, -43, -67, -163$$

For real quadratic extensions, there are a lot more, for example:

$$2, 3, 5, 6, 7, 11, 13, 14, 17, 19, 22, 23, 29, 31, 33, \cdots$$

it is unknown where there are infinitely many real quadratic fields of class number 1, or even if there are infinitely many algebraic number fields (of any degree) with class number 1. In general, it is in fact very difficult to determine some structure in the class group given some class of number fields, with an important notable exception cyclotomic extensions which due to the work of Kenkichi Iwasawa we know behave in a regular way.

The importance of studying cyclotomic extensions links back to Fermat's last theorem which the reader surely recalls states that the equation $x^p + y^p = z^p$ has no nonzero integer solutions for $p \geq 3$. For $p = 2$, we take the cyclotomic extension $\mathbb{Q}(\zeta_4) = \mathbb{Q}(i)$ to get

$$x^2 + y^2 = (x + iy)(x - iy)$$

and then we get the Fermat's twin prime theorem that fully solved the problem in this case. If p is prime, then considering the equation $y^p = z^p - x^p$ over $\mathbb{Q}(\zeta_p)$, we may factor this in $\mathbb{Z}[\zeta_p]$ as

$$\begin{aligned} y^p &= x^p - z^p \\ &= z^p\left(\left(\frac{x}{z}\right)^p - 1\right) \\ &= z^p \prod_{k=0}^{p-1}\left(\frac{x}{z} - \omega_k\right) \\ &= \prod_{k=0}^{p-1} z\left(\frac{x}{z} - \omega_k\right) \\ &= \prod_{k=0}^{p-1}(x - \omega_k z) \end{aligned}$$

where $\omega_k = \zeta_p^k$. Thus, if we assume an existence of a solution, we obtain two multiplicative decompositions of the same number in $\mathbb{Z}[\zeta_p]$. Using this, we can show it contradicts unique factorization *provided* that $\mathbb{Z}[\zeta_p]$ is a unique factorization domain. It was due to some mathematician erroneously assuming unique factorization (equivalently for us, that the class number is always 1) that lead to many fake proofs of Fermat's last theorem[18]. Kummer fixed this by introducing the notion of ideal primes, and translated the statement into one where we must show that $p \nmid h_p$ instead of assuming $h_p = 1$. If this is the case, such a prime is called *regular*, and *irregular* otherwise. Unfortunately, not all primes are regular. Of the first 25 primes less than 100, the primes 37, 59, and 67 are irregular. As of writing this book, it is unknown whether there are infinitely many regular primes.

The regular and irregular prime are going to play important roles in our coming theory, but they do not play much of a role in the eventual proof of Fermat's Last theorem. Due to the work of Gerhard Frey, there was a reformulation of Fermat's last theorem into a statement about elliptic curves. This lead to a new development of mathematics which is beyond the scope of this book, but the interested reader may feel free to search up the *Taniyama-Shimura-Weil Conjecture* to see how Fermat's Last Theorem got translated into a problem of elliptic curves.

We end this section with showing a certain Diophantine equation has no integer solution as it combines nicely all the machinery we have done, and some generalizations that is motivation for class field theory. Starting with the Diophantine equation:

Theorem 50.2.33: No Solution To Diophantine Equation

The equation

$$y^2 = x^3 - 5$$

has no integer solutions

***Proof*:**
Suppose the pair (x, y) is an integer solution. If x is even, then $x^3 - 5$ is odd, and we get

$$y^2 \equiv -1 \bmod 4 \equiv 3 \bmod 4$$

which is easy to check is impossible. Next, x and y must be coprime, for if they weren't then

[18] It is speculated that this is the proof Fermat was referring to as being too long for the margins of his book

their common factor must be 5 (since then $p \big| y^2 - x^3 = -5$), so

$$5^2 y_0^2 = 5^3 x_0 - 5 = 5y_0^2 = 5^2 x_0 - 1$$

But then mod 5 the equation has no solution, hence it has no solution in general.

Now, factoring in $\mathbb{Z}[\sqrt{-5}]$, we get

$$(y - \sqrt{-5})(y + \sqrt{-5}) = (x)^3$$

The ideals $(y - \sqrt{5})$ and $(y + \sqrt{5})$ are coprime; for is $\mathfrak{p}$ divides both, then $\mathfrak{p}\big|(x)^3$, so $\mathfrak{p}\big|(x)$, and since $(y - \sqrt{5}), (y + \sqrt{5}) \subseteq \mathfrak{p}$ then $(y - \sqrt{-5}) + (y + \sqrt{-5}) = 2y \in \mathfrak{p}$ so $\mathfrak{p}\big|(2y)$. Since x is odd and $\mathfrak{p}\big|(x)$, $\mathfrak{p}\big|(y)$. Then since $\mathfrak{p}\big|(y^2 - x^3) = (5)$, we must have $\mathfrak{p} = (\sqrt{-5})$. So $(\sqrt{-5})\big|(y + \sqrt{-5})$, implying $(5)\big|(x)$. But now we can again work in mod 5 and reach a contradiction.

Hence, they are co-prime. Thus, as the left hand side is the cube of (x), we must have:

$$(y - \sqrt{-5}) = \mathfrak{a}^3 \qquad (y + \sqrt{-5}) = \mathfrak{b}^3$$

Finally, since the class group is of size 2 and a third power produces a principal ideal, it must be that $\mathfrak{a}, \mathfrak{b}$ are both principal. Given that the only units are ± 1 (something we shall prove in the next section), we have that:

$$y + \sqrt{-5} = (a + b\sqrt{-5})^3 = a^3 + 3a^2 b\sqrt{-5} - 3ab^2 \cdot 5 - b^4 \cdot 5\sqrt{-5} = (a^3 - 15ab^2) + (3a^2 b - 5b^3)\sqrt{-5}$$

Manipulating and comparing the coefficients of $\sqrt{-5}$, we get that:

$$1 = 3ba^2 - 5b^3 = b(3a^2 - 5b^2)$$

implying $b = \pm 1$ since $a, b \in \mathbb{Z}$. But then:

$$3a^2 - 5 = \pm 1$$

but now this can be inspected to see that it's impossible, hence no such integer solution exists.

Note that a few things lined up well here:

- There were only two units, if there are more then the considerations are more complicated.
- The class group happened to let us deduce the ideal is principal; if the ideal was not principal there would be more to consider.
- The equation was easily factorizable in the extension (ex. $y^2 = x^5 + x + 1$ is a good deal more difficult)
- The factors are coprime.

Exercise 50.2.1

1. Let $A, B \subseteq R$ with $B \subseteq A$ and $A \neq R$. Show there exists a $\gamma \in K$ such that $\gamma B \subseteq R$, but $\gamma B \not\subseteq A$

2. Show that $IJ = (I+J)(I\cap J) = \gcd(I,J)\mathrm{lcm}(I,J)$
3. Let $\alpha \in \mathcal{O}_K \setminus \{0\}$. Show that there exists a $\beta \in \mathcal{O}_K$ st $\alpha\beta \in \mathbb{Z}\setminus\{0\}$
4. Let $K = \mathbb{Q}(\sqrt{-3})$. Show that $\mathcal{O}_K \neq \mathbb{Z}[\sqrt{-3}]$. Show that
5. Show that $3 = x^2 + 5y^2$ has no integer solutions. Note that 3 splits in $\mathbb{Z}[\sqrt{-3}]$ showing that if the ringer of integers is not UFD then it is more complicated to use factorizations.
6. exercise for quotient ideals
   a) here

50.2.4 Dirichlet's Unit Theorem

(Current intuition when it comes to solving equations: we are working with ideals, but equations use elements. We must be concious of the units at play to reduce back to elements)

As we saw in example 50.2.32, it is important to know the unit group of $\mathcal{O}_K$ to find elements in the class group. We start this section by showing that we may embed $\mathcal{O}_K^\times$ to form a lattice, and then use this to find the structure of $\mathcal{O}_K$.

The group $\mathcal{O}_K^\times$ may have some torsion elements, namely all roots of unity that lie in K; this collection is labeled as $\mu(K)$. This group will in fact be determined by the number of embeddings into Minkowski space. On a high-level, the structure of this group is within this diagram:

$$\begin{tikzcd}
K^\times \arrow[r, "\sigma"] \arrow[rr, bend left, "\sigma^\times"] \arrow[d, "N_{K/\mathbb{Q}}"] & K_\mathbb{R}^\times \arrow[r, "\log"] \arrow[d, "\mathrm{nm}"] & {[\prod_\tau \mathbb{R}]^+} \arrow[d, "\mathrm{Tr}"] \\
\mathbb{Q}^* \arrow[r, hook] & \mathbb{R}^* \arrow[r, "\log|\ |"] & \mathbb{R}
\end{tikzcd}$$

where we shall write $K_\mathbb{R}^\times = (\mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2})^\times$. In particular, the top row of the above commutative diagram can be replaced by:

$$\begin{aligned}
\mathcal{O}_K^\times &= \left\{ r \in \mathcal{O}_K \;\middle|\; N_{K/\mathbb{Q}(n)=\pm 1} \right\} \\
S &= \left\{ y \in K_\mathbb{R}^\times \;\middle|\; N(y) = \pm 1 \right\} && \text{norm-one surface} \\
H &= \left\{ x \in \left[\prod_\tau \mathbb{R}\right]^+ \;\middle|\; \mathrm{tr}(x) = 0 \right\} && \text{trace-zero hyperplane}
\end{aligned}$$

Then we get the homomorphism:

$$\mathcal{O}_K^\times \xrightarrow{\sigma} S \xrightarrow{\log} H$$

where $\sigma^\times = \log \circ \sigma$.

Proposition 50.2.34: Roots Of Unity In Group Of Units

Let $\Gamma_K^\times = \sigma^\times(\mathcal{O}_K^\times) \subseteq H$. Then the sequence

$$1 \to \mu(K) \to \mathcal{O}_K^\times \xrightarrow{\sigma^\times} \Gamma_K^\times \to 0$$

is exact.

***Proof*:**
Certainly $\mu(K) \subseteq \ker(\sigma^\times)$. Conversely, say $r \in \mathcal{O}_K^\times$ where $\sigma^\times(r) = 0$. Then $|\tau(r)| = 1$ for each embedding $\gamma : K \to \mathbb{C}$, hence $\sigma(r) = (\tau(r))$ is in a bounded domain of the $\mathbb{R}$-vector space $K_\mathbb{R}$. On the other hand, $\sigma(r)$ is a point of the lattice $\sigma(\mathcal{O}_K)$ of $K_\mathbb{R}$. Thus, the kernel of $\sigma^\times$ can contain only a finite number of elements, and so since it's a finite group, it contains only the roots of unity of $K^\times$.

We now build towards the structure of $\Gamma_K^\times$. Under the right adjustments $\mathcal{O}_K^\times$ can be embedded in a similar way to $\mathcal{O}_K$. Take $\sigma(\mathcal{O}_K^\times) \subseteq \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$. the way a mesh is formed is by taking the logarithm, for $\log(ab) = \log(a) + \log(b)$

$$\sigma^\times : K^\times \to \mathbb{R}^{r_1} \oplus \mathbb{R}^{r_2} \qquad \sigma^\times = \log \circ \sigma$$

Proposition 50.2.35: Multiplicative Group Forms Lattice

Let H be the trace-zero hyperplane. Then $\sigma^\times(\mathcal{O}_K^\times) \subseteq W$ and it is discrete.

***Proof*:**
First, the map $(\mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2})^\times \to \mathbb{R}^{r_1+r_2}$ mapping

$$(a_1, a_2, ..., a_{r_1}, b_1, b_2, ..., b_{r_2}) \mapsto (\log(a_1), ..., \log(a_{r_1}), ..., \log(b_{r_2}))$$

is a proper topological map, in particular the image of a discrete set is discrete. Since $\sigma(\mathcal{O}_K) \subseteq \mathbb{R}^{r_1} \oplus \mathbb{C}^{r_2}$ is discrete. $\sigma(\mathcal{O}_K \setminus \{0\}) \subseteq (\mathbb{R}^{r_1 \oplus r_2})^\times$ is discrete, Next, for $\epsilon > 0$, if $\sigma^\times(\alpha) \subseteq \overline{B_\epsilon}$, then $\forall \varphi \in \mathrm{Hom}_\mathbb{Q}(K, \mathbb{C})$, $e^{-\epsilon} < |\varphi(\alpha)| < e^\epsilon$. Now, since the ball is compact, by properness there are only finitely many α, but that completes the proof.

Theorem 50.2.36: Dirichlet Unit Theorem

The group of units $\mathcal{O}_K^\times$ is the direct product of the finite cyclic group $\mu(K)$ and a free abelian group of rank $r_1 + r_2 - 1$. The free-generators of $\mathcal{O}_K^\times$ are called the *fundamental units* of $\mathcal{O}_K^\times$:

$$\mathcal{O}_K^\times \cong_\mathbb{Z} \mathbb{Z}^{r_1+r_2-1} \oplus \mu(K)$$

We may also characterize $\mathcal{O}_K^\times$ by the following short exact sequence:

$$1 \to \mu(K) \to \mathcal{O}_K^\times \to \Gamma_K^\times \to 0$$

where since the right term is a free $\mathbb{Z}$-module, the sequence splits giving us $\mathcal{O}_K^\times \cong \mu(K) \oplus \Gamma_K^\times$.

***Proof*:**
(Marcus p.100 looks good)

Thus, there exist units $u_1, u_2, ..., u_t$, $t = r_1 + r_2 - 1$ such that for any other unit $u \in \mathcal{O}_K^\times$, it can be written as

$$u = \zeta u_1^{n_1} \cdots u_t^{n_t}$$

where $\zeta \in \mu(K)$ is a root of unity.

Example 50.2.37: Unit Group And Class Group

1. Let $K = \mathbb{Q}(\sqrt{2})$. Then $1 + \sqrt{2}$ generates the free part of the group of units. Similarly, for $K = \mathbb{Q}(\sqrt{3})$, $2 + \sqrt{3}$ generates the free part of the group of units.
2. Let us compute the class group and unit group of $\mathbb{Q}(\sqrt[3]{7})$ Let $K = \mathbb{Q}(\sqrt[3]{7})$ and $s = \sqrt[3]{7}$. We again look for the Minkowski bound. Doing a similar computation as before, we may workout

$$\mathcal{O}_K = \langle 1, \sqrt[3]{7}, \sqrt[3]{7}^2 \rangle$$

Hence, the discriminant is:

$$\det \begin{pmatrix} 1 & \sqrt[3]{7} & \sqrt[3]{7}^2 \\ 1 & \sqrt[3]{7}\zeta_3 & \sqrt[3]{7}^2\zeta_3^2 \\ 1 & \sqrt[3]{7}\zeta_3^2 & \sqrt[3]{7}^2\zeta_3 \end{pmatrix} = -1323$$

Thus:

$$M_K = \sqrt{1323}\frac{6}{27}\frac{4}{\pi} < 11$$

Hence, we check prime ideal $(2), (3), (5), (7)$ of $\mathbb{Z}$. Since the minimal polynomial of $\sqrt[3]{7}$ is $x^3 - 7$, we see that in $\mathbb{F}_p[x]/(x^3 - 7_p)$ we get:

(2) $(x+1)(x^2+x+1)$, hence

$$\mathfrak{p}_2 = (2, s+1) \qquad \mathfrak{p}_2' = (2, s^2+s+1)$$

(3) $(x-1)^3$, hence

$$\mathfrak{p}_3 = (3, s-1)$$

(5) $(x+2)(x^2+3x+4)$, hence

$$\mathfrak{p}_5 = (5, s+2) \qquad \mathfrak{p}_5' = (5, s^2+3s+4)$$

(7) x^3, hence

$$\mathfrak{p}_7 = (7, s) = (s)$$

Thus, just like before we have that $[\mathfrak{p}_2]$, $[\mathfrak{p}_3]$, and $[\mathfrak{p}_5]$ generate $Cl(K)$ (since $[\mathfrak{p}_7] = [1]$). Next, we see that

$$\mathfrak{p}_2\mathfrak{p}_3 = (6) \qquad \mathfrak{p}_3^2\mathfrak{p}_5 = (15)$$

Hence, $[\mathfrak{p}_3] = [\mathfrak{p}_2^{-1}]$ and $[\mathfrak{p}_3^2] = [\mathfrak{p}_5^{-1}]$. Then, with some computation we see that:

$$[\mathfrak{p}_3^3] = [\mathfrak{p}_3]^3 = [\text{id}]$$

Thus, we see that $Cl(K)$ is generated by $[\mathfrak{p}_3]$ and has order 3, hence $CL(K) \cong \mathbb{Z}/3\mathbb{Z}$. However, what if $\mathfrak{p}_3$ is in fact principal? For the sake of contradiction, let's say

$$\mathfrak{p}_3 = (\alpha) \implies \mathfrak{p}_3^3 = (3) = (\alpha^3)$$

Then $\alpha^3 = 3u$ for some unit u. To find u, we find the units of the ring of integers. To find its units, first notice that if:

$$1 = x^3 - 7 = (x - s)(x^2 + sx + s^2)$$

Then $x - s$ is a unit. But then, $x = 2$ works since $8 - 7 = 1$. Then by Dirichlet's Unit Theorem, we have that the rank of the unit group is:

$$r_1 + r_2 - 1 = 1 + 1 - 1 = 1$$

Hence, the group of units is

$$\langle 2 - \sqrt[7]{2} \rangle$$

which is the second object asked of us to find. Using this, we can finally conclude that there is no unit u that satisfies the equation $\alpha^3 = 3u$ (if $\alpha = a + bs + cs^2$, in the process of finding the coefficients a, b, c we shall be forced to have $b = c = 0$). Hence, we may properly conclude that

$$Cl(K) \cong \mathbb{Z}/3\mathbb{Z}$$

completing the proof.

In general, there is an algorithm for computing the ring of units that involved continued fractions. It is not covered in this book, but for those interested see *Borevich and Shafarevich, Number Theory* section 7.3 of chapter 2.

Proposition 50.2.38: Volume Of Unit Lattice

Let $\mathcal{O}_K$ be a ring of integers with unit group $\mathcal{O}_K^*$. Then the volume of the unit lattice $\sigma^\times(\mathcal{O}_K^\times)$ in the hyper-plane H is:

$$\text{vol}\left(\sigma^\times(\mathcal{O}_K^\times)\right) = \sqrt{r_1 + r_2}R$$

where R is the absolute value of the determinant of an arbitrary minor rank $t = r + s - 1$ of the following matrix:

$$\begin{pmatrix} \sigma_1^\times(u_1) & \cdots & \sigma_1^\times(u_t) \\ \vdots & \ddots & \ddots \\ \sigma_{t+1}^\times(u_1) & \cdots & \sigma_{t+1}^\times(u_t) \end{pmatrix}$$

***Proof*:**
computations

Definition 50.2.39: Regulator

The value of R in the above proof is called the *regulator* of $\mathcal{O}_K$.

Exercise 50.2.2

1. What number rings $\mathcal{O}_K$ have finitely many units?

50.3 Extension of Dedekind Domains and Number Fields

In section 26.3, we covered how prime ideals of a base ring correspond to prime ideals in an integral extension. Since all extensions that we are working with are integral extensions, the same theory applies. Working over Dedekind domains, we may further ask if the integral extension of a Dedekind domain is a Dedekind domain. This will be the case, and so we may further factor prime ideals in the extended ring, namely if a prime ideal $\mathfrak{p} \subseteq R$ factors in S where S/R is an integral extension. When focusing on rings of integers $\mathcal{O}_L$, the exploration of how primes factor into larger primes has a lot of consequences on the structure of $\mathcal{O}_L$ itself, and perhaps a bit surprisingly at first sight on the field extension L/K itself. We shall see in the next section that we can use the theory of factorization of prime ideals to classify all abelian extension over $\mathbb{Q}$, this is the *Kronecker-Weber Theorem* promised in example 20.1.29.

First, if R is a Dedekind domain with field of fraction K, $I \subseteq R$ an ideal, through them map $K \hookrightarrow L$ we get $I^e \subseteq \overline{R}^L$. We further generalize this for fractional ideals:

Definition 50.3.1: Extension Of Fractional Ideals

Let R be a Dedekind domain, K it's field of fractions, and L/K be a finite field extension. Then if $I \subseteq K$ is a fractional ideal and $\mathcal{O} = \overline{R}^L$,

$$I_L := I\mathcal{O} = \left\{ \sum a_i b_i \;\middle|\; a_i \in I,\ b_i \in \mathcal{O} \right\}$$

When necessary, the notation $I_{L/K}$ will be used to specify the base field over which I is taken.

It can be verified that $I_L \subseteq L$ is the minimal fractional ideal containing I, that if $M/L/K$, then $(I_L)_M = I_M$, and that $I_L = I \otimes_{\mathcal{O}_K} \mathcal{O}$. The results of lemma 26.2.3 follow quickly giving all the same results. Furthermore since $(I + J)_L = I_L + J_L$:

$$(\gcd_K(I, J))_L = \gcd_L(I_L, J_L)$$

However, by lemma 26.2.3, we so far only have

$$(\mathrm{lcm}_K(I, J))_L \subseteq \mathrm{lcm}_M(I_L, J_L)$$

Note that for $\alpha \in K$, $(\alpha)_L = (\alpha\mathcal{O}_K)_L = \alpha\mathcal{O}_L$, hence principal ideals extend to principal ideals. For reasons that shall become clearer later[19], the map

$$J_K \to J_L \qquad I \mapsto I_L$$

[19] we shall possibly increase the number of primes, hence change the "basis"

is called the *base change map*. To study the fractional ideals of L, the first immediate result we may want is that $\overline{R}^L$ remains a Dedekind domain:

Lemma 50.3.2: Extending Dedekind Domains

Let R be a Dedekind domain with field of fraction K and let L/K be a finite field extension of K. Then $\mathcal{O} = \overline{R}^L$ is a Dedekind domain.

***Proof*:**
By definition, $\mathcal{O}$ is integrally closed, and if $\mathfrak{p} \subseteq \mathcal{O}$ is prime, then $P = \mathfrak{p} \cap R$ is also prime (the contraction of a prime ideal is prime), but P is then maximal in R; hence $(\mathcal{O}/\mathfrak{p})/(R/P)$ is an integral extension over a field meaning $\mathcal{O}/\mathfrak{p}$ is a field, thus $\mathfrak{p}$ is maximal. It remains to show that $\mathcal{O}$ is Noetherian.

For now, we shall prove this for the separable case (the non-separable case has an easier proof with more machinery, and the separable case is all that is needed for number fields). Let $\alpha_1, \alpha_2, ..., \alpha_n$ be a K -basis for L. By multiplying by an appropriate constant, we may let $\alpha_1, \alpha_2, ..., \alpha_n \in \mathcal{O}$ (see proposition 50.1.7). By proposition 50.1.32,

$$\mathcal{O} \subseteq \frac{R\alpha_1}{d} + \cdots + \frac{R\alpha_n}{d}$$

Now, for any ideal $I \subseteq \mathcal{O}$, by the above it is contained in a finitely generated R-module, hence since R is Noetherian I (as a R-module) is finitely generated. But then *a fortiori*, it is a finitely generated $\mathcal{O}$-module, hence a finitely generated ideal, making $\mathcal{O}$ Noetherian.

Example 50.3.3: Dedekind Domains Via Extension
The result above shows that all rings of integers of a finite extension $L/K/\mathbb{Q}$ is a ring of integers. For an example that is not a number ring, take $R = k[x]$ for some field k. As R is a PID, it is a Dedekind domain. Then if $L/k(x)$ is an integral extension, the integral closure of R over L, $S = \overline{R}^L$, is a Dedekind domain. As $L \cong k(x)[y]/(p(y))$ for some irreducible polynomial over $k[x]$ L represents 1-dimensional curves. In section ref:HERE, we shall briefly show these curves are all 1-dimensional smooth curves.

Extending Number Fields

An immediate corollary of lemma 50.3.2 is the following:

Corollary 50.3.4: Extending Number Fields

Let L/K be a finite extension of numbers fields so that $\mathcal{O}_K = \overline{\mathbb{Z}}^K$ and $\mathcal{O} = \overline{\mathcal{O}_K}^L$. Then

$$\mathcal{O} = \mathcal{O}_L = \overline{\mathbb{Z}}^L$$

***Proof*:**
We have to show that $\mathcal{O}_L = \overline{\mathbb{Z}}^L \overset{!}{=} \overline{\mathcal{O}_k}^L = \mathcal{O}$, namely the $\overset{!}{=}$ equality. The $\subseteq$ direction is trivial, so consider the other direction: let $\alpha \in \mathcal{O}$. Then since $\mathcal{O}$ is Dedekind, it is Noetherian, it is finitely generated as a $\mathcal{O}_K$-module. Since $\mathbb{Z}[\alpha] \subseteq \mathcal{O}$:

$$\mathbb{Z}[\alpha] \subseteq \mathcal{O}_K a_1 + \cdots + \mathcal{O}_K a_n$$

Since each $\mathcal{O}_K$ is a finitely generated free $\mathbb{Z}$-module, we have that $\mathbb{Z}[\alpha]$ is a Noetherian $\mathbb{Z}$-module, hence finitely generated. But then by proposition 26.1.4 α is integral over $\mathbb{Z}$, and so $\alpha \in \overline{\mathbb{Z}}^L$, completing the equality.

Thus, when working with finite extensions of number ring L/K, there is a corresponding integral extensions are those of the ring of integers $\mathcal{O}_L/\mathcal{O}_K$ creating the diagram:

$$\begin{tikzcd} K \arrow[r, "\iota"] \arrow[d] & L \arrow[d] \\ \mathcal{O}_K \arrow[r, "\iota"] & \mathcal{O}_L \end{tikzcd}$$

As we saw, principal ideals extend to principal ideals. As it turns out, all non-principal ideals extend to be principal given a large enough extension. This result shall underpin a lot of future simplification and is good to see early on:

Lemma 50.3.5: Number Fields, Extension To Principal

Let $I \subseteq K$ be a fractional ideal where $K/\mathbb{Q}$ is a number field. Then in some finite extension L/K, I_L becomes a principal ideal.

***Proof*:**
As $K/\mathbb{Q}$ is a number fields, by theorem 50.2.30, $Cl(K)$ is finite. Thus, for every $I \in J_K$, there exists an $n \in \mathbb{N}$ such that $I^n = \alpha\mathcal{O}_K$. Let $L = K(\sqrt[n]{\alpha})$. letting $\beta = \sqrt[n]{\alpha}$, we get

$$(I_L)^n = (I_L^n) = (I^n\mathcal{O}_L) = (\alpha\mathcal{O}_L) = (\beta\mathcal{O}_L)^n$$

Thus, by unique factorization:

$$I_L = \beta\mathcal{O}_L$$

as we sought to show.

This result is quite useful; in the right cases we can pass to the field in which all our ideals become principal ideals, proof what we want for principal ideals, then try to come back down (coming back down is often called the descent argument). The following lemma gives a very common descent argument, and is important for computing the absolute norm of extended ideals: since the norm of an ideal gives a measure how space a given ideal is within its Dedekind, extending the domain shall make the given ideal sparser[20]:

[20] This means that the ideal doesn't "extend enough" to cancel the added density given by extending the ring

Lemma 50.3.6: Number Fields, Extension And Absolute Norm

Let $L/K/\mathbb{Q}$ be a finite extension of number fields and $I \subseteq K$ a fractional ideal. Then:

$$\mathfrak{N}_{L/\mathbb{Q}}(I_L) = \mathfrak{N}_{K/\mathbb{Q}}(I)^{[L:K]}$$

***Proof*:**
If $I = (\alpha) = \alpha\mathcal{O}_K$ is principal, then $\mathrm{Nm}(I) = \left|\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)\right|$ and $\mathrm{Nm}(I_L) = \left|\mathrm{Nm}_{L/\mathbb{Q}}(\alpha)\right|$. Since $\alpha \in K$, by proposition 50.1.12

$$\mathrm{Nm}_{L/\mathbb{Q}}(\alpha) = \mathrm{Nm}_{K/\mathbb{Q}}(\alpha)^{[L:K]}$$

In general, $I^n = \alpha\mathcal{O}_K$, thus using the multiplicity of the absolute norm:

$$\mathfrak{N}_{L/\mathbb{Q}}(I_L)^n = \mathfrak{N}_{L/\mathbb{Q}}(I_L^n) = \mathrm{Nm}_{L/\mathbb{Q}}(\alpha\mathcal{O}_L) = \mathrm{Nm}_{L/\mathbb{Q}}(\alpha\mathcal{O}_K)^{[L:K]} = \mathfrak{N}(I^n)^{[L:K]} = \mathfrak{N}_{K/\mathbb{Q}}(I)^{n[L:K]}$$

taking the nth root, and we're done

50.3.1 Ideal Correspondence in Extension

Let L/K be a finite extension, J_K and J_L be the corresponding ideal group. Then we have a map $J_K \to J_L$ given by $I \mapsto I_L$. Do we have a converse map, and if so is it an inverse of the natural extension map? If not, to what degree is it an inverse map? Recall in proposition 26.2.2 that $I \subseteq SI \cap R$, in other words $I \subseteq I_S \cap R$. This can be made an equality for when extending number fields, and further generalized to fractional ideals. Recall that this is not true in general (a counter-example for the general case is $(2) \subsetneq \mathbb{Z} = (2)_{\mathbb{Q}} \cap \mathbb{Z}$), hence this is special for extension of Dedekind domains:

Proposition 50.3.7: Ideal Correspondence In Extensions Of Dedekind Domains

let L/K be a finite field extension with Dedekind domain $\mathcal{O}$ and o respectively. Let $I \subseteq K$ a fractional ideal. Then:

$$I_L \cap K = (I^e)^c = I$$

Hence, unlike for general integral extensions, the contraction is an inverse map to the extension.

***Proof*:**
Let $\beta \in J = I\mathcal{O} \cap K$ so that $\beta = \sum_i a_i k_i$ where $a_i \in I_L$ and $k_i \in o$ (since $\mathcal{O} \cap K = o$). Then the following equality holds:

$$\beta^n = \mathrm{Nm}_{L/K}(\beta) = \prod_\tau \tau(\beta) = \prod_\tau \left(\sum_i k_i \tau(a_i)\right)$$

where the first equality comes from $\beta \in K$, the second comes from the equivalence definition of norm (given an appropriate normal closure N/L), and the third is expanding the definition of β. On the right hand side, we have that the sum is invariant under the Galois group $\mathrm{Gal}_K(N)$ for appropriate normal closure N/L from which we took each τ. Thus, the sum is an element in o, so the product is in $\mathcal{o}$. Then we have $\beta^n \in I^n$, so $\beta \in I$, completing the proof.

Due to the importance of this new paradigm of thinking, two other proofs shall be presented. Notice that $IJ^{-1} \subseteq \mathcal{o}$ and:

$$\mathfrak{N}(IJ^{-1}) = 1$$

giving that $IJ^{-1} = \mathcal{o}$, i.e. $I = J$.

Another proof goes as follows: Since $I \subseteq J$, $I_L \subseteq J_L$. Since $I_L \subseteq J_L \subseteq I_L$ by properties of extensions, $I_L = J_L$. Thus:

$$\mathfrak{N}(J) = \mathfrak{N}(I_L)^{1/[L:K]} = \mathfrak{N}(I)$$

and since $I \subseteq J$, the norms being equal means the index between the two are the same, hence $I = J$.

Note that in the case where $\mathfrak{p}$ is prime, the result can be essentially immediately proven since by proposition 26.2.2 $\mathfrak{p} \subseteq \mathfrak{p}\mathcal{O}_L \cap K$, but since $\mathfrak{p}$ is maximal we get equality.

Corollary 50.3.8: Homomorphism between Extensions of Ideal Group

Let J_K be the ideal group of a Dedekind domain R and let L/K be a finite field extension. Then the map $J_K \to J_L$ mapping $I \mapsto I_L$ is an injective group homomorphism that preserves gcd and lcm.

On the other hand, the map $Cl(K) \to Cl(L)$ is a homomorphism that need not be injective.

For class groups of number fields:

$$\varinjlim_{\substack{K \\ [K:\mathbb{Q}]<\infty}} (Cl(K)) = 0$$

***Proof*:**
By the previous proposition, $I_L = J_K$ if $I = J$, hence the map $\varphi : \mathscr{F}(K) \to \mathscr{F}(L)$ mapping $I \mapsto I_L$ is injective and is certainly a homomorphism by a simple generalization of lemma 26.2.3 (recall that $(\mathfrak{ab})^e = \mathfrak{a}^e\mathfrak{b}^e$ for ideals).

For the map between class groups of number fields, since the extension for every fractional ideal $I \subseteq \mathbb{Q}$, there exists an extension in which it is principle, we see that the colimit can only be satisfied by the trivial group, hence $\varinjlim_{\substack{K \\ [K:\mathbb{Q}]<\infty}} (Cl(K)) = 0$, as we sought to show.

A side consequence of the colimit definition is that we may define

$$Cl(\overline{\mathbb{Q}}) := \varinjlim(Cl(K)) = 0$$

This shows that to some degree, the lack of principal ideals is tied to what algebraic extension we choose. Though the extension map is injective, it is not in general surjective:

Example 50.3.9: Lack of Surjectivity

Let $L = \mathbb{Q}(\sqrt{-5})$ and $K = \mathbb{Q}$ so $\mathcal{O}_L = \mathbb{Z}[\sqrt{-5}]$. Then the (non-principal) ideal $I = (1+\sqrt{-5}, 1-\sqrt{-5})$ are all numbers of the form $m+n\sqrt{-5}$ where m, n are even, so $I \cap \mathbb{Q} = (2)$, hence I lies over (2). However, $I \neq (2)_L$ since I is not principal (recall $(-)_L$ maps principals to principals), and no other ideal can map to I or else I would lie over some different prime, hence I is not an extension. The ideal (2) is still related to I, namely $I^2 = (2)$ (this can be used to show I is not principal).

With these results, we have better control over the extension of primes and primes lying over (resp. lying under) relate:

Proposition 50.3.10: Dedekind Domain, Lying Over And Lying Under

Let $\mathcal{O}/o$ be a finite extension of Dedekind domains given by L/K, $0 \neq \mathfrak{p} \subseteq o$ a prime, and $\mathcal{O} = \overline{o}^L$, $\mathfrak{p}$, where $\mathfrak{p}$ may factor further. Then $\mathfrak{p}$ will never be trivialized in an extension, namely

$$\mathfrak{p}\mathcal{O} \neq \mathcal{O} = (1)$$

***Proof*:**
Let $p \in \mathfrak{p} \setminus \mathfrak{p}^2$. Then

$$(p) = \mathfrak{p}\mathfrak{a} \qquad \mathfrak{p} \nmid \mathfrak{a}$$

Hence, $\mathfrak{p} + \mathfrak{a} = (1)$ $(\gcd(\mathfrak{p}, \mathfrak{a}) = (1))$, and so $a + b = 1$ for $a \in \mathfrak{p}$ and $b \in \mathfrak{a}$. Certainly $b \notin \mathfrak{p}$ so $b\mathfrak{p} \subseteq \mathfrak{p}\mathfrak{a} = (p)$. Now, if $\mathfrak{p}\mathcal{O} = \mathcal{O}$, then $b\mathcal{O} = b\mathfrak{p}\mathcal{O} \subseteq p\mathcal{O}$. hence $b\mathcal{O}_K \subseteq \mathfrak{p}$ so $b = px$ for some $x \in \mathcal{O} \cap K = \mathcal{O}_K$, implying $b \in \mathfrak{p}$ – a contradiction.

Proposition 50.3.11: Equivalence Of Prime Division In Dedekind Domain

Let $\mathfrak{p} \subseteq R$, $\mathfrak{B} \subseteq \mathcal{O}$, $\mathcal{O}/R$ an integral extension where R is a Dedekind Domain. Then the following are equivalent:

1. $\mathfrak{B} \big| \mathfrak{p}\mathcal{O}$
2. $\mathfrak{B} \supseteq \mathfrak{p}\mathcal{O}$
3. $\mathfrak{B} \supseteq \mathfrak{p}$
4. $\mathfrak{B} \cap \mathcal{O} = \mathfrak{p}$
5. $\mathfrak{B} \cap K = \mathfrak{p}$

***Proof*:**
Since we are in a Dedekind domain, $A \big| B$ if and only if $A \supseteq b$, giving us $1 \Leftrightarrow 2$. Since $\mathfrak{B}$ is an ideal of $\mathcal{O}_L$, certainly $2 \Leftrightarrow 3$. We got $3 \Leftarrow 4 \Leftrightarrow 5$ by the above injectivity argument. For $3 \implies 4$, since $\mathfrak{p}$ is maximal and $\mathfrak{B} \cap \mathcal{O}_K \supseteq \mathfrak{p}$, we have either equality or $\mathcal{O}_K$, if $\mathfrak{p} \cap \mathcal{O}_K = \mathcal{O}_K$, then $1 \in Q$, implying $Q = \mathcal{O}_L$, contradicting it's maximality.

Corollary 50.3.12: Lying Over Unique Prime

Let $\mathfrak{p}, \mathfrak{q} \subseteq \mathcal{O}$, $\mathfrak{p} \neq \mathfrak{q}$. Let:

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_n^{e_n} \qquad \mathfrak{q}\mathcal{O}_L = \mathfrak{C}_1^{f_1} \cdots \mathfrak{C}_m^{f_m}$$

Then:

$$\{\mathfrak{B}_1, ..., \mathfrak{B}_n\} \cap \{\mathfrak{C}_1, ..., \mathfrak{C}_n\} = \emptyset$$

that is, extended prime ideals lie over a single prime

***Proof*:**
Let's say the intersection is non-empty, so that $\mathfrak{a}$ is a common factor. Then write:

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{a}^{e_1} \cdots \mathfrak{B}_n^{e_n} \qquad \mathfrak{q}\mathcal{O}_L = \mathfrak{a}^{f_1} \cdots \mathfrak{C}_m^{f_m}$$

Then:

$$(\mathfrak{p})_L^{-1}\mathfrak{p}^{e_1-1}\mathfrak{B}_2^{-e_2} \cdots \mathfrak{B}_n^{-e_n} = \mathfrak{a} = (\mathfrak{q})_L^{-1}\mathfrak{p}^{f_1-1}\mathfrak{C}_2^{-f_2} \cdots \cdots \mathfrak{C}_m^{-f_m}$$

Thus we get:

$$\mathfrak{q}\mathcal{O}_L = (\mathfrak{p})_L\mathfrak{p}^{e_1-1}\mathfrak{B}_2^{-e_2} \cdots \mathfrak{B}_n^{-e_n}\mathfrak{p}^{f_1-1} \cdots \mathfrak{C}_m^{f_m}$$

And in particular:

$$\mathfrak{C}_1^{f_1} \cdots \mathfrak{C}_m^{f_m} = q\mathcal{O}_L \subseteq p\mathcal{O}_L = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_n^{e_n}$$

But then, since $\mathfrak{p}\mathcal{O}_L \cap K = \mathfrak{p}$ and $\mathfrak{q}\mathcal{O}_L \cap K = \mathfrak{q}$, we have by corollary 50.3.8 that:

$$\mathfrak{q} \subseteq \mathfrak{p}$$

which since $\mathfrak{q}$ is maximal and $\mathfrak{p} \neq \mathcal{O}_K$ we have $\mathfrak{q} = \mathfrak{p}$, contradicting the fact that $\mathfrak{p} \neq \mathfrak{q}$, hence, it must be that they share no common factors.

Another proof goes as follows: if $\mathfrak{p} \subseteq \mathcal{O}_K$ is a prime and $\mathfrak{p}_L = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_k^{e_k}$ is the factorization of $\mathfrak{p}_L$ in $\mathcal{O}_L$, then if there was a prime ideal $\mathfrak{q}$ such that $\mathfrak{q} \mapsto \mathfrak{B}_i$ so that by the above for any $1 \leq i \leq k$, then since $\mathfrak{p} \subseteq \mathfrak{B}_i \cap \mathcal{O}_k$, by maximality $\mathfrak{p} = \mathfrak{B}_i \cap \mathcal{O}_K$. Hence if $\mathfrak{q} = \mathfrak{B}_I \cap \mathcal{O}_k$, by injectivity $\mathfrak{p} = \mathfrak{q}$.

Another consequence of the above theorem is that if two prime factorizations of a prime share a factor in an extended ring of integers, they are equal.

Relative Norm

Since the ideals of Dedekind domains share factorization structure to numbers, we may hope there is an equivalent of the field norm $\mathrm{Nm}_{L/K}$ for ideals. by lemma 50.3.5, we may hope that our new relative norm map gives us some information on the power to which we may rise our ideal to get a principal ideal. We now endeavour to find a map $J_L \to J_K$ that behaves more like the field norm and generalizes the absolute norm, which can be thought of as a map:

$$\mathfrak{N}_{L/\mathbb{Q}} : J_L \to \mathbb{Q}_L \cong \mathbb{Q}_{>0}^{\times}$$

In particular, if we work of *Galois* extensions L/K, then we may hope to translate some of the fact that

$$\mathrm{Nm}_{L/K}(\alpha) = \prod_{\sigma} \sigma(\alpha)$$

to prime ideals! In particular, this allows us to bring in the Galois theory in the study of prime ideals!

We start by showing the case for Galois extensions, the general case can be inferred from the Galois case. Given a Galois extension L/K with Galois group $G = \mathrm{Gal}_K(N)$, then we can recover L from K using G by taking $L^G = K$, hence $\mathcal{O}_L^G = \mathcal{O}_K$. Certainly, if $\tau \in G$ and $\mathfrak{a} \subseteq L$, then $\tau(\mathfrak{a}) \subseteq L$ Since L/K is normal, and hence $\tau(\mathfrak{a})$ is well-defined. It may be tempting to then say that $J_L^G = J_K$ and hence defining $J_L \to J_K$ by taking

$$I \mapsto \prod_{\tau} \tau(I)$$

However, it is not the case that $J_L^G = J_K$; the ideal in example 50.3.9 is invariant under the Galois group, but certainly an ideal of $\mathbb{Z}$. We fix this by the following:

Definition 50.3.13: Relative Norm

Let L/K be a finite field extension and $I \subseteq K$ a fractional ideal in L. Then the *relative norm* or *ideal norm* of L with respect to K is:

$$\mathfrak{N}_{L/K}(I) = \left(\left\{\mathrm{Nm}_{L/K}(\alpha) \;\middle|\; \alpha \in I\right\}\right) \in J_K$$

namely, $\mathrm{Nm}_{L/K}(I)$ is the ideal generated by all norms of elements in I.

Note that this is well-defined since $\mathrm{Nm}_{L/K}(\alpha) \in K$ as every minimal polynomial $m_{\alpha,K}(x) \in K[x]$. The norm as defined above gives us a map $\mathfrak{N}_{L/K} : J_L \to J_K$. The field norm can be thought of as the ideal norm, for example take

$$\mathfrak{N}_{\mathbb{Q}(\sqrt{2})/\mathbb{Q}}((\sqrt{2})) = \left(\left\{\mathrm{Nm}_{L/K}\left(\sqrt{2}b\right) \;\middle|\; \sqrt{2}b \in \sqrt{2}\mathbb{Z}\right\}\right) = (2)$$

suggesting that $(\mathrm{Nm}_{L/K}(\alpha)) = \mathfrak{N}_{L/K}((\alpha))$, which will indeed be the case and shall be proved after the next theorem. An important reason to choose this definition is that it works well with extension: Let $J_L \xrightarrow{\mathrm{Nm}_{L/K}} J_K \xrightarrow{I_L} J_L$. What will be the image of an ideal in this chain? In the simplest case, we may take principal ideal $\alpha\mathcal{O}_L \subseteq \mathcal{O}_L$ where $\alpha \in \mathcal{O}_K$. Then it's image is $\alpha\mathcal{O}_K$, and it's extension is $\alpha\mathcal{O}_L$. Thus for the simplest type of integral principal ideal, the map is a right-inverse. For more general cases, it is not necessarily a right inverse (it cannot be, since I_L is not surjective). However, the behavior of the image is well-behaved, and in fact tied with the "almost" definition of the ideal norm presented earlier:

Theorem 50.3.14: Ideal Correspondence in Extension

Let $N/L/K$ be finite field extension where N/K is a normal extension so that $G = \mathrm{Gal}_K(N)$. Then:

$$(\mathfrak{N}_{L/K}(I))_L = \prod_{\tau \in G} (\tau I)_{L/\tau K} =: \mathrm{Nm}'_{L/K}(I)$$

In particular

$$\begin{Bmatrix} \text{Fractional ideals of} \\ \mathcal{O}_K \end{Bmatrix} \underset{\mathfrak{N}_{L/K}}{\overset{I_L}{\rightleftarrows}} \begin{Bmatrix} \text{Fractional Ideals of} \\ \mathcal{O}_L \end{Bmatrix}$$

***Proof*:**
Let $I \subseteq L$ be a fractional ideal. Without loss of generality, we may make I integral. Then, certainly an ideal is a subset of it's extension (given the natural embedding) $\sigma_i I \subseteq (\sigma_i I)_{L/\sigma_i K}$, and so by definition of $\mathrm{Nm}'_{L/K}(I)$, forall $\alpha \in I$:

$$\mathrm{Nm}_{L/K}(\alpha) = \prod_{\tau} (\tau(\alpha)) \in \mathrm{Nm}'_{L/K}(I)$$

Hence $\mathrm{Nm}_{L/K}(I) \subseteq \mathrm{Nm}'_{L/K}(I)$. Extending both sides, we get $(\mathrm{Nm}_{L/K}(I))_L = (\mathrm{Nm}'_{L/K}(I))_L = \mathrm{Nm}'_{L/K}(I)$. Hence, since we are in a Dedekind domain, there exists an [integral] ideal J such that

$$\mathrm{Nm}_{L/K}(I)_L = J\mathrm{Nm}'_{L/K}(I)$$

We want to show that $J = (1)$. We shall use lemma 50.6.1, namely that there exists an ideal $B \subseteq K$ relatively prime to $J \cap K$ such that JB is principal, say $JB = (b)$ $(b \in K)$. Then since J is fixed under $\mathrm{Gal}_K(L)$, each $(\tau B)_{L/\tau K})$ is relatively prime to J for each τ. Then since $b \in J$:

$$\begin{aligned} \mathrm{Nm}_{L/K}(I) &\supseteq \left(\prod_{\tau} \tau(b) \right) \\ &= \left(\prod_{\tau} (\tau(B))_{L/\tau K)} \right) \left(\prod_{\tau} (\tau(J))_{L/\tau K} \right) \end{aligned}$$

Thus, $\prod_{\tau} (\tau B)_{L/\tau K}$ is a multiple of J. However, $(\tau B)_{L/\tau K}$ is relatively prime to J, hence it must be that $J = (1)$, as we sought to show.

Lemma 50.3.15: Ideal Norm Properties

Let $M/L/K$ be algebraic number fields, $\mathfrak{a}, \mathfrak{b} \subseteq M$ be ideals, $I \subseteq K$ an ideal, and $a \in M$ an element. Then:

1. $\mathfrak{N}_{M/K}(a) = (\mathrm{Nm}_{M/K}(a)) = \left(\prod_{\sigma \in \mathrm{Gal}_K(M)} \sigma(a)\right)$
2. $\mathfrak{N}_{L/K}(\mathfrak{N}_{M/L}(\mathfrak{a})) = \mathfrak{N}_{M/K}(\mathfrak{a})$
3. $\mathfrak{N}_{M/k}(\mathfrak{a}\mathfrak{b}) = (\mathrm{Nm}_{M/k}(\mathfrak{a}))\mathrm{Nm}_{M/k}(\mathfrak{b})$
4. $I^{[M:K]} = \mathfrak{N}_{M/K}((I)_M)$
5. $(\mathfrak{N}_K(I)) = \mathfrak{N}_{K/\mathbb{Q}}(I)$

***Proof*:**
Note that for all of these equalities, we immediately have $\supseteq$, hence we want to show $\subseteq$ for each of these.

1. comes straight from the definition
2. exercise
3. exercise
4. Use lemma 50.3.6 and the finiteness of the class group to make an argument on principal ideals, we see that if we take $J_K \xrightarrow{I_L} J_L \xrightarrow{\mathrm{Nm}_{L/K}} J_K$, we pick up a $[L : K]$ exponent.
5. use part (1)

Corollary 50.3.16: Relative Norm Of Prime Ideal

Let L/K be a finite extension of number fields and let $\mathfrak{B}$ lie above $\mathfrak{p}$. Then if $f = [\mathcal{O}_L/\mathfrak{B} : \mathcal{O}_K/\mathfrak{p}]$, then:

$$\mathfrak{N}_{L/K}(\mathfrak{B}) = \mathfrak{p}^f$$

***Proof*:**
Using the above lemma:

$$\begin{aligned}(\mathfrak{N}_L(\mathfrak{p}_L)) &= \mathfrak{N}_{L/\mathbb{Q}}(\mathfrak{p}_L)\\ &= \mathfrak{N}_{K/\mathbb{Q}}(\mathfrak{p}^{[L:K]})\\ &= (\mathfrak{N}_K(\mathfrak{p}))^{[L:K]}\end{aligned}$$

Thus, $\mathfrak{N}_{L/K}(\mathfrak{B})$ is a power of $\mathfrak{p}$ by the 4th point in the above lemma. and by the 2nd we get:

$$\mathfrak{N}_{K/\mathbb{Q}}(\mathfrak{N}_{L/K}(\mathfrak{B})) = \mathfrak{N}_{K/\mathbb{Q}}(\mathfrak{p}^f) \implies \mathfrak{N}_{L/K}(\mathfrak{B}) = \mathfrak{p}^f$$

as we sought to show.

The relative norm can in fact be defined to be the unique group homomorphism where

$$\mathfrak{N}(\mathfrak{B}) = \mathfrak{p}^{[\mathcal{O}_L/\mathfrak{B}:\mathcal{O}_K/\mathfrak{p}]}$$

which is left as an exercise. By multiplicity, we get that in general:

$$\mathfrak{N}_{L/K}(\mathfrak{p}\mathcal{O}_L) = \prod_i \mathfrak{N}_{L/K}\mathbb{F}_{L/K}(\mathfrak{B}_i)^{e_i} = \prod_i \mathfrak{p}^{f_i e_i}$$

Corollary 50.3.17: Ideal Norm Correspondence Not Galois

Let $M/L/K$ were field extensions, M/K normal but not necessarily L/K. Then

$$(\mathrm{Nm}_{L/K}(I))_M = \prod_{\tau \in \mathrm{Gal}_K(M)/\mathrm{Gal}_L(M)} \tau(I_M)$$

***Proof*:**
exercise

With the relative norm defined, it is perhaps natural to think there is a relative discriminant:

Definition 50.3.18: Relative Discriminant

Let L/K be a finite extension of number fields. Then:

$$\mathrm{disc}'_{L/K}(\mathcal{O}_L) = \left(\left\{\mathrm{disc}_{L/K}(\alpha_1, \alpha_2, ..., \alpha_n) \;\middle|\; \alpha_1, \alpha_2, ..., \alpha_n \text{ basis for } \mathcal{O}_L \right\}\right)$$

is the *relative discriminant* of L with respect to K.

This won't come up much, but is useful in a couple of tower arguments later on.

Though we have characterized a correspondence of the ideals, it is more difficult to characterize I_L. In the following section, we characterize prime extensions, and take advantage of the fact that the factorization to give us a characterization of I_L.

50.4 Prime Factorization in Extension

Since $\mathcal{O}$ is a Dedekind domain by lemma 50.3.2, we have that $\mathfrak{p}\mathcal{O}$ decomposes uniquely into a product of prime ideals:

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_r^{e_r}$$

If it is clear from context, we shall often write $\mathfrak{p}$ instead of $\mathfrak{p}\mathcal{O}$. Sometimes, we shall also write $\mathfrak{p}_L$ for $\mathfrak{p}\mathcal{O}_L$. We shall *almost always* find exactly how $\mathfrak{p}\mathcal{O}$ decomposes, sometimes without requiring knowledge of the ring of integers. When the extension L/K is Galois, we shall have even more control, and if L/K is not Galois, we can take $M/L/K$ to be a Galois extension, work within the Galois, and see if the results can be translated back to L/K.

Let's say $\mathfrak{B}$ lies over $\mathfrak{p}$ and that $\mathfrak{B}$ is in the prime decomposition of $\mathfrak{B}$ [21]. Then we have two important quantities associated to $\mathfrak{B}$: it's power in the prime decomposition, and the index $[\mathcal{O}/\mathfrak{B} : \mathcal{O}_K/\mathfrak{p}]$, that is the degree of the extension of the residue field. These quantities are given a name:

Definition 50.4.1: Ramification Index and Inertia Degree

Let R be a Dedekind domain, $K = \text{Frac}(R)$, L/K be a finite field extension, $\mathcal{O} = \overline{R}^L$ and $\mathfrak{p} \subseteq R$ a prime ideal. If $\mathfrak{B}_i$ is a prime in $\mathcal{O}$ lying above $\mathfrak{p}$, then it's degree is called the *ramification index* and is often denoted

$$e(\mathfrak{B}_i/\mathfrak{p}) \qquad \text{where} \qquad \mathfrak{B}^{e(\mathfrak{B}_i/\mathfrak{p})} \| \mathfrak{p}\mathcal{O}$$

or e_i for short, where $\|$ means *maximally divides.* The degree of the field extension

$$f(\mathfrak{B}_i/\mathfrak{p}) = [\mathcal{O}/\mathfrak{B}_i : R/\mathfrak{p}]$$

or f_i for short, and is called is called the *inertia degree* or *residue field degree* of $\mathfrak{B}_i$ over $\mathfrak{p}$.

For future reference, it will be important to keep track to "how much" a prime ideal splits. This will share strong similarities to the splitting of polynomials[22] (recall how "rare" an irreducible polynomial is inseparable)? This prompts the following vocabulary:

Definition 50.4.2: Split, Unramified, and Totally Ramified Primes

Let $\mathfrak{p} \subseteq R$ be a prime ideal of a Dedekind domain R, $K = K(R)$, L/K a finite extension, and $\mathcal{O} = \overline{R}^L$. Then given

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_g^{e_g}$$

If $g = [L : K]$, then $\mathfrak{p}$ is said to *split completely* ($e_i = f_i = 1$), giving:

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1 \cdots \mathfrak{B}_n$$

If $e_i = 1$ for all i (but some f_i are not necessarily 1), then we sy that $\mathfrak{p}$ is *unramified* and (if the residue field is separable):

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1 \cdots \mathfrak{B}_g$$

for some $g \leq n$. If $g = 1$, then $\mathfrak{p}$ is said to be *totally ramified*, *indecomposable*, or *nonsplit* if:

$$\mathfrak{p} = \mathfrak{B}_1^{e_1}$$

and we know there is only a single prime ideal $\mathfrak{B}_i$ lying over $\mathfrak{p}$.

Most of the time, we shall work in the case of character zero extensions, hence L/K is separable. In this case, the values e_i and f_i are connected; if $\mathfrak{p}$ factors in an extension, then there is a simple equation the ramification and inertia degree must satisfy which equals the degree of the extension:

[21] we shall soon show all primes lying above $\mathfrak{p}$ will be part of the prime decomposition

[22] Though there shall be important failures when this comparison will *not* hold! This shall be elaborated soon

Proposition 50.4.3: Fundamental Identity

Let L/K be a finite separable extension, $n = [L:K]$, $\mathcal{O} = \overline{\mathcal{O}_K}^L$, and $\mathfrak{p} \subseteq \mathcal{O}_K$ a prime ideal. If

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_g^{e_g}$$

is the prime decomposition of $\mathfrak{p}\mathcal{O}$ and f_i is the inertia degree of $\mathfrak{B}_i$ over $\mathfrak{p}$, then

$$\sum_i^g e_i f_i = n$$

***Proof*:**
Using absolute norms, this theorem becomes almost immediate, since:

$$\begin{aligned}\mathfrak{N}(\mathfrak{p})^{[L:K]} &\overset{\text{lem } 50.3.6}{=} \mathfrak{N}(\mathfrak{p}\mathcal{O}) = \mathfrak{N}\left(\prod_i \mathfrak{B}_i^{e_i}\right) \overset{\text{prop } 50.2.28}{=} \prod_i \mathfrak{N}(\mathfrak{B}_i)^{e_i} \\ &\overset{\text{cor } 50.3.16}{=} \prod_i \mathfrak{N}(\mathfrak{p})^{e_i f_i} = \mathfrak{N}(\mathfrak{p})^{\sum_i e_i f_i}\end{aligned}$$

taking log of both sides gives us:

$$n = [L:K] = \sum_I e_i f_i$$

This can also be proven directly: first by the CRT we have

$$\mathcal{O}/\mathfrak{p}\mathcal{O} \cong \bigoplus_i^r \mathcal{O}/(\mathfrak{B}_i^{e_i})$$

Next, we have that $\mathcal{O}/\mathfrak{p}\mathcal{O}$ and $\mathcal{O}/\mathfrak{B}_i^{e_i}$ are vector-spaces over $k = \mathcal{O}_K/\mathfrak{p}$. Hence, it suffices to show that

$$\dim_k(\mathcal{O}/\mathfrak{p}\mathcal{O}) = n \qquad \dim_k(\mathcal{O}/(\mathfrak{B}_i^{e_i})) = e_i f_i$$

To show the first equality, since $\mathcal{O}$ is a finitely generated $\mathcal{o}$-module, pick $x_1, x_2, ..., x_m \in \mathcal{O}$ such that $\overline{x_1}, ..., \overline{x_n}$ is a k-basis for $\mathcal{O}/\mathfrak{p}\mathcal{O}$. If $x_1, x_2, ..., x_m$ is a basis for L/K, then we're done. Let's first show they are linearly independent. For the sake of contradiction, let's say they weren't so that $x_1, x_2, ..., x_m$ are linearly dependent over K. Then they are linearly dependent over $\mathcal{O}_K$ by Gauss's lemma. Hence, there are elements $a_1, a_2, ..., a_m \in \mathcal{O}_K$ that are not all zero such that

$$a_1 x_1 + \cdots + a_m x_m = 0$$

We want to use this to show that the congruent mod $\mathfrak{p}$ is also linearly dependent. To that end, consider $\mathfrak{a} = (a_1, a_2, ..., a_m)$. Take $a \in \mathfrak{a}^{-1}$ such that $a \notin \mathfrak{a}^{-1}\mathfrak{p}$ so that $a\mathfrak{a} \not\subseteq \mathfrak{p}$. Hence, the element $aa_1, ..., aa_m$ lie in $\mathcal{O}_K$, but are not all in $\mathfrak{p}$. Hence, we have:

$$aa_1 x_1 + \cdots + aa_m x_m = 0 \text{ mod } \mathfrak{p}$$

giving linear dependence of the elements $\overline{x_1}, ..., \overline{x_m}$ over k – a contradiction.

Next, for spanning, consider the $\mathcal{O}_K$-module

$$M = \mathcal{O}_K x_1 + \cdots \mathcal{O}_K x_m$$

We shall show we can "upgrade" this to $L = Kx_1 + \cdots + Kx_m$. Consider $N = \mathcal{O}/M$. Since $\mathcal{O} = M + \mathfrak{p}\mathcal{O}$, $\mathfrak{p}N = N$. Since $\mathcal{O}$ is finitely generated (being a Dedekind domain), N is finitely generated. If $\alpha_1, \alpha_2, ..., \alpha_s$ are generators of N, then since $\mathfrak{p}N = N$:

$$\alpha_i = \sum_j a_{ij}\alpha_j \qquad a_{ij} \in \mathfrak{p}$$

Now, define the matrix $A = (a_{ij}) = I$ where I is the identity matrix of rank s. Let $B = A^*$ be the adjoint of A whose entries are the minors of rank $(s-1)$ of A. Then

$$A(\alpha_1, ..., \alpha_s)^t = 0 \qquad BA = \det(A)I = dI$$

Thus:

$$0 = BA(\alpha_1, \alpha_2, ..., \alpha_s)^t = d\alpha_1, ..., d\alpha_s)^t$$

thus, $dN = 0$, implying $d\mathcal{O} \subseteq M = \mathcal{O}_K x_1 + \mathcal{O}_K x_2 + \cdots + \mathcal{O}_K x_m$. Importantly, $d \neq 0$ since $d = \det((a_{ij}) = I) \equiv (-1)^s \mod p$ since $a_{ij} \in \mathfrak{p}$. Thus:

$$L = dL = Kx_1 + Kx_2 + \cdots + Kx_m$$

showing that it spans L/K, and hence it is a basis, establishing the first equality.

For the second, recall in proposition 50.2.28 that each $\mathfrak{B}_i^{n+1}/\mathfrak{B}_i^n \cong_{\mathcal{O}/\mathfrak{B}_i} \mathcal{O}/\mathfrak{B}_i$. Hence, since $f_i = [\mathcal{O}/\mathcal{B}_i : \mathcal{O}_k/\mathfrak{p}]$, we get

$$n = \dim_k(\mathcal{O}/\mathfrak{p}\mathcal{O}) \sum_i \dim_k(\mathcal{O}/(\mathfrak{B}_i^{e_i})) = \sum_i^r e_i f_i$$

as we sought to show.

Corollary 50.4.4: Multiplicity of Ramification And Inertia

Let $M/L/K$ be a finite extension of number fields. Then:

$$e_{M/K} = e_{M/L}e_{L/K} \qquad f_{M/K} = f_{M/L}f_{L/K}$$

***Proof*:**
immediate consequence of the arguments in the above theorem

Hence, we have a measure of how much a prime ideal splits in an extension.

Example 50.4.5: Decomposing Prime

1. It is possible that $\mathfrak{p}$ is totally ramified where $e_1 > 1$ and $f_1 = 1$: take $L = \mathbb{Q}(\sqrt{3})$ and $K = \mathbb{Q}$ with $I = (3)$. Then $(3)\mathcal{O} = (\sqrt{3})^2$

2. Similarly, it is possible that $\mathfrak{p}$ is totally ramified and $e_1 = 1$ and $f_1 > 1$: take $K = \mathbb{Q}$, $L = \mathbb{Q}(\sqrt{3})$, but $I = (5))$.

3. Let us consider the inertia degree to get some structure of the Dedekind domain. Let $L = \mathbb{Q}(\sqrt[3]{2})$ and $L/\mathbb{Q}$ be a finite extension. Since it is always the case that $\mathbb{Z}[\sqrt[3]{2}] \subseteq \mathcal{O}_L$ [a], Take $I = (\sqrt[3]{2}) \subseteq \mathcal{O}_L$, $I \cap \mathbb{Q} = (2)$, and $\mathfrak{N}((\sqrt[3]{2})) = |\mathrm{Nm}_{L/\mathbb{Q}}(\sqrt[3]{2})| = 2$, and $2 = (\sqrt[3]{2})^3$. Hence, $f_1 = 1$, meaning
$$[\mathcal{O}_L/\sqrt[3]{2}\mathcal{O}_L : \mathbb{Z}/2\mathbb{Z}] = 1$$
implying both fields only have two elements, hence
$$\mathcal{O}_L/\sqrt[3]{2}\mathcal{O}_L \cong \mathbb{Z}/2\mathbb{Z}$$
Notice how this also gave information on the ring of integers,

4. Let $\mathcal{O}_K = \mathbb{Z}[i]$ so that $2 = (1+i)(1-i)$. Then $\mathcal{O}_K/2\mathcal{O}_K$ has order 4 (look at it'snorm), and certainly $2\mathcal{O}_K \subseteq (1-i)$, hence $|\mathcal{O}_K/(1-i)| \big| 4$, which by direct computation we may see that $|\mathcal{O}_K/(1-i)| = 2$, hence $f = 1$. On the other hand, we can see that 3 is prime in $\mathcal{O}_K$, and $|\mathcal{O}_K/3\mathcal{O}_K| = 9$, giving $f_{3\mathcal{O}_K/3} = 2$.

[a] In fact, they are equal in this case, which is not needed at the moment

Since the factorization of $\mathfrak{p} \subseteq K$ in L/K is tied to the degree of L/K, we may venture into hoping that the structure of L/K may reflect something about the factorization of $\mathfrak{p}$. A natural question we may ask here is how do we find the prime factors in the extension? Finding them is split into two cases: the "good" primes and the "bad' primes. We shall see that the power of the exponentials has a lot to do with it. This is because we shall see that most primes shall decompose with ramification index 1, since it will correspond to the splitting of a polynomial in separable extension (note that all number field extensions are separable). However, as we saw it is possible that prime may have higher ramification index, however it is impossible that a polynomial splits irreducibly with multiplicity higher than 1 over a separable extension. Hence, we may think of such prime as "bad" primes. In the following we shall show how to find primes whose factorization mirrors that of a minimal polynomial, and how to detect when it is not the case.

let L/K be a finite separable extension. Then by the primitive extension theorem, there exists a $\theta \in K$
$$L = K(\theta)$$
Usually, we shall let L be Galois so that we may computationally find this element, namely it must not be fixed by any element of $\mathrm{Gal}_K(L)$ (hence, not in any intermediate extension). In fact, we may find θ so that $\theta \in \mathcal{O}_K$: if $L = K(\alpha)$, since $L = \overline{\mathcal{O}_K}^L$ we may multiply out the denominator by d to get $\alpha = \theta$; let us simply re-define θ to be in $\mathcal{O}_L$. Now we have a single element, θ with minimal polynomial $m_{K,\theta}(x)$ which characterizes L. It would be nice to say something about the nature of the decomposition of $\mathfrak{p}$ in $\mathcal{O}_L$ given this information. In the good case, we shall be able to do so, and in the bad case we shall require a bit more work. In particular, a finite number of primes ideals will be exclude; only those that are relatively prime to an ideal known as the *conductor* of the ring $\mathcal{O}_K[\theta]$ will be considered:

Definition 50.4.6: Conductor

Let $\mathcal{O}_K[\theta]$ be the ring of integers extended by θ. Then the conductor of $\mathcal{O}_K[\theta]$, is the largest ideal $\mathscr{F}_\theta \subseteq \mathcal{O}_L$ which is contained in $\mathcal{O}_K[\theta]$:

$$\mathscr{F}_\theta = \{\alpha \in \mathcal{O}_L \mid \alpha\mathcal{O}_L \subseteq \mathcal{O}_K[\theta]\}$$

In the case where $K = \mathbb{Q}$ and $\mathcal{O}_\mathbb{Q} = \mathbb{Z}$, then $\mathscr{F}_\theta = \{\alpha \in \mathcal{O}_L \mid (\alpha)_L \subseteq \mathbb{Z}[\theta]\}$. Since $\mathcal{O}_L$ is a finitely generated $\mathcal{O}_K$ module, $\mathscr{F}_\theta \neq 0$. The conductor is a measure of the "bad primes" (hence the ramification). In our case, the conductor is never 0, but it may be that $\mathscr{F}_\theta = (1)$, in which case the bad primes will be "tame" (or the field is "tamely ramified")

Theorem 50.4.7: Dedekind-Kummer Theorem

Let L/K be a separable extension, $L = K(\theta)$ where θ is a primitive element where $m_{\theta,K}(x) \in \mathcal{O}_K[x]$. Let $\mathfrak{p}$ be a prime ideal of $\mathcal{O}_K$ which is relatively prime to the conductor $\mathscr{F}$ of $\mathcal{O}_K[\theta]$ and let $m(x) = m_{\theta,K}(x)$ and consider:

$$\overline{m}(x) = \overline{m}_1(x)^{e_1}\cdots\overline{m}_r(x)^{e_r} \bmod \mathfrak{p}$$

be the factorization of the polynomial $\overline{m}(x) = m(x) \bmod \mathfrak{p}$ into irreducible over the residue field $\mathcal{O}_K/\mathfrak{p}$. Then

$$\mathfrak{B}_i = \mathfrak{p}\mathcal{O} + m_i(\theta)\mathcal{O} = (\mathfrak{p}\mathcal{O}, m_i(\theta))_L$$

are different prime ideals of $\mathcal{O}$ over $\mathfrak{p}$. The inertia degree f_i of $\mathfrak{B}_i$ is the degree of $\overline{m}_i(x)$, and

$$\mathfrak{p} = \mathfrak{B}_1^{e_1}\cdots\mathfrak{B}_r^{e_r}$$

Note that if $\mathfrak{p}$ is not relatively prime to $\mathscr{F}$, then $\mathfrak{p}$ is not relatively prime to the relative discriminant, hence $\mathfrak{p}$ will surely ramify, and hence this is a problem for primes whose ramification is somehow "more bad"; such primes are often said to have *wild ramification* and they shall be studied in section 50.4.3.

***Proof*:**
Let $\mathcal{O}' = \mathcal{O}_K[\theta]$ and $\overline{\mathcal{O}_K} = \mathcal{O}_K/\mathfrak{p}$. The key isomorphism that we can establish since $\mathfrak{p}$ is relatively prime to the conductor $\mathscr{F}_\theta$ is:

$$\mathcal{O}_L/\mathfrak{p}\mathcal{O}_L \overset{!}{\cong} \mathcal{O}_K[\theta]/\mathfrak{p}\mathcal{O}_K[\theta] \cong \overline{\mathcal{O}_K}[x]/(\overline{m}(x))$$

where the $\overset{!}{\cong}$ isomorphism is the hard one to prove; the 2nd one comes from:

$$\mathcal{O}_K[\theta]/\mathfrak{p} \cong \mathcal{O}_K[x]/(\mathfrak{p}, m(x)) \cong \overline{\mathcal{O}}_K[x]/(\overline{m}(x))$$

For the $\overset{!}{\cong}$ isomorphism, from the relative primality of $\mathfrak{p}$ and $\mathscr{F}$ we get $\mathfrak{p}\mathcal{O}_L + \mathscr{F} = \mathcal{O}_L$. Since $\mathscr{F} \subseteq \mathcal{O}' = \mathcal{O}_k[\theta]$, we get that $\mathcal{O}_L = \mathfrak{p}\mathcal{O}_L + \mathcal{O}'$. From this, we get that the homomorphism

$$\mathcal{O}' \to \mathcal{O}_L/\mathfrak{p}\mathcal{O}_L$$

is surjective (every element of $\mathcal{O}_L$ is a linear combination of an element in $\mathcal{O}'$ and $\mathfrak{p}\mathcal{O}_L$) with kernel $\mathfrak{p}\mathcal{O}_L \cap \mathcal{O}'$. What's left to show is that this kernel equals $\mathfrak{p}\mathcal{O}'$. $\mathfrak{p}\mathcal{O}' \subseteq \mathfrak{p}\mathcal{O}_L \cap \mathcal{O}'$ is immediate, so for the other direction since $\mathfrak{p} + \mathscr{F} \cap \mathcal{O}_K = \gcd(\mathfrak{p}, \mathscr{F} \cap \mathcal{O}_K) = (1)$, $1 = pq + fs$ for some $p \in \mathfrak{p}$, $f \in \mathscr{F} \cap \mathcal{O}_K$. Then certainly $1 = pq + fs \in \mathfrak{p} + \mathscr{F}$, hence $\mathcal{O}' = \mathfrak{p} + \mathscr{F}$. Then:

$$\begin{aligned}\mathfrak{p}\mathcal{O}_L \cap \mathcal{O}' &= (\mathfrak{p} + \mathscr{F})(\mathfrak{p}\mathcal{O}_L \cap \mathcal{O}') \\ &= \mathfrak{p}(\mathfrak{p}\mathcal{O}_L \cap \mathcal{O}') + \mathscr{F}(\mathfrak{p}\mathcal{O}_L \cap \mathcal{O}') \\ &\subseteq \mathfrak{p}\mathcal{O}'\end{aligned}$$

where the last inclusion comes from the fact that any element of in the 2nd equality has the form $p(p\ell + f\ell')$ where $p\ell, f\ell' \in \mathcal{O}'$ by definition (namely the intersection), and so $\mathcal{O}_L/\mathfrak{p}\mathcal{O}_L \cong \mathcal{O}'/\mathfrak{p}\mathcal{O}'$. Then by our above argument we have $\mathcal{O}'/\mathfrak{p}\mathcal{O}' \cong \overline{\mathcal{O}}_K/(\overline{m}(x))$, hence we have:

$$\mathcal{O}_L/\mathfrak{p}\mathcal{O}_L \cong \overline{\mathcal{O}_K}[x]/(\overline{m}(x))$$

Now looking at the ring on the right, since in $\bmod \mathfrak{p}$ we have $\overline{m}(x) = \prod_i^r \overline{m}_i(x)^{e_i}$, by the CRT we get:

$$\overline{\mathcal{O}}_K[x]/(\overline{m}(x)) \cong \bigoplus_i^r \overline{\mathcal{O}}_K[x]/(\overline{m}_i(x))^{e_i}$$

But now we know the structure of each direct summand, $\overline{\mathcal{O}}_k[x]/(\overline{m}_i(x))^{e_i}$ is a principal ideal ring, and by the isomorphism we may deduce the prime ideal of $R = \overline{\mathcal{O}_K}[x]/(\overline{m}(x))$ are the principal ideal

$$(\overline{m_i}) = (\overline{m}_i(x) \bmod \overline{m}(x)) \qquad 1 \leq i \leq r$$

By ring extension theory, the degree of $[R/(\overline{m}_i) : \overline{\mathcal{O}}_K]$ equals the degree of the polynomial $\overline{m}_i(x)$, and by definition of the $(\overline{m}_i)$:

$$(0) = \bigcap_i^r (\overline{m}_i)^{e_i}$$

Now, through the isomorphism $\overline{\mathcal{O}}_K[x]/(\overline{m}(x)) \cong \mathcal{O}_L/\mathfrak{p}\mathcal{O}_L$ given by $\overline{f}(x) \mapsto \overline{f}(\theta)$, we get the same result for the primes ideals of $\overline{\mathcal{O}}_L = \mathcal{O}_L/\mathfrak{p}\mathcal{O}_L$. Namely, the prime ideals $\overline{\mathfrak{B}}_i$ of $\overline{\mathcal{O}}_L$ correspond to the prime ideals

$$\overline{\mathfrak{B}}_i = (\overline{m}_i) = (m_i(\theta) \bmod \mathfrak{p}\mathcal{O}_L)$$

with degrees $[R/\overline{\mathfrak{B}}_i : \mathcal{O}_K/\mathfrak{p}]$ where $R = \overline{\mathcal{O}_K}[x]/(\overline{m(x)})$ equalling the degrees of the polynomials $\overline{m}_i(x)$. Furthermore:

$$(0) = \bigcap_i^r \overline{\mathfrak{B}}_i^{e_i}$$

Now, given the canonical projection $\mathcal{O}_L \to \mathcal{O}_L/\mathfrak{p}\mathcal{O}_L$, let $\mathfrak{B}_i = \mathfrak{p}\mathcal{O}_L + m_i(\theta)\mathcal{O}_L$, (the preimage of $\overline{\mathfrak{B}}_i$). Then since the pre-image of a prime ideal is prime, each $\mathfrak{B}_i$ is prime, and

$$\mathfrak{B}_i \cap \mathcal{O}_K = \mathfrak{p}$$

since, when written in element form, we have that

$$p\ell + m_i(\theta)\ell' \in \mathcal{O}_K$$

which is true if and only if $\ell' = 0$ and $p\ell \in \mathcal{O}_K$, showing that $\mathfrak{B}_i$, $i \leq i \leq r$, varies over the prime ideals of $\mathcal{O}_L$ above $\mathfrak{p}$, with $f_i = [\mathcal{O}_L/\mathfrak{B}_i : \mathcal{O}_K/\mathfrak{p}]$ being the degree of the polynomial $\overline{m}_i(x)$. Furthermore, $\mathfrak{B}_i^{e_i}$ is the pre-image of $(\overline{\mathfrak{B}}_i^{e_i})$ (since $e_i = \#\left\{\overline{\mathfrak{B}}^n \;\middle|\; n \in \mathbb{N}\right\}$) and

$$(0) = \cap_{i=1}^r \mathfrak{B}_i^{e_i} = \prod \mathfrak{B}_i^{e_i} \subseteq \mathfrak{p}\mathcal{O}_L$$

so that

$$\mathfrak{p}\mathcal{O}_L \mid \prod_{i=1}^{r} \mathfrak{B}_i^{e_i}$$

since $\deg(m(x)) = [L : K] = n = \sum e_i f_i$, we in fact has no other factors or powers, showing us that in fact:

$$\mathfrak{p}\mathcal{O}_L = \prod_{i=1}^{r} \mathfrak{B}_i^{e_i}$$

as we sought to show.

Corollary 50.4.8: Factorization For Number Rings (Dedekind-Kummer Theorem)

Let L/K be a finite extension of number fields, $L = K(\theta)$ for a primitive element θ where $m_{\theta,K}(x) \in \mathcal{O}_K[x]$. Let $\mathfrak{p} \subseteq \mathcal{O}_K$ a prime ideal lying over $p \in \mathbb{Z}$. If $p \nmid [\mathcal{O}_L : \mathcal{O}_K[\alpha]]$, then

$$\mathfrak{B}_i = \mathfrak{p}\mathcal{O}_L + m_i(\theta)\mathcal{O}_L = (\mathfrak{p}\mathcal{O}_L, m_i(\theta))_L$$

are different prime ideals of $\mathcal{O}$ over $\mathfrak{p}$. The inertia degree f_i of $\mathfrak{B}_i$ is the degree of $\overline{m}_i(x)$, and

$$\mathfrak{p} = \mathfrak{B}_1^{e_1} \cdots \mathfrak{B}_r^{e_r}$$

***Proof*:**
In the proof of theorem 50.4.7 we used the conductor to show that:

$$\mathcal{O}_L/\mathfrak{p}\mathcal{O}_L \cong \mathcal{O}'/\mathfrak{p}\mathcal{O}' \cong \overline{\mathcal{O}_K}[x]/(\overline{m}(x))$$

In particular, we could have used the CRT earlier and shown that:

$$\frac{\mathcal{O}_L}{\mathfrak{B}} \cong \frac{\overline{\mathcal{O}_K}[x]}{(\overline{m_i(x)})}$$

Hence, if we can show this condition, we are done. Take the map $\varphi : \mathcal{O}_K[x] \to \mathcal{O}_L/\mathfrak{B}_i$ mapping $p(x) \mapsto p(\theta)$. We claim that this map is surjective. To see this, it suffices to show that

$$\mathcal{O}_L = \mathcal{O}_K[\theta] + \mathfrak{B}_i$$

We know that $p \in \mathfrak{p} \subseteq \mathfrak{B}_i$, hence $p\mathcal{O}_L \subseteq \mathfrak{B}_i$. We now claim the slightly stronger:

$$\mathcal{O}_L = \mathcal{O}_K[\theta] + p\mathcal{O}_L$$

Now, by assumption $p \nmid |\mathcal{O}_L : \mathcal{O}_K[\theta]|$. Since the index of $\mathcal{O}_K[\theta] + p\mathcal{O}_L$ in $\mathcal{O}_L$ is the common divisor of $[\mathcal{O}_L : \mathcal{O}_K[\theta]]$ and $[\mathcal{O}_L : p\mathcal{O}_L]$, and these *must* be relatively prime since

$$[\mathcal{O}_L : p\mathcal{O}_L] = p^k$$

for some $k \in \mathbb{N}$. Thus $\mathcal{O}_K[x] \to \mathcal{O}_L/\mathfrak{B}_i$ is surjective. Now Certainly $(\mathfrak{p}, m_i) \subseteq \ker\varphi$. Furthermore, it is clear that $(\mathfrak{p}, m_i) \subseteq \mathcal{O}_K[x]$ is a maximal ideal hence $\ker\varphi$ is either $(\mathfrak{p}, m_i)$ or $\mathcal{O}_K[x]$. since the map is surjective, then either $\mathfrak{B}_i = \mathcal{O}_L = (1)_L$ (i.e. $\mathfrak{B}_i$ is *not* a prime, a contradiction), or it is indeed the desired kernel, meaning:

$$\frac{\mathcal{O}_L}{\mathfrak{B}} \cong \frac{\overline{\mathcal{O}_K}[x]}{(\overline{m_i(x)})}$$

but now the proof follows from the rest of the proof of theorem 50.4.7, as we sought to show.

Corollary 50.4.9: Monogenic Number Rings

Let L/K be a finite extension of number rings such that $\mathcal{O}_L = \mathcal{O}_K[\alpha]$ for some $\alpha \in \mathcal{O}_L$. Then all primes split as given in the above

***Proof*:**
Choose $\theta = \alpha$. Then $[\mathcal{O}_L : \mathcal{O}_K[\alpha]] = [\mathcal{O}_K[\alpha] : \mathcal{O}_K[\alpha]] = 1$. Since certainly no prime divides 1, we have that all primes factor in given their minimal polynomials and modular factorization, as we sought to show.

Note that not all number rings are of the form $\mathcal{O}_L = \mathcal{O}_K[\alpha]$, that is not all number rings are monogenic. We shall show a counter-example in example 50.4.29. This contrasts to finite extension of field where every separable finite extension of is a simple extension by theorem 19.6.20. Note how this is dependent on finding a θ and $\mathfrak{p}$ being relatively prime to $\mathscr{F}_\theta$ (or $[\mathcal{O}_L : \mathcal{O}_K[\theta]]$ in the case of number fields)[23].

As it turns out, the power of an extended prime has important geometric and algebraic consequences; it can be thought of as the measure of how much the Galois group moves a field around. We hence give it an name:

Definition 50.4.10: Ramified and Unramified Extensions

Let $\mathfrak{p} \subseteq R$ be a prime ideal, $K = K(R)$, L/K a finite extension, and $\mathcal{O} = \overline{K}^L$. Then given

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1^{e_1} \cdots \mathcal{B}_r^{e_r}$$

Then the prime ideal $\mathfrak{B}_i$ is called *unramified* over $\mathcal{O}_k$ (or over K) if $e_i = 1$ and if the residue fields $(\mathcal{O}/\mathfrak{B}_i)/(\mathcal{O}_K/\mathfrak{p})$ is separable[a]:

$$\mathfrak{p}\mathcal{O} = \mathfrak{B}_1 \cdots \mathfrak{B}_r$$

Otherwise, $\mathfrak{B}_i$ is called *ramified*, and *totally ramified* if furthermore $f_i = 1$. The prime ideal $\mathfrak{p}$ is called *unramified* if all $\mathfrak{B}_i$ are unramified, and $\mathfrak{p}$ is ramified otherwise. The extension L/K is called *unramified* or an *unramified extension* if all prime ideals $\mathfrak{p}$ of K are unramified.

[a]which for number fields this is always the case

It is in fact rare that a prime ideal $\mathfrak{p}$ of K is ramified in L[24], however every [nontrivial] extension of $\mathbb{Q}$ is ramified (i.e. some primes ramify). Later, we shall see that there do exist [nontrivial] unramified extension L/K where $K \neq \mathbb{Q}$. To understand ramification in extension, we first show how we can factor most $\mathfrak{B}_i$. The term "ramification" comes from complex analysis, where if a holomorphic function f has a root, $f(a) = 0$, the order of the root is the ramification index[25].

[23]However, if K is a local field, as defined in [39], every extension *is* monogenic. This property, among many other similar niceties, makes developing number theory over local fields much more streamlined. The interested teacher should see [39] as a follow up to this chapter

[24]This correspond to the algebro-geometric fact that all but finitely many points of curve are *nonsingular*

[25]if $f(a) = 0$ has order n, there exists a g such that $f = g^n$ in some neighbourhood, which shows how much f "winds" around the root

Theorem 50.4.11: Counting Ramified Primes

Let L/K be a separable extension where $K = \mathrm{Frac}(R)$ or a Dedekind domain R. Then there are only finitely many prime ideals of K which are ramified in L, in particular the ideals $\mathfrak{p} \subseteq K$ that are *not* relatively prime to the discriminant of $m_{K,\theta}(x)$ and $\mathscr{F}_\theta$.

Note that it is still possible that primes factor as given in theorem 50.4.7 since a prime may be relatively prime to $\mathscr{F}_\theta$ but not the discriminant of $m_{K,\theta}(x)$.

***Proof*:**
Let $\theta \in \mathcal{O}$ be a primitive element for L, $L = K(\theta)$, and let $m(x) = m_{K,\theta}(x) \in R[x]$ be the minimal polynomial. Take the discriminant of $m(x)$

$$\mathrm{disc}(m_{\theta,K}(x)) = \mathrm{disc}_{L/K}(1, \theta, ..., \theta^{n-1}) = \prod_{i<j}(\theta_i - \theta_j)^2 \in R$$

We shall show every prime (fractional) ideal $\mathfrak{p} \subseteq K$ which is relatively prime to d and to the conductor $\mathscr{F}_\theta$ of $R[\theta]$ is unramified. Note that there are finitely many primes $\mathfrak{p} \subseteq K$ that are not relatively prime to the conductor and the discriminant since both have finitely many factors, hence this proofs the result.

By theorem 50.4.7, $\mathfrak{p}\mathcal{O}$ factors in the same way $\overline{m}_{\theta,K}(x)$ factors (mod $\mathfrak{p}$). Then the ramification indices e_i equal 1 when $\overline{m}(x)$ has no multiple roots. But this is the case since $\overline{0} \neq \overline{d} = d \bmod \mathfrak{p}$ is nonzero by assumption of being relatively prime, and the discriminant is nonzero if and only if all the roots are distinct. Thus, the residue class field extension $(\mathcal{O}/\mathfrak{B}_i)/(R/\mathfrak{p})$ are generated by $\overline{\theta} \equiv \theta \bmod \mathfrak{B}_i$, and thus are separable, showing $\mathfrak{p}$ is unramified, as we sought to show.

We can in fact be more precise than the above result: the ramified primes ideals will be given by the *relative discriminant* of $\mathcal{O}_L/\mathcal{O}_K$, which will be given by the ideal $\mathfrak{o} \subseteq \mathcal{O}_K$ which is generated by the discriminants $d(\omega_1, \omega_2, ..., \omega_n)$ for all bases $\omega_1, \omega_2, ..., \omega_n$ of L/K contained in $\mathcal{O}_L$. A special case is that of the base-field being $K = \mathbb{Q}$.

Proposition 50.4.12: Detecting Ramification In Number Fields

Let p be a prime in $\mathbb{Z}$. Suppose p is ramified. Then:

$$p \big| \mathrm{disc}(\mathcal{O}_K)$$

In proposition 50.4.16, we will show the converse, showing this is an iff.

***Proof*:**
Let $\mathfrak{B}$ lie over $\mathfrak{p}$ and $e_{\mathfrak{B}/\mathfrak{p}} > 1$. Thus

$$p\mathcal{O}_K = \mathfrak{B}I$$

where I is divisible by *all* primes of $\mathcal{O}_K$ lying over p. Let $\sigma_1, \sigma_2, ..., \sigma_n$ denote the embeddings of K in $\mathbb{C}$, and extend each σ_i to automorphisms of some extension of L/K which is normal over $\mathbb{Q}$. Let $\alpha_1, \alpha_2, ..., \alpha_n$ be some integral basis for R. What we shall do is replace one of the α_i be a suitable element that will show that $p\big|\mathrm{disc}(\mathcal{O}_K)$.

Take $\alpha \in I - p\mathcal{O}_K$. Then certainly α is in every prime ideal lying over p but *not* in $p\mathcal{O}_K$. writing

$$\alpha = m_1\alpha_1 + \cdots m_n\alpha_n$$

for appropriate $m_i \in \mathbb{Z}$, then since $\alpha \notin p\mathcal{O}_K$, we have that p does not divide each m_i. Re-arrange the terms so that $p \nmid m_1$. Then if d is the discriminant of $\mathcal{O}_K$, through direct computation, we can see that

$$\text{disc}(\alpha, \alpha_2, ..., \alpha_n) = m_1^2 d$$

Since $p \nmid m_1$, we shall show that $p \big| \text{disc}(\alpha, \alpha_2, ..., \alpha_n)$

Given $L/K/\mathbb{Q}$, since α is in every prime of $\mathcal{O}_K$ lying over p, it certainly is in every prime in $\mathcal{O}_L$ lying over p. Fixing any $\mathfrak{B}$ of S lying over p, we see that for any automorphism σ_i, $\sigma(\alpha) \in \mathfrak{B}$. To see this ,$\sigma^{-1}(\alpha)$ is a prime of $\sigma^{-1}(S) = S$ lying over p, hence must contain α. In particular, this gives $\sigma_i(\alpha) \in \mathfrak{B}$ for all i. But then $\mathfrak{B}$ contains $\text{disc}(\alpha, \alpha_2, ..., \alpha_n)$. Since the discriminant is in $\mathbb{Z}$, we get that:

$$\mathfrak{B} \cap \mathbb{Z} = p\mathbb{Z}$$

but then $p \big| \text{disc}(\mathcal{O}_K)$, as we sought to show.

Corollary 50.4.13: Ramification Over Number Fields

Let $\alpha \in R$ so that $K = \mathbb{Q}(\alpha)$ and let f be a monic polynomial over $\mathbb{Z}$ such that $f(\alpha) = 0$. Then if p is a prime such that

$$p \not\big| \text{Nm} f'(\alpha)$$

Then p is unramified in K

***Proof*:**
This follows from the above an the fact that if α is an algebraic integer and $f \in \mathbb{Z}[x]$ monic such that $f(\alpha) = 0$, then by proposition 50.1.29:

$$\text{disc}(\alpha) \big| \text{Nm}_{\mathbb{Q}(\alpha)/\mathbb{Q}}(f'(\alpha))$$

Using this result, we have an easier verification for ramification of primes of $\mathbb{Z}$ to number fields, since they must divide the discriminant, but the discriminant may only have finitely many factors. In fact, it is easy to generalize this result for extension of number fields

Corollary 50.4.14: Ramification In Number Fields

Let L/K be an extension of number fields Then only finitely many primes of $\mathcal{O}_K$ are ramified in $\mathcal{O}_L$.

***Proof*:**
Let $\mathfrak{p}$ be a prime of $\mathcal{O}_K$ which is ramified in $\mathcal{O}_L$. Then $\mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$ is ramified in S. Hence there are only finitely many possible primes p that ramify, meaning there are only finitely many possible $\mathfrak{p}$.

The converse is also true, namely

$$p\Big|\mathrm{disc}(\mathcal{O}_K) \Leftrightarrow p \text{ ramifies in } K$$

The full proof shall be given in greater generality in 50.4.3 where it is generalized for primes $\mathfrak{p} \subseteq \mathcal{O}_K$ being ramified in $\mathcal{O}_L$ for algebraic extension L/K. However, it is instructive for the reader to prove it in the following special case that is particularly important for the study of local fields (see [39]):

Lemma 50.4.15: Partial Converse For Ramification

Let $K = \mathbb{Q}(\alpha)$ where $\alpha \in \mathcal{O}_K$ and $p \nmid [\mathcal{O}_K : \mathbb{Z}[\alpha]]$. Then if $p\Big|\mathrm{disc}(\mathcal{O}_K)$, p ramifies in K

***Proof*:**
This is a good exercise!

For the result when *only* considering primes of $\mathbb{Z}$, the result is easier:

Proposition 50.4.16: Characterizing Ramification In Number Fields

Let p be a prime in $\mathbb{Z}$. Suppose $p\Big|\mathrm{disc}(\mathcal{O}_K)$. Then p is ramified.

***Proof*:**
(difficult) exercise; or see[36, p. 79]

50.4.1 Example: Eisenstein Polynomials

We say $f \in \mathbb{Z}[x]$ is *Eisenstein* with respect to p is p divides each coefficient but p^2 does not divide the constant coefficient. Then by Eisenstein's criterion (proposition 11.3.10), such a polynomial is irreducible in $\mathbb{Q}[x]$. We shall use these to quickly determine a few useful ring of integer.

Lemma 50.4.17: Eisenstein Polynomial Modular Roots

Let $K/\mathbb{Q}$ be a number field of degree n and assume $K = \mathbb{Q}(\alpha)$ for $\alpha \in \mathcal{O}_K$ with minimal polynomial $m_{\alpha,\mathbb{Q}}$ Eisenstein at p. Then then for some $f(x) \in \mathbb{Z}[x]$ of degree at most $n-1$ with coefficients $a_0, a_1, ..., a_{n-1}$, if:

$$f(\alpha) \equiv 0 \text{ mod } p\mathcal{O}_K$$

Then:

$$a_i \equiv 0 \text{ mod } p\mathbb{Z} \qquad 1 \leq i \leq n-1$$

***Proof*:**
we shall do an argument by induction. Certainly if $a_0 \equiv 0 \text{ mod } p\mathcal{O}_K$ then $a_0 \equiv 0 \text{ mod } p\mathbb{Z}$ (since $a_0 \in \mathbb{Z}$). Thus, assume for $i < j$, $j \in \{0, 1, ..., n-1\}$ that $a_i \equiv 0 \text{ mod } p\mathbb{Z}$. Then for $i < j$:

$$a_j\alpha^j + a_{j+1}\alpha^{j+1} + \cdots + a_{n-1}\alpha^{n-1} \equiv \text{ mod } p\mathcal{O}_K$$

Multiply the above by α^{n-1-j} to make all but the first term $a_j\alpha^{n-1}$ a multiple of α^n. Since α is a root of an Eisenstein polynomial at p, we have

$$\alpha^n \equiv 0 \bmod p\mathcal{O}_K$$

Hence:

$$a_j\alpha^{n-1} \equiv p\mathcal{O}_K$$

Then $a_j\alpha^{n-1} = p\gamma$, for $\gamma \in \mathcal{O}_K$. Taking the norm, we get:

$$a_j^n \mathrm{Nm}_{K/\mathbb{Q}}(\alpha)^{n-1} = p^n \mathrm{Nm}_{K/\mathbb{Q}}(\gamma) \in \mathbb{Z}$$

the left hand side is divisible by the constant term of the minimal polynomial (since that is the value of $\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)$). By Eisenstein, p divides $\mathrm{Nm}_{K/\mathbb{Q}}(\alpha)$ exactly once, so since p^n must divide the left hand side gives that $p \big| a_j^n$, thus $p \big| a_j$, thus $a_i \equiv 0 \bmod p\mathbb{Z}$ for $i < j+1$, giving us the result.

Lemma 50.4.18: Eisenstein Polynomial divisibility by p

Let $K/\mathbb{Q}$ be a number field of degree n, $K = \mathbb{Q}(\alpha)$ where $\alpha \in \mathcal{O}_K$ with minimal polynomial Eisenstein at p. Then if

$$r_0 + r_1\alpha + \cdots + r_{n-1}\alpha^{n-1} \in \mathcal{O}_K \qquad r_i \in \mathbb{Q}$$

then each r_i has no p in its denominator

***Proof*:**
For the sake of contradiction, assume some r_i has a p in its denominator. Let d be the lcm of the denominators so the r_i's so $p \big| d$ so that we may write $r_i = a_i/d$ for appropriate $a_i \in \mathbb{Z}$ where $a_i \nmid p$. Then:

$$r_0 + r_1\alpha + \cdots + r_{n-1}\alpha^{n-1} \in \mathcal{O}_K \implies \frac{a_0 + a_1\alpha + \cdots + a_{n-1}\alpha^{n-1}}{d} \in \mathcal{O}_K$$

multiplying by d,w e get:

$$a_0 + a_1\alpha + \cdots + a_{n-1}\alpha^{n-1} \in d\mathcal{O}_K \subseteq p\mathcal{O}_K$$

Then by lemma 50.4.17 we have that $a_i \in p\mathbb{Z}$ for each i, a contradiction!

Theorem 50.4.19: Eisenstein Polynomial Divisibility Test

Let $K = \mathbb{Q}(\alpha)$ where $\alpha \in \mathcal{O}_K$ a root of an Eisenstain polnomial at p of degree n. Then:

$$p \nmid [\mathcal{O}_K : \mathbb{Z}[\alpha]]$$

***Proof*:**
For the sake of contradiction, suppose $p\big|[\mathcal{O}_K : \mathbb{Z}[\alpha]]$. Then $\mathcal{O}_K/\mathbb{Z}[\alpha]$ has an element of order p, that is there is some $\gamma \in \mathcal{O}_K$ such that $\gamma \notin \mathbb{Z}[\alpha]$ but $p\gamma \in \mathbb{Z}[\alpha]$. Now, given basis $\{1, \alpha, ..., \alpha^{n-1}\}$ for $K/\mathbb{Q}$, then

$$\gamma = r_0 + r_1\alpha + \cdots + r_{n-1}\alpha^{n-1}$$

where $r_i \in \mathbb{Q}$. Since $\gamma \notin \mathbb{Z}[\alpha] <$ not all $r_i \in \mathbb{Z} >$ Since $p\gamma \in \mathbb{Z}[\alpha]$, $pr_i \in \mathbb{Z}$. Thus, r_i has p in its denominator, but that contradicts lemma 50.4.18, as we sought to show.

Example 50.4.20: Using Eisenstein Test

1. Let $K = \mathbb{Q}(\sqrt[3]{2})$. We shall quickly find $\mathcal{O}_K$. Recall that:

$$-2^2 3^3 = -108 = \operatorname{disc}(\mathbb{Z}[\sqrt[3]{2}]) = [\mathcal{O}_K : \mathbb{Z}[\sqrt[3]{2}]]^2 \operatorname{disc}(\mathcal{O}_K)$$

Since $\sqrt[3]{2}$ is a root of $x^3 - 2$, which is eisenstien at 2, we see that $2 \nmid [\mathcal{O}_K : \mathbb{Z}[\sqrt[3]{2}]]$. Furthermore, $1 + \sqrt[3]{2}$ is the root of

$$(x-1)^3 - 2 = x^3 - 3x^2 + 3x - 3$$

which is eisenstein at 3 s o

$$3 \nmid [\mathcal{O}_K : \mathbb{Z}[1 + \sqrt[3]{2}]] = [\mathcal{O}_K : \mathbb{Z}[\sqrt[3]{2}]$$

since $\mathbb{Z}[\sqrt[3]{2}] = \mathbb{Z}[1 + \sqrt[3]{2}]$. THus, the index must be 1, giving us:

$$\mathcal{O}_K = \mathbb{Z}[\sqrt[3]{2}]$$

2. Let $K = \mathbb{Q}(\sqrt[4]{2})$. Then:

$$-2^{11} = \operatorname{disc}(\mathbb{Z}[\sqrt[4]{2}]) = [\mathcal{O}_K : \mathbb{Z}[\sqrt[4]{2}]]^2 \operatorname{disc}(\mathcal{O}_K)$$

and $\sqrt[4]{2}$ is a root of $x^4 - 2$ which is eisenstein at 2, hence by the eisenstein divisibility test the idnex is 1 and

$$\mathcal{O}_K = \mathbb{Z}[\sqrt[4]{2}]$$

Let $K = \mathbb{Q}(\sqrt[5]{2})$. Then

$$2^4 5^4 = \operatorname{disc}(\mathbb{Z}[\sqrt[5]{2}]) = [\mathcal{O}_K : \mathbb{Z}[\sqrt[5]{2}]]^2 \operatorname{disc}(\mathcal{O}_K)$$

Certainly 2 doesn't divide the index. Next, the minimal polynomial of $\sqrt[5]{2} - 2$ is

$$(x+2)^5 - 2 = x^5 + 10x^4 + 40x^3 + 80x^2 + 80x + 30$$

which is Eisenstein at 5 and $\mathbb{Z}[\sqrt[5]{2} - 2] = \mathbb{Z}[\sqrt[5]{2}]$ Hence:

$$\mathcal{O}_K = \mathbb{Z}[\sqrt[5]{2}]$$

3. show that $\mathcal{O}_{\mathbb{Q}(\sqrt[3]{3})} = \mathbb{Z}[\sqrt[3]{3}]$ and $\mathcal{O}_{\mathbb{Q}(\sqrt[3]{5})} = \mathbb{Z}[\sqrt[3]{5}]$.

4. Recall the three cubic extension K_1, K_2, K_3 in example 50.1.42 with the same discriminant, but it was claimed that they where not isomorphic as fields. The three polynomials in question where:

$$f_1(x) = x^3 - 18x - 6 \qquad f_2(x) = x^3 - 36x - 78 \qquad f_3(x) = x^3 - 54x - 150$$

each having discriminant $22345 = 5 \cdot 41 \cdot 109$. It can be verified that these three polynomials have real roots (by either graphing or doing some guess-work with derivative test and evaluating), and from the above methods we can check that

$$\mathcal{O}_{K_i} = \mathbb{Z}[\alpha_i]$$

for appropriate root α_i. Since the ring of integers is Monogenic, by Dedekind-Kummers theorem the factorization of primes p mirrors the factorization of $f_i(x)$ mod p. Then it can be verified that

(a) f_1, f_2 are irreducible mod 5, but

$$f_3(x) \equiv x(x-2)(x-3) \bmod 5$$

(b) f_2, f_3 are irreducible mod 11, but

$$f_1(x) \equiv (x-3)(x-9)(x-10) \bmod 11$$

Thus, we see that these fields cannot be isomorphic, or else the prime factorization would have been equivalent (recall that ring homomorphisms map primes to primes)

It may be asked if $K = \mathbb{Q}(\sqrt[n]{2})$

$$\mathcal{O}_K = \mathbb{Z}[\sqrt[n]{2}]$$

This is true for $n \leq 1000$, but is *not always true*. For those interested, they may search for *Wieferich primes* (see Keith Conrad *The ring of integers in radical extensions*).

Eisenstein polynomials also allow us to identify when a polynomial totally ramifies:

Theorem 50.4.21: Eisenstein Polynomial And Total Ramification

Let $K = \mathbb{Q}(\alpha)$. Then α is a root of a $\mathbb{Z}$-polynomial that is Eisenstein at p iff p is totally ramified in K.

Note how there is no reference to the ring of integers

***Proof*:**
(*must* add this here! this link

Example 50.4.22: Dececting Ramification Using Eisenstein

Since $\alpha = \sqrt[3]{10}$ is a root of $x^3 - 10$, which is eisenstein at 2 and 5, then in $K = \mathbb{Q}(\alpha)$, $(2) = \mathfrak{p}^3$ and $(5) = \mathfrak{q}^3$. Note however htat

$$\mathcal{O}_K \neq \mathbb{Z}[\sqrt[3]{10}]$$

It is in fact equal to

$$\mathcal{O}_K = \mathbb{Z}[\beta] \qquad \beta = \frac{1}{3}\left(1 + \sqrt[3]{1-} + \sqrt[3]{100}\right)$$

which is a root of $x^3 - x^2 - 3x - 3$.

50.4.2 Primes in Galois Extensions

The question of prime decomposition in extension becomes more interesting when L/K is also a Galois extension since $\mathrm{Gal}_K(L)$ can act on the set of primes.

Lemma 50.4.23: Galois Group Acts On Primes

Let L/K be a finite galois extension with galois group $G = \mathrm{Gal}_K(L)$, $\mathfrak{p} \subseteq \mathcal{O}_K$ a prime ideal of $\mathcal{O}_K$, and $\mathfrak{P} = \{\mathfrak{B}_1, \mathfrak{B}_2, ..., \mathfrak{B}_n\}$ the set of primes lying above $\mathfrak{p}$. Then:

$$G \curvearrowright \mathfrak{P} \qquad \text{via} \qquad \sigma \cdot \mathfrak{B}_i = \sigma(\mathfrak{B}_i)$$

***Proof*:**
let $G = \mathrm{Gal}_K(L)$. Then for each $a \in \mathcal{O}_L$, $\tau(a) \in \mathcal{O}_L$ for all $\tau \in G$ since K is invariant under τ and all conjugates have an integral minimal polynomial (i.e. the same minimal polynomial with coefficients in $\mathbb{Z} \subseteq K$), so there is a natural action of G on $\mathcal{O}_L$; $G \curvearrowright \mathcal{O}_L$. Next, given that τ is a field isomorphism, $\tau : \mathcal{O}_L \to \mathcal{O}_L$ is a ring isomorphism, importantly it sends primes to primes. If $\mathfrak{B}$ is a prime ideal of $\mathcal{O}_L$ above $\mathfrak{p}$, then $\tau(\mathfrak{B})$ is also a prime ideal above $\mathfrak{p}$ for each prime $\mathfrak{B}$ since

$$(\tau(\mathfrak{B})) \cap \mathcal{O}_K = \tau(\mathfrak{B} \cap \mathcal{O}_K) = \tau(\mathfrak{p}) = \mathfrak{p}$$

since τ is K-invariant, hence $\mathcal{O}_K \subseteq K$ is invariant.

Definition 50.4.24: Prime Ideal Conjugate

Let $\mathcal{O}_L/\mathcal{O}_K$ be an extension of rings of integers where L/K is Galois, and $\mathfrak{B}$ lie above $\mathfrak{p}$. An ideal $\tau(\mathfrak{B})$ is called a *prime ideal conjugate* to $\mathfrak{B}$.

As we saw, most primes split similarly to a minimal polynomial. The following is further parallel between prime numbers and polynomials: just like conjugate elements, the Galois group acts transitively:

Proposition 50.4.25: Galois Group Transitive Action On Ideals

Let $G = \mathrm{Gal}_K(L)$. Then G acts transitively on the set of all ideal $\mathfrak{B}$ of $\mathcal{O}$ lying above $\mathfrak{p}$, that is the prime ideals are all conjugates of each other.

***Proof*:**
Say $\mathfrak{B}, \mathfrak{B}'$ are two primes ideals lying above $\mathfrak{p}$ where, for the sake of contradiction, $\sigma(\mathfrak{B}) \neq \mathfrak{B}'$

for any $\sigma \in G$. By the CRT, there exists an $x \in \mathcal{O}$ such that

$$x \equiv 0 \bmod \mathfrak{B}' \qquad x \equiv 1 \bmod \sigma(\mathfrak{B}) \qquad \forall \sigma \in G$$

Then

$$\mathrm{Nm}_{L/K}(x) = \prod_{\sigma \in G} \sigma(x) \overset{!}{\in} \mathfrak{B}' \cap \mathcal{O}_K = \mathfrak{p}$$

On the other hand, $x \notin \sigma(\mathfrak{B})$ for all $\sigma \in G$, hence $\sigma(x) \notin \mathfrak{B}$ for all $\sigma \in G$ since if $\sigma(x) = b \in \mathfrak{B}$, then $x = \sigma^{-1}(b) = \tau(b)$ for some $\tau \in G$. Thus,

$$\prod_{\sigma \in G} \sigma(x) \overset{!}{\notin} \mathfrak{B} \cap \mathcal{O}_K = \mathfrak{p}$$

Hence, $\prod_{\sigma \in G} \sigma(x)$ is both in and not in $\mathfrak{p}$, a contradiction.

Using the Galois group, we may encode in group-theoretic terms the number of different primes ideals a prime ideal $\mathfrak{p} \subseteq \mathcal{O}_K$ decompose to in $\mathcal{O}_L$. One of the properties of an element being acted on by a [transitive] group is it *stabalizer*:

Definition 50.4.26: Decomposition Group And Field

Let $G = \mathrm{Gal}_K(L)$. Let $\mathfrak{B} \subseteq \mathcal{O}$ be a prime ideal. Then the subgroup

$$D_{\mathfrak{B}/\mathfrak{p}} = D_{\mathfrak{B}} = \{\tau \in G \mid \tau(\mathfrak{B}) = \mathfrak{B}\} = \mathrm{stab}_G(\mathfrak{B})$$

is called the *decomposition group* of $\mathfrak{B}$ over K. The fixed field

$$L^{D_{\mathfrak{B}}} = \{x \in L \mid \tau(x) = x \ \forall \tau \in G_{\mathfrak{B}}\}$$

is called the *decomposition field* of $\mathfrak{B}$ over K, and is often labeled as $L_{\mathfrak{B}}$ or $L_{\mathfrak{B}}$ if unambiguous.

Notice that the less primes that are fixed, the larger the decomposition field is, hence there is a contravariant relation between the size of the group and the extension of the field, just like in Galois theory. Due to transitivity and the introduction of Galois theory, we immediately get many counting arguments. If $\mathfrak{B}$ is a prime ideal lying over $\mathfrak{p}$, and we let σ vary over a set of representatives from the cosets in $G/D_{\mathfrak{B}}$, then by transitivity $\sigma(\mathfrak{B})$ varies over the different primes ideals above $\mathfrak{p}$, each occurring exactly once, hence the number of prime ideals is equal to the index $[G : D_{\mathfrak{B}}]$. For reference, we shall write:

Definition 50.4.27: Prime Counter

Let L/K Then the number of prime numbers is equal to:

$$g_{L/K}(\mathfrak{p}) = [G : D_{\mathfrak{B}}]$$

for any prime $\mathfrak{B}$ over $\mathfrak{p}$. If clear from context, we shall write $g(\mathfrak{p})$.

Thus, if $D_{\mathfrak{B}} = 1$, then no $\sigma \in G$ fixes $\mathfrak{B}$ unless it's the identity and $[G : D_{\mathfrak{B}}] = |G| = [L : K]$, and so by the fundamental identity (proposition 50.4.3):

$$D_{\mathfrak{B}} = 1 \quad \iff \quad L_D = L \quad \iff \quad \mathfrak{p} \text{ totally splits}$$

On the other hand, if $D_{\mathfrak{B}} = G$, then every $\mathfrak{B}$ lying over $\mathfrak{p}$ is fixed by σ, and so there must only be one prime ideal above $\mathfrak{p}$ by transitivity giving:

$$D_{\mathfrak{B}} = G \quad \iff \quad L_D = K \quad \iff \quad \mathfrak{p} \text{ totally ramifies}$$

If $1 \subsetneq D_{\mathfrak{B}} \subsetneq G$, there is ambiguity on how $\mathfrak{p}$ splits. For example, if $[L : K] = 50 = 2 \cdot 5^2$ and $|G/D_{\mathfrak{B}}| = 5$, then either

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}_1^2\mathfrak{B}_2^2\mathfrak{B}_3^2\mathfrak{B}_4^2\mathfrak{B}_5^2 \qquad \text{or} \qquad \mathfrak{p}\mathcal{O}_L = \mathfrak{B}_1^5\mathfrak{B}_2^5\mathfrak{B}_3^5\mathfrak{B}_4^5\mathfrak{B}_5^5$$

depending on whether the inertia degree is 5 or 2 respectively. The distinction between the two shall be given with the inertia group in proposition 50.4.37. Choosing a different prime does change the resulting index: if we were to choose a different prime $\mathfrak{B}$ lying over $\mathfrak{p}$, then $D_{\mathfrak{B}}$ is conjugate to $D_{\sigma(\mathfrak{B})}$:

$$D_{\sigma(\mathfrak{B})} = \sigma D_{\mathfrak{B}} \sigma^{-1}$$

In particular:

$$\begin{aligned} \tau \in D_{\sigma(\mathfrak{B})} &\iff \tau\sigma\mathfrak{B} = \sigma\mathfrak{B} \\ &\iff \sigma^{-1}\tau\sigma\mathfrak{B} = \mathfrak{B} \\ &\iff \sigma^{-1}\tau\sigma \in D_{\mathfrak{B}} \\ &\iff \tau \in \sigma D_{\mathfrak{B}} \sigma^{-1} \end{aligned}$$

This should make sense, for by the proceeding theorem, the inertia and ramification of each prime lying ove $\mathfrak{p}$ in a galois extension is equal. At the end of this section, we shall show how to partially recover these results when working over non-Galois extensions. A key result when working with Galois extensions is that each prime has the same behavior in it's decomposition:

Proposition 50.4.28: Galois Extension, Inertia Degree And Ramification Index Independent

Let $\mathfrak{p} \subseteq K$ be a prime ideal, L/K a Galois extension, and

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}_1^{e_i} \cdots \mathfrak{B}_r^{e_r}$$

Then

$$f_1 = \cdots = f_r = f \qquad e_1 = \cdots = e_r = e$$

***Proof*:**
Let $\mathfrak{B} = \mathfrak{B}_1$ and $\mathfrak{B}_i = \sigma_i(\mathfrak{B})$ (which goes through all primes by transitivity). Then the isomorphism $\sigma_i : \mathcal{O}_L \to \mathcal{O}_L$ induces an isomorphism:

$$\mathcal{O}_L/\mathfrak{B} \xrightarrow{\sim} \mathcal{O}_L/\mathfrak{B}_i \qquad a \bmod \mathfrak{B} \mapsto \sigma_i(a) \bmod \sigma_i(\mathfrak{B})$$

But then:

$$f_i = [\mathcal{O}_L/\sigma_i(\mathfrak{B}) : \mathcal{O}_K/\mathfrak{p}] = [\mathcal{O}_L/\mathfrak{B} : \mathcal{O}_K/\mathfrak{p}]$$

Next, since $\sigma_i(\mathfrak{p}\mathcal{O}_L) = \mathfrak{p}\mathcal{O}_L$ (since $\mathfrak{p} \subseteq K$), we get

$$\mathfrak{B}^n \big| \mathfrak{p}\mathcal{O} \quad \iff \quad \sigma_i(\mathfrak{B}^n) \big| \sigma_i(\mathfrak{p}\mathcal{O}) \quad \iff \quad (\sigma_i(\mathfrak{B}))^n \big| \mathfrak{p}\mathcal{O}$$

showing that $e_1 = \cdots = e_r$.

Hence, the prime decomposition of $\mathfrak{p}$ can be written as :

$$\mathfrak{p} = \left(\prod_{\substack{\sigma \in S \\ S \subseteq G/D_{\mathfrak{B}}}} \sigma(\mathfrak{B}) \right)^e$$

where $S \subseteq G/D_{\mathfrak{B}}$ represents a set of representatives of $G/D_{\mathfrak{B}}$ and $|S| = g_{L/K}(\mathfrak{p})$. This information is already very powerful, the following is a use-case of such information:

Example 50.4.29: Biquadratic Extension That Is Not Monogenic

Let $K = \mathbb{Q}(\sqrt{7}, \sqrt{13})$. Without computing $\mathcal{O}_K$, it can be shown that $\mathcal{O}_K$ is *not* monogenic, that is there does not exists $\alpha \in \mathcal{O}_K$ such that $1, \alpha, \alpha^2, \alpha^3$ generates $\mathcal{O}_K$, in other words $\mathcal{O}_K$ is not isomorphic to a quotient of $\mathbb{Z}[x]$. The key is to look at the behavior of factorizations of small primes (for they can only have so many rood $\mod p$)

What we shall do is consider the factorization of (3) in $\mathcal{O}_K$, which will be our setup for a contradiction. First, notice that K has 3 intermediary fields[a]:

$$\begin{tikzcd}
& K & \\
\mathbb{Q}(\sqrt{7}) \arrow[ur, "2"] & \mathbb{Q}(\sqrt{91}) \arrow[u, "2"] & \mathbb{Q}(\sqrt{13}) \arrow[ul, "2"'] \\
& \mathbb{Q} \arrow[ul, "2"] \arrow[u, "2"] \arrow[ur, "2"'] &
\end{tikzcd}$$

Since we know the ring of integers of quadratics, by direct computation, we see that (3) splits into two primes in each quadratic extension. For example, in $\mathbb{Q}(\sqrt{7})$, we have:

$$\mathcal{O}_{\mathbb{Q}(\sqrt{7})}/3\mathcal{O}_{\mathbb{Q}(\sqrt{7})} = \frac{\mathbb{F}_3[x]}{(x-1)(x+1)}$$

Hence:

$$(3) = (3, 1+\sqrt{7})(3, 1-\sqrt{7})$$

Doing a similar computation for the other two computation, we get:

$$(3) = (3, 1+\sqrt{13})(3, 1-\sqrt{13})$$
$$(3) = (3, 1+\sqrt{91})(3, 1-\sqrt{91})$$

Thus, over K, there must be at least 2 prime ideals, and since

$$g_{K/\mathbb{Q}}(3) = [G : D_{\mathfrak{B}}] \qquad [G : D_{\mathfrak{B}}] \bigm| |\mathrm{Gal}_{\mathbb{Q}}(K)| \qquad |\mathrm{Gal}_{\mathbb{Q}}(K)| = |(\mathbb{Z}/2\mathbb{Z})^2| = 4$$

for any prime ideal $\mathfrak{B}$ over (3), we get that $g_{K/\mathbb{Q}}(3) \big| 4$. I claim that $g_{K/\mathbb{Q}}(3) = 4$. For, if $g_{K/\mathbb{Q}}(3) = 2$, then for any of the two primes lying over (3) in $\mathcal{O}_K$, say $\mathfrak{B}$:

$$\{e\} \neq D_{\mathfrak{B}} = \{\sigma \in \mathrm{Gal}_{\mathbb{Q}}(K) \mid \sigma(\mathfrak{B}) = \mathfrak{B}\} \subsetneq \mathrm{Gal}_{\mathbb{Q}}(K)$$

Since $D_{\mathfrak{B}}$ non-trivial proper subgroup acting transitively on the two primes of K lying over (3), we have $|D_{\mathfrak{B}}| = 2$, implying there is one non-trivial automorphism $\rho \in \mathrm{Gal}_{\mathbb{Q}}(K)$ fixing the prime ideals (since there are two prime ideals, if $\rho(\mathfrak{B}) = \mathfrak{B}$, then $\rho(\mathfrak{B}') = \mathfrak{B}'$, or else ρ wouldn't be bijective), and two non-trivial automorphisms σ, τ not fixing the primes. Consider now $\sigma \in \mathrm{Gal}_{\mathbb{Q}}(K)$ and take the fixed field $K^{\langle\sigma\rangle}$, which by some Galois theory we see must be one of the 3 quadratic extensions found above. Then by the 3rd fundamental theorem of Galois theory:

$$G := \mathrm{Gal}_{\mathbb{Q}}(K^{\langle\sigma\rangle}) \cong \frac{\mathrm{Gal}_{\mathbb{Q}}(K)}{\mathrm{Gal}_{K^{\langle\sigma\rangle}}(K)}$$

Importantly, since $G \cong \mathbb{Z}/2\mathbb{Z}$ and $[\sigma] = [\mathrm{id}]$, the map $\varphi : \mathrm{Gal}_{\mathbb{Q}}(K) \to \mathrm{Gal}_{\mathbb{Q}}(K^{\langle\sigma\rangle})$ maps $\rho, \tau \mapsto \rho|_{K^{\langle\sigma\rangle}}$. Since ρ is an automorphism and fixes both prime ideals in K over (3) (say $\mathfrak{B}, \mathfrak{B}'$), and all prime ideal of $K^{\langle\sigma\rangle}$ over (3) lie below $\mathfrak{B}, \mathfrak{B}'$:

$$\rho|_{K^{\langle\sigma\rangle}}(\mathfrak{B} \cap K^{\langle\sigma\rangle}) = \rho|_{K^{\langle\sigma\rangle}}(\mathfrak{B}) \cap K^{\langle\sigma\rangle} = \mathfrak{B} \cap K^{\langle\sigma\rangle}$$
$$\rho|_{K^{\langle\sigma\rangle}}(\mathfrak{B}' \cap K^{\langle\sigma\rangle}) = \rho|_{K^{\langle\sigma\rangle}}(\mathfrak{B}') \cap K^{\langle\sigma\rangle} = \mathfrak{B}' \cap K^{\langle\sigma\rangle}$$

Hence, G fixes all primes; but we saw that all intermediate fields of K have two primes, thus this contradicts the transitivity of action of the Galois group on the prime ideals. Thus, it must be that $g_{K/\mathbb{Q}}(3) = 4$.

Now, for the sake of contradiction let's say

$$\mathcal{O}_K \cong \frac{\mathbb{Z}[x]}{m_\alpha(x)}$$

for some $\alpha \in \mathcal{O}_K$ and minimal polynomial $m_\alpha(x)$ of degree 4. Then

$$\mathcal{O}_K/3\mathcal{O}_K \cong \frac{\mathbb{F}_3[x]}{(m_\alpha(x) \bmod 3)} \tag{50.4}$$

By our previous calculations, we see that there must be 4 prime ideals in the right hand side. Decomposing $m_\alpha(x)$ mod 3 into irreducible, by the CRT we get that the right hand side is isomorphic to the direct sum of $\mathbb{F}_3[x]/(m_i(x) \bmod 3)$ for each irreducible $m_i(x)$ mod 3. Since each $m_i(x)$ mod 3 is irreducible, each direct summand is a field, and hence by some ring theory we see that the number of primes on the right hand side of equation 50.4 is equal to the number of direct summands, implying $m_\alpha(x)$ splits into linear factors giving us:

$$\frac{\mathbb{F}_3[x]}{(m_\alpha(x) \bmod 3)} \cong \bigoplus_i^4 \mathbb{F}_3$$

However, this is impossible: any degree 4 polynomial over $\mathbb{F}_3$ that breaks down into linear factors has the form:

$$(x-1)^\alpha (x+1)^\beta x^\gamma$$

where one of α, β, γ is 2 and the other two are 1. But then $\mathbb{F}_3[x]/((x-1)^\alpha (x+1)^\beta x^\gamma)$ is not isomorphic to $\bigoplus_i^4 \mathbb{F}_3$ (the quotient contains nilpotent elements), showing that our assumption that $\mathcal{O}_K$ is monogenic is not possible.

[a] this can be seen by taking the fixed fields $\sqrt{7}, \sqrt{13}$, and $\sqrt{91}$, corresponding to the subgroups of $\mathrm{Gal}_{\mathbb{Q}}(K) = \mathbb{Z}_2 \oplus \mathbb{Z}_2$

Our next goal is to break down extension L/K into intermediary extensions which will "capture" the inertial degree and ramification index, similarly to how any field extension F/k may be broken down into intermediary extensions into separable, inseparable, and transcendental extensions. In our case, we shall get the tower:

$$K \xrightarrow[1]{1} L_D \xrightarrow[f]{1} L_I \xrightarrow[1]{e} L$$

where the ramification index of each field extension is on top, and the inertia degree is on the bottom.

Proposition 50.4.30: Prime Ideals in Decomposition Field

Let L/K be a finite field extension, $\mathfrak{p} \subseteq \mathcal{O}_K$ a prime ideal and $\mathfrak{B} \subseteq \mathcal{O}_L$ lying over $\mathfrak{p}$. Let $\mathfrak{B}_Z = \mathfrak{B} \cap L_D$ be the prime ideal of L_D below $\mathfrak{B}$. If $\mathfrak{B}$ has inertia degree f and ramification index e, then:

1. $\mathfrak{B}_Z$ is nonsplit in L, that is $\mathfrak{B}$ is the only prime ideal of L above $\mathfrak{B}_D$
2. $\mathfrak{B}$ over L_D has a ramification index e and inertia index f
3. The ramification index and inertia index of $\mathfrak{B}_D$ over K are both 1

Visually, we have:

$$\begin{array}{c} \mathfrak{B}^e J \\ e \Big\uparrow f \\ \mathfrak{B}_D I \\ 1 \Big\uparrow 1 \\ \mathfrak{p} \end{array}$$

where I and J are the remainder of the factorization. Note that the factorization of each prime factor of J lying above $\mathfrak{p}$ has the same e and f since L/K is Galois, but L_D/K is not necessarily Galois, and so the factorization of I may be quite different (for ex. another prime $\mathfrak{B}'_D$ in L_D lying ove $\mathfrak{B}$ may have ramification and inertia degree)

***Proof*:**

1. Notice that $\mathrm{Gal}_{L_\mathfrak{B}}(L) = D_\mathfrak{B}$: the automorphisms of L that fix $L_\mathfrak{B}$ are by definition the elements of $D_\mathfrak{B}$. Hence, the prime ideals above $\mathfrak{B}_D$ are the $\sigma(\mathfrak{B})$ for $\sigma \in \mathrm{Gal}_{L_\mathfrak{B}}(L)$, but $\sigma(\mathfrak{B}) = \mathfrak{B}$ by definition. Hence, $\mathfrak{B}_D$ is nonsplit in L.

2-3. The fundamental identity gives us:

$$n = efr$$

where $n = |\mathrm{Gal}_K(L)| = |G|$ and $r = [G : D_\mathfrak{B}]$. hence,

$$|D_\mathfrak{B}| = [L : L_\mathfrak{B}] = ef \tag{50.5}$$

Now, let e', e'' be the ramification index of $\mathfrak{B}$ over $L_\mathfrak{B}$ and $\mathfrak{B}_D$ over K respectively. Then $\mathfrak{p}$ is:

$$\mathfrak{p}\mathcal{O}_{L_\mathfrak{B}} = \mathfrak{B}_D^{e''} I$$

for some I and
$$\mathfrak{B}_D \mathcal{O}_L = \mathfrak{B}^{e'}$$
in L. Then
$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}^{e''e'} J$$
for some J. By the tower property, $e = e'e''$ and $f = f'f''$. Then the fundamental identity for the decomposition of $\mathfrak{B}_D$ in L gives us that the degree of L/L_D is:
$$[L : L_{\mathfrak{B}}] = e'f'$$
in particular, by equation (50.5), we get,
$$e'f' = ef = e'e''f'f''$$
Hence $e' = e$, $f' = f$, and $e'' = f'' = 1$, as we sought to show

This gives us:
$$K \xrightarrow[1]{1} L_{\mathfrak{B}} \xrightarrow[f]{e} L$$
Next, let us see how we can separate out an extension splitting the ramification and the inertia degree into different groups/fields. Since $\sigma(\mathcal{O}_L) = \mathcal{O}_L$ and $\sigma(\mathfrak{B}) = \mathfrak{B}$ for every $\sigma \in D_{\mathfrak{B}}$, there is an induced automorphism on the residue field $\mathcal{O}_L/\mathfrak{B}$:
$$\begin{aligned} \overline{\sigma} : \mathcal{O}_L/\mathfrak{B} &\to \mathcal{O}_L/\mathfrak{B} \\ (a \bmod \mathfrak{B}) &\mapsto (\sigma(a) \bmod \mathfrak{B}) \end{aligned}$$
Letting $\kappa(\mathfrak{B}) = \mathcal{O}_L/\mathfrak{B}$ and $\kappa(\mathfrak{p}) = \mathcal{O}_K/\mathfrak{p}$, we have that
$$f = [\kappa(\mathfrak{B}) : \kappa(\mathfrak{p})]$$
Recall that in Dedekind-Kummer's theorem, when $\mathfrak{p}$ is relatively prime to the conductor, the inertia degree of $\mathfrak{B}$ is given by the degree of $\overline{m_i}(x)$ which within the proof is derived by $\left[R/(\overline{m_i(x)}) : \overline{\mathcal{O}}_K\right]$. This shows that the above map has information about the inertia degree. The following links this quantity to $D_{\mathfrak{B}}$. To understand the result, the reader may see that $\mathrm{Gal}_K(L)$ would naturally surjects onto $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$ via restriction if the restriction was well-defined. The domain of this map can be restricted to the decomposition group to make it well-defined:

Proposition 50.4.31: Decomposition and Inertia Group Relation

The extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is normal and admits a surjective homomorphism:
$$D_{\mathfrak{B}} \twoheadrightarrow \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$
where $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) = \mathrm{Gal}_{\mathcal{O}_K/\mathfrak{p}}(\mathcal{O}_L/\mathfrak{B}) \cong \mathrm{Gal}_{\mathbb{F}_p}(\mathbb{F}_q)$.

***Proof*:**
As we are working over finite fields, we know that $\kappa(\mathfrak{B}) = \kappa(\mathfrak{p})(\overline{\theta})$ for some θ with minimal polynomial $\overline{g}(x)$ over $\kappa(\mathfrak{p})$ ($\overline{g}(x) \in \kappa(\mathfrak{p})[x]$)). Let $\theta \in \mathcal{O}_L$ be a representative of $\overline{\theta}$, and let $f(x)$ be its minimal polynomial over $\mathcal{O}_K$. Then by definition $\overline{g}(\overline{\theta}) \equiv 0 \bmod \mathfrak{B}$. Since $f(\theta) = 0$,

$\overline{f}(\overline{\theta}) \equiv 0 \bmod \mathfrak{B}$. Hence, taking $\overline{f}(x) \in \kappa(\mathfrak{p})[x]$, we have by minimality that:

$$\overline{g}(x) \big| \overline{f}(x)$$

Next, we know that finite field extensions are normal as we saw in section 19.7.2, however here is another way of seeing this worth pointing out: since L/K is normal, $f(x)$ splits over $\mathcal{O}_L$ into linear factors. Thus, $\overline{f}(x)$ splits into linear factors over $\kappa(\mathfrak{B})$, and similarly for $\overline{g}(x)$. But then, $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is a normal extension.

Now, consider:

$$\overline{\sigma} \in \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) = \mathrm{Gal}_{\kappa(\mathfrak{p})}\left(\kappa(\mathfrak{p})(\overline{\theta})\right)$$

By corollary 19.2.29, these homomorphisms are determined by where they send the root θ. Then $\overline{\sigma}(\overline{\theta})$ is a root of $\overline{g}(x)$ and hence of $\overline{f}(x)$, that is there exists a root θ' of $f(x)$ such that $\theta' \equiv \overline{\sigma}(\overline{\theta}) \bmod \mathfrak{B}$. θ' is a conjugate of θ, i.e. $\theta' = \sigma(\theta)$ for some $\sigma \in D_{\mathfrak{B}}$ (as the automorphism in $D_{\mathfrak{B}}$ fix $\mathfrak{B}$ and make the map well-defined). Since $\sigma(\theta) \equiv \overline{\sigma}(\overline{\theta}) \bmod \mathfrak{B}$, the automorphism σ is mapped by the homomorphism in question to $\overline{\sigma}$, proving surjectivity, as we sought to show.

Definition 50.4.32: Inertia Group And Field

The kernel $I_{\mathfrak{B}} \subseteq D_{\mathfrak{B}}$ of the homomorphism

$$D_{\mathfrak{B}} \to \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

is called the *inertia group* of $\mathfrak{B}$ over K which is a normal subgroup of $D_{\mathfrak{B}}$ (as it is the kernel of a homomorphism). Equivalently:

$$I_{\mathfrak{B}} = \{\sigma \in \mathrm{Gal}_K(L) \mid \sigma(\alpha) \equiv \alpha \bmod \mathfrak{B}\}$$

The fixed field:

$$L_I = L^{I_{\mathfrak{B}}} = \{x \in L \mid \sigma(x) = x, \ \forall \sigma \in I_{\mathfrak{B}}\}$$

is called the *inertia field* of $\mathfrak{B}$ over K.

We thus get the following tower:

$$K \subseteq L_D \subseteq L_I \subseteq L$$

and short exact sequence:

$$1 \to I_{\mathfrak{B}} \to D_{\mathfrak{B}} \to \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \to 1$$

Corollary 50.4.33: Isomorphism Of Two Galois Groups

Let $L/K/\mathbb{Q}$ be a finite galois extension, and let $\mathfrak{B}$ be a prime lying over $\mathfrak{p} \subseteq \mathcal{O}_K$. Then:

$$\mathrm{Gal}_{L_D}(L_I) \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

***Proof*:**
exercise.

Corollary 50.4.34: Quotient Group of Decomposition Group

Let L/K be a finite extension. Then the group $D_{\mathfrak{B}}/I_{\mathfrak{B}}$ is cyclic of order f (hence $[D_{\mathfrak{B}} : I_{\mathfrak{B}}] = f$), and the generator $[\varphi] \in D_{\mathfrak{B}}/I_{\mathfrak{B}}$ that generates the group (and hence $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong \mathbb{Z}/m\mathbb{Z}$) is called the *Frobenius Element*. The Frobenius element $\varphi \in D_{\mathfrak{B}}$ can be represented in the simple form

$$\varphi(x) = x^{\mathfrak{N}}(\mathfrak{p})$$

Proof:
This is an immediate consequence of the surjectivity of $D_{\mathfrak{B}}$ onto the Galois group of finite field extensions, which is always cyclic.

The order of $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is f, giving the order of the quotient. As the galois group of a finite field is cyclic, it is generated by a Frobenius element. The Frobenius element can be explicitly described, namely

$$\varphi(x) = x^{\mathfrak{N}(\mathfrak{p})} = x^f$$

giving us the rest of the results.

Notice that this means that Frobenius elements and Cyclotomic extensions naturally appear when studying galois extensions; this motivates the study of Cyclotomic extensions in section 50.5.

Corollary 50.4.35: Equivalent Characterization Of Inertia Group

L/K be a finite Galois extension, $I_{\mathfrak{B}} \leqslant D_{\mathfrak{B}}$. Then:

$$I_{\mathfrak{B}} = \{\sigma \in \mathrm{Gal}_K(L) \mid \sigma(\mathfrak{B}) = \mathfrak{B}, \text{ and } \forall \alpha \in \mathcal{O}_L, \sigma(\alpha) - \alpha \in \mathfrak{B}\}$$

Proof:
Let $\sigma \in I_{\mathfrak{B}}$ so that $\overline{\sigma\overline{\alpha}} = \overline{\alpha}$. Then $\sigma(\alpha) = \alpha + b$ for $b \in \mathfrak{B}$. But then:

$$\sigma(\alpha) - \alpha = b \in \mathfrak{B}$$

as we sought to show.

Corollary 50.4.36: Finding Element Of Galois Group

Let K be a number field, $f(x) \in \mathcal{O}_K[x]$ an irreducible polynomial over $\mathcal{O}_K$, L/K the splitting field extension of $f(x)$. Let $\mathfrak{p} \subseteq \mathcal{O}_K$ such that

$$f(x) \bmod \mathfrak{p} \equiv g_1(x) \cdots g_m(x)$$

for distinct irreducibles with degree $\deg(g_i(x)) = d_i$. Then in $\mathrm{Gal}_K(L) \lesssim S_n$, there exists an element α with cycle type

$$(d_1, d_2, ..., d_m)$$

***Proof*:**
Since L is the splitting field, let $\alpha_1, \alpha_2, ..., \alpha_m$ be the roots of f so that

$$f(\alpha_i) = 0$$

Let $\mathfrak{B}$ in L lie above $\mathfrak{p}$. Then:

$$f(\alpha_i) \bmod \mathfrak{p} \equiv 0$$

Since each each g_i are distinct, each α_i mod $\mathfrak{p}$ are disticnt. Hence, $D_{\mathfrak{B}}$ acts on the roots of f mod $\mathfrak{p}$. Now, taking $g \in D_{\mathfrak{B}}$ that maps to the generator of $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$, we shall get the desired cycle type, completing the proof.

Proposition 50.4.37: Inertia Group Properties

The extension L_I/L_D is normal, and

$$\mathrm{Gal}_{L_D}(L_I) \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

and $\mathrm{Gal}_{L_I}(L) = I_{\mathfrak{B}}$. If the residue field extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is separable, then:

$$|I_{\mathfrak{B}}| = [L : L_I] = e \qquad [D_{\mathfrak{B}} : I_{\mathfrak{B}}] = [L_I : L_D] = f$$

and we can find the prime ideals $\mathfrak{B}_I$ of L_I bellow $\mathfrak{B}$:

1. The ramification index of $\mathfrak{B}$ over $\mathfrak{B}_I$ is e and the inertia degree is 1
2. The ramification index of $\mathfrak{B}_I$ over $\mathfrak{B}_D$ is 1, and the inertia degree if f

Hence:

$$\mathfrak{B}_Z \mathcal{O}_{L_I} = \mathfrak{B}_T I \qquad \mathfrak{B}_T \mathcal{O}_K = \mathfrak{B}^e J$$

for some appropriate ideals I, J.

***Proof*:**
The fact that:

$$|I_{\mathfrak{B}}| = [L : L_I] = e \qquad [D_{\mathfrak{B}} : I_{\mathfrak{B}}] = [L_I : L_D] = f$$

follow from $|D_{\mathfrak{B}}| = [L : L_D] = ef$ and Galois theory (namely $[L : L_I] = |\mathrm{Gal}_{L_I}(L)| = |I_{\mathfrak{B}}|$), hence we need to show $(1)-(2)$. Using the fundamental identity, it all follows from $\kappa(\mathfrak{B}_I) = \kappa(\mathfrak{B})$. Since the inertia group $I_{\mathfrak{B}}$ of $\mathfrak{B}$ over K is also the inertia group of $\mathfrak{B}$ over L_I, it follows from proposition 50.4.31 applied to L/L_I that $\mathrm{Gal}_{\kappa(\mathfrak{B}_I)}(\kappa(\mathfrak{B})) = 1$, thus

$$\kappa(\mathfrak{B}_I) = \kappa(\mathfrak{B})$$

but then the rest follows.

To sum up the results in a diagram

$$K \xrightarrow[1]{1} L_D \xrightarrow[f]{1} L_I \xrightarrow[1]{e} L$$

with a corresponding [contravariant] diagram of groups:

$$G \leftarrow D_{\mathfrak{B}} \leftarrow I_{\mathfrak{B}} \leftarrow \{e\}$$

where the ramification index of each field extension is on top, and the inertia degree is on the bottom. If the residue field extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is separable, then:

$$I_{\mathfrak{B}} = 1 \qquad \iff \qquad L_I = L \qquad \iff \qquad \mathfrak{p} \text{ is unramified in } L$$

and in this case the Galois group $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong D_{\mathfrak{B}}$, so the galois group of residue field extension can be viewed as a subgroup of $\mathrm{Gal}_K(L)$. This means that the inertia group can be thought of as the "ramification group". In fact, the generalizations of the inertia group (giving more nuanced information on the ramificaion) are called the *higher order ramification group* (which we shall cover soon). The reason the inertia group is not called the 1st ramification group is because the corresponding fixed field only effects the inertia of a prime; ultimately this is due to the contravariant relation the galois correspondence gives, hence we must make a choice on naming convention depending if fields or groups are prioritised. In this case, fields were prioritised.

From the previous proposition, we may think that L_D and L_I are the *maximal* fields with these properties with respect to $\mathfrak{B}$, and this is indeed the case, making them "natural" with respect to these properties:

Proposition 50.4.38: Intermediary Fields Are Maximal

Let L/K be a finite extension of number fields, $\mathfrak{B}$ live over $\mathfrak{p}$. Then:

1. $L_{D_{\mathfrak{B}}}$ is the smallest intermediary field such that $\mathfrak{B}$ is the only prime of $\mathcal{O}_L$ lying over $\mathfrak{B}' = \mathfrak{B} \cap \mathcal{O}_{L_{D_{\mathfrak{B}}}}$
2. $L_{D_{\mathfrak{B}}}$ is the largest intermediate such that $e(\mathfrak{B}_D/\mathfrak{p}) = f(\mathfrak{B}_I/\mathfrak{p}) = 1$
3. $L_{I_{\mathfrak{B}}}$ is the smallest intermediary field such that $\mathfrak{B}$ is totally ramified over $\mathfrak{B}_I$ (that is $e(\mathfrak{B}/\mathfrak{B}_I) = [L : L_I]$)
4. $L_{I_{\mathfrak{B}}}$ is the largest intermediary field such that $e(\mathfrak{B}_I/\mathfrak{p}) = 1$

***Proof*:**
First, L_D and L_I have these properties as we've in proposition 50.4.30 and proposition 50.4.37, hence we prove they are maximal/minimal.

Let $K' = L^H$ for some $H \leqslant \mathrm{Gal}_K(L)$ where only $\mathfrak{B} \subseteq L$ is lying over $\mathfrak{p}' \subseteq K'$. Since H acts transitively on the primes of L over K' but there is only one prime $H \subseteq D_{\mathfrak{B}}$, so $L_D \subseteq K'$, giving (1).

Next, assume $e_{\mathfrak{p}'/\mathfrak{p}} = f_{\mathfrak{p}'/\mathfrak{p}} = 1$. Consider the following diagram:

$$\begin{tikzcd}
L & \\
& L_I K' \arrow[ul, "e'"'] \\
L_I \arrow[uu, "e"] & \\
& L_D K' \arrow[uu, "f'"'] \\
L_D \arrow[uu, "f"] \arrow[ur] & \\
& K' \arrow[uu, "g'"'] \\
K \arrow[uu, "g"] \arrow[ur] &
\end{tikzcd}$$

Then by multiplicativity of towers, $e = e'$ and $f = f'$. Then by the above diagram, L_D and $L_D K'$ voth ahve the same index in L. Since one contains the other, this means they must be equal, hence

$$K' \subseteq L_D$$

giving (2). A similar arguments works for (3) and (4): if $e_{\mathfrak{p}'/\mathfrak{p}} = 1$, then $e = e'$, so $L_I = L_I K'$, so $K' \subseteq L_I$, and if $\mathfrak{B}$ is totally ramified over $\mathfrak{p}'$, then $[L : K'] = e'$, then by the above diagramwe get $K' = L_I K'$, so $L_I \subseteq K'$, as we sought to show.

Ramification

An importance consequence of this is that we may consider primes that are completely ramified/totally unramified in their galois closure. we first require the following result:

Theorem 50.4.39: Composition Field And Primes

Let L/K and M/K be finite extensions of number fields, and let $\mathfrak{p}$ be a prime of K. Then if $\mathfrak{p}$ is unramified in both L and M, then $\mathfrak{p}$ is unramified in LM. If $\mathfrak{p}$ splits completely in L and M, then $\mathfrak{p}$ splits completely in LM

***Proof*:**
Let $\mathfrak{p}$ be unramified in L and M, and take $\mathfrak{B}$ to be any prime in LM lying over $\mathfrak{p}$. We want to show $e(\mathfrak{B}/\mathfrak{p}) = 1$. Let F be the normal closure of K containing LM, and let $\mathfrak{A}$ be any prime in F lying over $\mathfrak{B}$, namely it lies over $\mathfrak{p}$. Let $I_{\mathfrak{A}/\mathfrak{p}}$ be the inertial group corresponding to the field F_I. Then we see that F_I contains both L and M since the primes $\mathfrak{A} \cap L$ and $\mathfrak{A} \cap M$ are necessarily unramified over $\mathfrak{p}$. Hence, F_I contains LM, implying that $\mathfrak{A} \cap LM$ is unramified over

$\mathfrak{p}$.

The argument for splitting follows exactly the same pattern, replacing $I_{\mathfrak{B}}$ with $D_{\mathfrak{B}}$.

Corollary 50.4.40: Primes In Normal Closure

Let L/K be a finite extension of number fields and $\mathfrak{p}$ a prime in K. Then:

1. If $\mathfrak{p}$ is unramified in L, then it is unramified in the normal closure of M of L over K
2. If $\mathfrak{p}$ splits completely in L, then it splits completely in the normal closure of M of L over K

***Proof*:**
If $\mathfrak{p}$ is unramified in L, then it is unramified in every $\sigma_i(L)$ where i runs over all the automorphism. But since $M = L\sigma_1(L)\cdots\sigma_n(L)$, we use induction on theorem 50.4.39 to get our desired result (similarly for splitting completely).

Example 50.4.41: More Decomposition Of Primes
Let $K = \mathbb{Q}(i, \sqrt{2}, \sqrt{5})$, which is abelian of degree 8. Take the prime $5 \in \mathbb{Z}$. Then it splits into tow primes in $\mathbb{Q}(i)$, stays inert in $\mathbb{Q}(\sqrt{2})$, and becomes a square in $\mathbb{Q}(\sqrt{5})$. Hence in L 5 must have ramification index at least 2, and split into at least 2 primes. Since the inertia field must be a field of degree 4 over $\mathbb{Q}$ in which 5 is unramified, the only choice is $\mathbb{Q}(i, \sqrt{2})$. Now, $(2+i)$ and $(2-i)$ remain prime in $\mathbb{Q}(\sqrt{i}, \sqrt{2})$, and become squares in L, hence 5 must have exactly 2 primes and ramification index 2.

Since normal subgroups over characteristic 0 fields are galois, it is meaningful to ask the behavior of normal subgroups of the galois subgroups:

Proposition 50.4.42: Decomposition Subgroup Is Normal

Suppose $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$. Then $\mathfrak{p}\mathcal{O}_L$ splits into r distinct primes in L_D. If $I_{\mathfrak{B}} \trianglelefteq G$, then each prime remains as primes in L_I (i.e. they are inert). Furthermore, each become an eth power in L.

In general, we can only hope for:

$$\mathfrak{B}_D\mathcal{O}_{L_I} = \mathfrak{B}_I I \qquad \mathfrak{B}_I\mathcal{O}_K = \mathfrak{B}^e J$$

for some ideals, while in the normal case of D and I, we get:

$$\begin{aligned}\mathfrak{p}\mathcal{O}_{L_D} &= \mathfrak{B}_{L_1}\cdots\mathfrak{B}_{L_e}\\ \mathfrak{p}\mathcal{O}_{L_I} &= \mathfrak{B}_{L_1}\cdots\mathfrak{B}_{L_e}\\ \mathfrak{p}\mathcal{O}_L &= \mathfrak{B}_1^e\cdots\mathfrak{B}_g^e\end{aligned}$$

which also shows better why the groups $D_{\mathfrak{B}}$ and $I_{\mathfrak{B}}$ are called the “decomposition” and “inertia” groups respectively.

***Proof*:**
This is taking advantage of the fact that $L^{D_{\mathfrak{B}}}/K$ would now be a Galois extension since $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$. Then we know that

$$f(\mathfrak{B}_D) = e(\mathfrak{B}_D) = 1$$

and that (since $L^{D_{\mathfrak{B}}}$ is Galois), each other prime must also have the same ramification and inertia degree. Thus, $\mathfrak{p}$ splits into exactly g distinct primes in $L^{D_{\mathfrak{B}}}$. Then by a simple counting argument, we see that each $\mathfrak{B}_D$ must lie under a unique $\mathfrak{B}_I$. It may be that some of these ramify. However, if $I_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$, then we have that each prime must have ramification index 1, showing they are all inert. Finally, a counting argument gives that each $\mathfrak{B}_I$ becomes an eth power in L

Corollary 50.4.43: Normal Subgroup And Completely Split Prime

Let $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$. Then $\mathfrak{p}$ splits completely in K' if and only if $K' \subseteq L_D$

***Proof*:**
exercise.

In the non-Galois case L/K, take $M/L/K$ where M/K is the Galois closure of L. Then M/L is Galois. Let $G = \mathrm{Gal}_K(M)$ and $H = \mathrm{Gal}_L(M)$ so that $H \leqslant G$. Take the following tower of primes:

$$\begin{tikzcd}
M \arrow[r] & \mathfrak{A} \\
L \arrow[u] \arrow[r] & \mathfrak{B} \arrow[u] \\
K \arrow[u] \arrow[r] & \mathfrak{p} \arrow[u]
\end{tikzcd}$$

Then by definition:

$$D_{\mathfrak{A}/\mathfrak{p}} \cap H = D_{\mathfrak{A}/\mathfrak{B}}$$
$$I_{\mathfrak{A}/\mathfrak{p}} \cap H = I_{\mathfrak{A}/\mathfrak{B}}$$

Proposition 50.4.44: Prime Decomposition Over Finite Extension

Let

$$\mathfrak{p}_M = \prod_{1}^{g_{M/K}} \mathfrak{A}_i^{e_i}$$

Let $\mathfrak{O}_1, \mathfrak{O}_2, ..., \mathfrak{O}_{g_{L/K}}$ be the orbits of H acting on the primes $\{\mathfrak{A}_1, \mathfrak{A}_2, ..., \mathfrak{A}_{g_{M/K}}\}$. Then:

$$\mathfrak{p}_L = \prod_{i}^{g_{L/K}} \mathfrak{B}_i^{e_{\mathfrak{B}_i/\mathfrak{p}}}$$

where each $\mathfrak{B}_i$ comes form an $\mathfrak{O}_i$. Furthermore:

$$e_{\mathfrak{B}_i/\mathfrak{p}} = \frac{|I_{\mathfrak{A}_i/\mathfrak{p}}|}{|\text{stab}_H(\mathfrak{A}_i) \cap I_{\mathfrak{A}_1/\mathfrak{p}}|} \qquad f_{\mathfrak{B}_i/\mathfrak{p}} = \frac{|D_{\mathfrak{A}_i/\mathfrak{B}_i}|}{|e_{\mathfrak{A}_i/\mathfrak{p}}|} = \frac{|\text{stab}_H(\mathfrak{A}_i)|}{|e_{\mathfrak{A}_i/\mathfrak{p}}|}$$

Proof:
exercise

It is also enlightening to have a second perspective here: for subgroup $U, V \leqslant G$, we may consider the equivalence class $\sigma \sim \sigma' \iff \sigma' = u\sigma v$ giving us the double-coset[26]:

$$U\sigma V = \{u\sigma v \mid u \in U, v \in V\}$$

This partition will give us the similar information in the non-Galois case. Let $N/L/K$ be two separable extensions where N/K is Galois with Galois group G. Let $H = \text{Gal}_L(N) \leqslant \text{Gal}_K(N)$. Let $\mathfrak{p}$ be a prime ideal of K and $P_\mathfrak{p}$ the set of all prime ideal of L above $\mathfrak{p}$. Then if $\mathfrak{B}$ is a prime ideal of N above $\mathfrak{p}$, then we get a well-defined bijection:

$$H \setminus G/D_\mathfrak{B} \to P_\mathfrak{p} \qquad H\sigma D_\mathfrak{B} \mapsto \sigma\mathfrak{B} \cap L$$

Exercise 50.4.1

1. Let L/K be a galois extension of Number fields, $G = \text{Gal}_K(L)$, $\mathfrak{B}$ lie over $\mathfrak{p}$.
   a) If $\mathfrak{B}$ is inert, then G Is cyclic
   b) If $\mathfrak{p}$ is totally ramified in each intermediary field but not totally ramified in L, then there does not exist non-trivial proper intermediary field, hence G is cyclic (of prime order)
   c) Simiarly, Suppose every intermediate field contains a unique prime lying over $\mathfrak{p}$, but L does not. Show the same as the previous
   d) Let $\mathfrak{p}$ be unramified in every proper non-trivial intermediate field, but ramified in L. Show that G has unique smallest subgroup H and that $H \trianglelefteq G$. Use this to show that $|G| = p^k$ for some k and prime p, that $|H| = p^l$ for some l, and $H \leqslant Z(G)$.
   e) Similarly, show the same for when $\mathfrak{p}$ splits compeltely in every proper non-trivial intermediate field, but not in L.

[26]warning: double cosets need not all have the same size!

f) Let $\mathfrak{p}$ be inert in every proper non-trivial intermediate field but not in L. Prove that G is a cyclic where $|G| = p^k$.

2. (the non-normal case for Frobenius element by taking normal closure, p.78 Marcus)

50.4.3 Detecting Ramification

(Part of the problem here is that there is some local field theory going on here, so I will need to separate the local field theory for [39])

(also, this strongly motivate having a separate book for number theory. This is imo the best place in my series to have this, but at the same it is too much for this textbook. So once EYNTKA gets its first version so some theorems are set in stone, it will make sense to have ll this detail)

50.4.45 AKLB setup For generality, let A be a Dedekind domain, K the field of fraction of A, L a finite separable extension of K, and B the integral closure of A in L.

Furthermore, let κ be the residue field of A and λ be the residue field for L. Assume λ/κ and B/A are separable extensions.

Definition 50.4.46: Trace Dual of Fractional Ideal

Take AKLB and let $\mathfrak{P} \subseteq B$ be a fractional ideal. Then the *trace dual* of $\mathfrak{P}$ is:

$$^*\mathfrak{P} = \{x \in L \mid \operatorname{tr}(x\mathfrak{P}) \subseteq A\}$$

By proposition 50.1.32, $^*\mathfrak{P}$ is a finitely generated B-module, and hence by definition a fractional ideal. Note that as the trace-pairing is non-degenerate:

$$^*\mathfrak{P} \xrightarrow{\cong} \operatorname{Hom}_A(\mathfrak{P}, A) \qquad x \mapsto (y \mapsto \operatorname{tr}(xy))$$

which works even when $\mathfrak{P} = (1)_B$, that is:

$$^*B \cong \operatorname{Hom}_A(B, A)$$

This particular trace dual shall be very relevant in detecting ramification:

Definition 50.4.47: Different

Assume AKLB. Then the *different* is the ideal

$$\mathfrak{C}_{B/A} = \{x \in L \mid \forall y \in A,\ \operatorname{tr}(xy) \subseteq A\}$$

is called the *Dedekind's complementary module* or *inverse different*. It's inverse:

$$\mathfrak{D}_{B/A} := \mathfrak{C}_{B/A}^{-1}$$

is called the *Different* of B/A

Since $\mathfrak{C}_{B/A} \supseteq \mathcal{O}$, $\mathfrak{D}_{B/A} \subseteq \mathcal{O}$ is an integral ideal of L. Naturally, we will often denote the different as $\mathfrak{D}_{L/K}$ and $\mathfrak{C}_{B/A}$ as $\mathfrak{C}_{L/K}$ given the rings B an A are evident from context.

Proposition 50.4.48: Tower Law For Different

Assume $AKLB$ and let M/L be a finite separable extension. Then

1. If $M/L/K$, then $\mathfrak{D}_{M/k} = \mathfrak{D}_{M/L}\mathfrak{D}_{L/K}$
2. If $S \subseteq \mathcal{o}$ is a multiplicative subset, then $\mathfrak{D}_{S^{-1}\mathcal{O}/S^{-1}\mathcal{o}} = S^{-1}\mathfrak{D}_{\mathcal{O}/\mathcal{o}}$
3. If $\mathfrak{B}/\mathfrak{p}$ is a prime ideal of $\mathcal{O}$ with respect to $\mathcal{o}$, and $\mathcal{O}_{\mathfrak{B}}/\mathcal{o}_{\mathfrak{p}}$ is the associated completion, then $\mathfrak{D}_{\mathcal{O}/\mathcal{o}}\mathcal{O}_{\mathfrak{B}} = \mathfrak{D}_{\mathcal{O}_{\mathfrak{B}}/\mathcal{o}_{\mathfrak{p}}}$

***Proof*:**

1. If we show that
$$\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K} = \mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_L}\mathfrak{C}_{\mathcal{O}_L/\mathcal{O}_K}$$
we are done. For $\supseteq$:
$$\begin{aligned}\mathrm{tr}_{M/K}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_L}\mathcal{O}_{L/\mathcal{O}_A}(\mathcal{O}_M)) &= \mathrm{tr}_{L/K}\mathrm{tr}_{M/L}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_L}\mathfrak{C}_{\mathcal{O}_L/\mathcal{O}_K}(\mathcal{O}_M)) \\ &= \mathrm{tr}_{L/K}(\mathfrak{C}_{\mathcal{O}_L/\mathcal{O}_K}\mathrm{tr}_{M/L}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_L)}\mathcal{O}_M) \\ &\subseteq \mathcal{O}_K\end{aligned}$$
For the $\subseteq$, since $\mathcal{O}_L\mathcal{O}_M = \mathcal{O}_M$, we get:
$$\mathrm{tr}_{M/K}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K}\mathcal{O}_M) = \mathrm{tr}_{L/K}(\mathcal{O}_L\mathrm{tr}_{M/L}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K}\mathcal{O}_M)) \subseteq \mathcal{O}_K$$
Hence $\mathrm{tr}_{M/L}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K}\mathcal{O}_M) \subseteq \mathfrak{C}_{\mathcal{O}_L/\mathcal{O}_K}$, thus:
$$\mathrm{tr}_{M/L}(\mathfrak{C}^{-1}_{\mathcal{O}_L/\mathcal{O}_K}\mathcal{O}_{\mathcal{O}_M/C\mathcal{O}_K}\mathcal{O}_M) = \mathfrak{C}^{-1}_{\mathcal{O}_L/\mathcal{O}_K}\mathrm{tr}_{M/L}(\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K}C) \subseteq \mathcal{O}_L$$
Thus, we get $\mathfrak{C}^{-1}_{\mathcal{O}_L/\mathcal{O}_K}\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K} \subseteq \mathfrak{C}_{\mathcal{O}_M/\mathcal{O}}$, hence
$$\mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K} \subseteq \mathfrak{C}_{\mathcal{O}_M/\mathcal{O}_K}\mathfrak{C}_{\mathcal{O}_L/\mathcal{O}_K}$$
completing the proof.
2. follows from definition pushing
3. (Neukirch p.195)

Example 50.4.49: Different

1. Let $K = \mathbb{Q}(\sqrt{5})$ so that $\mathcal{O}_K = \mathbb{Z}\left[\frac{1+\sqrt{5}}{2}\right]$. Then:
$$\mathfrak{C}_{K/\mathbb{Q}} = \sqrt{5}^{-1}\mathcal{O}_K \implies \mathfrak{d} = \sqrt{5}\mathcal{O}_K$$

2. Let $K = \mathbb{Q}(\sqrt{3})$. So that $\mathcal{O}_K = \mathbb{Z}[\sqrt{3}]$. Then:

$$\mathfrak{C}_{K/\mathbb{Q}} = \langle \frac{1}{2}, \frac{1}{\sqrt{3}} \rangle_{\mathbb{Z}} = \frac{1}{2\sqrt{3}} \mathcal{O}_K \implies \mathfrak{d}_{K/\mathbb{Q}} = 2\sqrt{3}\mathcal{O}_K$$

Theorem 50.4.50: Norm Of Different

$$\mathfrak{N}(\mathfrak{d}_{K/\mathbb{Q}}) = |\text{disc}(\mathcal{O}_K)|$$

Proof:
good exercise!

(This next proposition gives a special case of the different and the origin of it's name)

Proposition 50.4.51: Different In Monogenic Extension

Let $\mathcal{O} = o[\alpha]$. Then the different is equal to:

$$\mathfrak{D}_{L/K} = (\delta_{L/K}(\alpha))$$

where

$$\delta_{L/K}(\alpha) = \begin{cases} f'(\alpha) & L = K(\alpha) \\ 0 & L \neq K(\alpha) \end{cases}$$

Proof:
Neukirch p.197

Theorem 50.4.52: Generation Of Different

The different $\mathfrak{D}_{L/K}$ is the ideal generated by all the different of the elements $\delta_{L/K}(\alpha)$ for all $\alpha \in \mathcal{O}$

Proof:
Neukirch p.198

Theorem 50.4.53: Detecting Ramification Using Different

A prime ideal $\mathfrak{P}$ of L is ramified over K if and only if

$$\mathfrak{B} | \mathfrak{d}_{L/K}$$

Proof:
Neukirch p. 199

(relation between different and discriminant)

Definition 50.4.54: Relative Discriminant

The *discriminant* $\mathfrak{D}_{\mathcal{O}/\mathfrak{o}}$ is the ideal of $\mathfrak{o}$ generated by the discriminants $d(\alpha_1, ..., \alpha_n)$ for all bases $\alpha_1, \alpha_2, ..., \alpha_n$ of L/K contained in $\mathcal{O}$:

$$\mathfrak{D}_{\mathcal{O}/\mathfrak{o}} = \{(d(\alpha_1, \alpha_2, ..., \alpha_n)) \mid \alpha_1, \alpha_2, ..., \alpha_n \text{ basis }, \alpha_i \in \mathcal{O}\}$$

In the case where $K = \mathbb{Q}$ and $L/\mathbb{Q}$ is a number field, then $\mathfrak{d} = (d_L)$ is the principal ideal of the usual discriminant.

Theorem 50.4.55: Relating Different And Relative Discriminant

$$\mathfrak{D}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{d}_{L/K})$$

***Proof*:**
Neukirch p.201

Corollary 50.4.56: Tower For Relative Discriminant

Let $M/L/K$. Then:

$$\mathfrak{D}_{M/K} = \mathfrak{D}_{L/K}^{[M:L]}\mathfrak{N}_{L/K}(\mathfrak{D}_{M/L})$$

***Proof*:**
Neukirch p.202

Corollary 50.4.57: Discriminant And Ramified Primes

Let $\mathfrak{p} \subseteq K$ be a prime. Then $\mathfrak{p}$ is ramified in L if and only if

$$\mathfrak{p} | \mathfrak{D}_{L/K}$$

In particular, the extension L/K is unramified if and only if

$$\mathfrak{D}_{L/K} = (1)$$

***Proof*:**
Immediate consequence

Proposition 50.4.58: Coprime Discriminants And Difference

Let K_1, K_2 be galois over $\mathbb{Q}$ with coprime discriminants and $K = K_1K_2$. Then:

$$\mathfrak{d}_{K/\mathbb{Q}} = \mathfrak{d}_{K_1/\mathbb{Q}}\mathfrak{d}_{K_2/\mathbb{Q}}$$

***Proof*:**
Using the tower

(Neukirch goes on to prove some important results which are really cool! For example, if K is an algebraic number field and S a finite set of primes of K, then there exists only finitely many extensions L/K of degree n which are unramified outside of S!)

Exercise 50.4.2

1. Show that L_D is the maximal field in which the ramification and inertial degree is 1, and similarly for L_I.
2. Let K be a number fields. Show that if disc(K) is square free, then K has no intermediary number field (this is a generlization of exercise re:HERE(galPoly))

Wild and Tame Ramification

(see this! here)

(This section is essentially here for the proof of Kronecker-Weber Theorem. May choose to move it down to that section).

We end off by exploring some more about the inertia group, namely we shall like at *wild* and *tame* inertia.

Definition 50.4.59: Wild Inertia Group

Let L/K be an extension of number fields, $I_{\mathfrak{B}} \leqslant D_{\mathfrak{B}}$ be the inertia group. Then $W_{\mathfrak{B}} \trianglelefteq I_{\mathfrak{B}}$ is defined to be:

$$W_{\mathfrak{B}} := \left\{ g \in I_{\mathfrak{B}} \;\middle|\; \forall \overline{\alpha} \in \mathcal{O}_L/\mathfrak{B}^2,\ g(\overline{\alpha}) = \overline{\alpha} \right\}$$

the wild inertia group can be thought of as a parallel to "local coordinates". In particular if we have an extension $K/\mathbb{Q}$ of number fields, then we have an extension $K/\mathbb{Q}_p$ then $W_{\mathfrak{B}}$ is the unique sylow p-subgroup of the inertia group. If you know some algebraic geometry, an intuitive reason to see why the quotient $\mathfrak{B}^2$ shows up is since the tangent space of a variety/scheme is given by $\mathfrak{m}/\mathfrak{m}^2$.

Lemma 50.4.60: Wild Inertia And Uniformizer

Let $\pi \in \mathcal{O}_L$ be the uniformizer for Q (i.e. $Q \| \pi$). Let $\sigma \in I_Q$. Then:

$$\sigma \in W_Q \qquad \Leftrightarrow \qquad \sigma(\pi) - \pi \in Q^2$$

that is, $\sigma(\pi) = \pi \bmod Q^2$

***Proof*:**
The $\Rightarrow$ direction is by definition. For $\Leftarrow$, note that we have calculated before that:

$$\left|(\mathcal{O}_L/Q^2)^{\times}\right| = \left|(\mathcal{O}_L/Q)^{\times}\right| \left|Q\mathcal{O}_L/Q^2\right| = (q-1)q$$

where $q = |\mathbb{F}_{p^r}|$ for appropriate p^r. Hence, there exists $H \leqslant (\mathcal{O}_L/Q^2)^{\times}$ such that $|H| = q - 1$

and $H \xrightarrow{\sim} \mathbb{F}_Q^\times$. Hence

$$(\mathcal{O}_L/Q^2)^\times \cong H \oplus (1+\pi\mathcal{O}_L)_{Q^2} \bmod Q^2$$

Hence $\sigma \in I_G$, then σ acts trivially on $\mathbb{F}_Q^\times$, and hence acts trivially on $H>$ Thus $\sigma \in W_Q$ if and only if σ fixes $(1+\pi\mathcal{O}_L)_{Q^2}$ if and only if $(\pi\mathcal{O}_L)_{Q^2}$ if and only if σ fixes π mod Q^2

Example 50.4.61: Example from Class for wild inertia

$K = \mathbb{Q}(\sqrt[8]{1})$, $i^4 = 1$, $\left(\frac{1+i}{\sqrt{2}}\right)^2 = i$. $[K : \mathbb{Q}] = |\mathbb{Z}/8\mathbb{Z}^\times| = 4$. and $(\mathbb{Z}/8\mathbb{Z})^\times \cong (\mathbb{Z}/2\mathbb{Z}) \oplus \mathbb{Z}/2\mathbb{Z}$. So K is biquadratic. Note that

$$K = \mathbb{Q}\left(\frac{1+i}{\sqrt{2}}\right) = \mathbb{Q}(\alpha) = \mathbb{Q}(i, \sqrt{2})$$

(diagram of the 3 quadratic extensions). Notice that 2 is the only prime that ramifies. In $\mathbb{Q}(\sqrt{d})$ where $d = -1, 2, 2$, so 2 ramifies

$$(e, f, g) = (2, 1, 1)$$

It may not be immediately clear, but in K, $2\mathcal{O}_K = \mathfrak{B}^4$, i.e. 2 totally ramifies (we have not seen cases where e increases when it's coprime). This cannot happen with unramified fields. What is $\mathfrak{B}$? Explicitly, we know that

$$\mathfrak{B} = (1-\alpha)$$

which we can directly see because $\mathfrak{B}^2 = (1 - 2\alpha + \alpha^2) = (1 + i - 2\alpha) = (1 + i)(1 - (1 - i)\alpha)$, and we see that $(1 - (1 - i)\alpha)$ is a unit.

Let $\pi = 1 - \alpha$, which is a uniformizer of $\mathfrak{B}$. Recall that we looked at $\sigma(\pi) - \pi$ for $\sigma]in\mathrm{Gal}_{\mathbb{Q}}(K)$. Computing it's valuation at $\mathfrak{B}$

$$v_{\mathfrak{B}}(\sigma(\pi) - \pi)$$

we can do this by independence of valuation on the prime. First

$$\sigma(\alpha) = \alpha^3 \implies (1-\alpha^3) - (1-\alpha) = v_{\mathfrak{B}}(\alpha^2 - 1) = 1 + v_{\mathfrak{B}}((\alpha-1)+2) = 2$$

Next, we do

$$\sigma(\alpha) = \alpha^7 = \alpha^{-1} \implies v_{\mathfrak{B}}(\alpha^7 - \alpha) = v_{\mathfrak{B}}(\alpha^{-1} - \alpha) = v_{\mathfrak{B}}(\alpha^2 - 1) = 2$$

Finally, we have

$$\sigma(\alpha) = \alpha^5 \implies v_{\mathfrak{B}}(\alpha^5 - \alpha) = v_{\mathfrak{B}}(\alpha^4 - 1) = v_{\mathfrak{B}}(\alpha - 1) + v_{\mathfrak{B}}(\alpha + 1) + v_{\mathfrak{B}}(\alpha^2 + 1) = 1 + 1 + 2 = 4$$

Hence, we have a chain:

$$\langle 1 \rangle \subseteq \langle 1, 5 \rangle \subseteq (\mathbb{Z}/\gamma\mathbb{Z})^\times = \mathrm{Gal}_{\mathbb{Q}}(K)$$

It may not jump out, but notice that 2 divides the difference (linked to a theorem called *Hasse-Arf* Theorem).

Theorem 50.4.62: Abelian Extension Wild Map

Let L/K Galois and abelian, $G = \mathrm{Gal}_K(L)$, $P \subseteq \mathcal{O}_K$ a prime ideal of $\mathcal{O}_K$, Q a prime lying over P W_Q the wild inertia group, and π a uniformizer so that $Q \| \pi$. Then:

$$\varphi : I_Q/W_Q \hookrightarrow \mathbb{F}_Q^\times \qquad [\sigma] \mapsto \frac{\sigma(\pi)}{\pi} \bmod Q$$

Assume G is abelian. Then $\mathrm{im}\varphi \subseteq \mathbb{F}_P^\times$.

***Proof*:**
Look at $\varphi(\sigma) = \varphi(\tau^{-1}\sigma\tau)$ (because abelian), so:

$$\frac{\tau^{-1}\sigma\tau(\pi)}{\pi} \bmod Q$$

and write it as:

$$\frac{\tau - 1(\sigma(\tau(\pi)))}{\tau(\pi)} \bmod Q$$

Now, it doesn't matter what uniformizer we pick. If $\tau \in D_Q$, then we can mod by Q before or after, so

$$\tau^{-1}\varphi(\sigma)$$

What kind of element can be written as τ^{-1}? We know the decomposition group surjects onto $\mathrm{Gal}_{\mathbb{F}_p}(\mathbb{F}_Q)$, we can pick τ^{-1} to be the Frobenius operator, that is

$$\varphi(\sigma) = \varphi(\sigma)^{\mathrm{Nm}(P)} \implies \varphi(\sigma) \in \mathbb{F}_p$$

Theorem 50.4.63: Wild Inertia Group Is Sylow Subgroup

Take $W_Q \leqslant \mathrm{Gal}_{\mathbb{Q}}(L)$ where Q is a prime lying over p. Then W_Q the unique p-sylow subgroup, hence $W_Q \trianglelefteq I_Q$.

***Proof*:**
check notes for now

Exercise 50.4.3

1. (Define higher-order ramification. Show that the inertia group is solvable, and when the residue fields are finite then the decomposition group is solvable).

50.4.4 Frobenius Automorphism

This is a short section to single out the Frobenius automorphisms from corollary 50.4.34 due to its importance in Class Field Theory (CFT); namely the Frobenius automorphism is central to relating the structure of abelian galois groups to the structure of the class group. The full exposition is beyond the scope of this textbook, but the reader can still get an appreciation behind why the Frobenius automorphism is so important. For a full exposition, see [39].

Assume $\mathfrak{B}$ over $\mathfrak{p}$ is unramified in $L/K/\mathbb{Q}$, so that $I_{\mathfrak{B}}$ is trivial (which by proposition 50.4.12 and proposition 50.4.16 can be shown to be the case for all put finitely many primes). Then $D_{\mathfrak{B}} \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong (\mathbb{Z}/n\mathbb{Z})$. By finite field theory, we know that there exists the *Frobenius generator* sending $x \mapsto x^{\mathfrak{N}(\mathfrak{B})}$ since $\mathfrak{N}(\mathfrak{B}) = f$ and the order of this group is f. Thus, for each prime $\mathfrak{B}/\mathfrak{p}$, have a corresponding automorphism in the decomposition group, and hence the Galois group:

Definition 50.4.64: Frobenius Automorphism of a Prime

Let $\sigma \in D_{\mathfrak{B}}$. Then σ is called the *Frobenius* if $\sigma(\alpha) \equiv \alpha^f \mod \mathfrak{B}$ where f is the inertia degree of $\mathfrak{B}$ over $\mathfrak{p}$. The collection of element $\sigma \in D_{\mathfrak{B}}$ with this property is denoted $\mathrm{Frob}_{\mathfrak{B}/\mathfrak{p}}$ so that is $\sigma \in \mathrm{Frob}_{\mathfrak{B}/\mathfrak{p}}$:

$$\sigma(\alpha) \equiv \alpha^f \mod \mathfrak{B}$$

Note that if $\mathfrak{B}$ were ramified, then the Frobenius automorphism is defined up to the coset $I_{\mathfrak{B}}$: $\sigma + I_{\mathfrak{B}}$. If another $\mathfrak{B}' = \sigma(\mathfrak{B})$[27] is considered, the Frobenius element differ conjugation:

$$\mathrm{Frob}_{\sigma(\mathfrak{B}/\mathfrak{p})} = \sigma \mathrm{Frob}_{\mathfrak{B}/\mathfrak{p}} \sigma^{-1}$$

If $D_{\mathfrak{B}}$ is abelian, then the Frobenius element is *only* determined by the prime $\mathfrak{p}$ as

$$\mathrm{Frob}_{\sigma(\mathfrak{B}/\mathfrak{p})} = \sigma \mathrm{Frob}_{\mathfrak{B}/\mathfrak{p}} \sigma^{-1} = \mathrm{Frob}_{\mathfrak{B}/\mathfrak{p}}$$

Thus, we may denote it as $\mathrm{Frob}_{\mathfrak{p}}$. In this case, we have:

$$\sigma(\alpha) = \alpha^{\mathfrak{N}(\mathfrak{p})} \mod \mathfrak{p}\mathcal{O}_L$$

because $\mathfrak{p}\mathcal{O}_L$ is the product of all primes $\mathfrak{B}$ over $\mathfrak{p}$. Another immediate observation is that if $\mathfrak{p}$ spits completely, then $f = 1$, and the Frobenius element for $\mathfrak{p}$ shall be the identity, and hence the Frobenius element captures behaviour in the case where a prime doesn't completely split.

The important realization is that if $\mathrm{Gal}_k(F)$ is abelian, there exist $\sigma \in \mathrm{Gal}_k(F)$ that are associated to primes $\mathfrak{p}$ in the sense that the structure of $\sigma \mod \mathfrak{B}/\mathfrak{p}$ is simply the power map (i.e. cyclic)! If each element $\sigma \in \mathrm{Gal}_k(F)$ can have such an association, then that means that primes have a strong link to the structure of an abelian galois group! Even better, the decomposition of primes is regulated by the class group. The culminating result of 20th century number theory is that any abelian galois group is isomorphic to a class group! Thus, abelian galois theory and number theory have a strong correspondence to each other.

When $\mathrm{Gal}_k(F)$ is non-abelian, the situation become more tenuous. Robert Langland is credited for finding the right framework to extend this correspondence through the use of *representation theory*. This is the origins of the famous *Langland's Conjecture*.

50.4.5 Example: Cyclotomic Fields

As we saw in example 50.1.31, the discriminant of $\mathbb{Z}[\zeta_{p^n}]$ is a prime power of p. We now generalize this result for arbitrary n, and find how p, and will find the discriminant is a power of p. Thus, p is the only prime that ramifies in K, and we shall find how p ramifies:

[27] by transitivity and definition of the decomposition group, any $\mathfrak{B}'$ is of this form

Lemma 50.4.65: Cyclotomic Fields Lemma

Let $n = p^k$ be a prime power, ζ_{p^k} a root of unity, and $\lambda = 1 - \zeta_{p^k}$. Then the principal ideal $(\lambda) \subseteq \mathcal{O}$ in the ring of integers of $\mathbb{Q}(\zeta_{p^k})$ is a prime ideal of degree 1, and:

$$p\mathcal{O} = (\lambda)^d$$

where $d = \varphi(n) = [\mathbb{Q}(\zeta_{p^k}) : \mathbb{Q}]$. Furthermore, the basis $1, \zeta_{p^k}, ..., \zeta_{p^k}^{d-1}$ of $\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}$ has discriminant:

$$d_{\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}}(1, \zeta_{p^k}, ..., \zeta_{p^k}^{d-1}) = \pm p^s$$

where $s = p^{k-1}(kp - k - 1)$

Note that in order for the above discriminant to be the discriminant of the ring of integers, we would have to insure the ring of integers has the above basis up to change of coordinates, which shall be the result of the next theorem.

***Proof*:**
Recall that the minimal polynomial of ζ_{p^k} over $\mathbb{Q}$ is:

$$m_{\zeta_{p^k},\mathbb{Q}}(x) = \frac{x^{l^n} - 1}{x^{l^{n-1}} - 1} = x^{l^{n-1}(l-1)} + \cdots + x^{l^{n-1}} + 1$$

Letting $x = 1$, we get

$$n = p^k = \prod_{r \in (\mathbb{Z}/n\mathbb{Z})^\times} (1 - \zeta_{p^k}^r)$$

Next, we know that

$$(1 - \zeta_{p^k}^r) = (1 - \zeta_{p^k})(1 + \zeta_{p^k} + \cdots + \zeta_{p^k}^{r-1}) = (1 - \zeta_{p^k})\epsilon_r$$

If r' is an integer such that $rr' = 1 \bmod n$, then

$$\frac{1 - \zeta_{p^k}}{1 - \zeta_{p^k}^r} = \frac{1 - (\zeta_{p^k}^r)^{r'}}{1 - \zeta_{p^k}^r} = 1 + \zeta_{p^k}^r + \cdots + (\zeta_{p^k}^r)^{r'-1}$$

is integral as well, namely ϵ_r is a unit. Thus,

$$p = \epsilon(1 - \zeta_{p^k})^{\varphi(n)}$$

with unit $\epsilon = \prod_r \epsilon_r$. Thus:

$$p\mathcal{O} = (\lambda)^{\varphi(n)}$$

Since $[\mathbb{Q}(\zeta_{p^k}) : \mathbb{Q}] = \varphi(n)$, the fundamental identity ($\sum e_i f_i$) shows that (λ) is a prime ideal of degree 1.

Now, take $\zeta_{n,1}, ..., \zeta_{n,d}$ be the conjugates of ζ_{p^k} (i.e. powers of ζ_{p^k} that are coprime with the order of ζ_{p^k}). Then the cyclotomic polynomial:

$$\Phi_{p^k}(x) = \prod_{i=1}^{d} (x - \zeta_{n,i})$$

and

$$\pm\text{disc}(1, \zeta_{p^k}, ..., \zeta_{p^k}^{d-1}) = \prod_{i\neq j}(\zeta_{n,i} - \zeta_{n,j}) = \prod_{i=1}^{d} \Phi'_{p^k}(\zeta_{n,i}) = \text{Nm}_{\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}}(\Phi'_{p^k}(\zeta_{p^k}))$$

Differentiating the equation:

$$(x^{p^{k-1}} - 1)\Phi_{p^k}(x) = x^{p^k} - 1$$

and substituting ζ_{p^k} for x gives:

$$(\zeta_{p^k}^{p^{k-1}} - 1)\Phi'_{p^k}(\zeta_{p^k}) = (\eta - 1)\Phi'_{p^k}(\zeta_{p^k}) = n\zeta_{p^k}^{-1}$$

But we know $\text{Nm}_{\mathbb{Q}(\eta)/\mathbb{Q})}(\epsilon - 1) = \pm p$, thus

$$\text{Nm}_{\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}}(\eta - 1) = \text{Nm}_{Q(\eta)/\mathbb{Q}}(\eta - 1)^{p^{k-1}} = \pm p^{p^{k-1}}$$

since $\zeta_{p^k}^{-1}$ has norm ± 1, we get:

$$d(1, \zeta_{p^k}, .., \zeta_{p^k}^{d-1}) = \pm\text{Nm}_{\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}}\left(\Phi'_{p^k}(\zeta_{p^k})\right) = \pm p^{k^{p^{k-1}(k-1)-p^{k-1}}} = \pm p^s$$

where s is the exponent

For completeness of this section, here is a quick proof of the ring of integers of cyclotomic fields:

Proposition 50.4.66: Ring Of Integers Of Cyclotomic Fields

Let $K = \mathbb{Q}(\zeta_n)$ be a cyclotomic field. Then

$$\mathcal{O}_{K_n} \cong \mathbb{Z}[\zeta_n]$$

With discriminant:

$$\text{disc}(\mathcal{O}_{K_n}) = (-1)^{\varphi(n)/2}\frac{n^{\varphi(n)}}{\prod_{p\mid n} p^{\frac{\varphi(n)}{p-1}}}$$

***Proof*:**
Let's start with n being a prime power p^k. Since $\text{disc}(1, \zeta, ..., \zeta^{d-1}) = \pm p^s$, we have:

$$p^s\mathcal{O}_K \subseteq \mathbb{Z}[\zeta_n] \subseteq \mathcal{O}$$

Putting $\lambda = 1 - \zeta_n$, by lemma 50.4.65 we have $\mathcal{O}_K/\lambda\mathcal{O}_K \cong \mathbb{Z}/p\mathbb{Z}$, thus $\mathcal{O}_K = \mathbb{Z} + \lambda\mathcal{O}_K$, hence we *a fortiori* get

$$\lambda\mathcal{O}_K + \mathbb{Z}[\zeta] = \mathcal{O}$$

Multiplying by λ, and substituting $\lambda\mathcal{O}_K = \lambda^2\mathcal{O}_K + \lambda\mathbb{Z}[\zeta]$, we get

$$\lambda^2\mathcal{O}_K + \mathbb{Z}[\zeta] = \mathcal{O}$$

Iterating this procedure, we get:

$$\lambda^t\mathcal{O}_K + \mathbb{Z}[\zeta] = \mathcal{O} \qquad \forall t \geq 1$$

When $t = s\varphi(p^k)$, then given $p\mathcal{O}_K = \lambda^{\varphi(p^k)}\mathcal{O}_K$, we get

$$\mathcal{O} = \lambda^t\mathcal{O}_K + \mathbb{Z}[\zeta] = p^s\mathcal{O}_K + \mathbb{Z}[\zeta] = \mathbb{Z}[\zeta]$$

For the general case, let $n = p_1^{k_1}\cdots p_r^{k_r}$. Then $\zeta_i = \zeta^{n/p_i^{k_i}}$ is a primitive $p_i^{k_k}$-th root of unity, and hence:

$$Q(\zeta) = \mathbb{Q}(\zeta_1)\cdots\mathbb{Q}(\zeta_r)$$

and $\mathbb{Q}(\zeta_1)\cdots\mathbb{Q}(\zeta_{i-1})\cap\mathbb{Q}(\zeta_i) = \mathbb{Q}$. Then for each $i \in \{1, ..., r\}$, the elements $1, \zeta_i, ..., \zeta_i^{d_i-1}$, where $d_i = \varphi(p_i^{k_i})$ form an integral basis of $\mathbb{Q}(\zeta_i)/\mathbb{Q}$. Since the discriminants $d(1, \zeta_i, ..., \zeta_i^{d_i-1}) = \pm p_i^{s_i}$, are relatively prime, we get from successive uses of (Proposition 2.11 in Neukirch, I should add it to my notes!!) we get that

$$\zeta_1^{j_1}\cdots\zeta_r^{j_r}$$

where $j_i \in \{0, ..., (d_i - 1)\}$ form an integral basis of $\mathbb{Q}(\zeta)/\mathbb{Q}$. But then each of these elements is a power of ζ. Thus, every $\alpha \in \mathcal{O}$ may be written as a polynomial $\alpha = f(\zeta)$ with coefficients in $\mathbb{Z}$. Since ζ has degree $\varphi(n)$ over $\mathbb{Q}$, the degree of $f(\zeta)$ may be reduced to $\varphi(n) - 1$. But then, we may obtains:

$$\alpha = a_1 + a_1\zeta + \cdots + a_{\varphi(n)-1}\zeta^{\varphi(n)-1}$$

Thus, $1, \zeta, ..., \zeta^{\varphi(n)-1}$ is an integral basis, as we sought to show.

by theorem 50.4.53 commented this theorem out! , we know that the primes that ramify are those that divide $\mathrm{disc}(\mathcal{O}_{K_n})$, hence by the above the primes that ramify are the factors of n. The following gives exactly how they factor:

Proposition 50.4.67: Prime Decomposition In Cyclotomic Field

Enumerates all the primes $p_1, p_2, ...$, then let $n = \prod_n p_n^{n_k}$ be a prime factorization of $n \in \mathbb{Z}$. Let f_k be the smallest positive integer such that

$$p_k^{f_k} \equiv 1 \bmod (n/p_k^{n_k})$$

Then in $\mathbb{Q}(\zeta_n)$, we have:

$$p_k = (\mathfrak{p}_1\cdots\mathfrak{p}_r)^{\varphi(p_k^{n_k})}$$

where $\mathfrak{p}_1, ..., \mathfrak{p}_r$ are distinct prime ideals all of degree f_k.

Note that if $p_k \nmid n$, then $n_k = 0$, so the condition becomes

$$p_k^{f_k} \equiv 1 \bmod n$$

and $\varphi(p_k^{n_k}) = 1$, giving us:

$$p_k = \mathfrak{p}_1\cdots\mathfrak{p}_r$$

***Proof*:**
Since $\mathcal{O}_K = \mathbb{Z}[\zeta]$, we have that the conductor of $\mathbb{Z}[\zeta]$ is 1, and hence we may apply theorem 50.4.7 to any prime number p, in particular every p decompose into prime ideals in the exact same way that $\Phi_n(x)$ (the minimal polynomial of ζ_n) factors into irreducible mod p. Thus, we are reduced to showing that:

$$\Phi_n(x) \equiv (p_1(x)\cdots p_r(x))^{\varphi(p^{\nu_p})} \bmod p$$

where $p_1(x), p_2(x), ..., p_r(x)$ are distinct irreducible polynomials over $\mathbb{Z}/p\mathbb{Z}$ of degree f_p. Write n as $p^{\nu_p}m$ $(p \nmid m)$. Let ξ_i and η_j vary over the primitive roots of unity over order m and p^{ν_p} respectively. Then the product $\xi_i\eta_j$ vary over the nth root of unity, namely we have the decomposition:

$$\Phi_n(x) = \prod_{i,j}(x - \xi_i\eta_j)$$

Since $x^{p^{\nu_p}} - 1 \equiv (x-1)^{p^{\nu_p}} \bmod p$, we have that $\eta_j \equiv 1 \bmod \mathfrak{p}$ for any prime ideal where $\mathfrak{p}\big|p$. This, we get:

$$\Phi_n(x) \equiv \prod_i (x - \xi_i)^{\varphi(p^{\nu_p})} = \Phi_n(x)^{\varphi(p^{\nu_p})} \bmod \mathfrak{p}$$

Hence, we have when modding by p:

$$\Phi_n(x) \equiv \Phi_n(x)^{\varphi(p^{\nu_p})} \bmod p$$

Now, notice that f_p is the smallest positive integer such that $p^{f_p} \equiv 1 \bmod m$, hence the congruence reduces to th case where $p \nmid n$, and then $\varphi(p^{\nu_p}) = \varphi(1) = 1$.

Now, since the characteristic of $\mathcal{O}_K/\mathfrak{p}$ (i.e. p) does not divide n, the polynomial $x^n - 1$ and nx^{n-1} have no common roots in $\mathcal{O}_K/\mathfrak{p}$ by the derivative test. Thus, $x^n - 1 \bmod p$ has *no multiple roots*. Thus, we get that $\mathcal{O}_K \to \mathcal{O}_K/\mathfrak{p}$ maps the group of nth roots of unity μ_n bijectivity onto the nth roots of unity of $\mathcal{O}_K/\mathfrak{p}$. In particular ,the primitive nth roots of unity modulo $\mathfrak{p}$ ($\zeta \bmod \mathfrak{p}$) remain primitive nth roots of unity. Since the extension field of $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$ containing it is the field $\mathbb{F}_{p^{f_p}}$, since the multiplicative group $\mathbb{F}^*_{p^{f_p}}$ is cyclic of order $p^{f_p} - 1$. Thus, $\mathbb{F}_{p^{f_p}}$ is the field decomposition of the reduced cyclotomic polynomial:

$$\overline{\Phi}_n(x) = \Phi_n(x) \bmod p$$

Since it is a divisor of $X^n - 1 \bmod p$, this polynomial has no multiple roots, and if

$$\overline{\Phi}_n(x) = \overline{p}_1(x) \cdots \overline{p}_r(x)$$

i it's factorization into irreducible over $\mathbb{F}_p$, then every $\overline{p}_i(x)$ is the minimal polynomial of a primitive nth root of unity $\overline{\xi}\ in \mathbb{F}^*_{p^{f_p}}$. It's degree is thus f_p, as we sought to show.

Corollary 50.4.68: Special Case Of Factorization

A prime number p is ramified in $\mathbb{Q}(\zeta_n)$ iff

$$n \equiv 0 \bmod p$$

except in the case where $p = 2 = (4, n)$. A prime number $p \neq 2$ is totally split in $\mathbb{Q}(\zeta)$ iff

$$p \equiv 1 \bmod n$$

***Proof*:**
direct consequence of last proposition

Corollary 50.4.69: Subfield Of Cyclotomic Field

Let $K \subseteq \mathbb{Q}(\zeta_n) = L$ with corresponding subgroup $H \leqslant \mathrm{Gal}_K(L) \cong (\mathbb{Z}/n\mathbb{Z})^\times$ considered as a subgroup of $(\mathbb{Z}/n\mathbb{Z})^\times$. For prime p where $p \nmid n$, let f be the least positive integer such that $\overline{p^f} \in H$. Then for prime $\mathfrak{p}$ lying above p in K:

$$f = f_{\mathfrak{p}/p}$$

***Proof*:**
Notice hat $f_{\mathfrak{p}/p}$ is the order of the Frobenius automorphism.

Overall, the ring of integers of a cyclotomic field is monogenic, the only primes that ramify are those that divide n (where n is the order of the root of unity) since the divisors of the discriminant are completely dependent on n, the discriminant is a product of the powers of primes of n, and we know exactly how the each element $n \in \mathbb{Z}$ factors in cyclotomic fields!

50.4.6 Application: Quadratic Extensions and Quadratic Reciprocity

We now take a moment to solve a classical number theory problems with the developed tools. Let $p \in \mathbb{Z}$ be a prime number. In section 10.3, it was shown that p can be written as the sum of two squares if and only if $p \equiv 1 \bmod 4$. Let us now ask another question that may shed further light on the nature of primes: the square-root of primes is always an irrational number. However, when modding by $n \in \mathbb{N}$, it is possible that there is an answer. By the Chinese Remainder Theorem, it suffices to check when $n = q$ is a prime. Thus:

what primes p have the property that there exists an n such that $n^2 \equiv p \bmod q$

Example 50.4.70: Concrete Example
Let $p = 3$. Then:

mod	1^2	2^2	3^2	4^2	5^2	6^2
2	1					
3	1	1				
5	1	4	4	1		
7	1	4	2	2	4	1
11	1	4	9	5	***3***	***3***

Note the table is mirrored as $(-n)^2 = n^2$. Hence, for a reason that is yet to be explained in this book, the prime 3 is somehow tied to 11 when looking for square-roots of 3. The reader can verify that 13, 23, 37, and so forth also have a square-root of 3.

The reader should play around with different pairs (p, q) and flip them around to consider (q, p), there shall appear some symmetry that at first is not obvious.

This relation between primes and square-root in modular arithmetics was first documented to be discovered by Euler, however it took a generation before a complete proof by Gauss appeared. As it turns out, the condition translates into a condition on rings of integers of quadratic extensions!

Definition 50.4.71: Quadratic Residue

Let $n \in \mathbb{Z}$. Then if there exists an $m \in \mathbb{Z}$ such that $m^2 \equiv n \mod p$, then n is called a *quadratic residue* mod p.

First, to as whether p has a square-root $\mod q$ is is equivalent to solving $x^2 - p \equiv 0 \mod q$. Let $K = \mathbb{Q}(\sqrt{p})$. Then we we may consider $\mathcal{O}_K/q\mathcal{O}_K$; this ring is isomorphic to $(\mathbb{Z}/q\mathbb{Z})^n$ for some $n \in \mathbb{N}_{>0}$ Note that having a root in $\mathcal{O}_K$ implies having a root in $\mathcal{O}_K/p\mathcal{O}_K$ for any p (as shown in example 11.3.9, the converse does not hold even if an equation has a solution mod every prime). This shall in fact be the key property to detecting whether p has a square-root mod q. This question in a slightly more general framework where $K = \mathbb{Q}(\sqrt{m})$ where m is square-free. To start off, we have found the integral basis of the ring of integers of quadratic extension in 50.1.6[4], namely we have integral basis

$$\begin{aligned} &\{1, \sqrt{m}\} && m \not\equiv 1 \mod 4 \\ &\left\{1, \frac{1+\sqrt{m}}{2}\right\} && m \equiv 1 \mod 4 \end{aligned}$$

and $\operatorname{disc}(\mathcal{O}_K) = 4m$ in the first case and $\operatorname{disc}(\mathcal{O}_K) = m$ in the second. Now, take $(p) \subseteq \mathbb{Z}$ a prime ideal. Then we know that either p can split as:

$$p\mathcal{O}_K = \mathfrak{B} \qquad p\mathcal{O}_K = \mathfrak{B}^2 \qquad p\mathcal{O}_K = \mathfrak{B}_1\mathfrak{B}_2$$

and that only m and possibly 2 ramifies.

Theorem 50.4.72: Primes In Quadratic Extensions

Let $p \subseteq \mathbb{Z}$ be a prime ideal and $K = \mathbb{Q}(\sqrt{m})$ a quadratic extension where m is square-free. Then:

1. If $p \big| m$:
$$p\mathcal{O}_K = (p, \sqrt{m})^2$$
2. if m is odd, then 2 splits as:
$$2\mathcal{O}_K = \begin{cases} (2, 1+\sqrt{m})^2 & m \equiv 3 \mod 4 \\ \left(2, \frac{1+\sqrt{m}}{2}\right)\left(2, \frac{1-\sqrt{m}}{2}\right) & m \equiv 1 \mod 8 \\ (2) & m \equiv 5 \mod 8 \end{cases}$$

   and if p is odd and $p \nmid m$:
$$p\mathcal{O}_K = \begin{cases} (p, n+\sqrt{m})(p, n-\sqrt{m}) & m = n^2 \mod p \\ (p) & m \neq n^2 \mod p \end{cases}$$

***Proof*:**

1. Assume $p|m$. Then as it divides the discriminant, it certainly ramifies. More concretely, note this implies $m \equiv 0 \bmod p$ so $\sqrt{m} \equiv 0 \bmod p$, and $(p, \sqrt{m})$ is certainly prime by corollary 50.2.19. With this, it can be verified by hand that $(p, \sqrt{m})^2 = (p^2, p\sqrt{m}, m)$ and that (since $p|m$):
$$(p, \sqrt{m})^2 \subseteq (p)_K$$
2. let us first deal with the single prime $p = 2$ where $p \nmid m$ so that m is odd.
   (a) If $m \equiv 4 \bmod 4$, the discriminant is $4m$, hence 2 ramifies. Then by direct computation it can be verified that:
   $$(2, 1 + \sqrt{m})^2 = (2)_L$$
   giving us the splitting prime.
   (b) Assume $m \equiv 1 \pmod 8$. Then $m \equiv 1 \bmod 4$, so $\mathcal{O}_K = \mathbb{Z}\left[\frac{1+\sqrt{m}}{2}\right] = \mathbb{Z}[\omega]$. Then ω satisfies $\omega^2 - \omega + \frac{1-m}{4} = 0$. Then as $m \equiv 1 \pmod 8$, we have $\frac{1-m}{4} \equiv 0 \pmod 2$, so
   $$\omega^2 \equiv \omega \pmod 2$$
   The two prime ideals above 2 are generated by the two roots of $x^2 - x \equiv 0 \pmod 2$, which are $x \equiv 0$ and $x \equiv 1 \pmod 2$. Thus, the two prime ideals are $(2, \omega)$ and $(2, \omega - 1)$ (the reader can proof these are distinct primes)
   (c) Assuming $m \equiv 5 \bmod 8$, a similar process shows that 2 is inert.

   Now let p be any odd prime and $p \nmid m$. Note that as $p \nmid m$, $p \nmid \operatorname{disc}(\mathcal{O}_K) \in \{4m, m\}$, hence p will not ramify. Thus by corollary 50.4.8 The behavior of p in $\mathcal{O}_K$ depends on whether $f(x)$ factors over $\mathbb{F}_p$.

   (a) Assume $m \equiv n^2 \bmod p$ so that $x^2 - m$ has two roots in $\mathbb{F}_p$. Then $x^2 - m \equiv (x-n)(x+n) \pmod p$ In this case, we can show that p splits as:
   $$p\mathcal{O}_K = \mathfrak{p}_1\mathfrak{p}_2$$
   where $\mathfrak{p}_1 = (p, \sqrt{m} - n)$ and $\mathfrak{p}_2 = (p, \sqrt{m} + n)$. Indeed, $\mathcal{O}_K/\mathfrak{p}_1 \cong \mathbb{F}_p$ since $\sqrt{m} \equiv n \pmod{\mathfrak{p}_1}$ (Similarly for $\mathfrak{p}_2$). Then it is not too hard to notice they are distinct; notice that $\mathfrak{p}_1 + \mathfrak{p}_2 = (p, 2n) = \mathcal{O}_K$ (when $p \neq 2$)
   (b) Assume $m \not\equiv n^2 \bmod p$. Then $x^2 - m$ is irreducible over $\mathbb{F}_p$, so $\mathcal{O}_K/p\mathcal{O}_K \cong \mathbb{F}_{p^2}$ is a field, and so by the fundamental identity (p) must remain innert.
   This means $p\mathcal{O}_K$ is a prime ideal, so p remains inert.

Coming back to the question of the existence of quadratic reciprocity, the following notation shall be useful:

Definition 50.4.73: Legendre Symbol

Let p be an odd prime in $\mathbb{Z}$. Then for $n \in \mathbb{Z}$, $p \nmid n$, the *Legendre symbol* is defined to be:

$$\left(\frac{n}{p}\right) = \begin{cases} 1 & \exists m,\ m^2 \equiv n \bmod p \\ -1 & \text{otherwise} \end{cases}$$

The intuition behind the notation is that if n is the square mod p, it is "divisible" in mod p, motivating the $\left(\frac{n}{p}\right)$ notation.

Theorem 50.4.74: Quadratic Reciprocity

Let p, q be two distinct odd prime numbers. Then:

$$\left(\frac{q}{p}\right)\left(\frac{p}{q}\right) = (-1)^{\frac{q-1}{2}\frac{p-1}{2}}$$

In other words, if:

$$p^* = \begin{cases} 1 & p \equiv 1 \bmod 4 \\ -p & p \equiv -1 \bmod 4 \end{cases}$$

Then q is a quadratic residue modulo p if and only if p' is a quadratic residue modulo p

Quadratic reciprocity can also be interpreted as:

$$\left(\frac{2}{p}\right) = \begin{cases} 1 & p \equiv \pm 1 \bmod 8 \\ -1 & p \pm 3 \bmod 8 \end{cases}$$

and for odd $p \neq q$:

$$\left(\frac{p}{q}\right) = \begin{cases} \left(\frac{p}{q}\right) & p \text{ or} q \equiv 1 \bmod 4 \\ -\left(\frac{p}{q}\right) & p \equiv q \equiv 3 \bmod 4 \end{cases}$$

***Proof*:**
Let $q \neq p$ be odd primes. We want to show that

$$n^2 \equiv q \bmod p \qquad \text{if and only if} \qquad m^2 \equiv p' \bmod q$$

for some numbers $n, m \in \mathbb{Z}$. By theorem 50.4.72 it suffices to show hat q splits if and only if $m^2 \equiv p' \bmod q$. Let's first say that q splits, so we have $\mathfrak{B}_1, \mathfrak{B}_2$ lying above q, and $(q)_L \subsetneq \mathfrak{B}_1, \mathfrak{B}_2$. Since $p' \equiv 1 \bmod 4$, we know the number ring of L is:

$$\mathbb{Z}\left[\frac{1+\sqrt{p'}}{2}\right]$$

Hence, we have that there is an element

$$a + b\sqrt{p'} \in \mathfrak{B} - (q) \qquad a, b \in \frac{1}{2}\mathbb{Z} \tag{50.6}$$

and since q is odd, we may without loss of generality choose a, b to be in $\mathbb{Z}$ by multiplying by 2. Now, Consider the norm of the element:

$$(a+b\sqrt{p'})(a-b\sqrt{p'}) = a^2 - b^2p' \in \mathfrak{B} \cap \mathbb{Z} = (q)$$

Hence, $q \big| a^2 - b^2p'$. Notice that q cannot divide a or b by our choice in equation (50.6). Hence, get that:

$$a^2 - b^2p' \equiv 0 \bmod q$$

re-arranging (and dividing since b is invertible), we get:

$$(ab^{-1})^2 \equiv p' \bmod q$$

showing one direction of the implication.

Now, for the other direction, it suffices that q splits in L. By assumption:

$$m^2 \equiv p' \bmod q \qquad \Leftrightarrow \qquad m^2 - p' = (m-\sqrt{p'})(m+\sqrt{p'}) = cq$$

for some constant $c \in \mathbb{Z}$. I claim that $(m+\sqrt{p'}, q)$ divides q in L. Certainly

$$(q) \subsetneq (m+\sqrt{p'}, q)$$

since $m+\sqrt{p'} \notin (q)$ (since $m+\sqrt{p'}$ is not divisible by q). Furthermore, $(m+\sqrt{p'})$ is not a unit, for if it were, then if $\alpha = (m-\sqrt{p'})$ and $u = (m+\sqrt{p'})$:

$$u\alpha = (m+\sqrt{p'}, q)(m-\sqrt{p'}) = (x^2 - p', q) = (cq, q)$$

hence $q \big| u\alpha$, implying $q \big| \alpha$, but $q \not| m - \sqrt{p'}$. Thus, it must be that q splits.

But then,this implies that q is a quadratic residue modulo p if and only if p' is a quadratic residue modulo q, as we sought to show.

50.5 Application: Kronecker Weber Theorem

We now apply our finding to Field Theory and find some important consequences' on *Abelian Extension*. This shall also lead to proving one of the central theorems in field theory, The *Kronecker-Weber Theorem*, which states that all finite abelian extensions show up as sub-extensions of Cyclotomic extensions over $\mathbb{Q}$! Since Cyclotomic extensions are generated by roots of unity, every algebraic integers whose Galois group is abelian can be written as a $\mathbb{Q}$-linear combination of roots of unity! For example:

$$\sqrt{5} = e^{2\pi i/5} - e^{4\pi i/5} - e^{6\pi i/5} + e^{8\pi i/5}$$

namely, all square roots of integers may be written as $\mathbb{Q}$-linear combinations of roots of unity! We first give the setting in which we work in:

Definition 50.5.1: Universal Cyclotomic Field and Abelian Closure

1. Let $K^{\mathbf{cycl}} = \bigcup_{n\in\mathbb{N}} K(\zeta_n)$. If $K = \mathbb{Q}$, then:
$$\mathrm{Gal}(\mathbb{Q}^{\mathbf{cycl}}) = \varprojlim \mathrm{Gal}(\mathbb{Q}(\zeta_n)) = \varprojlim (\mathbb{Z}/n\mathbb{Z})^{\times} = \hat{\mathbb{Z}}^{\times}$$
is the pro-finite group given by the limit of units of cyclic groups.
2. Let K be a field. Then
$$K^{\mathbf{ab}} \subseteq \overline{K}$$
is the maximal extension for which $\mathrm{Gal}_K(K^{\mathbf{ab}})$ is abelian.

Proposition 50.5.2: Properties of Abelian Extensions

1. If $L_1, L_2 \subseteq K^{\mathrm{ab}}$ have finite abelian groups, then $\mathrm{Gal}_K(L_1L_2)$ is a finite abelian group.
2. If $G_K = \mathrm{Gal}_K(\overline{K})$ and $H = [G, G]$ (the commutator [closed] subgroup), then
$$K^{\mathrm{ab}} = \overline{K}^H$$
with Galois group G_K/H.

***Proof*:**

1. See proposition 20.1.32
2. This comes from the universal property of abelian quotients, see proposition 5.2.3

Note that in general, $K^{\mathbf{cycl}} \subsetneq K^{\mathrm{ab}}$:

Example 50.5.3: Abelian, But Not Cyclotomic

Let $k = \mathbb{Q}(i)$ and $F = \mathbb{Q}(\sqrt{1+2i})/\mathbb{Q}(i)$. Since every quadratic extension is abelian, F is an abelian extension. However, it is not a cyclotomic extension: for if it was a sub-cyclotomic extension, then since $\mathbb{Q}(i)$ is a cyclotomic extension over $\mathbb{Q}$, then $\mathbb{Q}(\sqrt{1+2i})$ would be a cyclotomic extension, but that is not possible since $\mathbb{Q}(\sqrt{1+2i})/\mathbb{Q}$ is not Galois (but all sub-extensions of a cyclotomic extension are necessarily Galois).

It is thus quite interesting that if $K = \mathbb{Q}$, we have the following:

Theorem 50.5.4: Kronecker Weber's Theorem

Let $K = \mathbb{Q}$. Then:
$$\mathbb{Q}^{\mathbf{cycl}} = \mathbb{Q}^{\mathrm{ab}}$$
In other words, every abelian extension of $\mathbb{Q}$ is contained in a cyclotomic extension.

We'll first show we can assume $\mathrm{Gal}_{\mathbb{Q}}(K)$ is a p-group for some prime p. For if $\mathrm{Gal}_{\mathbb{Q}}(K)$ is abelian, we have

$$\mathrm{Gal}_{\mathbb{Q}}(K) \cong \bigoplus_p G_p$$

where G_p is a p-group.

Proof. **Reduction #1**:

Define $K_{p'} = K^{(\bigoplus_{p \neq p'} G_p)}$. Then $K = K_2 K_3 \cdots$ is the join of all these fields. Hence, if all such fields is inside a Cyclotomic extension, so is K. This can naturally be extended to reduce to cyclic groups in the same manner. $\square$

Next, we show that p is the *only* prime which ramifies in K

Proof. **Reduction #2**:

Assume not. Assume ℓ ramifies in K as well. Let I be the inertia group (doesn't matter what prime we pick). Then the wield inertia group W is trivial (by group theory). Then by theorem 50.4.62:

$$I \hookrightarrow \mathbb{F}_\ell^\times \qquad I \cong \mathbb{Z}/\ell\mathbb{Z}, \quad e \big| \ell - 1$$

Let $L \in \mathbb{Q}(\mu_\ell)$ be the (unique) extension such that $[L : \mathbb{Q}] = e$. So ℓ totally ramifies in L. Then take:

$$\begin{tikzcd}
& M = KL & \\
L \arrow[ur] & & K \arrow[ul] \\
& \mathbb{Q} \arrow[ul] \arrow[ur] &
\end{tikzcd}$$

K and L are abelian, thus so is M. Let I_M be the inertia group of a prime over ℓ. Then

$$I_M \hookrightarrow \mathbb{Z}/e\mathbb{Z} \oplus \mathbb{Z}/\ell\mathbb{Z}$$

Hence

$$I_M \cong \mathbb{Z}/e\mathbb{Z}$$

Let $K' = M^{I_M}$. Then $K' \cap L = \mathbb{Q}$ since nothing ramifies in $K' \cap L$.

Now, $K'L/K'$ has degree at least e, in particular$\geq e$, since ℓ has to ramify (ℓ doesn't ramify in K', and ramifies in L by e). But then,

$$K'L = M = KL$$

Note that we have not introduced any new ramifications, since no other primes ramify that ramify in L, K. We can afterward inductively remove (if it ramifies, it has to have some inertia group, but it will be trivial in the intermediate extensions).

With this, let's now prove the $p = 2$ case.

Assume $K/\mathbb{Q}$ is abelian $[K : \mathbb{Q}] = 2^n$ and 2 is the only prime which ramifies. I claim that K is cyclotomic.

Without loss of generality, let's assume $\mathbb{Q}(i) \subseteq K$ (just adjoin it if need be). Then $K_0 = K \cap \mathbb{R}$ (fixed field under conjugation). This is still abelian since K is abelian, and $[K : K_0] = 2$, so $K = K_0(i)$.

Now, let $K_n/\mathbb{Q}$ be the real cyclotomic field where $\mathrm{Gal}(K_n/\mathbb{Q}) \cong \mathbb{Z}/2^n\mathbb{Z}$ (done it in comments). Consider now

$$M = KK_n$$

Then $\mathrm{Gal}_{\mathbb{Q}}(M) \subseteq \mathbb{Z}/2^n\mathbb{Z} \oplus \mathbb{Z}/2^n\mathbb{Z}$. If $K_n \neq K$, then this Galois group is *not* cyclic (too large order). Therefore, M has ≥ 3 real quadratic subfields (real, since everything is real). But there is only 2 with ramified primes – a contradiction ($\mathbb{Q}(\sqrt{2})$ is the only real quadratic extension in which 2 ramifies). ☐

Now, for the other primes, we have the following key proposition:

Proposition 50.5.5: Ramification Of Primes in $\mathbb{Z}/n\mathbb{Z}$-Extensions

Let p be an odd prime. Then there exists a unique field $K/\mathbb{Q}$ which is Galois with Galois group $\mathbb{Z}/p\mathbb{Z}$ in which p is the only ramified prime.

***Proof*:**
Let ζ be a pth primitive root of 1, let $L = \mathbb{Q}(\zeta)$. $\pi = 1 - \zeta$. So that $(\pi)^{p-1} = (p)$. Let $\gamma \in \mathcal{O}_L$ be a non pth power. Assume $\gamma \equiv 1 \bmod \pi^p$. Take the field $M = L(\sqrt[p]{\gamma})/L$. Then π is unramified. Suppose not. Then $\pi\mathcal{O}_M = Q^p$ for some prime Q where $\mathbb{F}_Q \cong \mathbb{F}_{(\pi)} \cong \mathbb{F}_p$. Let δ be such that $\delta^p = \gamma$. Let $r = \frac{\delta-1}{\pi}$. Claim that $r \in \mathcal{O}_M$. Take the conjugates of r over L, i.e. they are

$$\frac{\zeta^i\delta - 1}{\pi} \qquad i \in \mathbb{Z}/p\mathbb{Z}$$

So the minimal polynomial is the product:

$$\prod \left(x - \frac{\zeta^i\delta - 1}{\pi}\right) = \frac{1}{\pi^p}\prod_{i=1}^{p-1}((\pi x - 1) - \zeta^i\delta) = \frac{(\pi x - 1)^p - \gamma}{\pi^p}$$

So this is inside $\mathcal{O}_L[x]$, so r is inside of integers. Thus, there exists some $m \in \mathbb{Z}$ such that $r - m \in \mathbb{Q}$ (because $\mathbb{F}_Q$ is just $\mathbb{F}_p$). But then for all $\sigma \in \mathrm{Gal}_K(M)$, $\sigma(r - m) \in \mathbb{Q}$ since it's the inerta group. But

$$\frac{\zeta\gamma - 1}{\pi} - m \in \mathbb{Q}$$

and so is $\frac{\gamma-1}{\pi} \in \mathbb{Q}$. Subtracting we get

$$\frac{1-\gamma}{\pi}\gamma = \frac{\pi}{\pi}\gamma = \gamma \in \mathbb{Q}$$

But this is a contradiction of our $\gamma \equiv 1 \bmod Q$, as we sought to show.

With this, we can continue the second reduction

Proof. **Reduction #2 cont.**:

By reduction # 2, we only need to work with $K/\mathbb{Q}$ abelian of prime power order p^n, and without loss of generality $K/\mathbb{Q}$ may be assumed to be cyclic since every field is a compositum which have cyclic subgroups.

Now consider $K_n \subseteq \mathbb{Q}(\zeta_{n+1})$ be the field such that

$$[K_n : \mathbb{Q}] = p^n \qquad \mathrm{Gal}(K_n/\mathbb{Q}) \cong \mathbb{Z}/p^n\mathbb{Z}$$

Let $M + KK_n$. In general $\mathrm{Gal}(M/\mathbb{Q}) \hookrightarrow \mathbb{Z}/p^n\mathbb{Z} \oplus \mathbb{Z}/p^n\mathbb{Z}$. If $K \neq K_n$, then like for the $p = 2$ case, this Galois group is not cyclic. Thus, M contains at least $p+1$ subfields which have Galois group $\mathbb{Z}/p\mathbb{Z}$ over $\mathbb{Q}$ in which only p ramifies, a contradiction □

***Proof*:**
Of Kronecker-Weber's Theorem

We shall show that if p is an odd prime, $K/\mathbb{Q}$ is a $\mathbb{Z}/p\mathbb{Z}$ extension, and p is the only prime that ramified in K, then $K \subseteq \mathbb{Q}(\zeta_{p^2})$, which by our earlier reduction shall complete the proof.

Let $\mathrm{Gal}_{\mathbb{Q}}(M) = \langle \sigma \mid \sigma^{p(p-1)} = \mathrm{id}\rangle$, $K = M^{\langle \sigma^p \rangle}$ and $L = M^{\langle \sigma^{p-1}\rangle}$. Consider:

$$\begin{tikzcd}
 & M = KL & \\
L = \mathbb{Q}(\zeta_p) \arrow[ur] & & K \arrow[ul] \\
 & \mathbb{Q} \arrow[ul, "\mathbb{Z}/(p-1)\mathbb{Z}"] \arrow[ur, "\mathbb{Z}/p\mathbb{Z}"'] \arrow[uu, "\mathbb{Z}/p(p-1)\mathbb{Z}"] &
\end{tikzcd}$$

We hat that p is the only prime that ramifies in M. Thus, by Kummer theory, we know that $M = L(\alpha)$ where $\alpha^p = \beta \in L^\times$. Next, we know that

$$\frac{\sigma(\alpha)}{\alpha}$$

is a non-trivial rot of unity. Without loss of generality say that $\frac{\sigma^{p-1}(\alpha)}{\alpha} = \zeta_p$ (so $\langle \sigma^{p-1}\rangle = \mathrm{Gal}_L(M)$). Note that $\sigma(\zeta_p) = \zeta_p^n$, where $\overline{n} \in (\mathbb{Z}/p\mathbb{Z})^\times$ (i.e. is a primitive root).

I claim that

$$M = L\left(\frac{\sigma(\alpha)}{\alpha}\right)$$

For suppose not. Then $\frac{\sigma(a)}{\alpha} \in L$, and

$$\frac{\sigma(\alpha)}{\alpha} = \sigma^{p-1}\left(\frac{\sigma(\alpha)}{\alpha}\right) = \frac{\sigma^p(\alpha)}{\sigma^{p-1}(\alpha)} = \frac{\sigma(\zeta_p\alpha)}{\zeta_p\alpha} \implies 1 = \frac{\sigma(\zeta_p)}{\zeta_p}$$

but that is a contradiction, hence $M = L\left(\frac{\sigma(\alpha)}{\alpha}\right)$.

For the rest of this proof, we write

$$\alpha \mapsto \frac{\sigma(\alpha)}{\alpha} = \alpha' \qquad \beta \mapsto \frac{\sigma(\beta)}{\beta} = \beta'$$

Let P_k, P_L, P_M be the primes ideals above $p\mathbb{Z}$. Take the prime decomposition:

$$\beta\mathcal{O}_L = \prod Q^{n_Q} = P_L^r \cdot \prod_{Q \neq P} Q^{n_Q} \qquad n_Q \in \mathbb{Z}$$

Then:

$$\sigma(\beta)\mathcal{O}_L = P_L^r \prod_{Q \neq P_L} \sigma(Q)^{n_Q}$$
$$\frac{\sigma(\beta)\mathcal{O}_L}{\beta} = \prod_{Q \notin P_L} Q^{m_Q}$$

Hence, P_L does not occur in $\beta\mathcal{O}_L$. Take $\beta'' = \beta' N^P$ and $\alpha'' = \alpha' N$ for $N \in \mathbb{Z}$ such that $\beta'' \in \mathcal{O}_L$ Then:

$$M = L(\alpha'') \qquad (\alpha'')^P = \beta''$$

Now let $\pi = 1 - \zeta_p \in \mathcal{O}_L$ so that $P_L = (\pi)$. Then $\mathbb{F}_{P_L} \cong \mathbb{F}_P$ implies β'' mod $P_L = m$ mod P_L for $m \leq N$. Let $m_0 = m^{-1}$ mod p, so $\beta'' \to m_0\beta''$ and $\alpha'' \to m_0\alpha''$. Without loss of generality say $\beta'' = 1$ mod P_L. Then for some $c \in \mathbb{Z}/p\mathbb{Z}$

$$\beta'' = 1 + c\pi \bmod P_L^2 \qquad \zeta_p = 1 - \pi \bmod P_L^2 \qquad \zeta_p^r = 1 - r\pi \bmod P_L^2 \implies \beta'' = \zeta_p^{-c}\nu$$

where $\nu \equiv 1$ mod P_L^2. I claim that $\nu \in (L^\times)^P$, which will imply $M = \mathbb{Q}(\zeta_{p^2})$ and complete the proof. First:

$$\begin{aligned}
(\alpha'')^p &= \beta'' = \zeta_p^{-c}\nu \\
\sigma^{p-1}(\alpha'') &= \alpha''\zeta_p \\
\implies \sigma(\zeta_p) &= \zeta_p^n && n \in (\mathbb{Z}/p\mathbb{Z})^\times \\
\implies \sigma^p(\alpha'') &= \sigma(\sigma^{p-1}(\alpha'')) = \sigma(\alpha''\zeta_p) = \sigma(\alpha'') \cdot \zeta_p^n \\
\implies \sigma^{p-1}((\alpha'')^n) &= (\alpha'')^n\zeta_p^n \\
\implies \sigma^{p-1}\left(\frac{\sigma(\alpha'')}{(\alpha'')^n}\right) &= \frac{\sigma(\alpha'')}{(\alpha'')^n} \\
\implies \frac{\sigma(\alpha'')}{(\alpha'')^n} &\in M^{\langle \sigma^{p-1} \rangle} = L \\
\implies \frac{\sigma(\beta'')}{(\beta'')^n} &\in (L^\times)^P \\
\implies \frac{\sigma(\nu\zeta_p^{-c})}{\nu^n\zeta_p^{-nc}} &\in (L^\times)^p
\end{aligned}$$

Thus $\frac{\sigma(\nu)}{\nu^n} \in (L^\times)^p$.

Next, we claim that $\nu = 1$ mod P_L^p. Suppose not. Then let $p^M \| \nu - 1$ where $1 \leq m \leq p-1$, and $\nu = 1 + c\pi^m$ mod P_L^{m+1} (where $c \in (\mathbb{Z}/p\mathbb{Z})^\times$). Then by this:

$$\nu^n = 1 + nc\pi^m \bmod P_L^{m+1}$$

hence,

$$\sigma(\pi) = \sigma(1 - \zeta_p) = 1 - \zeta_p^n = (1 - \zeta_p)(1 + \zeta_p + \cdots + \zeta_p^{n-1}) = \pi n \bmod P_L^2$$

implying

$$\sigma(\pi^m) = \pi^m n^m \bmod P_L^{m+1} \implies \sigma(\nu) = 1 + cn^m\pi^m \bmod P_L^{m+1}$$

Note that $n^m \not\equiv n \bmod p$ for $n \in (\mathbb{Z}/p\mathbb{Z})^\times$. Now as a corollary:

$$\frac{\sigma(\nu)}{\nu^m} \equiv 1 + d\pi^m \bmod P_L^{m+1} \qquad d \in \mathbb{Z}/p\mathbb{Z}^\times$$

However,

$$\frac{\sigma(\nu)}{n\nu} = S^p \qquad S \in L$$

where P_L does not occur in S, and:

$$S^p \equiv 1 \bmod P_L \implies S = 1 \bmod P_L$$

Giving us $S = 1 + t$, $P_L \big| t$, so

$$S^P = 1 + pt + \cdots + t^p \equiv 1 \bmod P_L^P$$

a contradiction!

Finally, $L(\sqrt[p]{\nu})/L$ is unramified above P_L. Let

$$F = L(\sqrt[p]{\nu}),\ F \subseteq M(\zeta_{p^2}) \qquad F/Q \text{ abelian}$$

and $I \leqslant \mathrm{Gal}_{\mathbb{Q}}(\mathbb{F})$ where I is the inertia group above P, and $|I| = p-1$, so $F^I/\mathbb{Q}$ is unramified everywhere, namely $F^I = \mathbb{Q}$, so $F = L$. This implies

$$\nu \in (L^\times)^P$$

But then

$$M = \mathbb{Q}(\zeta_{p^2})$$

as we sought to show.

Let us use it in an actual example:

Example 50.5.6: Using Kronecker-Weber

Let $K/\mathbb{Q}$ be a galois extension with Galois group $\mathbb{Z}/5\mathbb{Z}$ whose discriminant is only divisible by $5, 11$, and 31. How many such number fields are there?

Proof. By Kronecker Weber, we know that K is an intermediary field of a Cyclotomic extension:

$$K \subseteq \mathbb{Q}(\zeta_n)$$

We may without loss of generailty assume n is minnimal for which this containment makes sense. Since only $5, 11, 31$, divide the discriminant, we know the discriminant of K is of the form:

$$\mathrm{disc}(\mathcal{O}_K) = 5^a 11^b 31^c$$

which also mean only $5, 11, 31$ ramify in K. Now, I claim that only $5, 11, 31$ divide n and no other number those. For the sake of contradiction, let's say $p \big| n$ but $p \notin \{5, 11, 31\}$. By minimality, we have:

$$\begin{tikzcd} & \mathbb{Q}(\zeta_n) \\ \mathbb{Q}(\zeta_{n/p}) \arrow[ur] & K \arrow[u] \\ & \mathbb{Q} \arrow[u] \arrow[ul] \end{tikzcd}$$

Let $I_{\mathfrak{B}}$ be the inertia group (for any prime $\mathfrak{B}$ lying above p). Since $p \nmid \mathrm{disc}(\mathcal{O}_K)$, p is unramified. If p is unramified in $\mathbb{Q}(\zeta_{n/p})$, then since $\mathbb{Q}(\zeta_{n/p}) \subseteq \mathbb{Q}(\zeta_n)$, we get that $\mathbb{Q}(\zeta_{n/p}) \subseteq \mathbb{Q}(\zeta_n)^{I_p} \subseteq \mathbb{Q}(\zeta_n)$

$$K \subseteq \mathbb{Q}(\zeta_n)^{I_{\mathfrak{B}}} \subseteq \mathbb{Q}(\zeta_{n/p})$$

contradicting minimality of n. Hence, we get $n = 5^a 11^b 31^c$. Thus:

$$\mathrm{Gal}_{\mathbb{Q}}(\mathbb{Q}(\zeta_n)) \cong (\mathbb{Z}/n\mathbb{Z})^\times \cong \mathbb{Z}/4\mathbb{Z} \times (\mathbb{Z}/5^{a-1}\mathbb{Z}) \times \mathbb{Z}/10\mathbb{Z} \times (\mathbb{Z}/11^{b-1}\mathbb{Z}) \times \mathbb{Z}/30\mathbb{Z} \times (\mathbb{Z}/31^{c-1}\mathbb{Z})$$

which now become a counting argument of how many subgroups of index 5 there are, counting the number of intermediary subfields, thus completing the proof. □

50.6 *Modules Over Dedekind Domains

(Useful for alg-geo, theory itself is also really nice. Also $\mathcal{O}_K$-modules appear in the next section)

Lemma 50.6.1: all Ideal co-maximal up to Module Isomorphism

Let $I, J \subseteq R$ be fractional ideals of a Dedekind domain R. Then $I \oplus J \cong_R R$

***Proof*:**
By corollary 50.2.12, we may choose in fact choose I, J to be integral ideals. We shall show that $I + j^{-1}J = R$ for some appropriate j^{-1}, which since $j^{-1}J \cong_R J$, we have $I \oplus J \cong_R R$

In particular, we shall show that for any ideal J, there exists an element $j \in J$ such that $I + jJ^{-1} = R$ (that is, every ideal is "almost" comaximal with any fractional ideal). It is equivalent to show that $IJ = (j) = J$. By corollary 50.2.19, IJ is generated by at most 2 elements, say $IJ = (a, b)$. Then since $a \in IJ \subseteq J$, we may choose a c such that $(a, c) = J$ (see proof of corollary 50.2.19 if you're not convinced we can choose such a c). Then since $b \in J$ (since $b \in IJ$)

$$IJ + (c) = (a, b) + (c) = (a, b, c) = (a, c) = J$$

hence, $I + jJ^{-1} = R$, which by corollary 50.2.12 we get $I + J \cong_R R$, completing the proof.

Proposition 50.6.2: Ideals Are Projective

Let R be a Dedekind domain and $I \subseteq R$ an ideal. Then I is a projective R-module

***Proof*:**
By lemma 50.6.1, we may choose any J such that $I + jJ^{-1} = R$, or equivalently $IJ + (j) = J$. We shall define an isomorphism $I \oplus J \to IJ \oplus R$ via

$$(x, y) \mapsto (iy - jx, x + ky)$$

This map is certainly well-defined since $iy, jx \in IJ$, so $iy - jx \in IJ$, and it is certainly R-linear. It is bijective, since it's inverse is $IJ \oplus R \to I \oplus J$

$$(x, y) \mapsto (jx + y, ix - ky)$$

Hence, we have $I \oplus J \cong IJ \oplus R$. Finally, by corollary 50.2.18, choose J so that $IJ = (a)$ is principal. Then it is a free R-module of rank 1, and so

$$I \oplus J \cong IJ \oplus R \oplus R^2$$

as we sought to show.

Proposition 50.6.3: IBN equivalent for Dedekind Domains

Let $I_1, ..., I_n$ and $J_1, ..., J_m$ be fractional ideals of a Dedekind domain R. Then

$$I_1 \oplus I_2 \oplus \cdots \oplus I_n \cong_r J_1 \oplus J_2 \oplus \cdots \oplus J_m$$

if and only if $n = m$ and

$$I_1 I_2 \cdots I_n = (a) J_1 J_2 \cdots J_n$$

that is, the product differs by a principal ideal (they belong to the same equivalence class in the class group). In particular,

$$I_1 \oplus I_2 \oplus \cdots \oplus I_n \cong_R \underbrace{R \oplus R \oplus \cdots \oplus R}_{n-1 \text{ times}} \oplus (I_1 I_2 \cdots I_n)$$

and $R^n \oplus I \cong R^n \oplus J$ if and only if $I = (a)J$ for some $a \in K(R)$.

***Proof*:**
First, let $I, J \subseteq R$ be two fractional ideals. By lemma 50.6.1, we may choose I, J to be integral ideals that are up to R-isomorphism relatively prime: $I + J = R$. Then $I \cap J = IJ$, and $\varphi : I \oplus J \to R$ given by $(x, y) \mapsto x + y$ has kernel $I \cap J = IJ$. Then:

$$0 \to IJ \to I \oplus J \to R \to 0$$

is a short exact sequence. Since R is a free R-module, it is projective, and hence the sequence splits, giving us

$$I \oplus J = IJ \oplus R$$

Theorem 50.6.4: Classifying Torsion-Free Modules Over Dedekind Domain

Let M be a torsion-free R-module over a Dedekind domain R of rank n. Then

$$M \cong R^{n-1} \oplus I$$

where we I may be replaced with any ideal J such that $I = (a)J$ (they belong in the same element in the class group). As a consequence, any torsion-free module over a Dedekind domain is projective.

***Proof*:**
If there exists a non-trivial map $\varphi : M \to R$, then since R-submodules of R are projective, we may iteratively split M as $M \cong N \oplus I$ to get a direct sum of ideals of R, which we may then use to conclude by using proposition 50.6.3.

Since M is torsion-free of rank n, we may extend scalars we get a n-dimensional $K = K(R)$ vector space $K \otimes_R M$ where $M \hookrightarrow K \otimes_R M$ naturally embeds injectively. Let $\beta_1, \beta_2, ..., \beta_n$ be a basis for $K \otimes_R M$ and $m_1, m_2, ..., m_k$ be a set of generators for M. Then

$$m_i = \sum_j (a_{ij}/b_{ij})\beta_j$$

Let $d = \prod_{ij} b_{ij}$ and $y_j = \beta_j/d$. Then

$$M = Ry_1 + \cdots + Ry_n \subseteq K\beta_1 + \cdots + K\beta_n$$

Hence, M is a R-submodule of a free R-module! Importantly, for each $m \in M$, it can be written as

$$m = \sum a_i y_i \qquad a_i \in R$$

hence, we may define $\varphi : M \to R$ by $\varphi(m) = a_n$. Then $\varphi(M) \subseteq R$ is an ideal of R, and so

$$M = \ker(M) \oplus I$$

Notice that $\text{Tor}(\ker(M)) = 0$, and so we may inductively repeat this procedure until we have products of prime ideals!

since the product of projective module is projective, any torsion-free module over a Dedekind domain is projective, as we sought to show.

50.7 *Geometric Idea: 1-Dimensional Schemes

See Neukirch, and put orders here too for their geometric interpretation. I think it is important to include (especially once this chapter becomes its own book) since (to me) this explains why ramification happens. We naturally can't prove the Riemann-Hurwitz Formula here, but this still is very interesting.

50.7.1 Localization of Dedekind Domains

For the motivation to CFT

50.7.2 Orders: Curves with Singularities

This entire section is completely inspired by Neukirch p.72

should also include how if finite L/K then $\operatorname{Spec}(\mathcal{O}_L)$ is the normalization of $\operatorname{Spec}(\mathcal{O}_K[\alpha])$ where $L = K(\alpha)$. And I would really love a discussion linking $\operatorname{Spec}(\mathcal{O}_L)$ to the "generic point" $\operatorname{Spec}(L)$ and to $y - m_{\alpha,K}(x)$ where $m_{\alpha,K}(x)$ is the minimal polynomial of L/K

All smooth 1-dimensional curves correspond to Dedekind domains. However, there are some curves with singularities. These curves are associated to sub-rings of Dedekind domains called *orders*

Definition 50.7.1: Order

Let $K/\mathbb{Q}$ be a number field of degree n. Then an order of K is a subring of $\mathcal{O}_K$ which contains an integral basis of length n. The ring $\mathcal{O}_K$ is called a *maximal order*.

By the above definition, an order is of the form:

$$\mathbb{Z}[\alpha_1, ..., \alpha_n]$$

where $K = \mathbb{Q}(\alpha_1, ..., \alpha_n)$, which motivates why $\mathcal{O}_K$ is the maximal order; it is the maximal ring with this property. This also implies that orders need not be normal, hence an order is a one-dimensional Noetherian integral domain (prime remain maximal as if $a \in \mathfrak{p} \cap \mathbb{Z}$ then $a\mathcal{O} \subseteq \mathfrak{p} \subseteq \mathcal{O}$ that is $\mathfrak{p}$ and $\mathcal{O}$ have the same rank n, and thus $\mathcal{O}/\mathfrak{p}$ is a finite integral domain, showing $\mathfrak{p}$ is maximal) . An example of an order is $\mathbb{Z} = \mathbb{Z}(\sqrt{5})$. Many order's naturally are as "rings of multipliers. For example if $\alpha_1, .., \alpha_n$ is a basis for $K/\mathbb{Q}$ and $M = \sum_i \mathbb{Z}\alpha_i$, then

$$\mathcal{O}_M = \{\alpha \in K \mid \alpha M \subseteq M\}$$

is an order.

It is important that we re-prove the Chinese remainder

Here

As orders are not Dedekind domain in general, *not* all ideals are invertible. This also means that the collection of fractional ideals does not form a group.

Proposition 50.7.2: Invertible Fracitonal Ideals

Let I be a fractional ideal of a Noetherian domain R. Then I is invertible iff its localization at every maximal ideal of R is invertible, equivalently, iff its localization at every prime ideal of R is invertible.

Proof:
MIT notes p.17

Example 50.7.3: non-invertible ideal of an order
put this example here

(I want this build up here)

Definition 50.7.4: Picard Group Of An Order

Let $J(\mathcal{O})$ be the collection of invertible ideals and $P(\mathcal{O})$ the fractional principal ideals. Then

$$\operatorname{Pic}(\mathcal{O}) = \frac{J(\mathcal{O})}{P(\mathcal{O})}$$

A lot more to be said.

The Picard group ignore s ideals that are not invertible. Another approach that gives some useful results is to define the following for A Dedekind domain:

$$\operatorname{Div}(\mathcal{O}) = \mathcal{O}_{\mathfrak{p}}\mathbb{Z}\mathfrak{p}$$

Then $\operatorname{Div}(\mathcal{O})$ is isomorphic to the ideal group. For an order, the divisor group shall be a quotient of this group. We would then need to define the divisor elements, which gives the divisor class group/chow group.

50.8 *Profinite Groups

(original title: infinite galois extensions)

I moved this from the galois theory chapter. I actually want to make this its own chapter when I extract these notes into their own book so that the many books that use profinite groups can reference this namely: the class field theory book, the p-adic rep book, and the galois cohomology book.

In this section, we shall explore the case of infinite separable normal extensions L/K. This section shall require the notion of topological groups and topological completion, which is covered in appendix C. Most of this material will be important for a course in *Class Field Theory* (see cite:HERE for a reference where this material is used).

In this section, a Galois extension is a normal separable extension, where the finiteness condition is dropped. We may want to keep the galois correspondence between the fixed fields and the subgroups, however there are simply way too many subgroups. Consider

$$\overline{\mathbb{Q}}/\mathbb{Q} \qquad \text{and} \qquad \operatorname{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$$

Then the reader should check that there are only countably many intermediary extension of degree 2 corresponding to the extensions of the form $\mathbb{Q}(\sqrt{\alpha})/\mathbb{Q}$ where α is either a prime p, ip, or a finite compositum of such elements. However, there are uncountably many index two subgroups. To see this, consider $\varphi_S : \operatorname{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}}) \to \mathbb{Z}/2\mathbb{Z}$ where S is a finite collection of primes where if σ fixes each $\sqrt{p}$. Then $\varphi_S(s) = 0$, and it is 1 otherwise. This is a group-homomorphism, as the composition of two maps that fix each $\sqrt{p}$ for $p \in S$ shall still fix those primes. Furthermore, There are certainly always morphisms τ such that $\varphi_S(\tau) = 1$ for each finite subset S. Thus, each φ_S is a surjective homomorphism, whose kernel is index 2. But then, there are uncountably distinct $\ker(\varphi_S)$. In fact, we don't even need S to be finite (exercise). In this case, we shall even have index two subgroups whose fixed field corresponds to $\mathbb{Q}$!

The reader may feel that there is some simple solutions that can be found, as it seems there are many galois subgroups corresponding to an intermediary. Indeed, we may still recover the galois correspondence if we appropriately limit which subgroups of $\mathrm{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ we consider (and more generally which subgroups of $\mathrm{Gal}_K(L)$ we consider). This is done by taking the *Krull topology* on the galois group, which we shall naturally derive by first taking the *profinite topology*. The profinite topology shall make us limit our attention to normal subgroups of finite index (namely, such subgroups shall be open in the profinite topology), while in the Krull topology we shall limit our attention to normal subgroups of finite index which also have a [finite] galois group (namely, such subgroups shall be open in the Krull topology). Both of these topologies are achieved by showing that the infinite galois group, as a topological group, is a profinite group. The main idea is that all of the information of infinite galois extension is in fact fully captured by the finite normal extension, due to the fact galois groups represent the relationship of polynomials (where an infinite galois groups stores the information of infinitely many polynomials).

50.8.1 Profinite Groups

In this section, a brief introduction to profinite groups is given. This is not an in-depth coverage, but rather it gives enough information to describe infinite galois theory.

Definition 50.8.1: Profinite Group

Take an inverse system of finite groups with the discrete topology. Then a *profinite group* is a topological group that is the limit of the system. Given any topological group G, we can take its *profinite completion* by taking:

$$\widehat{G} = \varprojlim_N G/N$$

where N ranges over all finite index open normal subgroups ordered by containment.

Any group G can be given a topology by given it the profinite topology given by taking the cosets of finite-index normal subgroups as a basis. The reader should check that if G is a topological group and $\widehat{G}$ is its profinite completion, then the continuous homomorphism $\varphi : G \to \widehat{G}$ can be shown that G is dense in $\widehat{G}$.

Example 50.8.2: Profinite Groups

1. Let G be finite. Then all normal subgroups have finite index and there are finitely many. It follows that $G \cong \widehat{G}$.
2. Let $G = \mathbb{Z}$. Then
$$\widehat{Z} = \varprojlim_n \mathbb{Z}/n\mathbb{Z} \cong \prod_p \mathbb{Z}_p$$
where $\mathbb{Z}_p = \varprojlim_n \mathbb{Z}/p^n\mathbb{Z}$ is the p-adic completion of $\mathbb{Z}$.
3. Take $G = \mathbb{Q}$. Then $\mathbb{Q}$ has only one finite-index normal subgroup, namely itself. Hence $\widehat{\mathbb{Q}} = \{1\}$.

The above examples show that the map $\varphi : G \to \widehat{G}$ could be injective, surjective, both. The map will be injective if the intersections of all finite-index open normal subgroups of G is trivial (where we would then say G is residually finite). The completion comes equipped with a natural universal property where a continuous homomorphism $\varphi : G \to H$ with H a profinite group has a unique continuous homomorphism such that the following diagram commutes:

$$\begin{tikzcd} G \arrow[r, "\varphi"] \arrow[dr, "\varphi"'] & \widehat{G} \arrow[d, "\exists!"] \\ & H \end{tikzcd}$$

A word on strongly complete? MIT notes p.275 Remark 26.15

Theorem 50.8.3: Characterizing Profinite Groups

A topological group is profinite if and only if it is a totally disconnected compact group

***Proof*:**
exercise: Compactness comes from Tychnoff's Theorem, while totally disconnected shall come from the discreteness in each finite quotient

Corollary 50.8.4: Distinguishing Profinite Completion

Let G be a profinite group. Then G is naturally isomorphic to its profinite completion, or even stronger:

$$G \cong \varprojlim G/U$$

where U ranges over all open normal subgroups ordered by contain need.
If G is isomorphic to its profinite completion *as a group* (i.e. is strongly complete) if and only if every finite index subgroup is open

***Proof*:**
MIT notes p.276

50.8.2 Infinite Galois Theory

Let us now find which topology to put on galois groups. Let us first make sure that the notion of there being a correspondence between subfields and fixed fixed fields of subgroups of galois group is still well-defined

Lemma 50.8.5: Fixed Field Infinite Extension

Let L/K be a galois extension with galois group $G = \mathrm{Gal}_K(L)$. Then if F/K is a normal subextension of L/K, then $\mathrm{Gal}_F(L) = H \trianglelefteq G$ is a normal subgroup of G wit fixed field F. As the subgroup is normal,we have the short exact sequence:

$$1 \to \mathrm{Gal}_F(L) \to \mathrm{Gal}_K(L) \to \mathrm{Gal}_K(F) \to 1$$

which implies:

$$G/H \cong \mathrm{Gal}_K(F)$$

***Proof*:**
As F/K is normal, the map $\sigma \mapsto \sigma|_F$ is a well-defined surjective map (as every $\tau \in \mathrm{Gal}_K(F)$ can be extended to an element $\sigma \in \mathrm{Gal}_K(L)$, see exercise ref:HERE) and has kernel $\mathrm{Gal}_F(L)$ by definition. Then by definition $F \subseteq L^H$, and $L^H \subseteq F$ since if $\alpha \in L^H \setminus F$, then we can construct an element of H that sends α to a distinct root $\alpha' \neq \alpha$ of its minimal polynomials f over F, completing the proof.

Hence, every normal subextension has (at least one) corresponding normal subgroup. However, there are many normal subgroups whose fixed field F is *not* equal to $\mathrm{Gal}_F(L)$, but is contained in $\mathrm{Gal}_F(L)$ The index two example of $\mathrm{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ is the prototypical example, where there are uncountably many index 2 subgroups $H \leqslant \mathrm{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ whose fixed field is $\mathbb{Q}$ but naturally H is not the galois subgroup of $\overline{\mathbb{Q}}/\mathbb{Q}$, nor is it the galois group of $\overline{\mathbb{Q}}/K$ for any subextension $K/\mathbb{Q}$. Hence, the following topology limits our attention to the right groups:

Definition 50.8.6: Krull Topology On Galois Group

Let L/K be a Galois (i.e. normal separable) extension with $G = \mathrm{Gal}_K(L)$. Then the *Krull Topology* on G is the basis given by the basis consisting of cosets of the subgroups

$$H_F = \mathrm{Gal}_F(L)$$

where F ranges over finite normal extensions of K in L.

In this topology, every open normal subgroups has finite index, but not every normal subgroup of finite index is open (think $\mathrm{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ again). Hence, this topology is (strictly) coarser than the porfinite topology, however it is still a profinite group:

Proposition 50.8.7: Galois Group is Profinite Group

Let L/K be a galois extension. Then under the Krull topology, the restriction maps induce a natural isomorphism of topological groups:

$$\mathrm{Gal}_K(L) \cong \varprojlim_F \mathrm{Gal}_K(F)$$

where F ranges over finite galois extension of K in L. Hence, $\mathrm{Gal}_K(L)$ is a profinite group whose open normal subgroups are those of the form $\mathrm{Gal}_F(L)$ for some finite normal extension F/K.

***Proof*:**
Let's first show the map is bijective. For injectivity, for every $\alpha \in L$ it is algebraic over K, and hence liens ins some finite normal subextensions F/K, and so every automorphism in $\mathrm{Gal}_K(L)($ is uniquely determined by all its restrictions to finite normal F/K, showing φ is injective. For surjectivity, given any $(\sigma_F) \in \varprojlim_F \mathrm{Gal}_K(F)$, we may define a corresponding $\sigma \in \mathrm{Gal}_K(L)$ that maps to it by point-wise defining:

$$\sigma(\alpha) := \sigma_F(\vec{\alpha})$$

where F is the normal closure of $K(\alpha)$. This map is well-defined by construction of the inverse limit, giving surjectivity.

For continuity, Letting $G = \mathrm{Gal}_K(L)$ and $H_F = \mathrm{Gal}_F(L)$, we can view φ as the natural continuous map:

$$\varphi : G \to \varprojlim G/H_F$$

Finally, to show the inverse is continuous, we'll show the equivalent of φ being an open map, which translates to showing that φ maps open subgroups $H \subseteq G$ (i.e. the basis) to open subsets in $\varprojlim G/H_F$. Taking $H = \mathrm{Gal}_F(L)$, we get:

$$\varphi(H) = \{(\sigma_E) \mid \sigma_{E_{E\cap F}} = \mathrm{id}_{E\cap F}\} = \pi_F^{-1}(\mathrm{id}|_F)$$

as E/K ranges over all finite normal subextension of L/K and π_F is the projection from the limit to $\mathrm{Gal}_K(F)$. Then the singleton set $\{\mathrm{id}|_F\}$ is open in the discrete group $\mathrm{Gal}_K(F)$, and so its inverse is open, completing the proof.

Theorem 50.8.8: Fundamental Theorem of Galois Theory, Infinite Extensions

Let L/K be a galois extension with galois group $G = \mathrm{Gal}_K(L)$ endowed with the Krull topology. Then the maps

$$F \mapsto \mathrm{Gal}_F(L) \qquad H \mapsto L^H$$

define inclusion reversing bijections between subextensions F/K of L/K and closed subgroups H of G. Thus, subextensions of finite degree n correspond to subgroups of finite index n, and normal subextensions F/K correspond to normal subgroups $H \trianglelefteqslant G$ such that as topological groups:

$$\mathrm{Gal}_K(F) \cong G/H$$

***Proof*:**
First off, recall that every open subgroup is clopen, as the compliment is the union of non-trivial cosets, and so closed subgroups of finite index are open. Next, the correspondence between finite galois subextensions F/K and finite index closed normal subgroups H is given by proposition 50.8.7, and furthermore we have $[F : K] = [G : H]$ as $G/H \cong \mathrm{Gal}_K(F)$ by lemma 50.8.5.

For the correspondence maps, if F/K is any finite subextension with normal closure E, then $H = \mathrm{Gal}(L/F)$ contains the normal subgroup $N = \mathrm{Gal}(L/E)$ with finite index. The subgroup N is open and therefore closed, thus H is closed since it is a finite union of cosets of N. The fixed field of H is F (by the same argument as in the proof of lemma 50.8.5), thus finite subextensions correspond to closed subgroups of finite index. Conversely, every closed subgroup H of finite index has a fixed field F of finite degree, since the intersection of its conjugates is a normal closed subgroup $N = \mathrm{Gal}(L/E)$ of finite index whose fixed field E contains F and has finite degree. The degrees and indices match because $[G : N] = [G : H][H : N]$ and $[E : K] = [F : K][E : F]$; by the previous argument for finite normal subextensions, $[E : K] = [G : N]$ and $[E : F] = [H : N]$ (for the second equality, replace L/K with L/F and G with H).]

Next, for the closed part, any subextension F/K is the union of its finite subextensions E/K. The intersection of the corresponding closed finite index subgroups $\mathrm{Gal}(L/E)$ is equal to $\mathrm{Gal}(L/F)$, which is therefore closed. Conversely, every closed subgroup H of G is an intersection of basic closed subgroups, all of which have the form $\mathrm{Gal}(L/E)$ for some finite subextension E/K, thus $H = \mathrm{Gal}(L/F)$, where F is the union of the E, completing the proof.

Finally, we see that the isomorphism $\mathrm{Gal}_K(F) \cong G/H$ of topological groups follows from lemma 50.8.5, completing the proof.

Corollary 50.8.9: Closure in Krull Topology

Let L/K be a galois extension and $H \leqslant \mathrm{Gal}_K(L)$ with fixed field F. Then the closure $\overline{H}$ in the Krull Topology is $\mathrm{Gal}_F(L)$:

$$\overline{H} = \mathrm{Gal}_F(H)$$

***Proof*:**
First, $H \subseteq \mathrm{Gal}_F(L)$ since by definition $\mathrm{Gal}_F(L)$ contains every $\sigma \in \mathrm{Gal}_K(L)$ that fixes F . Next, $\mathrm{Gal}_F(L)$ is closed and is the group characterized by $L^{\mathrm{Gal}_F(L)} = F$ by theorem 50.8.8. Thus

$$H \subseteq \overline{H} \subseteq \mathrm{Gal}_F(L)$$

Then in the bijection presented in theorem theorem 50.8.8, we have that they are equal, completing the proof.

Let us conclude with a result proven by Waterhouse in 1973 that generalizes theorem 20.2.10:

Theorem 50.8.10: Profinite Group Representable By Galois Group

Let G be a profinite group. Then G is isomorphic to the galois group of some galois extension L/K

> ***Proof*:**
> MIT notes p.279

Just like for finite groups where $K = \mathbb{Q}$ is a difficult (as of writing this book unsolved) problem called the *inverse Galois Problem*, there is little control on what base field K we can choose.

Exercise 50.8.1

1. Find $G = \mathrm{Gal}_{\mathbb{F}_p}(\overline{\mathbb{F}}_p)$ recalling that for each degree n, there is only one extension of $\mathbb{F}_p$. Show that there are too many subgroups to correspond to the fixed fields. Define the Krull topology on G.

Part X

Representation Theory

There are many domains of mathematics which have made huge amounts of progress, having very-well understood objects and morphisms, theorems, results, and properties. One of the most well-understood area's of mathematics has become linear algebra, where vector-spaces and linear transformations. One of the goals of this chapter will be do be able to study the following 3 objects where the operations becomes matrix addition and multiplication

1. (Finite) groups as a subgroup of $\mathrm{GL}(V)$, where the group operation becomes the matrix multiplication
2. Associative algebras
3. Lie Algebras

The further advantage of bringing these objects into linear algebra is that many field intersect with it: If the vector-spaces are infinite dimensional, we can make them Hilbert spaces and use tools from analysis. Vector-spaces are at the heart of differential geometry allowing us to use such theories to study groups!

For the reader who is really interested in number theory, we shall see in ref:HERE that matrix algebras have many parallels with some number theory results. The reader who goes onto learn class field theory[28] will to their delight find that these parallels continue. It was observed by Langland[29] that the study of simple k-algebras (algebras with trivial two-sided ideals) can be a higher-dimensional parallel to field extensions and the central results of class field mathematics known as the *Langland's Program*.

(The reader may want to go back to section 12.3 to review about direct sums of modules)

(Also, this entire link is really cool: from wiki. Also has some cool examples of duality!!!)

[28]See [39] for the continuation of this textbook into class field theory
[29]Or at least formalized by Langland, as these ideas were floating around during his time

51

Semisimple Rings and Modules

As mentioned in the introduction, representation theory is all about decomposing structures. In part I, we showed in chapter 3, section 3.7, that all finite groups can uniquely be represented as a series of extensions with simple factors (i.e. G_i/G_{i+1} is simple). The simplest type of composition series would be when G is a direct product of simple groups, which would be in the terminology of exact sequences a series of trivial extensions with simple factors: such a group is sometimes *semi-simple* group[1]. When it came to modules, we found that we may decompose it in different ways depending on what rings acts on it, in particular we saw in chapter 13 that if $R = k$ is a field k, then any k-module is free, and in chapter 14 we saw that if R is a Principal Ideal Domain, where we got that any R-module decompsoed into a free part R-isomorphic to R^k, and a torsion part $R/(a_1) \times \cdots \times R/(a_n)$. It is evident that the ring that acts on the abelian group can have a large impact on it's structure. In this section, we define a new type of ring, which will come to be called a *semi-simple* ring, that will force the module M to *always* be a direct product of *simple modules* (so that we are analysing the "building blocks" of modules).

To define this ring, we first shift focus and start by work with the module itself to find the "simplest" structure it may be[2], and explore in a manner which at the beginning parallels groups: we will look for *simple R-modules*, and direct product of simple modules (since they are the simplest extension of simple module).[3]. After defining such a strucutre, we will define which rings acting on moduels will *always* make the module semi-simple

[1] the term "semi-simple group" is not a completely standard terminology, as direct product of simple groups is not generally very heavily studied, see this

[2] "simple" here means no non-trivial sub-structures that can be used to build an extension, just like for simple groups or simple rings

[3] It might be tempting to say that this means we are exploring projective modules. However, we have yet to establish whether simple modules are free-modules. Are they?

51.1 Decomposing Modules

Definition 51.1.1: Decomposition Terminology

Let M be a nonzero R-module.

1. M is said to be *simple* (or *irreducible*) if the only submodules of M are 0 and M. Otherwise, M is *reducible*
2. M is said to be *indecomposable* if there do not exist submodules $M_1, M_2 \subseteq M$ such that $M = M_1 \oplus M_2$. Otherwise, M is said to be *decomposable*.
3. The module M is said to be *semisimple* (or *completely reducible*) if it is the direct summand of simple modules
4. The module M is said to be semi-indecomposable (or completely indecomposable) if it is a direct summand of indecomposable modules.
5. If M is semisimple, any direct summand of M is called a *constituent* of M (i.e. N is a constituent of M if there exists a submodulde N' such that $M = N \oplus N'$)

A moment should be taken to find the relations between these definitions:

1. Simple modules are semi-simple and indecomposable. The prototypical example of a simple module is a field k over itself.
2. Semi-Simple $\not\Rightarrow$ Simple: take k^2 over k (the 2 dimensional vector-space over k). The cannonical example of a semi-simple module would be vector-spaces, since they are all direct sums of the underlying field, which is a simple k-module.
3. Indecomposable $\not\Rightarrow$ Simple: this statement is equivalent to saying that not all short exact sequence spilt (i.e., not all modules are *projective*, see section 17.2). For a concrete example, let $\mathbb{Z}^2$ be a module over $\mathbb{Z}$ with the action:

   $$r \cdot (a, b) = (a + rb, b)$$

   Then it should be checked that it is not simple since $\mathbb{Z} \times \{0\}$ is a submodule, but it is indecomposable[4].
4. Every semi-simple module is a semi-indecomposable module, however the converse is not true: $\mathbb{Z}$ is a semi-indecomposable $\mathbb{Z}$-module (more genreally any module module over a PID is semi-indecomposable due to the Decomposition Theorem from chapter 14), however $\mathbb{Z}$ is not semi-simple a semi-simple $\mathbb{Z}$-module as $p\mathbb{Z}$ is a submodule (the general case will be immediate after lemma 51.1.7)[5]

As stated in the introduction, we want to determine a semi-simple module or semi-simple modules in terms of the ring that is acting on it. The following defintion was made for this purpose:

[4]Hint: Is it possible to write $\mathbb{Z} = n\mathbb{Z} \oplus m\mathbb{Z}$?
[5]This is a version of Krull-Schmidt's theorem for the decomposition of Noetherian or Artinian modules into the direct sum of indecomposable

Definition 51.1.2: Semi-Simple Ring

Let R be a ring. Then R is *semi-simple* if every R-module is semi-simple. Recall that R is *simple* if the only two-sided ideals are (0) and R.

Notice how a semi-simple ring was *not* defined as the direct product of simple rings. In the following proofs, we will show that the definition of semi-simple ring implies that R is the direct product of simple rings, however the converse is not true: there exists simple rings that are *not* semi-simple modules over themselves (and hence not simple R-modules). The problem is that of dimension; we will soon explore the relation between being semi-simple and Noetherian/Artinian. If we impose the condition that R be Noetherian and Artinian, then we are able to say that R is a semi-simple ring if and only if R is the direct product of simple rings.

We next establish many properties of simple and semi-simple modules, and show how closely related they are to the ring acting on them:

Lemma 51.1.3: Simple Module Characterization

Let M be an R-module. Then M is a simple R-module if and only if there exists a two-sided maximal ideal $\mathfrak{m} \subsetneq R$ such that

$$M \cong_R R/\mathfrak{m}$$

***Proof*:**

($\Rightarrow$) Let M be a simple [non-trivial] R-module so that the only sub-modules of M are $\{0\}$ and M. Consider any $0 \neq x \in M$ and the R-module homomorphism:

$$\varphi : R \to M \qquad r \mapsto r \cdot x$$

Since $\varphi(R) \subseteq M$ is a sub-module and M is a non-trivial R-module, it must be that $\varphi(R) = M$. Hence:

$$R/\ker(\varphi) \cong M$$

But then, $R/\ker(\varphi)$ cannot have any submodules, since M doesn't, and so $\ker(\varphi)$ must be maximal.

($\Leftarrow$) Let $R/\mathfrak{m} \cong M$ as R-module where $\mathfrak{m}$ is maximal. If $0 \subsetneq N \subsetneq M$, then there would exist an ideal $\subsetneq J \subsetneq R/\mathfrak{m}$, but that would make $\mathfrak{m} \subseteq J$, contradicting maximality of $\mathfrak{m}$.

If R is commutative, then $R/\mathfrak{m}$ is a field. For the non-commutative case, $R/\mathfrak{m}$ need not be a field, not even a division ring, the canonical example being $M_n(k)$ for $n \geq 2$ (see the remark ref:HERE or go over section 9.4.3). Do not confuse the isomorphism in the above statement as a ring isomorphism: the structure of M is isomorphic to the R-module structure of left-multiplication on $R/\mathfrak{m}$. Notice how this also shows that a simple R-module M is cyclic since $R \cdot \varphi(1) = \varphi(R \cdot 1) = \varphi(R/\mathfrak{m}) = M$[6]. If $R = k$ is a field, then M is isomorphic to a 1-dimensional vector-space over k. There do exist non-commutative rings R that are *not* of the form $M_n(k)$; we shall explore in ref:HERE that there is a family of quaternion algebras that are degree two extensions of a field k that is simple ring (more specifically, a simple k-algebra).

[6] In fact, any element must generate it, can you see why?

Using this result, we see that any semi-simple R-module is of the form:

$$M \cong_R \bigoplus_{i \in I} R/\mathfrak{m}_i$$

for maximal ideals $\mathfrak{m}_i \subseteq R$. In fact, we can further characterize $\mathfrak{m}_i$:

Corollary 51.1.4: Simple Module's And Annihilators

Let M be a simple left (or right) R-module. Then $M \cong R/\text{Ann}(m)$ for any nonzero m, and $\text{Ann}(m)$ is a maximal ideal.

***Proof*:**
Since M is a simple left R-module, for any $0 \neq m \in M$, $mR \subseteq M$ is a submodule (by identifying R in M by the map $r \mapsto r \cdot 1$). As it is nonzero and M is simple, $M \cong_R Rm$. Then we have a surjective R-module homomorphism

$$R \to Rm \qquad r \mapsto r \cdot m$$

Thus, $R/\mathfrak{m} \cong_R Rm$ for some ideal $\mathfrak{m}$ (note that the R-submodules of R are ideals). In particular, $\varphi(\mathfrak{m}) = \mathfrak{m}m = 0$, so $\mathfrak{m} = \text{Ann}(m)$ by definition. Thus, we have the isomorphism chian:

$$M \cong_R Rm \cong_R R/\text{Ann}(m)$$

Finally, since Rm is simple, $R/\text{Ann}(m)$ must have no other two-sided ideal,s i.e. $\text{Ann}(m)$ is a two-sided maximal ideal, completing the proof.

Since we've seen the limitations of the structure of simple modules, it is also natural to ask if there are any limitations on the structure of the hom-set given two simple modules:

Lemma 51.1.5: Schur's Lemma

Let M and N be simple R-modules, $\varphi : M \to N$ an R-module homomorphism. Then either $\varphi = 0$ or φ is an isomorphism. As a consequence, $\text{End}_R(M)$ is a division ring.

***Proof*:**
Since N is simple, either $\varphi(M) = N$ or $\varphi(M) = 0$. If $\varphi(M) = N$, it has to be that $\ker(\varphi) = 0$, since M is simple, and hence φ would be an isomorphism.

As a consequence, every element in $\text{End}_R(M)$ is either 0 or is a unit, i.e. has a multiplicative inverse, which by definition makes $\text{End}_R(M)$ a divising ring under $(+, \circ)$.

Since $M \cong_R R/\mathfrak{m}$ for some maximal ideal $\mathfrak{m} \subsetneq R$, we have that $\text{End}_R(R/\mathfrak{m})$ is always a division ring, whether R is commutative or not. In a sense, this can be thought of as "generalization" to proposition 9.4.19, where it was shown that $R/\mathfrak{m}$ is a field if R is commutative.

Notice that if $M = V$ was an 1-dimensional vector-space over k, then $\text{End}_R(V)$ is a known division ring, in particular it's ring-isomorphic to k. If V is a finite dimensional semi-simple module over k, i.e. it is n-dimensional, then $\text{End}_R(V)$ is ring-isomorphic to $M_n(k)$. We might hope for something similar for the structure of $\text{End}_R(M)$ is M is semi-simple. Take a moment to ponder this before reading the next lemma (hint: recall proposition 12.3.36)

Lemma 51.1.6: Hom's of Semisimple Modules

Let M be a semisimple R-module, so that:

$$M = S_1^{\oplus n_1} \oplus S_2^{\oplus n_2} \oplus \cdots \oplus S_k^{\oplus n_k}$$

where each S_i are simple R-modules, $S_i \not\cong S_j$. Then as a ring:

$$\text{End}_R(M) \cong_{\textbf{Ring}} \text{End}_R(S_1^{\oplus n_1}) \oplus \cdots \oplus \text{End}_R(S_k^{\oplus n_k})$$

Furthermore, for each $S_i^{\oplus n_i}$, we have that direct sums "pull out" to become matrices:

$$\text{End}_R(S_i^{\oplus n_i}) \cong_{\textbf{Ring}} M_{n_i}(\text{End}_R(S)) = M_{n_i}(D_i)$$

where $D = \text{End}_R(S_i)$ and $M_{n_i}(D_i)$ is the matrix ring over the division ring $\text{End}_R(S_i)$.

***Proof*:**
We invoke proposition 12.3.36 to get the result in terms of groups, and then use Schur's lemma and check that the ring operation is compatible:

$$\begin{aligned}
\text{End}_R(M) &= \text{Hom}_R\left(\bigoplus_i S_i^{\bigoplus n_i}, \bigoplus_j S_j^{\bigoplus n_j}\right) \\
&\cong_{\textbf{Grp}} \bigoplus_{i,j} \text{Hom}_R\left(S_i^{\bigoplus n_i}, S_j^{\bigoplus n_j}\right) \\
&\cong_{\textbf{Grp}} \bigoplus_{i,j} \text{Hom}_R\left(S_i, S_j\right)^{\bigoplus n_i n_j}
\end{aligned}$$

where when $S_i \neq S_j$, by Shur's lemma we must have:

$$\text{Hom}_R(S_i, S_j)^{n_i n_j} = 0$$

Hence we get that $\text{End}_R(M) \cong_{\textbf{Grp}} \oplus_i \text{Hom}_R(S_i^{n_i}, S_i^{n_i}) = \oplus_i \text{End}_R(S_i^{n_i})$. Next, this map is compatible with the ring structure, since the map:

$$\varphi \to (\varphi|_{S^{n_i}} : S_i^{n_i} \to S_i^{n_i} \subseteq M)$$

is clearly clearly compatible with composition, and hence

$$\text{End}_R(M) \cong_{\textbf{Ring}} \bigoplus_i \text{End}_R(S_i^{n_i})$$

For part 2, we follow the same steps as for part (1): re-indexing so that $S^n = S_1 \oplus S_2 \oplus \cdots \oplus S_n$ so that $S_i = S_j = S$, we get

$$\text{Hom}_R\left(\bigoplus_i S_i, \bigoplus_j S_j\right) \cong_{\textbf{Grp}} \bigoplus_{i,j} \text{Hom}_R(S_i, S_j) \stackrel{!}{=} \bigoplus_{i,j} D \cong_{\textbf{Grp}} M_n(D)$$

where $\overset{!}{=}$ comes from Shur's lemma with $D = \mathrm{End}_R(S)$ since $S_i = S_j = S$. The last equality comes from the fact that the matrix $M_n(D)$ when treated like a group is simply re-arranging where the addition is happening in $\bigoplus_{i,j} D$. To show that the ring structure is compatible, observe that

$$\varphi \mapsto \varphi_{ji}$$

is the desired map, where

$$\varphi \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix} = \begin{pmatrix} \varphi_{11} & \varphi_{12} & \cdots & \varphi_{1n} \\ \varphi_{21} & \varphi_{22} & \cdots & \varphi_{2n} \\ \vdots & \vdots & \ddots & \cdots \\ \varphi_{n1} & \varphi_{n2} & \cdots & \varphi_{nn} \end{pmatrix} \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix}$$

which is simply a formalization of what the group-isomorphism give us, showing us that composition is compatible, completing the proof. (see this for a more detailed explanation)

Hence, for any semi-simple R-module M, we get that:

$$\mathrm{End}_R(M) \cong_{\mathbf{Ring}} \prod_i M_{n_i}(D_i) \cong_{\mathbf{Ring}} \prod_i \mathrm{End}_R(S_i^{\oplus n_i})$$

and since each S_i is a simple R-module, $S \cong_R R/\mathfrak{m}_i$ for appropriate maximal ideal $\mathfrak{m}_i \subseteq R$, $\mathrm{End}_R(S_i) \cong \mathrm{End}_R(R/\mathfrak{m}_i)$. Thus:

$$\mathrm{End}_R(M) \cong_{\mathbf{Ring}} \prod_i M_{n_i}(\mathrm{End}_R(R/\mathfrak{m}_i)) = \prod_i M_{n_i}(D_i)$$

If $R = k$ is a field making $M = V$ a vector-sapce over k (say n-dimensonal), then the only simple k-submodule up to isomorphism is k, and so this result reduces to:

$$\mathrm{End}_R(V) \cong_{\mathbf{Ring}} M_n(\mathrm{End}_k(k/(0))) = M_n(k)$$

where $\mathrm{End}_k(k) \cong_{\mathbf{Ring}} k$, aligning with the results we found in secion 13.2. This shows that when generlizing from linear algebra, due to the fact that a ring is non-commutative, we may have multiple non-isomorphic maximal ideals giving us multiple products of matrix rings. With a better understanding of simple modules and their endomorphisms, we continue by characterizing semi-simple modules:

Lemma 51.1.7: Semi-Simple Module Equivalence

Let M be a semi-simple module. Then the following are equivalent:

1. M is an external direct sum of simple modules:
$$M \cong \bigoplus_{i \in I} S_i$$
2. M is is the internal direct sum of simple modules:
$$M = \bigoplus_{i \in \mathfrak{m}} S_i$$
3. If $N \subseteq M$, there exists a complimentary module, that is there exists another submodule $N' \subseteq M$ such that
$$M = N \oplus N'$$
i.e., every semi-simple R-module M is *projective* and *injective*.

***Proof*:**
(1) $\Rightarrow$ (2) is proposition 12.3.6.

For (2) $\Rightarrow$ (3), Let $N \subseteq M$. Then using Zorn's lemma, we take a maximal submodule $N' \subseteq M$ ordered by inclusion with the property that $N \cap N' = 0$ (upper-bounds naturally exist in this set, and 0 is in this set, and hence Zorn's lemma does apply). If $M = N + N'$, we're done, since we can use the isomorphism from proposition 12.3.6. For the sake of contradiction, let's say $N + N' \subsetneq M$. Then since $M = \sum_i S_i$, there must exist some $i \in I$ and $s_i \in S_i$ such that $s_i \notin N + N'$, since $0 \in S_j$ for all $j \in I$. Hence $S_i \subsetneq N + N'$, so $S_i \cap (N + N') \subsetneq S_i$, however S_i is simple, and hence:
$$S_i \cap (N + N') = 0$$
But then:
$$(S_i + N') \cap N \subseteq N' \cap N = 0$$
Thus, by maximality of N', $S_i + N' = N'$, so $S_i \subseteq N' \subseteq N + N'$, contradicting the assumption that $s_i \notin N + N'$, as we sought to show.

For (3) $\Rightarrow$ (1), Let $\mathcal{S}$ be the collection of simple submodule of M where their direct sum maps injectively into M. Since $0 \in \mathcal{S}$ and taking the sum's of all the modules is an upper bound, Let N be the maximal submodule with this property. By proposition 12.3.6,
$$N = \sum_{i \in I} S_i \cong \bigoplus_{i \in I} S_i$$
If the map is surjective, we are done. For the sake of contradiction, suppose it is not. Then by part (3), there exists an N' such that $M = N + N'$. If $N' = 0$, we found a contradiction. So, let's say $N' \neq 0$. Then it is enough to show that N' contains a simple module, say S, since then we can make the collection $\{(S_i)_{i \in I}, S\}$ which will map injectively into M, contradicting maximality.

(here is what the professor posted Suppose every submodule N of M has a complement (i.e. a submodule N' of M such that $M = N \oplus N'$ (internal direct sum)). Then every nonzero submodule N' of M contains a simple submodule.

Proof: first we show that every submodule K of M has the same property (every submodule has a complement): suppose L is a submodule of K. by assumption, $M = L \oplus L'$ for some submodule L' of M. then note that $K = L \oplus (L' \cap K)$.

Now, suppose N' is nonzero submodule of M. Take a nonzero $x \in N'$, so Rx is a nonzero submodule and by 1st isomorphism theorem we have $Rx \cong_R R/I$ for some proper left ideal I. By the previous paragraph, every submodule of Rx has a complement, i.e. every submodule of R/I has a complement. Take any maximal left ideal $\mathfrak{m}$ containing I. Then M/I is a submodule of $R/\mathfrak{m}$ with complement L' in R/I, i.e. $R/I = \mathfrak{m}/I \oplus L'$, so $L' \cong (R/I)/(\mathfrak{m}/I \cong R/\mathfrak{m}$ is simple, i.e. L' is a simple submodule of N' (via the isomorphism $Rx \cong R/I$))

This theorems shows that every vector-space over k is a semisimple k-module, however by remark internalSumVsSumRmk, $\mathbb{Z}$ is *not* a semi-simple $\mathbb{Z}$-module, since $2\mathbb{Z}$ is a submodule with no compliment (showing that not all free modules are semi-simple).We can characterize semi-simple rings by saying that R is semi-simple if and only if every R-module is projective. This also shows us that $\mathbb{Z}$ is not a semi-simple ring; though $\mathbb{Z}$ is projective over itself, any finite ablıean group is a non-projective $\mathbb{Z}$-module. Thus, a module of a semi-simple ring is stronger then being a projective module. Hence being semi-simple is stronger (in a sense much stronger) than being projective, but may not be free: even though many example of semi-simple modules are free-modules, we would require the underlying ring to be semi-simple over itself. In fact, it is enough that the underlying ring be a semi-simple module over itself, giving us an easier condition for defining a semi-simple ring! We first intorduce an important result we will use:

Corollary 51.1.8: Extension Closure Of Semisimple Modules

Let M an R-module. Then submodule and quotient modules of M are semisimple if and only if M is semi-simple. Furthermore, if $(M_i)_{i\in I}$ is a collection of semi-simple modules, then $\bigoplus_{i\in I} M_i$ is a semi-simple module.

***Proof*:**
The direct sum of semi-simple modules is semi-simple by definition, and so we check the other two statements.

Let M be a semi-simple R-module so that $M = \bigoplus_{i\in I} S_i$ is by lemma 51.1.7. First, consider a surjection $M \twoheadrightarrow N$.

$$\varphi(M) = \varphi\left(\bigoplus_{i\in I} S_i\right) = \bigoplus_{i\in I} \varphi(S_i)$$

then by Schur's lemma, either $\varphi(S_i) = 0$ or $\varphi(S_i) \cong S_i$, and hence N is semisimple.

If $N \subseteq M$, then by lemma 51.1.7, we have that $M = N \oplus N'$, and so by proposition 12.3.6

$$M/N' \cong N$$

which we just showed makes N semi-simple.

Using these two facts, it is not difficult to show that if $N \subseteq M$ and $M/N \cong N'$ are semi-simple, then so is M, where if $x \in M$, $x = \sum_i n_i + \sum_j n'_j$.

These properties of semi-simple modules allow us to characterize semi-simple rings much more easily:

Corollary 51.1.9: Semi-Simple Rings Condition

Let R be a ring. Then R is a semi-simple ring if and only if R is a semi-simple R-module, that is we only need to check that R is a semi-simple R-module for one R-module structure (namely R itself)

***Proof*:**
By definition, R if R is a semi-simple ring then any R-module is a semi-simple R-module, including R over itself.

Now R is given some R-action becomes a semi-simple R-module, then by corollary 51.1.8 so is $\oplus_{i\in I} R$. We will use this to show that any R-module M is semi-simple, which will make R semi-simple by definition.

Let M is any other R-module, by by the universal property of the direct sum and free-modules:

$$M = \bigoplus_i Rm_i$$

for appropriate m_i (for ex. we can pick all nonzero elemetnts of M). Then we get a surjective map:

$$\bigoplus_{i\in I} R \to M \qquad (r_i)_{i\in I} \mapsto \sum r_i m_i$$

hence, M is the quotient of a semi-simple module, and hence semi-simple. Thus, R is semi-simple, as we sought to show.

Due to this, we get a nice description of semi-simple rings which is even stronger than semi-simple modules:

Lemma 51.1.10: Decomposing Semi-Simple Rings

Let R be a semi-simple ring. Then:

$$R = I_1 \oplus \cdots \oplus I_n$$

for a finite collection of I_k, where I_k are simple left-submodules of R, i.e. *minimal* left ideals[a] of R

[a]These are *left ideals* as we are working with *left* submodules

***Proof*:**
Since R is a semi-simple ring, it is a semi-simple R-module and so by definition:

$$R = \bigoplus_{i\in\mathcal{C}} I_i$$

for simple submodules I_i (i.e. minimal left ideals I_i). To make this a finite sum, since $1 \in R$, we get for an appropraite finite subset $A \subseteq \mathcal{C}$

$$1 \in I_{\alpha_1} + \cdots + I_{\alpha_n}$$

But then, since these are all ideals,

$$R = R \cdot 1 \subseteq I_{\alpha_1} \oplus \cdots \oplus I_{\alpha_n} \subseteq R$$

and hence $R = I_{\alpha_1} \oplus \cdots \oplus I_{\alpha_n}$, completing the proof.

51.1.11 Remark As a consequence of this, any semi-simple ring R is a left-Noetherian/Artinian ring. Interestingly, we will soon show that this also implies that R is a *right*-Noetherian/Artinian ring (see rightNoethArtRemark)

Furthermore, this shows how it is necessary for the condition that R be left-Noetherian/Artinian so that the notion of being semi-simple coincide between the two definitions.

Since we characterized simple R-modules for any ring R to be R-isomorphic to $R/\mathfrak{m}$, and we've given a structure of R if R is a semisimple ring, we can make lemma 51.1.3 more precise:

Corollary 51.1.12: Structure Of Simple Modules Of Semi-Simple Ring

Let R be a semi-simple ring so that $R = I_1 \oplus I_2 \oplus \cdots \oplus I_n$ for minimal left ideal I_k (equivalently, simple left R-modules). Then if M is a simple left R-module,

$$M \cong_{R\text{-}\mathbf{Mod}} I_i$$

for some $1 \leq i \leq n$.

***Proof*:**
Let M be a simple nonzero left R-module, and consider the R-module homomorphism:

$$\varphi : R \to M \qquad r \mapsto r \cdot x$$

where $x \neq 0$. Since M is simple, it is nonzero, so φ is surjective. Since $R = \bigoplus_i^n I_i$, for some i's

$$\varphi|_{I_i} \neq 0$$

and since $\varphi|_{I_i} = \pi_i \circ \varphi$ we have the R-module homomorphism:

$$\varphi|_{I_i} I_i \to M$$

and since both modules are simple and this is a nonzero homomorphism, by Schur's lemma this map must be an isomorphism, as we sought to show.

Note that there can be multiple I_i's that are isomrophic to M, which we will show in a following theorem.

This shows that any simple R-module over a semi-simple ring R is in fact isomorphic to a simple

R-module over R (i.e. R-isomorphic to a minimal ideal of R). Thus, studying simple R-modules over semi-simple rings comes down to studying the ring R itself, and that there are only *finitely many* simple R-modules. Furthermore, we have that $R/(\mathfrak{m}_1 \oplus \cdots \mathfrak{m}_{n-1}) \cong_R \mathfrak{m}_n$. Here is a good example of where the ring structure of the left hand side cannot exist in the right hand side. For example, if R is commutative, then $R/\mathfrak{m}$ is a field that is R-module isomorphic to a minimal ideal, but ideals cannot be fields (over the same identity[7]). Thus, in the case where R is semi-simple, for a maximal ideal $\mathfrak{m}$, $R/\mathfrak{m}$ is R-isomorphic to a minimal ideal of R.

Exercise 51.1.1

1. Let S be a simple module. Show that any nonzero submodule of the injective enveloppe $E(S)$ is indecomposable, but not simple.
2. Show that if M is a simple R-module, then it necessarily has to be cyclic (the converse, however, is not true).
3. Show that $A = \mathbb{Q}[x,y]/(xy - yx - 1)$ is a simple ring, but no a semi-simple ring (this is a special example of an algebra called a *Weyl* Algebra)
4. Let R be a ring, not necessarily commutative, and let $[R, R] = \{rs - sr \mid r, s \in R\}$. Show that the trace map induces an isomorphism

$$\frac{M_n(R)}{[M_n(R), M_n(R)]} \cong \frac{R}{[R, R]}$$

From this perspective, matrix rings are the natural “nonabelian” extension of a ring!

51.2 Artin-Wederburn

We just showed how studying simple and semi-simple R-modules comes down to studying the ring R, especially if the ring R is semi-simple. Thus, it is fruitful to classify semi-simple rings, which leads us to the main classification result for semi-simple rings, namely we build on lemma 51.1.10 and show that we can find more precisely how to represent each minimal ideal $\mathfrak{m}_i$, and furthermore show that this classification is exhaustive, and that any semi-simple ring uniquely breaks down into the result we'll show. We will then finish by showing that if we upgrade our ring to k-algebras (that is, we can put a vector-space structure on our ring), we get some stronger results due to the fact we can count dimensions.

First, we try to relate what we've shown for the hom-sets of simple modules with the strucure of simple modules. You may perhaps recall that we commented in exercise ref:HERE (in 9.1.1) and example 9.1.15 that R is note necessarily isomorphic to R^{op}. There is in fact a very nice way of linking R^{op} and R, which will be demonstrated after formally define R^{op} for reference

[7] $k \times \{0\} \subseteq k \times k$ is an ideal and a field with identity $(1, 0)$

Definition 51.2.1: Opposite Ring

Let R be a ring. Then we define a new ring labelled R^{op} that has the same underlying set and addition operation, whith the multiplication operation $*$ being:

$$x * y = yx$$

where the multiplication yx happens in R

If R is commutative, then $R = R^{\text{op}}$, and so we only get non-trivial results when R is not commutative. An example of $R \ncong R^{\text{op}}$ would be a free-algebra over two variables (say $k\langle x, y\rangle$).

Proposition 51.2.2: Properties Of Opposite Ring

Let R be a ring and R^{op} its oppposite ring. Then:

1. $(R^{\text{op}})^{\text{op}} = R$
2. $(R \times S)^{\text{op}} = R^{\text{op}} \times S^{\text{op}}$
3. $M_n(R)^{\text{op}} = M_n(R^{\text{op}})$ where the isomorphism is $A \mapsto A^t$ (essentially since $(AB)^t = B^tA^t$)

***Proof*:**
exercise

With this, we can make a link between R and R^{op}:

Lemma 51.2.3: Yonneda's Lemma for opposite Rings

Let R be a ring and consider the ring $\text{End}_R(R)$ to be the set of all R-module homomorphisms from R (as an R-module) to itself. Then $\varphi : R^{\text{op}} \to \text{End}_R(R)$, $r \mapsto (x \mapsto xr)$ is a ring isomorphism:

$$R^{\text{op}} \cong_{\textbf{Ring}} \text{End}_R(R)$$

***Proof*:**
Let φ_r be the given map. Let's first check that $\varphi_r \in \text{End}_R(R)$. Then we see that:

$$\begin{aligned}\varphi_r(\lambda x + \lambda y) &= (\lambda x + \lambda y)r \\ &= \lambda(xr) + \lambda(yr) \\ &= \lambda\varphi_r(x) + \lambda\varphi_r(y)\end{aligned}$$

showing that $\varphi_r \in \text{End}_R(R)$. Next, we check that φ is ineed a ring-homomorphism. By the properties of modules, it is easy to see that:

1. $\varphi_1 = \text{id}$, and hence φ sends the identity to the identity.
2. $\varphi_{r+r'} = \varphi_r + \varphi_{r'}$
3. $\varphi_{rr'} = \varphi_{r'} \circ \varphi_r$ (don't forget we are working with R^{op})

Finally, showing bijectivity, for injectivity we see that if $\varphi_r = 0$, then $0 = \varphi_r(1) = r$, and hence $\varphi_r = \varphi_0$. For surjectivity, let $\varphi \in \mathrm{End}_R(R)$. Let's say $\varphi(1) = r$. Then $\varphi(x) = x\varphi(1) = xr$, so $\varphi = \varphi_r$, completing the proof.

In the special case where R is commutative, then $R \cong R^{\mathrm{op}}$, showing that in this case $R \cong \mathrm{End}_R(R)$. Using this, we will use lemma 51.2.3 along with lemma 51.1.6 to upgrade lemma 51.1.10:

Theorem 51.2.4: Artin-Wedderburn, one Direction

Let R be a semisimple ring. Then:

$$R \cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$$

where each D_i is a division ring and $M_{n_i}(D_i)$ is the matrix ring over D_i

The key realization about this theorem is that while the multiplication on the left hand side can "send you" all over the place, the multiplication on the right hand side only sends you back into your particular component. To see this more clearly, let's say R was a k-algebra for a field k so that it has a basis. If R was a semi-simple ring, then that means that when multiplying elements of R (so figuring out where the basis elements go while multiplying), we can isolate the problem down to the components on the right hand side, and figure out where they go through matrix multiplication!

***Proof*:**
First, by lemma 51.1.10, for we get simple R-submodule of R, i.e. minimal ideals of R,

$$R = I_1 \oplus \cdots \oplus I_n$$

Now, we can always re-order the sums (i.e. $I_1 \oplus I_2 \cong I_2 \oplus I_1$, since $R \cong I_1 \oplus \cdots \oplus I_n$ by proposition 12.3.6). Hence, we will group all the I_i's that belong to the same isomrophism class (as R-modules), letting us re-write R as:

$$R \cong_{\mathbf{Ring}} I_1^{n_1} \oplus \cdots \oplus I_k^{n_k}$$

where $I_i \ncong I_j$ for $i \neq j$. Hence by lemma 51.2.3 and lemma 51.1.6:

$$\begin{aligned} R^{\mathrm{op}} &\cong_{\mathbf{Ring}} \mathrm{End}_R(R) \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k) \end{aligned}$$

where $D_i = \mathrm{End}_R(I_i)$ is a divison ring. Finally, Taking the opposite ring on both sides, we get:

$$\begin{aligned} R &\cong_{\mathbf{Ring}} (R^{\mathrm{op}})^{\mathrm{op}} \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1)^{\mathrm{op}} \times \cdots \times M_{n_k}(D_k)^{\mathrm{op}} \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1^{\mathrm{op}}) \times \cdots \times M_{n_k}(D_k^{\mathrm{op}}) \end{aligned}$$

and it is clear the D_i^{op} is still a division ring, hence completing the proof.

Thus, if we have a simple-ring then the ring breaks down into the product of matrix rings over division rings. In the special case where $R = k$ is a field, then k has only one minimal ideal, namely itself, and $\mathrm{End}_k(k) \cong M_1(k) \cong k$, and hence we reduce to $k \cong k$. If $R = k^n$ is a product of the same field, then the minimal ideals of R are $R = k \oplus \cdots \oplus k$, so that we get back $k^n \cong_{\mathbf{Ring}} k^n$.

We will now show that the converse of this theorem is true, that the product of matrix rings over division rings is semi simple. We start by showing that matrix ring are simple modules[8].

Proposition 51.2.5: Matrix Ring over Division Rings are semi-simple

Let $R = M_n(D)$ be a matrix ring over a divison ring. Let $C = D^{\oplus n}$ be the left $M_n(D)$-module where the action is left matrix multiplication (imagine C as a column). Then C is a simple $M_n(D)$-module, and

$$M_n(D) \cong_{M_n(D)\text{-}\mathbf{Mod}} C^{\oplus n} = (D^{\oplus n})^{\oplus n}$$

showing that $M_n(D)$ is semisimple ring and $M_n(D) \cong_{\mathbf{Ring}} C^{\oplus n}$

***Proof*:**
Let $R = M_n(D)$ and $C = D^{\oplus n}$ (C for *column*). For notational simplicity, let $E_{ij} \in R$ be the elementary matrix which is 1 in position ij and zero everywehre else. Let $e_i \in C$ be the column where it is 1 at position i and zero everywehre else:

$$E_{ij} = \begin{pmatrix} 0 & & & & 0 \\ & \ddots & & \iddots & \\ & & 1 & & \\ & \iddots & & \ddots & \\ 0 & & & & 0 \end{pmatrix} \qquad e_i = \begin{pmatrix} 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{pmatrix}$$

Then $E_{ij}e_k = \delta_{jk}e_i$ where δ_{jk} is the Kronecker Delta:

$$\delta_{jk} = \begin{cases} 1 & j = k \\ 0 & j \neq k \end{cases}$$

Now, we will start by showing that C is a simple $M_n(D)$-module. Since $C = D^{\oplus n}$,

$$C = \bigoplus_i De_i$$

for some basis $e_1, e_2, ..., e_n$. To show that C is simlpe, it is enough to show that for any $0 \neq x \in C$, $C = Rx$ since then any nonzero submodule would in fact be C. Given our above notation, we have that:

$$x = \sum_k d_k e_k$$

for appropriate $d_k \in D$, where at least one of these is nonzero, let's say $d_j \neq 0$. Then consider $E_{ij}x \in Rx$:

$$E_{ij}x = \sum_k \delta_{jk} d_k e_k = d_j e_i$$

since $d_j \neq 0$. Since D is a division ring, we get that $d_j^{-1}e_i \in Rx$, for all $1 \leq i \leq n$. But then, we get:

$$C = \sum De_i \subseteq Rx \subseteq C$$

[8]This will be an example of R being both a simple R-module and a simple ring

showing that $C = Rx$ for any $0 \neq x \in C$, showing that C is indeed simple.

Now, we can re-write this ring as the internal direct sum of matrices I_i which are zero outisde the ith column:

$$R = M_n(D) = I_1 \oplus \cdots \oplus I_n$$

$$I_k = \begin{pmatrix} 0 & \cdots & a_{1,k} & \cdots & 0 \\ 0 & & a_{2,k} & & 0 \\ \vdots & & \vdots & & \vdots \\ 0 & & a_{2,n-1} & & 0 \\ 0 & \cdots & a_{n,k} & \cdots & 0 \end{pmatrix}$$

This decomposition works since each I_i is stable under *left* multiplication by elements of $M_n(D)$ (since left multiplication is a *column* transformation, right multiplication would be *row* transformation). Finally, $C \cong_{R\textbf{-mod}} I_i$ by simply moving the column to the right place, and so each I_i is simple. Hence, we have decomposed $M_n(D)$ as a dierct product of simple left $M_n(D)$-modules, and hence $M_n(D)$ is a semisimple $M_n(D)$-module, which by corollary 51.1.9 makes $M_n(D)$ a semi-simple ring. Finally, since $C^{\oplus n}$ represents the n rows of n-length columns, we see that the action of $M_n(D)$ on $C^{\oplus n}$ is identical to that of matrix multiplying elements of $C^{\oplus n}$, which gives us that $M_n(D) \cong_{\textbf{Ring}} C^{\oplus n}$, as we sought to show.

51.2.6 Remark In fact, $M_n(D)$ is a simple ring, meaning the only *two-sided* ideals of R are 0 and R; the above proof can be modified to show this. This gives us a nice class of non-commutative simple rings (since all simple commutative rings are fields).

Notice that it is quite sepcial that the ring opration and the module operation coincided, this because of the special way in which we decompoed the $M_n(D)$-module $M_n(D)$ and by the fact that it is a module over itself. In the previous proposition, we showed that $D^{\oplus n}$ is a simple $M_n(D)$-module. In fact, all simple modules of $M_n(D)$ are isomorphic to $D^{\oplus n}$:

Corollary 51.2.7: Structure of Simple $M_n(D)$-Module

Let $R = M_n(D)$ be a matrix ring over a division ring. Then any simple $M_n(D)$-module is isomorphic to $D^{\oplus n}$.

***Proof*:**
Let M be a simple $M_n(D)$-module. By proposition 51.2.5

$$M_n(D) \cong_{\textbf{Ring}} D^{\oplus n} \oplus \cdots_{\textbf{Ring}} \oplus D^{\oplus n}$$

And by corollary 51.1.12,

$$M \cong D^{\oplus n}$$

Corollary 51.2.8: Endomorphism Of Simple $M_n(D)$-Module

Let S be a simple $M_n(D)$-module. Then

$$\mathrm{End}_{M_n(D)}(S) \cong_{\mathbf{Ring}} D^{\mathrm{op}}$$

***Proof*:**
Since S is simple, $S \cong_R D^{\oplus n}$ for some n. Let $\varphi_d : S \to S$, $\varphi_d(x) = x \cdot d$ where $x \cdot d$ is x times dI. Then:

$$\varphi_d(Ax) = (Ax) \cdot d = A(x \cdot d) = A\varphi_d(x)$$

and

$$\varphi_d(x+y) = (x+y) \cdot d = (x+y)dI = xdI + ydI = x \cdot d + y \cdot d = \varphi_d(x) + \varphi_d(y)$$

hence $\varphi_d \in \mathrm{End}_R(S)$. Conversely, if $\varphi \in \mathrm{End}_R(S)$, Since $S \cong D^{\oplus n}$, and

$$D^{\oplus n} \cong \begin{pmatrix} D^{\oplus n} & 0^{\oplus n} & \cdots & 0^{\oplus n} \end{pmatrix}$$

we will treat S as a $M_n(D)$ submodule of $M_n(D)$. Now, since φ is a group homomorphism, we know that:

$$\varphi \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} \varphi_{11} & \cdots & \varphi_{n1} \\ \vdots & \ddots & \vdots \\ \varphi_{n1} & \cdots & \varphi_{nn} \end{pmatrix} \begin{pmatrix} 1 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} \varphi_{11}(1) + \cdots + \varphi_{n1}(1) \\ \vdots \\ 0 \end{pmatrix}$$

hence let $d = \sum_i^n \varphi_{i1}(1)$, and let the right-action on $\mathrm{End}_{M_n(D)}(S)$ be right multiplication by the identity matrix dI. Then: Then for all $x \in S$, we have:

$$\begin{aligned}
\varphi \begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} &= \varphi \left(\begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} \begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 0 \end{pmatrix} \right) \\
&\overset{!}{=} \begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} \varphi \begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 0 \end{pmatrix} \\
&= \begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} \cdot d
\end{aligned}$$

where $\overset{!}{=}$ comes from the fact that we can treat that matrix as an element of $M_n(D)$, and since φ is an $M_n(D)$-module homomorphism, we can pull it out. But then, the action is completely dependent on on d, an so we have a bijection between right multiplication by $d \in D$ an $M_n(D)$-endomrophisms. It is an easy taks to check that:

$$\varphi_{dd'} = \varphi_{d'} \circ \varphi_d$$

showing that

$$D^{\mathrm{op}} \cong_{\mathbf{Ring}} \mathrm{End}_{M_n(D)}(S)$$

as we sought to show.

The next thing we will need is to show that if R, S are semisimple rings, then so is $R \times S$. Since R and S are semi-simple R-modules and S-modules, if we can show that $R \times S$ is a semi-simple $(R \times S)$-module, we are done. For this to be the case, we must be able to decompose $R \times S$ into simple $(R \times S)$-submodules. Forunately, many universal propeties play in our favour to be able to easily identify simple $(R \times S)$-modules of $R \times S$ given we know the simple R-modules and S-modules.

To see the key idea of the following proof, we define some terms

Definition 51.2.9: Idempotent And Orthogonal Elements

Let R be a ring. Then $e \in R$ is said to be *idempotent* if

$$e^2 = e$$

Furthermore, if e_1, e_2 are idempotent elements in R, if

$$e_1 e_2 = e_2 e_1 = 0$$

then they are said to be *orthogonal.* If e is idempotent and cannot be written as the sum of two (commuting) idempotent elements, then e is said to be a *primitive* idempotent element.

Example 51.2.10: Idempotent Elements

Naturally, for any ring R, $1 \in R$ is an idempotent element.

For a more interesting example the product ring $R \times S$, and take $e = (1, 0) \in R \times S$, $f = (0, 1) \in R \times S$. Then:

1. $e^2 = e$ and $f^2 = f$ (i.e. they are both *idempotent*)
2. $ef = fe = 0$ (implying also that $ef \in Z(R \times S)$)
3. $e + f = 1$ (i.e. e and f are *not* primitive)

What happens if the number of terms in the product increases?

Next, if M is an R-module an N is an S-module, we can M and N to be $(R \times S)$-module by ignoring what happens to S (resp. R), i.e. think of the action being defined by the following function

$$R \times S \twoheadrightarrow R \to \mathrm{End}_{\mathbf{ab}}(M)$$

and similarly for a S-module N. Hence, we can define $M \oplus N$ as an $(R \times S)$-module. Conversely, if M is an $(R \times S)$-module, then using what we've shown in example 51.2.10, given $e = (1, 0)$ and $f = (0, 1)$:

$$M = eM + fM$$

Notice that eM is killed by Rf, so it's a $A \cong A \times B/(\{0\} \times B)$-module, and similarly for fM. In other words, idempoent elements characterize the splitting of modules! This gives us the following:

Proposition 51.2.11: Direct Product Decomposition

If A-**Mod** and B-**Mod** are the categoies of A-modules and B-modules, and A-**Mod** $\times$ B-**Mod** is the category where every object and morphism is a product of objects or morphisms. Then there is an equivalence:

$$A\textbf{-Mod} \times B\textbf{-Mod} \underset{\psi}{\overset{\varphi}{\rightleftarrows}} (A \times B)\textbf{-Mod}$$

sending:

$$(M, N) \mapsto M \oplus N$$
$$(eM, fM) \leftarrow\!\shortmid M$$

where we further get: $\varphi(\psi(M \oplus N)) \cong M \oplus N$ and $\psi(\varphi(M)) \cong M$

***Proof*:**
easy to check

Proposition 51.2.12: Classifying Simple $(A \times B)$-Modules

Let P be a simple $(A \times B)$-module. Then

$$P \cong_{A\times B\text{-Mod}} M \oplus (0) \qquad \text{or} \qquad P \cong_{A\times B\text{-Mod}} (0) \oplus N$$

where M is a simple A-module and N is a simple B-module.

***Proof*:**
By proposition 51.2.11, $P \cong_{A\times B\text{-Mod}} M \oplus N$ where M is an A-module and N is a B-module. BUt then:

$$P \cong_{A\times B\text{-Mod}} (M \oplus (0)) \oplus ((0) \oplus N)$$

since P is simple, one of these has to be zero, and the other one has to be simple.

Corollary 51.2.13: Product Of Semi-Simple Rings

Let R and S be semi-simple rings. Then $R \times S$ is a semi-simple ring. Furtheromre, if $R_1, R_2, ..., R_n$ are the simple R-module up to isomorphism and $S_1, S_2, ..., S_m$ are the simple S-modules, then the simple $R \times S$-modules are of the form:

$$R_i \oplus (0) \qquad (0) \oplus (S_j)$$

***Proof*:**
By proposition 51.2.11, since R is a semi-simple R-module and S is a semi-simple S-module, $R \times S$ is a semi-simple $(R \times S)$-module, and so $R \times S$ is a semi-simple ring. Then by proposition 51.2.12,

if $P \subseteq R \times S$ is a simple $(R \times S)$-module, then they it must be of the form:

$$R_i \oplus (0) \qquad (0) \oplus (S_j)$$

Corollary 51.2.14: Structure Of $\prod_i M_{N_i}(D_i)$: Artin Wedderburn part II

Let $R = M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$. Then

1. R is semi-simple
2. There exist exactly k simple R-modules up to isomorphism, each of the form:

$$0 \oplus \cdots \oplus D_i^{\oplus n_i} \oplus \cdots \oplus 0$$

***Proof*:**
The ring R is semi-simpleby corollary 51.2.13 using induction. Furthermore, each $M_{n_i}(D_i)$ has $D_i^{\oplus n_i}$ is it's unique simple $M_{n_i}(D_i)$-module, since there are k matrix rings in the productt, there must be exactly k simple R-modules, as we sought to show.

51.2.15 Remark We can as before get that

$$R^{\text{op}} \cong M_{n_1}(D_1^{\text{op}}) \times \cdots \times M_{n_k}(D_k^{\text{op}})$$

and hence R^{op} is left Noetherian/Artinian, which we know now is true if and only if R is right Noetherian/Artinian (Since a left R^{op})-module is a right R-module). By leftNoethArtRemark, we have that any semisimple ring is left-Noetherian/Artinian, and hence any semisimple ring is both left and right Noetherian/Artinian, even though R is not necesarily commutative!

Thus, we have the following statemnt, were the last thing we need to prove is uniquness

Theorem 51.2.16: Artin-Wedderburn

Let R be a ring. Then R is a semi-simple ring if and only if

$$R \cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$$

where each D_k is a division ring and $M_{n_i}(D_i)$ is the matrix ring over D_i, and each D_i n_i are unique up to isomorphism

***Proof*:**
All that is left to prove is the uniqueness. Let:

$$M_{n_1}(D_1) \oplus \cdots \oplus M_{n_s}(D_s) \cong_{\mathbf{Ring}} R \cong_{\mathbf{Ring}} M_{n'_1}(D'_1) \oplus \cdots \oplus M_{n_s}(D'_s)$$

By corollary 51.2.14, R has exactly s and t simple module, and so $s = t$. Hence, for any $D_i^{\oplus n_i}$, there must exist a $(D'_i)^{\oplus n'_i}$ such that

$$D_i^{\oplus n_i} \cong_R (D'_i)^{\oplus n'_i}$$

Since $D_i^{\oplus n_i} \cong_R (D_i')^{\oplus n_i'}$, $\mathrm{End}_{M_{n_i}(D_i)}(D_i^{\oplus n_i}) \cong_{\mathbf{Ring}} \mathrm{End}_{M_{n_i'}(D_i')}((D_i')^{\oplus n_i'})$. By corollary 51.2.8,

$$D_i^{\mathrm{op}} \cong_{\mathbf{Ring}} \mathrm{End}_{M_{n_i}(D_i)}(D_i^{\oplus n_i}) \cong_{\mathbf{Ring}} \mathrm{End}_{M_{n_i'}(D_i')}((D_i')^{\oplus n_i'}) \cong_{\mathbf{Ring}} (D_i')^{\mathrm{op}}$$

which, taking op on both sides, we see that:

$$D_i \cong_{\mathbf{Ring}} D_i'$$

Finally, we need to show that $D^{\oplus n} \cong_R D^{\oplus m}$ implies $n = m$. Treating $D^{\oplus n}$ and $D^{\oplus m}$ as D-modules, then we get that each have a basis of dimension n and m. Importantly, the results of the Replacement Theorem (theorem 13.1.12) applies to divions rings (notice that commutativity was not necessary), and so corollary 13.1.14 and theorem 13.1.8 give us that $n = m$, completing the proof.

This theorem also shows us that if R is a [finitely-generated] semi-simple ring, then R is indeed the direct product of simple rings (since $M_{n_i}(D_i)$ is a simple ring). Notice too that this theorem just gave use the answer to the classification of all *finite simple rings*: namely they would have ot be of the form $M_n(\mathbb{F}_q)$[9] for some finite field of order q (which is a power of some prime p). Contrast this to how hard it is to find all finite simple groups! Furthermore, the finite dimensional assumption was key: the *Weyl Algebra*:

$$W = k\langle x, y\rangle/(xy - yx - 1)$$

is a simple algebra that is not the matrix ring of a division algebra.

Example 51.2.17: Artin Wedderburn

$\mathrm{End}_{M_2(k)}(M_2(k)) = \mathrm{End}_{M_2(k)}((k^2)^{\oplus 2}) = M_2(\mathrm{End}_{M_2(k)}(k^2)) = M_2(k)$

Corollary 51.2.18: Artin-Wedderburn For k-Algebras

Let R be a semi-simple k-algebra for some field k. Then

$$R \cong_{k\text{-}\mathbf{Alg}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

where each D_i is a divsion k-algebra, finite dimensional as a k-vector space:

$$\dim_k R = \sum n_i^2 \dim_k(D_i)$$

and has exactly l simple R-modules as we've classified before.

***Proof*:**

By the Artin-Wedderburn theorem, we have that

$$R \cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

Let's now further assume R is a k-algebra for some field k, so that there is a map $k \hookrightarrow Z(R)$.

[9]Why is the division ring a field? The answer lies in proposition 9.1.20

Then by the above isomorphism:

$$\begin{aligned} k \mapsto Z(R) &\cong Z(M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)) \\ &\cong Z(M_{n_1}(D_1)) \times \cdots \times Z(M_{n_l}(D_l)) \\ &\cong Z(D_1) \times \cdots \times Z(D_l) \end{aligned}$$

where the last one comes form the fact that $Z(M_{n_i}(D_i))$ are the diagonal elements, and $z \mapsto zI$. This shows that D_i each have a natural k-algebra strucure induced by R, and so the above isomrophsim was already a k-algebra isomorphism:

$$R \cong_{k\text{-}\mathbf{Alg}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

Finally, treating $M_{n_i}(D_i)$ as k-vector spaces we have:

$$M_{n_i}(D_i) \cong_{k\text{-}\mathbf{Vect}} D^{\oplus n_i^2}$$

which gives the desired result, completing the proof.

Corollary 51.2.19: Special Case: k Algebraically Closed

Let $k = \overline{k}$ be an algebraically clsoed field and D a k-algebra that is finite-dimensional as a k-vector-space. Then $D = k$

***Proof*:**
Let's say $k \subsetneq D$. Then pick any $\delta \in D \setminus k$. Then

$$k \subseteq k[\delta] \subseteq D$$

the key thing to observe is that $k[\delta]$ is still commutative!! This is essentially the same reasoning for why any cyclic group is commutative! Since D is a finite-dimensional vector-sapce over k, some power of δ^n must be a k-linear combination of every smaller term. Since D is a division ring, every δ has an inverse, and so every element of $k[\delta]$ is in fact a unit. Hence $k[\delta]/k$ is an algebraic field extension. However, k is an *algebraically cloased field*, and hence $k[\delta] = k$. Since δ was arbitary, we must have that $D = k$, as we sought to show.

Corollary 51.2.20: Artin-Wedderburn For $\overline{k}$-Algebras

Let R be a semi-simple k-algebra for some algebraically closed field $k = \overline{k}$. Then

$$R \cong_{k\text{-}\mathbf{Alg}} M_{n_1}(k) \times \cdots \times M_{n_l}(k)$$

showing that R is a finite dimensional vector-space over R with dimension:

$$\dim_k(R) = \sum_{i}^{l} n_i^2$$

and has exactly l simple R-modules as we've classified before.

As a consequence of this, if R is a semi-simple $\mathbb{C}$-algebra, the simple R-modules are all R-isomorphic to $\mathbb{C}^{n_i}$ for appropriate power n_i. As a final word of warning, it is natural to wonder if all simple rings are of the form $M_n(D_i)$

Exercise 51.2.1

1. Let k be a field, k^n be a direct product of fields a k^n-module over itslef. Let $0 \oplus \cdots \oplus k \oplus \cdots \oplus 0 = k_i \subseteq k^n$. Then $\text{End}_{k^n}(k_i) \cong_{\mathbf{Ring}} k$, $\text{End}_{k^n}(k^n) \cong_{\mathbf{Ring}} k^n$, and $\text{End}_{k^n}(k^n) \cong_{\mathbf{Ring}} M_n(\text{End}_{k^n}(k_i)) \cong_{\mathbf{Ring}} M_n(k)$. But that would imply $k^n \cong_{\mathbf{Ring}} M_n(k)$ – what's the contradiction?

2. Let k be an algebraically closed field, and let R be a finite-dimensional k-algebra. Let M be a simple R-module. Prove that if r is an element of the centre $Z(R)$ of R, there exists $c \in k$ such that $rm = cm$ for all $m \in M$

51.3 Central Simple Algebras

Definition 51.3.1: Algebra Representation

Let A be a finite dimensional (associative) algebra over k. Then a *representation* of A is a k-homomorphism:

$$\rho : A \to \text{End}_k(V)$$

for some vector space V.

Recall that one definition of an R-module is given by a ring homomorphism $\rho : R \to \text{End}_{\mathbf{Ab}}(M)$ for an abelian group M. If we restrict to k-homomorphisms and k-endomorphisms, we can define the A-module $\rho : A \to \text{End}_k(V)$, hence we can think of representation of and algebra A as a left A-modules. This makes sense, as representation theory can be thought of the study of associative algebras (the study of group representation is the study of group algebras, the study of the representation of lie algebras is universal enveloping algebras, the study of the representation of quiver algebras is the study of path algebras, and so forth). Because of this, we shall see that many of the results for the representation of associative algebras outlined bellow to be familiar to anyone who has taken a basic course in representation theory.

Next, we define the object that shall represent the generalization of number rings:

Definition 51.3.2: Central Simple Algebra

Let A be an algebra over a field k. Then A is called *simple* if it is a simple ring. It is called a *central simple algebra* (CSA) if it is simple, is finite dimensional over k, and its center is k.

The idea behind this definition is that it generalizes field extensions F/k, for we have a distinguished field k, and we are interested in the "algebraic case", hence the extension ought to be finite. Contrasting to fields, a CSA need not be commutative and need be a division ring

Example 51.3.3: Simple and Central Simple Algebras

1. Naturally, $M_n(k)$ is a central simple algebra of dimension n^2
2. It is possible to be simple and have center k but not be finite: the Weyl algebra $k[x, \delta_x]$ is infinite dimensional over k.
3. $\mathbb{C}$ is a central simple algebra over $\mathbb{C}$, but not over $\mathbb{R}$ (as it's center contains more than $\mathbb{R}$
4. Let $A = \mathbb{H}$ be the quaternions (or Hamiltonians). Then this is a CSA over $\mathbb{R}$ with dimension 4. We shall soon define a quaternion algebra, and see that all 4-dimensional central simples algebra's over a field k is a quaternion algebra, and it shall be limited to 2-by-2 matrices or division algebras.

Let us now generalize some of basic representation theory results. Let E be an irreducible representation of A (take for example a minimal left ideal of A).

Lemma 51.3.4: Schur's Lemma - updated

Let E be an irreducible representation of a k-algebra A, and let $K \subseteq \text{End}_k(E)$ be the endomorphisms that commute with the operations of A: it is the centralizer of A in $\text{End}_k(E)$, $K = C_{\text{End}_k(E)}(A)$. Then K is a division ring.

Note that this makes K an A-algebra

***Proof*:**
Take $u \in K$. We want to show that $u^{-1} \in K$. Consider $u^{-1}(0) = V \subseteq E$. For $x \in V$, we have:

$$0 = a \cdot u(x) = u(a \cdot x)$$

hence, V is stable under A, and as $u \neq 0$ we must have $V = 0$ as u is invertible in $\text{End}_k(E)$. It follows that $u^{-1} \in K$.

Notice from this that we may say that the representation E must be faithful (the map must be injective). Indeed, the kernel of this representation would be an ideal of A but

Lemma 51.3.5: Minimal Centralizer of Representations

Let E be a semi-simple an faithful representation of A, $K = C_{\mathrm{End}_k(E)}(A)$, $B = C_{\mathrm{End}_k(E)}(K)$ (i.e. the centralizer of A and K in $\mathrm{End}_k(E)$). Then

$$A = B$$

***Proof*:**
Let $x \in E$ and $b \in B$. We shall show that there exists an $a \in A$ such that $a(x) = b(x)$.

Let $Ax = V \subseteq E$ be a stable subspace. Then V admits a (stable) compliment: $E = V \oplus V^{\perp}$. Let $\pi : E \to V$ be the natural projection map. Then certainly π is A-linear and commutes with K, namely $\pi \in K$. Then:

$$\pi(b(x)) = b(\pi(x)) = b(x)$$

namely, $b(x) \in V = aX$, implying $a(x) = b(x)$, as we sought to show.

Lemma 51.3.6: Generator lemma

Let E be a semi-simple an faithful representation of A, $K = C_{\mathrm{End}_k(E)}(A)$, $B = C_{\mathrm{End}_k(E)}(K)$ (i.e. the centralizer of A and K in $\mathrm{End}_k(E)$). Let $x_1, ..., x_n \in E$ and $b \in B$. Then there exits values $a_i \in A$ such that:

$$ax_1 = bx_1, \; ax_2 = bx_2 \qquad \cdots \qquad ax_n = bx_n$$

***Proof*:**
Let F be the direct sum space of n copies of representation E. Then F is formed of elements $(y_1, ..., y_n)$, $y_i \in E$, on which A acts by

$$a \cdot (y_1, ..., y_n) = (ay_1, ..., ay_n)$$

The representation F is still semi-simple. The centralizer of A in $\mathrm{End}_k(F)$ is formed of matrices (u_{ij}), $u_{ij} \in K$, and it follows that, if we let B operate on F by the formula:

$$b \cdot (y_1, ..., y_n) = (by_1, ..., by_n)$$

the elements of $\mathrm{End}_k(F)$ thus defined will still be in the centralizer of the centralizer of A (in the theory of semi-groups, this is sometimes called the bicommutant). By lemma 51.3.5 applying to the point $x = (x_1, ..., x_n) \in F$, and to $b \in B$ giving us the desired result.

Serre write K_n for $M_n(K)$ for a division ring K, but we shall stick to $M_n(D)$ where our division ring is D instead of K. If D contains k in its center, we have:

$$M_n(D) = M_n(k) \otimes D$$

as can be easily seen.

We present one more important result that has two useful corollaries. Let A be a k-algebra. Then A acting on itself by left multiplication gives something called the *regular left representation*. If

$A = M_n(D)$, it has basis e_{ij}, $1 \leq i, j \leq n$. The elements e_{i,j_0} for a fixed j_0 gives a subspace of $M_n(D)$, say $N_{j_0} \subseteq M_n(D)$. It is easy to see that N_{j_0} is a minimal left ideal (namely, an irreducible representation). Then we see that for any other choice of j_0, say j_1, we get an isomorphic irreducible representation N_{j_1}. Then this gives the following classical result:

Theorem 51.3.7: Representation of Simple Algebra

Let A be a simple k-algebra. Then all representation of A is isomorphic to the direct sum of irreducible representation

***Proof*:**
use corollary 51.2.20.

Corollary 51.3.8: Representation of Simple Algebra

Let A be a simple k-algebra. Then:

1. All representations of A are semi-simple (completely reducible in Serre's words)
2. Two representation of A which have the same dimension are isomorphic

***Proof*:**
immediate from the above

Let us now turn towards the tensor product of simple algebras.

Lemma 51.3.9: Centralizer of Tensor Product of Algebras

Let A, A' be two k-algebras, B, B' be sub k-algebras of A, A' (respectively) with C, C' their centralizers on A, A' (respectively). Then the centralizer of $B \otimes B'$ in $A \otimes A'$ is $C \otimes C'$.

***Proof*:**
Let us first find the centralizer of $B \otimes 1$. For this, let a_i' be a basis of A'. Any $x \in A \otimes A'$ can be written uniquely in the form:

$$x = \sum_i a_i \otimes a_i' \qquad \text{for appropriate } a_i \in A$$

If x commutes with $b \otimes 1$, then $a_i b = b a_i$ that is $a_i \in C$ for all i. We thus see that the centralizer of $B \otimes 1$ is $C \otimes A'$. Similarly, that of $1 \otimes B'$ is $A \otimes C'$. It follows that the centralizer of $B \otimes B'$ is equal to the intersection of the centralizers of $B \otimes 1$ and $1 \otimes B'$, namely

$$(C \otimes A') \cap (A \otimes C') = C \otimes C'$$

as we sought to show.

Thus, the centre of the tensor product of two algebras is the tensor product of the centre of the two algebras. Applying this to the special case of $A = M_n(k) \otimes D$ for some division ring D, then:

$$Z(A) = k \otimes Z(D)$$

Corollary 51.3.10: Centre of simple algebra is a Field

Let A be a simple k-algebra, finitely generated over k. Then $Z(A)$ is a field.

***Proof*:**
Consider $Z(A)$. As A is a finitely generated k-algebra, $Z(A)$ is a finitely generated k-algebra. For any $0 \neq z \in Z(A)$, consider zA. As z is central,we have that zA is two-sided ideal. As A is simple, it must be that $zA = A$, that is z is there exists a $w \in A$ such that $za = 1$. Therefore, $Z(A)$ is a division ring. It is by definition commutative, and hence it is a field. Since z was an arbitrary nonzero element, $Z(A)$ is a division ring. It is by definition commutative, and hence it is a field.

We shall next require to see the interaction between the tensor product of central simple algebras. We require the following lemma:

Theorem 51.3.11: Ideal Generation Tensor Product

Let A be a k-algebra and K' a left division ring with center k. Then every ideal $N \subseteq A \otimes K'$ is generated (as a left module over K') by its intersection with $A \otimes 1$.

Note that neither A nor K' are assumed finite over k

***Proof*:**
We will first note that we can make K' operate on the left on $A \otimes K'$ by:

$$k'(a \otimes k'') = a \otimes k'k''$$

If N is an ideal of the algebra $A \otimes K'$, it is in particular a K'-module subspace of $A \otimes K'$.

Let a_i be a basis of A over k; the elements $a_i \otimes 1$ equally form a basis of the K'-module $A \otimes K'$. Let x be a primitive element of N with respect to this basis (Bourbaki, Alg.II, paragraph 5):

$$x = \sum_i a_i \otimes k'_i$$

Consider the element $x \cdot m$ ($m \in K'$); we have $x \cdot m \in N$ (N is an ideal), and on the other hand:

$$x \cdot m = \sum_i a_i \otimes k'_i m$$

It then follows from the properties of primitive elements that we have:

$$k'_i m = n k'_i \text{ for all } i \quad (n \in K')$$

Since one of the k'_i is equal to 1, we have $m = n$, and the preceding equality simply means that k'_i commutes with all $m \in K'$, i.e., that $k'_i \in k$. We can then write: $x = a \otimes 1$, by setting: $a = \sum_i k'_i a_i$. We have thus shown that every primitive element x is in $A \otimes 1$; the theorem follows immediately since every vector space is generated by its primitive elements.

Theorem 51.3.12: Tensor Product CSA

Let A, A' be simple k-algebras finitely generated over k, where one of them is a CSA. Then $A \otimes A'$ is a simple k-algebra

***Proof*:**
Suppose that $A' = M_n(k) \otimes K'$ is central, in other words that the center of the left field K' is reduced to k. It will suffice to show that $A \otimes K'$ is a simple algebra. Indeed, if this is demonstrated, $A \otimes K' = M_m(k) \otimes K''$, and $A \otimes A' = M_m(k) \otimes M_n(k) \otimes K'' = M_{mn}(k) \otimes K'' = M_{nm}(K'')$. The algebra $A \otimes A'$ will thus be isomorphic to a matrix algebra for which simplicity is immediately verified. Then the general case of $A \otimes K'$ being simple follow from theorem 51.3.11, completing the proof.

Corollary 51.3.13: Tensor Product of Two CSA's

The tensor product of two CSA is a CSA

***Proof*:**
In the previous proof, it was enough for one of them to be a CSA.

Corollary 51.3.14: Opposite Algebra Tensoring

Let A be a CSA over k and A^{op} the opposite algebar. Then:

$$A \otimes A^{\mathrm{op}} \cong M_{n^2}(k)$$

***Proof*:**
Let us denote by E the algebra A considered as a vector space over k. We can make A act naturally on E by the left or right by multiplication to create a left or right A-module. This amounts to identifying A and A^{op} as sub-algebras of the algebra $\mathrm{End}_k(E)$ of k-endomorphisms of E. Since the algebras A and A^{op} commute in $\mathrm{End}_k(E)$, we can define a canonical homomorphism of $A \otimes A^{\mathrm{op}}$ into $\mathrm{End}_k(E)$ which extends the isomorphisms: $A \to \mathrm{End}_k(E)$ and $A^{\mathrm{op}} \to \mathrm{End}_k(E)$. The algebra $A \otimes A^{\mathrm{op}}$ being simple, this homomorphism is an isomorphism; moreover, as;

$$[A \otimes A^{\mathrm{op}} : k] = [A : k]^2 = n^2 = [\mathrm{End}_k(E) : k]$$

this isomorphism maps $A \otimes A^{\mathrm{op}}$ onto $\mathrm{End}_k(E) = M_{n^2}(k)$, as we sought to show.

51.3.1 Brauer Group

Let A be a CSA over k. As A is simple, we get by Artin-Wedderburn that it is isomorphic to $M_n(D) \cong M_n(k) \otimes D$. For example, if $n = 1$ and $k = \mathbb{R}$ we get (by a classical theorem from algebraic topology) that $A \cong \mathbb{R}$ or $A \cong \mathbb{H}$ (the quaternions). If $n > 1$, we get $M_n(\mathbb{R})$ and $M_n(\mathbb{H})$ (which are no longer division algebras). We see that the division ring is one of the "characterizing" feature of the CSA (the other being its matrix ring), especially that up to Morita-equivalence we get the same category. We thus have the following natural equivalence we may define:

Definition 51.3.15: Brauer Equivalence

Let k-**CSA** be a collection of central simple algebras over k. Then define the equivalence relation $A \sim A'$ where the two are equivalent if and only if their associated division rings are isomorphic.

Proposition 51.3.16: Brauer Group

The Brauer equivalence on a collection of CSA's forms a commutative group under the tensor product. This group will be denoted $\mathrm{Br}(k)$.

In Serre, this group is denoted G_k.

***Proof*:**
By corollary 51.3.13, it is closed under the tensor product, the equivalence class containing k is certainly the identity, and corollary 51.3.14 shows that every equivalence class has an inverse. Associativity and commutativity is a classical result for tensor products.

Example 51.3.17: Brauer Groups

1. Let $k = \overline{k}$. Then $\mathrm{Br}(\overline{k}) = 0$ by corollary 51.2.20.
2. If $k = \mathbb{R}$, then we shall show in the next section that $\mathrm{Br}(\mathbb{R}) = \mathbb{Z}/2\mathbb{Z}$, namely we shall have $\mathbb{R}$ and $\mathbb{H}$, the quaternions.
3. Let k be a finite field. Then $\mathrm{Br}(k) = 0$, as all finite division rings are fields.
4. If $k = \mathbb{Q}_p$, then $\mathrm{Br}(k) \cong \mathbb{Q}/\mathbb{Z}$ (Serre references Algebren - Chap. VII - 2nd paragarph).
5. If $k = \mathbb{Q}$, $\mathrm{Br}(\mathbb{Q})$ will be a subgroup of
$$\mathbb{Z}/2\mathbb{Z} \oplus (\mathbb{Q}/\mathbb{Z})^{\oplus \mathbb{N}}$$
which can be thought of as a result similar to that in number theory where we study the "global field" $\mathbb{Q}$ by looking at all its localizations (note that $\mathbb{Z}/2\mathbb{Z}$ comes from $\mathrm{Br}(\mathbb{R})$!) Serre references Deuring for the proof (see Sere p.8)

Theorem 51.3.18: Field Extensions and CSA

Let A be a CSA over k, L/k a field extension (either finite or infinite). Then $A \otimes L$ is simple

***Proof*:**
If A is a division ring, then all ideals of $A \otimes L$ will be given with in part with the intersection of the ideals of L, which is simply (0), making $A \otimes L$ simple.

If A is any CSA, write $A \cong M_n(k) \otimes D$. Then:

$$A \otimes L \cong M_n(k) \otimes (D \otimes L) \stackrel{!}{=} M_n(k) \otimes M_m(D')$$

where for $\stackrel{!}{=}$, D' is the division ring naturally given by $D \otimes_k L$! But this gives the result.

Corollary 51.3.19: Index of CSA

Let A be a simple, central and finite algebra over k. Then $[A : k]$ is a perfect square.

***Proof*:**
Let L be an algebraically closed extension of k. The algebra $A \otimes L$ can be endowed with an algebra structure over L, and we have:

$$[A \otimes L : L] = [A : k]$$

But $A \otimes L$ is a simple algebra, central over L, and finite over L. It then follows from example 51.3.17[1] that it is a matrix algebra over L, and $[A \otimes L : L]$ is indeed a perfect square.

Looking at the field extension of a k-algebra, it is natural to consider that $-\otimes_k L$ gives a homomorphism of Brauer groups $\varphi_{k,L} : \mathrm{Br}(k) \to \mathrm{Br}(L)$, namely due to the following result from linear algebra:

$$(A \otimes_k L) \otimes_L (A' \otimes_k L) \cong (A \otimes_k A') \otimes_k L$$

The kernel $\ker \varphi_{k,L}$ consists of all k-algebra's that become trivial (matrix algebras) when extending to L. Serre calls these algebras the algebras that *admit L as a field of decomposition.* (or admit a decomposition by L). More recently, the term *splitting field* is adopted due to the parallels to number theory. Naturally, if $L = \overline{k}$, then every algebra admits a decomposition as $\mathrm{Br}(\overline{k}) = 0$. We only require a finite extension:

Theorem 51.3.20: Splitting Field is Finite

The Brauer group $\mathrm{Br}(k)$ is the union of $\ker \varphi_{k,L}$ going over each L/k where L is a finite field extension. In particular, there exists a finite extension L/k such that for a CSA A over k, $[A \otimes_k L] = [1]$ in $\mathrm{Br}(L)$.

***Proof*:**
By example 51.3.17[1] we have that for a CSA A over $\overline{k}$, $A \otimes_k \overline{k} \cong M_n(D)$. Then the right hand side is generated by finitely many elements of the left hand side. We need only take the elements that map to the generators of the right hand side and to choose the appropriate field elements to get find L/k, as we sought to show.

51.4 Build up to Quaternion Algebras

Theorem 51.4.1: Skolem-Noether Theorem

Let A, B be CSA's over k, and let $f, g : A \to B$ be k-algebra isomorphism. Then there exists a unit $b \in B$ such that:

$$g(a) = bf(a)b^{-1}$$

In particular, every automorphism is an inner automorphism

***Proof*:**
Let's first prove the special case of $B = M_n(k)$. Then the isomorphisms $f, g : A \to M_n(k)$ define actions on k^n, or said differently these define two A-modules (with two different actions): V_f, V_g. Then using f, g we have an A-module isomorphism $g \circ f^{-1} : V_f \to V_g$. But any isomorphism between vector-spaces is representable as (unit) matrix in $M_n(k)$, and so we we get our value by linear algebra.

For the general case, we know that $B \otimes_k B^{\text{op}} \cong M_n(k)$ and $A \otimes_k B^{\text{op}}$ is simple as B^{op} is still simple (use theorem 51.3.12). As $B \otimes_k^B$ op is a (finite dimensional) matrix algebra, we may apply our special case to:

$$f \otimes 1,\ g \otimes 1 : A \otimes_k B^{\text{op}} \to B \otimes_k B^{\text{op}} \cong M_n(k)$$

which shows that:

$$(f \otimes 1)(a \otimes c) = b(g \otimes 1(a \otimes c)b^{-1}$$

which is true for all $a \in A$ and $c \in B^{\text{op}}$. Thus, it is true for $a = 1$, giving us:

$$1 \otimes c = b(1 \otimes c)b^{-1}$$

for all $c \in B^{\text{op}}$. Thus,

$$b \in Z_{B \otimes_k B^{\text{op}}}(k \otimes B^{\text{op}}) = B \otimes k$$

Hence, as constants move through the tensor we get that $b = b \otimes_k 1$. And so, by setting $z = 1$, we find:

$$f(a) = b' g(a) b'^{-1}$$

as we sought to show.

Theorem 51.4.2: Centralizer of Subalgebras

Let A be a CSA over k, $B \subseteq A$ a simple subalgebra, $C = C_A(B)$ the centralizer of B in A. Then C is simple, $B = C_A(C)$, and:

$$[B : k][C : k] = [A : k]$$

***Proof*:**
Let E be B with only the structure of a k-vector space. Then B acts on E via left multiplication; this action isomorphically embeds B into $\text{End}_k(E)$. Then the centralizer of B in $\text{End}_k(E)$ is nothing more than the algebra of right translations by E, that is B^{op}.

Given this, we can consider the simple algebra $A \otimes_k \mathrm{End}_k(E)$. We can now embed B into this tensored algebra in two ways: via $B \otimes 1$ or $1 \otimes B$. Their centralizers are $C \otimes \mathrm{End}_k(E)$ and $A \otimes B^{\mathrm{op}}$ respectively.

By theorem 51.4.1, there exists an inner automorphism of $A \otimes_k \mathrm{End}_k(E)$ mapping $B \otimes 1$ to $1 \otimes B$; it is then a simple algebra exercise to see that this inner automorphism induces a map on the centralizers. As a consequence, as $A \otimes B^{\mathrm{op}}$ is simple, so is $C \otimes \mathrm{End}_k(E)$, which must make C simple.

Furthermore:

$$[C \otimes \mathrm{End}_k(E) : k] = [C : k][B : k]^2 \qquad \text{and} \qquad [A \otimes B^{\mathrm{op}} : k][A : k][B : k]$$

From which we get $[A : k] = [B : k][C : k]$. What's left to show is the centralizer of C in A is B. Say that B' is this centralizer. Then $B \subseteq B'$. Then as $[A : k] = [B : k][C : k]$, we get:

$$[B' : k] = [B : k]$$

But then as they contain we must get $B = B'$, completing the proof.

52

The Jacobson Radical and Non-Semisimple Algebras

The Artin-Wedderburn theorem (theorem 51.2.16) is a complete answer to a narrow question: it classifies the semisimple rings and, in the process, shows that a semisimple k-algebra is nothing more than a finite product of matrix rings over division algebras. When R is semisimple, every module splits into simples, every short exact sequence splits, and the entire representation theory of R collapses onto the finite list of its simple modules. This is the best possible situation, and it is also the exception. The algebras whose representation theory occupies most of this book are precisely the ones that fail to be semisimple: the group algebra $k[G]$ when $\mathrm{char}(k)$ divides $|G|$ (where Maschke's theorem breaks down), the truncated polynomial algebra $k[x]/(x^n)$, universal enveloping algebras of Lie algebras, and the path algebra of a quiver with an oriented cycle. For all of these, some module fails to be a direct sum of simples, some sequence refuses to split, and Wedderburn has nothing to say.

This chapter builds the tools that take over where Wedderburn stops. The first of these, and the subject of the present section, is the *Jacobson radical* $\mathrm{Jac}(A)$: the two-sided ideal that measures, in a single invariant, exactly how far A is from being semisimple. It is the obstruction that vanishes precisely when A is semisimple, and dividing it out always produces a semisimple ring $A/\mathrm{Jac}(A)$ whose simple modules are the same as those of A. In the sections that follow, the radical becomes the engine behind the theory of indecomposable modules and the Krull-Schmidt theorem (which replaces "decomposition into simples" with "decomposition into indecomposables"), and behind the construction of projective covers, which repair the failure of projectivity that semisimplicity had guaranteed for free. The radical is where the non-semisimple story begins.

52.1 The Jacobson Radical

Throughout chapter 51 the simple modules did all the work: a semisimple ring was assembled out of its minimal left ideals, and every module was a direct sum of simples. When a ring is *not* semisimple, the simple modules are still present, but they no longer see everything. Some elements of the ring act as zero on every simple module without being zero themselves, and these elements form an ideal that records the discrepancy. To isolate them, we begin one level down, with modules, and ask which part of a module is invisible to all of its simple quotients.

The maximal submodules of a module M are exactly the kernels of the surjections $M \twoheadrightarrow S$ onto simple modules: a submodule $N \subsetneq M$ is maximal precisely when M/N is simple, and every simple quotient of M is of the form M/N for such an N (the classification of simples as quotients by maximal ideals is lemma 51.1.3). An element lying in every maximal submodule is one that every simple quotient sends to zero. Collecting these gives the radical of a module.

Definition 52.1.1: Radical of a Module

Let M be a left A-module. The *radical* of M, written $\operatorname{rad}(M)$, is the intersection of all maximal submodules of M:

$$\operatorname{rad}(M) = \bigcap_{\substack{N \subsetneq M \\ N \text{ maximal}}} N$$

If M has no maximal submodules, the intersection is empty and $\operatorname{rad}(M) := M$ by convention.

Since each maximal submodule is the kernel of a map onto a simple module, an equivalent description is

$$\operatorname{rad}(M) = \bigcap_{\substack{\varphi\colon M \to S \\ S \text{ simple}}} \ker(\varphi)$$

so that $\operatorname{rad}(M)$ is the set of elements killed by *every* homomorphism from M into a simple module. The quotient $M/\operatorname{rad}(M)$ is the largest quotient of M that embeds into a product of simple modules; it is the *semisimple quotient* of M, the part of M that its simple quotients can detect. Everything inside $\operatorname{rad}(M)$ is invisible to them.

Example 52.1.2: The Radical of a Cyclic $\mathbb{Z}$-Module

Take $A = \mathbb{Z}$ and $M = \mathbb{Z}/12\mathbb{Z}$. The maximal submodules of M correspond to the maximal ideals of $\mathbb{Z}$ containing $12\mathbb{Z}$, that is to the primes dividing 12, namely 2 and 3. The corresponding maximal submodules are $2\mathbb{Z}/12\mathbb{Z}$ and $3\mathbb{Z}/12\mathbb{Z}$, with simple quotients $\mathbb{Z}/2\mathbb{Z}$ and $\mathbb{Z}/3\mathbb{Z}$. Their intersection is

$$\operatorname{rad}(\mathbb{Z}/12\mathbb{Z}) = \frac{2\mathbb{Z}}{12\mathbb{Z}} \cap \frac{3\mathbb{Z}}{12\mathbb{Z}} = \frac{6\mathbb{Z}}{12\mathbb{Z}}$$

so $\operatorname{rad}(M) = 6\mathbb{Z}/12\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z}$, and the semisimple quotient is $M/\operatorname{rad}(M) \cong \mathbb{Z}/6\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$. The radical has stripped $\mathbb{Z}/12\mathbb{Z}$ down to its squarefree quotient: the extra factors of 2 and 3 that no simple quotient can see are exactly what lies in $6\mathbb{Z}/12\mathbb{Z}$.

Applying this construction to the ring itself, viewed as a module over itself, produces the central object of the chapter. The radical of A as a left A-module is the intersection of its maximal *left* ideals.

Definition 52.1.3: Jacobson Radical

Let A be a ring. The *Jacobson radical* of A, written $\mathrm{Jac}(A)$, is the radical of A regarded as a left module over itself, that is the intersection of all maximal left ideals of A:

$$\mathrm{Jac}(A) = \mathrm{rad}({}_A A) = \bigcap_{\substack{\mathfrak{m} \subseteq A \\ \mathfrak{m} \text{ maximal left ideal}}} \mathfrak{m}$$

The definition is one-sided: it uses left ideals, and a priori $\mathrm{Jac}(A)$ need only be a left ideal. One of the first surprises is that the resulting set is symmetric, a two-sided ideal that could equally have been defined with maximal *right* ideals. This symmetry, and several other faces of the same object, are the content of the next theorem. Before stating it, recall that an element $u \in A$ is *left-invertible* if there exists $v \in A$ with $vu = 1$.

Theorem 52.1.4: Characterizations of the Jacobson Radical

Let A be a ring and let $a \in A$. The following subsets of A coincide, and their common value is $\mathrm{Jac}(A)$:

1. the intersection of all maximal left ideals of A;
2. the intersection of the annihilators $\mathrm{Ann}_A(S)$ of all simple left A-modules S;
3. the set $\{a \in A \big| 1 - xa \text{ is left-invertible for all } x \in A\}$.

Consequently, $\mathrm{Jac}(A)$ is a two-sided ideal of A, and it is the largest two-sided ideal of A that annihilates every simple left A-module.

The three descriptions look at the same ideal from three angles. The first is the definition. The second recasts it representation-theoretically: $\mathrm{Jac}(A)$ is exactly the set of elements that act as zero on every simple module, which is why it is invisible to the simple representation theory. The third is an intrinsic ring-theoretic criterion that never mentions modules at all, and it is the one that makes the two-sidedness fall out for free, since it is symmetric in a way the definition is not.

***Proof*:**
We prove (1) = (2), then (2) = (3), and finally read off the two-sidedness and maximality statements.

Step 1: (1) = (2). Let J_1 denote the intersection of all maximal left ideals and J_2 the intersection of the annihilators of all simple left modules. If S is a simple left A-module, then for any $0 \neq s \in S$ we have $S = As$ (as As is a nonzero submodule of the simple module S), and by corollary 51.1.4 the map $a \mapsto as$ gives $S \cong A/\mathrm{Ann}_A(s)$ with $\mathrm{Ann}_A(s)$ a maximal left ideal. The annihilator of the whole module is

$$\mathrm{Ann}_A(S) = \bigcap_{0 \neq s \in S} \mathrm{Ann}_A(s)$$

an intersection of maximal left ideals, so $J_1 \subseteq \mathrm{Ann}_A(S)$ for every simple S, giving $J_1 \subseteq J_2$. Conversely, if $\mathfrak{m}$ is any maximal left ideal, then $S = A/\mathfrak{m}$ is a simple left module and $\mathrm{Ann}_A(S) \subseteq \mathfrak{m}$ (since $\mathrm{Ann}_A(S)$ kills the coset $1 + \mathfrak{m}$, so $\mathrm{Ann}_A(S) \cdot 1 \subseteq \mathfrak{m}$). Hence $J_2 \subseteq \mathfrak{m}$ for every maximal left ideal $\mathfrak{m}$, giving $J_2 \subseteq J_1$. Thus $J_1 = J_2$.

Step 2: (2) $\subseteq$ (3). Let $a \in J_2$, so a annihilates every simple left module, and fix $x \in A$. We must show $1 - xa$ is left-invertible. If not, then $A(1 - xa)$ is a proper left ideal, hence contained in some maximal left ideal $\mathfrak{m}$ (using that $1 \notin A(1 - xa)$ and Zorn's lemma). The quotient $S = A/\mathfrak{m}$ is simple, so a annihilates it: $a \cdot (1 + \mathfrak{m}) = 0$, meaning $a \in \mathfrak{m}$. But $xa \in \mathfrak{m}$ as well, since $\mathfrak{m}$ is a left ideal, and $1 - xa \in \mathfrak{m}$ since $1 - xa \in A(1 - xa) \subseteq \mathfrak{m}$. Adding, $1 = (1 - xa) + xa \in \mathfrak{m}$, contradicting that $\mathfrak{m}$ is proper. Hence $1 - xa$ is left-invertible for every x, so $a \in J_3$, the set in (3).

Step 3: (3) $\subseteq$ (2). Let $a \in J_3$, and suppose toward a contradiction that a does *not* annihilate some simple left module S. Then $as \neq 0$ for some $s \in S$, and since As is a nonzero submodule of the simple module S we have $As = S$. In particular $s \in As$, so $s = xas$ for some $x \in A$, giving $(1 - xa)s = 0$. By hypothesis $1 - xa$ is left-invertible, say $v(1 - xa) = 1$; applying v gives $s = v(1 - xa)s = 0$, contradicting the choice of s. Hence a annihilates every simple module, so $a \in J_2$.

Combining the three steps, $J_1 = J_2 = J_3 = \mathrm{Jac}(A)$.

Step 4: two-sidedness and maximality. As the intersection of the left ideals $\mathrm{Ann}_A(S)$, description (2) shows $\mathrm{Jac}(A)$ is a left ideal. But each $\mathrm{Ann}_A(S)$ is in fact a two-sided ideal: if $a \in \mathrm{Ann}_A(S)$ and $b \in A$, then for all $s \in S$ we have $(ab)s = a(bs) = 0$, so $ab \in \mathrm{Ann}_A(S)$. An intersection of two-sided ideals is two-sided, so $\mathrm{Jac}(A)$ is a two-sided ideal. Finally, if I is any two-sided ideal annihilating every simple left module, then $I \subseteq \mathrm{Ann}_A(S)$ for every simple S, hence $I \subseteq \bigcap_S \mathrm{Ann}_A(S) = \mathrm{Jac}(A)$; thus $\mathrm{Jac}(A)$ is the largest such ideal, completing the proof.

The left-invertibility criterion (3) deserves a second look, because it is what makes the radical robust. It says a lies in the radical exactly when $1 - xa$ can never be turned into a non-unit by any left multiplier x. A standard manipulation upgrades "left-invertible" to "two-sided invertible" for these particular elements: if $a \in \mathrm{Jac}(A)$ and $v(1 - xa) = 1$, then $v = 1 + vxa = 1 - (-vx)a$, and since $a \in \mathrm{Jac}(A)$ the element v is itself left-invertible by the same criterion; a left-invertible element with a left-invertible left inverse is a unit. So for $a \in \mathrm{Jac}(A)$ the element $1 - xa$ is a two-sided unit for every x, and by the right-handed version of the whole theorem $1 - ax$ is a unit as well. This is the working form of the radical: $\mathrm{Jac}(A)$ is the set of elements a such that $1 - xay$ is a unit for all $x, y \in A$, and it is exactly this that will drive Nakayama's lemma below.

Description (2) also settles the two-sided nature of the radical without any of the asymmetry of the original definition, and it makes precise the sense in which the radical is invisible to representation theory. If A is semisimple, every module is a sum of simples, so an element killing all simples kills everything: $\mathrm{Jac}(A) = 0$. The content of the non-semisimple theory is that $\mathrm{Jac}(A)$ can be nonzero, and it is this ideal that the simple modules fail to detect.

Before turning to that theory, the radical of a ring is anchored by two computations. The first is the archetype of a local non-semisimple algebra.

Example 52.1.5: The Radical of a Truncated Polynomial Algebra

Let k be a field and let $A = k[x]/(x^n)$ with $n \geq 1$, writing $\bar{x}$ for the image of x. This is a commutative local ring: an element $f(\bar{x}) = c_0 + c_1\bar{x} + \cdots + c_{n-1}\bar{x}^{n-1}$ is a unit if and only if $c_0 \neq 0$, since when $c_0 = 0$ the element is nilpotent ($\bar{x}^n = 0$ forces $f(\bar{x})^n = 0$), and when $c_0 \neq 0$ one inverts using the geometric series, which terminates because $\bar{x}^n = 0$:

$$(c_0 + \bar{x}g)^{-1} = c_0^{-1}\big(1 + c_0^{-1}\bar{x}g\big)^{-1} = c_0^{-1}\sum_{j=0}^{n-1}(-c_0^{-1}\bar{x}g)^j$$

The non-units are therefore exactly the elements with $c_0 = 0$, which is the ideal $(\bar{x})$. In a commutative ring the maximal ideals are the maximal left ideals, and here there is a single maximal ideal, namely $(\bar{x})$, because $A/(\bar{x}) \cong k$ is a field while any element outside $(\bar{x})$ is a unit. Hence

$$\mathrm{Jac}(A) = (\bar{x}) = \{c_1\bar{x} + c_2\bar{x}^2 + \cdots + c_{n-1}\bar{x}^{n-1} \big| c_i \in k\}$$

This ideal is nilpotent: $(\bar{x})^n = (\bar{x}^n) = 0$, so already $\mathrm{Jac}(A)^n = 0$. The quotient $A/\mathrm{Jac}(A) = A/(\bar{x}) \cong k$ is a field, hence semisimple, which is the general phenomenon established in theorem 52.1.9. The single simple A-module is $k = A/(\bar{x})$, and $\bar{x}$ acts on it as zero, confirming that $\mathrm{Jac}(A) = (\bar{x})$ annihilates every simple module.

The second computation is the model of a non-commutative, non-local radical, where the one-sided origin of the definition is easiest to see in matrices.

Example 52.1.6: The Radical of Upper-Triangular Matrices

Let k be a field and let $A = T_n(k)$ be the ring of $n \times n$ upper-triangular matrices over k. Write $N \subseteq A$ for the strictly upper-triangular matrices (zero on and below the diagonal). The claim is $\mathrm{Jac}(A) = N$.

N annihilates every simple module. For each $1 \leq i \leq n$ there is a one-dimensional A-module $S_i = k$ on which an upper-triangular matrix $a = (a_{pq})$ acts by its ith diagonal entry, $a \cdot v = a_{ii}v$; this is a ring homomorphism $A \to k$ because the (i, i) entry of a product of upper-triangular matrices is the product of the (i, i) entries. The S_i are pairwise non-isomorphic simple A-modules. Any strictly upper-triangular matrix has all diagonal entries zero, so it acts as 0 on each S_i; thus $N \subseteq \mathrm{Ann}_A(S_i)$ for all i, and $N \subseteq \mathrm{Jac}(A)$ by theorem 52.1.4.

Nothing outside N lies in the radical. If $a \in A \setminus N$, some diagonal entry a_{ii} is nonzero, so a acts invertibly on S_i, and a does not annihilate the simple module S_i. By part (2) of theorem 52.1.4, $a \notin \mathrm{Jac}(A)$. Combining, $\mathrm{Jac}(A) = N$.

As a check on the intrinsic criterion, N is nilpotent with $N^n = 0$ (each multiplication by a strictly upper-triangular matrix pushes nonzero entries one further diagonal above the main diagonal), so for $a \in N$ the element $1 - xa$ has the form $1-$ (nilpotent) and is a unit via the terminating geometric series $\sum_{j\geq 0}(xa)^j$. The quotient is $A/N \cong k^n$, the diagonal matrices, which is semisimple, and there are exactly n simple modules $S_1, \ldots, S_n$, matching the n factors of k^n.

The two examples share a feature: in each, $\mathrm{Jac}(A)$ turned out to be nilpotent, and the geometric series that inverts $1 - xa$ terminated precisely because a power of the radical vanished. This is not special to small examples. For the finite-dimensional and, more generally, left Artinian algebras that concern us, the radical is always nilpotent. The route to that fact runs through Nakayama's lemma, which converts the invertibility criterion into a statement about modules being forced to zero.

The lemma answers a question that recurs throughout module theory: if multiplying a module by the radical does not shrink it, must the module already be zero? The commutative version, over a local ring or with a general ideal contained in the radical, is proved in the companion volume 'NateCommAlg' [10]and will not be re-derived here; the module form over an arbitrary ring is the form needed here, and its proof uses only the invertibility criterion from theorem 52.1.4.

Lemma 52.1.7: Nakayama's Lemma

Let A be a ring and M a finitely generated left A-module.

1. If $\mathrm{Jac}(A)\,M = M$, then $M = 0$.
2. If $N \subseteq M$ is a submodule with $M = N + \mathrm{Jac}(A)\,M$, then $N = M$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

1. Suppose $M \neq 0$ and $JM = M$. Since M is finitely generated, choose a generating set $m_1, \ldots, m_r$ with r minimal, so no fewer than r elements generate M; as $M \neq 0$ we have $r \geq 1$. From $M = JM$ we may write the last generator as

$$m_r = \sum_{i=1}^{r} a_i m_i \qquad \text{with } a_i \in J$$

   Isolating m_r gives $(1 - a_r)m_r = \sum_{i=1}^{r-1} a_i m_i$. Because $a_r \in J = \mathrm{Jac}(A)$, the element $1 - a_r$ is a unit (the working form of theorem 52.1.4: $1 - a_r$ is left-invertible, and for radical elements this upgrades to a two-sided inverse). Multiplying on the left by $(1 - a_r)^{-1}$ expresses m_r as an A-combination of $m_1, \ldots, m_{r-1}$, so these $r-1$ elements already generate M, contradicting the minimality of r. Hence $M = 0$.

2. Apply part (1) to the finitely generated module M/N. Its finite generation is inherited from M (the images of generators of M generate the quotient). The hypothesis $M = N + JM$ gives, in the quotient, $M/N = J\,(M/N)$, since the image of JM is $J(M/N)$ and the image of N is 0. By part (1), $M/N = 0$, that is $N = M$, completing the proof.

The finite-generation hypothesis is not optional. Over the local ring $A = \mathbb{Z}_{(p)}$ (integers localized at p, whose radical is $p\mathbb{Z}_{(p)}$) the module $M = \mathbb{Q}$ satisfies $pM = M$ yet $M \neq 0$; it fails to be finitely generated, and the minimal-generator argument has nothing to grip. Part (2) is the form used in practice: it says that generators of $M/\mathrm{Jac}(A)M$ lift to generators of M. Once $\mathrm{Jac}(A)M$ is known (below) to be a "small" submodule, this becomes the statement that a minimal generating set of M is detected by the semisimple quotient $M/\mathrm{Jac}(A)M$, which is the seed of the theory of projective covers in a later section.

We now specialize to the setting where the radical is best behaved. A ring A is *left Artinian* if it satisfies the descending chain condition on left ideals; every finite-dimensional algebra over a field is left Artinian, since a descending chain of left ideals is a descending chain of subspaces and dimension cannot drop forever. In this setting the radical is not only an intersection of maximal ideals but a nilpotent ideal, and it is the largest one.

Theorem 52.1.8: The Radical Is Nilpotent for Artinian Rings

Let A be a left Artinian ring. Then $\mathrm{Jac}(A)$ is nilpotent: there exists $m \geq 1$ with $\mathrm{Jac}(A)^m = 0$. Moreover, $\mathrm{Jac}(A)$ contains every nilpotent left ideal and every nilpotent two-sided ideal of A, so it is the largest nilpotent one-sided or two-sided ideal.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

Step 1: J is nilpotent. The descending chain of two-sided ideals

$$J \supseteq J^2 \supseteq J^3 \supseteq \cdots$$

is a descending chain of left ideals, so by the descending chain condition it stabilizes: there is m with $I := J^m = J^{m+1} = J\,I$. Suppose for contradiction that $I \neq 0$. Consider the set Σ of left ideals $L \subseteq A$ with $IL \neq 0$; it is nonempty because $I \cdot I = J^{2m} = I \neq 0$ shows $I \in \Sigma$ (using $J^{2m} = (J^m)^2 = I \cdot I$ and $J^{2m} = J^m = I$ since the chain stabilized). By the descending chain condition, Σ has a minimal element L_0. Choose $x \in L_0$ with $Ix \neq 0$; then $Ix \subseteq L_0$ is a left ideal with $I(Ix) = I^2x = Ix \neq 0$ (as $I^2 = I$), so $Ix \in \Sigma$, and minimality forces $Ix = L_0$. In particular $x \in L_0 = Ix$, so $x = ax$ for some $a \in I \subseteq J$. Then $(1-a)x = 0$, and since $a \in J$ the element $1 - a$ is a unit, giving $x = 0$ and hence $Ix = 0$, a contradiction. Therefore $I = J^m = 0$.

Step 2: J contains every nilpotent one-sided or two-sided ideal. Let I be a nilpotent left ideal, say $I^t = 0$. For any $a \in I$ and any $x \in A$, the element xa lies in I (a left ideal absorbs left multiplication), so $(xa)^t \in I^t = 0$; thus xa is nilpotent. A nilpotent element y with $y^t = 0$ makes $1 - y$ a unit, with inverse the terminating sum $1 + y + y^2 + \cdots + y^{t-1}$. Hence $1 - xa$ is a unit, in particular left-invertible, for every $x \in A$, so $a \in \mathrm{Jac}(A)$ by part (3) of theorem 52.1.4. This holds for every $a \in I$, so $I \subseteq J$. A nilpotent two-sided ideal is in particular a nilpotent left ideal, so the same conclusion applies, completing the proof.

For a left Artinian ring, then, "the Jacobson radical" and "the largest nilpotent ideal" name the same object; the two definitions of the radical current in the literature (intersection of maximal left ideals versus largest nilpotent ideal) agree exactly when A is Artinian. The nilpotence is what powers the terminating geometric series seen in the truncated-polynomial and upper-triangular examples, and it is the property that fails for general rings. It also gives a concrete way to detect non-semisimplicity: a single nonzero nilpotent element of a two-sided ideal already forces the radical to be nonzero. This is exactly the obstruction that appears for modular group algebras.

Having pinned down $\mathrm{Jac}(A)$ as a nilpotent ideal, the pieces are in place for the structural payoff. Dividing A by its radical removes precisely the elements that the simple modules could not see, and what remains is semisimple.

Theorem 52.1.9: Semisimplicity of the Quotient by the Radical

Let A be a left Artinian ring. Then $A/\mathrm{Jac}(A)$ is a semisimple ring, and hence Artin-Wedderburn (theorem 51.2.16) applies to it. Moreover, the simple left A-modules are exactly the simple left $A/\mathrm{Jac}(A)$-modules: every simple A-module is annihilated by $\mathrm{Jac}(A)$ and so factors through $A/\mathrm{Jac}(A)$, and every simple $A/\mathrm{Jac}(A)$-module is a simple A-module via the quotient map $A \twoheadrightarrow A/\mathrm{Jac}(A)$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$ and $\bar{A} = A/J$.

Step 1: $\bar{A}$ is semisimple. By corollary 51.1.9 it suffices to show that $\bar{A}$ is semisimple as a left module over itself, that is that $\mathrm{rad}(\bar{A}) = 0$. The maximal left ideals of $\bar{A}$ are exactly the images $\mathfrak{m}/J$ of the maximal left ideals $\mathfrak{m}$ of A (which all contain $J = \mathrm{Jac}(A)$), by the correspondence theorem. Their intersection is

$$\mathrm{Jac}(\bar{A}) = \bigcap_{\mathfrak{m} \supseteq J} \mathfrak{m}/J = \Big(\bigcap_{\mathfrak{m}} \mathfrak{m}\Big)\Big/ J = J/J = 0$$

So $\mathrm{Jac}(\bar{A}) = 0$. It remains to convert this into semisimplicity, which is where the Artinian hypothesis is spent: $\bar{A}$ is Artinian (a quotient of the Artinian ring A), and for an Artinian ring $\mathrm{Jac}(\bar{A}) = 0$ forces $\bar{A}$ to be semisimple. Concretely, since $\bar{A}$ is Artinian we may pick finitely many maximal left ideals $\mathfrak{m}_1/J, \dots, \mathfrak{m}_r/J$ whose intersection is already 0 (take a minimal finite subintersection, which exists by the descending chain condition and equals the full intersection $\mathrm{Jac}(\bar{A}) = 0$). The map

$$\bar{A} \longrightarrow \bigoplus_{i=1}^{r} \bar{A}/(\mathfrak{m}_i/J)$$

is injective, since its kernel is $\bigcap_i(\mathfrak{m}_i/J) = 0$. Each summand $\bar{A}/(\mathfrak{m}_i/J)$ is a simple $\bar{A}$-module, so $\bar{A}$ embeds as a submodule of a semisimple module and is therefore semisimple by corollary 51.1.8. Thus $\bar{A}$ is a semisimple $\bar{A}$-module, and by corollary 51.1.9 a semisimple ring. Artin-Wedderburn now applies to $\bar{A}$.

Step 2: the simple modules coincide. Let S be a simple left A-module. By part (2) of theorem 52.1.4, $J = \mathrm{Jac}(A)$ annihilates every simple A-module, so $JS = 0$. Hence the A-action on S factors through the quotient $\bar{A} = A/J$: setting $(\bar{a})s := as$ is well-defined because J acts as zero. The A-submodules and $\bar{A}$-submodules of S are the same subsets (a subgroup of S is A-stable if and only if it is $\bar{A}$-stable, since the actions agree), so S is simple as an $\bar{A}$-module precisely because it is simple as an A-module.

Conversely, let T be a simple left $\bar{A}$-module. Pulling back the action along the surjection $\pi\colon A \twoheadrightarrow \bar{A}$, that is defining $a \cdot t := \pi(a)\, t$, makes T an A-module. Its A-submodules are exactly its $\bar{A}$-submodules (again the two actions have the same invariant subgroups, because π is surjective), so T is simple as an A-module. These two passages are mutually inverse, so the simple A-modules and the simple $\bar{A}$-modules are identified, as we sought to show.

This is the structural role of the radical: it is the exact obstruction one divides out to recover the Wedderburn world. The simple modules of A are unchanged by the passage to $A/\mathrm{Jac}(A)$, so the finite list of simples that a semisimple ring enjoys is available for *any* Artinian ring, read off from its semisimple quotient. What the radical takes away is not the simples but the way they fit together: over A the simples can be glued into indecomposable modules that do not split, and the gluing data lives in $\mathrm{Jac}(A)$. The theorem says that for an Artinian A there are finitely many simple A-modules, one for each simple factor of the Wedderburn decomposition of $A/\mathrm{Jac}(A)$, and this is the starting point for the character theory and the block theory developed later.

The special case $\mathrm{Jac}(A) = 0$ returns to chapter 51.

Corollary 52.1.10: Semisimplicity via the Radical

Let A be a left Artinian ring. Then A is semisimple if and only if $\mathrm{Jac}(A) = 0$.

***Proof*:**
If A is semisimple, then by corollary 51.1.9 it is a semisimple left module over itself, so its radical (the intersection of its maximal left ideals) is 0; that is, $\mathrm{Jac}(A) = \mathrm{rad}({}_A A) = 0$. Indeed, a semisimple module is a direct sum of simples, and its radical, the intersection of maximal submodules, is 0: writing $A = \bigoplus_i I_i$ as a sum of minimal left ideals (lemma 51.1.10), each $\bigoplus_{j \neq i} I_j$ is a maximal submodule, and their intersection is 0.

Conversely, if $\mathrm{Jac}(A) = 0$, then $A = A/\mathrm{Jac}(A)$, and by theorem 52.1.9 the quotient $A/\mathrm{Jac}(A)$ is semisimple; hence A itself is semisimple, completing the proof.

The corollary makes the radical the precise measure of the failure of semisimplicity: A is semisimple exactly when the measurement returns zero, and Artin-Wedderburn (theorem 51.2.16) describes what A looks like in that case, namely a product $M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$. For a general Artinian A, the same product describes $A/\mathrm{Jac}(A)$ rather than A, and the difference between A and this product is stored in the nilpotent ideal $\mathrm{Jac}(A)$. The truncated-polynomial algebra $k[x]/(x^n)$ with $n \geq 2$ is the simplest case where the measurement is nonzero: its radical $(\bar{x})$ is a nonzero nilpotent ideal, so it is not semisimple, even though its semisimple quotient is the field k.

The most consequential source of non-semisimple algebras in representation theory is the group algebra $k[G]$ when the characteristic of k divides the order of the group. Maschke's theorem guarantees semisimplicity precisely when $\mathrm{char}(k) \nmid |G|$; the radical detects, and measures, the failure in the opposite case.

Example 52.1.11: The Radical of a Modular Group Algebra
Let $G = \mathbb{Z}/p\mathbb{Z}$ be cyclic of order p and let k be a field. Writing g for a generator, the group algebra is

$$k[G] \cong k[t]/(t^p - 1)$$

via $g \mapsto t$, since g has order p. The structure of $\mathrm{Jac}(k[G])$ depends entirely on whether $\mathrm{char}(k)$ divides $|G| = p$.

The modular case $\mathrm{char}(k) = p$. In characteristic p the Frobenius identity gives $t^p - 1 = (t-1)^p$, so

$$k[G] \cong k[t]/\big((t-1)^p\big) \cong k[s]/(s^p) \qquad (s := t - 1)$$

the last isomorphism being the change of variable $s = t - 1$. This is precisely the truncated polynomial algebra of example 52.1.5 with $n = p$, so its radical is

$$\mathrm{Jac}(k[G]) = (s) = (g - 1)$$

the ideal generated by $g - 1$, which is the augmentation ideal (the kernel of the augmentation map $k[G] \to k$ sending $g \mapsto 1$). It is nilpotent, $(g-1)^p = g^p - 1 = 0$, and nonzero, so $k[G]$ is not semisimple: Maschke's theorem fails exactly because $p = \mathrm{char}(k)$ divides $|G|$. The unique simple $k[G]$-module is the trivial module k, on which g acts as the identity, so $g - 1$ acts as zero, confirming $\mathrm{Jac}(k[G]) = (g-1)$ annihilates the only simple module.

The coprime case $\mathrm{char}(k) \nmid p$. If the characteristic does not divide p, then the polynomial $t^p - 1$ is separable (its derivative pt^{p-1} is nonzero and shares no root with it), so it has no repeated factors. Over a field containing a primitive pth root of unity ζ it splits as $t^p - 1 = \prod_{i=0}^{p-1}(t - \zeta^i)$, and the Chinese remainder theorem gives

$$k[G] \cong \prod_{i=0}^{p-1} k[t]/(t - \zeta^i) \cong k^p$$

a product of p copies of k, which is semisimple with radical $\mathrm{Jac}(k[G]) = 0$. (Over a field without the roots of unity, $t^p - 1$ still factors into distinct irreducible separable factors and $k[G]$ is a product of finite separable field extensions of k, again semisimple with zero radical.) This is Maschke's theorem in the coprime case, seen through the radical: separability of $t^p - 1$ is exactly the condition $\mathrm{char}(k) \nmid |G|$, and it forces $\mathrm{Jac}(k[G]) = 0$.

The contrast in the two cases is the whole point of the chapter in miniature. When $\mathrm{char}(k) \nmid |G|$ the group algebra is semisimple, its radical is zero, and the representation theory of G over k is governed by Wedderburn and character theory. When $\mathrm{char}(k)\big||G|$ the radical becomes a nonzero nilpotent ideal, the group algebra acquires indecomposable modules that are not simple, and one enters modular representation theory, where the radical, the indecomposables, and the projective covers built in the following sections are the working tools.

52.2 Indecomposable Modules and Krull-Schmidt

The previous chapter rested on a single organizing principle: over a semisimple ring, every module splits into simple pieces, and Artin-Wedderburn turns that splitting into a matrix description of the ring itself. The trouble is that semisimplicity is a strong hypothesis. The ring $k[x]/(x^2)$ is a two-dimensional k-algebra, and the module $k[x]/(x^2)$ over itself has a proper nonzero submodule $(x)/(x^2)$, yet that submodule has no complement: there is no way to write $k[x]/(x^2) = (x)/(x^2) \oplus N$. So this module does not break into simples at all. Once the semisimple world is left behind, the simple modules stop being the building blocks, and the decomposition theory of lemma 51.1.7 collapses.

What survives is a weaker notion of "building block". A module that cannot be split into two nonzero summands is *indecomposable* (definition 51.1.1), and every module of finite length is at least a finite direct sum of indecomposables, for the trivial reason that one keeps splitting until nothing splits further. The content of this section is that this crude decomposition is in fact canonical: the list of indecomposable summands, taken up to isomorphism, is uniquely determined by the module. This is the Krull-Schmidt theorem, and it is the correct replacement for the semisimple decomposition when simples are no longer available. The engine driving uniqueness is a structural fact about the endomorphism ring of an indecomposable module of finite length, that it is a *local ring*, which is itself a consequence of Fitting's lemma. So the section runs Fitting's lemma to the local-ring theorem to Krull-Schmidt, each result feeding the next.

Throughout, A is an algebra over a field k (the arguments need only that modules have finite length, so the results apply verbatim to modules of finite length over any ring). Modules are left modules. The starting point is worth isolating, since it is the gap between this chapter and the last. A simple module is indecomposable, because a simple module has no proper nonzero submodule at all, let alone a complemented one. The converse fails, and it fails already in dimension two: the $k[x]$-module $k[x]/(x^2)$ has the unique proper nonzero submodule $(x)/(x^2)$, so it is not simple, but that submodule is not a summand (any complement would have to be one-dimensional and x-stable, and $(x)/(x^2)$ is the only such subspace), so the module is indecomposable. An indecomposable module of finite length can therefore sit strictly between "simple" and "decomposable", and it is exactly this middle ground that Krull-Schmidt organizes.

The first tool is a splitting result for a single endomorphism. Given $\varphi \in \mathrm{End}_A(M)$, the iterated kernels $\ker(\varphi) \subseteq \ker(\varphi^2) \subseteq \cdots$ increase and the iterated images $\mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^2) \supseteq \cdots$ decrease. When M has finite length, both chains must stabilize, and Fitting's lemma says that at a common stabilization point the module splits into the eventual kernel and the eventual image.

Lemma 52.2.1: Fitting's Lemma

Let M be an A-module of finite length and let $\varphi \in \mathrm{End}_A(M)$. Then there exists a positive integer n such that

$$M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$$

Consequently, if M is indecomposable, then every $\varphi \in \mathrm{End}_A(M)$ is either nilpotent or an automorphism.

***Proof*:**
Write $\ell = \ell(M)$ for the length of M, which is finite by hypothesis.

Step 1: The kernel and image chains stabilize. The submodules $\ker(\varphi^i)$ form an increasing chain and the submodules $\mathrm{im}(\varphi^i)$ form a decreasing chain:

$$\ker(\varphi) \subseteq \ker(\varphi^2) \subseteq \cdots \qquad \mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^2) \supseteq \cdots$$

A module of finite length is both Noetherian and Artinian, so an increasing chain of submodules cannot strictly ascend more than ℓ times and a decreasing chain cannot strictly descend more than ℓ times. Setting $n = \ell$ makes both chains stationary from index n onward: for all $m \geq n$,

$$\ker(\varphi^m) = \ker(\varphi^n) \qquad \mathrm{im}(\varphi^m) = \mathrm{im}(\varphi^n)$$

Indeed, once the kernel chain repeats, it is stationary forever after: if $\ker(\varphi^i) = \ker(\varphi^{i+1})$ and $x \in \ker(\varphi^{i+2})$, then $\varphi(x) \in \ker(\varphi^{i+1}) = \ker(\varphi^i)$, so $x \in \ker(\varphi^{i+1}) = \ker(\varphi^i)$, giving $\ker(\varphi^{i+2}) = \ker(\varphi^{i+1})$; iterating shows $\ker(\varphi^j) = \ker(\varphi^i)$ for all $j \geq i$. A chain that strictly increased past step ℓ would produce more than ℓ strict inclusions, violating finite length, so the first repeat occurs by step ℓ. The same bound applies to the image chain, and $n = \ell$ dominates both stabilization thresholds.

Step 2: The two submodules intersect trivially. Fix n as above and take $y \in \ker(\varphi^n) \cap \mathrm{im}(\varphi^n)$. Write $y = \varphi^n(x)$ for some $x \in M$. Then $\varphi^n(y) = 0$ gives $\varphi^{2n}(x) = 0$, so $x \in \ker(\varphi^{2n}) = \ker(\varphi^n)$ by the stabilization of the kernel chain. Hence $y = \varphi^n(x) = 0$, and $\ker(\varphi^n) \cap \mathrm{im}(\varphi^n) = 0$.

Step 3: The two submodules span M. Take any $z \in M$. Since $\mathrm{im}(\varphi^n) = \mathrm{im}(\varphi^{2n})$, the element $\varphi^n(z) \in \mathrm{im}(\varphi^n)$ also lies in $\mathrm{im}(\varphi^{2n})$, so $\varphi^n(z) = \varphi^{2n}(w)$ for some $w \in M$. Then

$$z = \varphi^n(w) + \big(z - \varphi^n(w)\big)$$

where $\varphi^n(w) \in \mathrm{im}(\varphi^n)$, and the second term lies in $\ker(\varphi^n)$ because $\varphi^n(z - \varphi^n(w)) = \varphi^n(z) - \varphi^{2n}(w) = 0$. Thus $M = \ker(\varphi^n) + \mathrm{im}(\varphi^n)$, and together with Step 2 this gives the internal direct sum $M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$.

Step 4: The dichotomy for indecomposable M. Suppose now that M is indecomposable. The decomposition $M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$ forces one of the two summands to be M and the other to be 0. If $\ker(\varphi^n) = M$, then $\varphi^n = 0$, so φ is nilpotent. If instead $\ker(\varphi^n) = 0$ and $\mathrm{im}(\varphi^n) = M$, then φ is injective, since $\ker(\varphi) \subseteq \ker(\varphi^n) = 0$, and φ is surjective, since $\mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^n) = M$. An injective and surjective endomorphism is an automorphism. In either case φ is nilpotent or an automorphism, completing the proof.

The decomposition in Fitting's lemma is the "eventual kernel" and "eventual image" of φ, and it works for any single endomorphism of any finite-length module, indecomposable or not. The sharp consequence appears only in the indecomposable case: an indecomposable module of finite length admits no interesting endomorphisms in the sense that the only two behaviors available to a $\varphi \in \mathrm{End}_A(M)$ are "eventually kills everything" (nilpotent) and "moves everything bijectively" (automorphism). There is no room in between, precisely because any intermediate behavior would produce a nontrivial Fitting decomposition and split the module. This is the mechanism that will make the endomorphism ring so rigid.

To see the dichotomy in a case where it can be checked by hand, take the endomorphism given by multiplication by x on $M = k[x]/(x^3)$. Multiplication by x has kernel $(x^2)/(x^3)$ and image $(x)/(x^3)$, which are not complementary. But the lemma is about a *power*: φ^3 is multiplication by $x^3 = 0$, so $\ker(\varphi^3) = M$ and $\mathrm{im}(\varphi^3) = 0$, giving the trivial decomposition $M = M \oplus 0$. This is the nilpotent branch of the dichotomy, and indeed multiplication by x is nilpotent. Multiplication by $1 + x$, on the other hand, is invertible (with inverse $1 - x + x^2$), landing in the automorphism branch. Every element of $\mathrm{End}_{k[x]}(M)$ is one or the other.

The endomorphism ring $\mathrm{End}_A(M)$ of an indecomposable finite-length module is close to being a division ring but not quite: Schur's lemma (lemma 51.1.5) gave a division ring only for *simple* M, and indecomposable is weaker. The right substitute is that $\mathrm{End}_A(M)$ is a *local ring*. A ring is local when its non-units form a two-sided ideal, equivalently when it has a unique maximal left ideal; the intuition is that "being a non-unit" is closed under addition, so failures of invertibility do not conspire to produce an invertible element. Fitting's lemma is exactly what closes the non-units under addition here, because a non-unit of $\mathrm{End}_A(M)$ is precisely a nilpotent endomorphism, and controlling sums of nilpotents is where the argument lives.

Theorem 52.2.2: Endomorphism Rings of Indecomposables are Local

Let M be a nonzero indecomposable A-module of finite length. Then $\mathrm{End}_A(M)$ is a local ring: the set of non-units of $\mathrm{End}_A(M)$ is a two-sided ideal, and it consists exactly of the nilpotent endomorphisms of M.

***Proof*:**
Write $E = \mathrm{End}_A(M)$ and let $\mathfrak{m} \subseteq E$ be the set of endomorphisms that are not units, that is, not automorphisms of M.

Step 1: The non-units are the nilpotents. By lemma 52.2.1, every $\varphi \in E$ is either an automorphism or nilpotent, and these are mutually exclusive (a nilpotent $\varphi \neq 0$ kills some nonzero element, and $\varphi = 0$ is not invertible since $M \neq 0$). Hence $\mathfrak{m}$ is exactly the set of nilpotent endomorphisms.

Step 2: $\mathfrak{m}$ is closed under left and right multiplication by E. Let $\varphi \in \mathfrak{m}$, so φ is not an automorphism, and let $\psi \in E$ be arbitrary. If $\psi\varphi$ were an automorphism, then φ would be injective (as $\psi\varphi$ is) and ψ surjective; an injective endomorphism of a finite-length module is bijective (its image has the same length as M, hence equals M), so φ would be an automorphism, a contradiction. Thus $\psi\varphi \in \mathfrak{m}$. Symmetrically, if $\varphi\psi$ were an automorphism, then φ would be surjective, hence bijective by the length argument, again contradicting $\varphi \in \mathfrak{m}$. So $\varphi\psi \in \mathfrak{m}$, and $\mathfrak{m}$ absorbs multiplication on both sides.

Step 3: $\mathfrak{m}$ is closed under addition. This is the step that uses indecomposability. Let $\varphi, \psi \in \mathfrak{m}$ and suppose, for contradiction, that $\varphi + \psi$ is an automorphism. Set

$$\alpha = (\varphi + \psi)^{-1}\varphi \qquad \beta = (\varphi + \psi)^{-1}\psi$$

so that $\alpha + \beta = (\varphi + \psi)^{-1}(\varphi + \psi) = \mathrm{id}_M$. By Step 2, $\mathfrak{m}$ absorbs left multiplication, so $\alpha, \beta \in \mathfrak{m}$; in particular α is nilpotent, say $\alpha^r = 0$. From $\beta = \mathrm{id}_M - \alpha$ the standard geometric-series identity gives an inverse for β:

$$(\mathrm{id}_M - \alpha)\big(\mathrm{id}_M + \alpha + \alpha^2 + \cdots + \alpha^{r-1}\big) = \mathrm{id}_M - \alpha^r = \mathrm{id}_M$$

so $\beta = \mathrm{id}_M - \alpha$ is an automorphism of M. But $\beta \in \mathfrak{m}$ means β is not an automorphism, a contradiction. Hence $\varphi + \psi \in \mathfrak{m}$.

Step 4: Conclusion. Steps 2 and 3 show $\mathfrak{m}$ is a two-sided ideal of E, and Step 1 identifies it as the set of non-units. A ring whose non-units form a two-sided ideal is local: any element outside $\mathfrak{m}$ is a unit, so $\mathfrak{m}$ is the unique maximal left ideal (a proper left ideal contains no units, hence lies in $\mathfrak{m}$). Therefore $E = \mathrm{End}_A(M)$ is local, as we sought to show.

The theorem sharpens Schur's lemma in exactly the direction needed. For a simple module, lemma 51.1.5 gave a division ring, where every nonzero element is a unit. For an indecomposable module of finite length, one gets the next best thing: a local ring, where the non-units are corralled into a single ideal and every element outside it is a unit. The residue $\mathrm{End}_A(M)/\mathfrak{m}$ is a division ring, and one can think of the local ring as a division ring with a nilpotent "fuzz" $\mathfrak{m}$ attached. The content used below is the geometric series in Step 3, which turns "id_M minus a nilpotent" into a unit; this is what will let one element of a decomposition be swapped for another in the exchange argument below.

The running example makes the local structure explicit.

Example 52.2.3: The Endomorphism Ring of a Truncated Polynomial Module

Fix $n \geq 1$ and let $M = k[x]/(x^n)$, viewed as a module over $A = k[x]$ (equivalently over $k[x]/(x^n)$, which acts through the same operators). This module is indecomposable of length n: its submodules are exactly the ideals $(x^j)/(x^n)$ for $0 \leq j \leq n$, forming a single chain

$$0 = (x^n)/(x^n) \subseteq (x^{n-1})/(x^n) \subseteq \cdots \subseteq (x)/(x^n) \subseteq M$$

and a chain of submodules has no way to split off a complementary summand (a decomposition $M = M_1 \oplus M_2$ with both $M_i \neq 0$ would give two submodules neither containing the other).

Every A-endomorphism of M is multiplication by some polynomial: since M is generated by the image of 1, a homomorphism φ is determined by $\varphi(1) = \overline{f(x)}$, and then $\varphi(\overline{g}) = \overline{gf}$. So

$$\mathrm{End}_A(M) \cong k[x]/(x^n)$$

as rings, the isomorphism sending φ to $\varphi(1)$. This is a local ring with maximal ideal $\mathfrak{m} = (x)/(x^n)$: an element $\overline{f} = \overline{a_0 + a_1 x + \cdots + a_{n-1}x^{n-1}}$ is a unit if and only if $a_0 \neq 0$ (with inverse computed by the geometric series when $a_0 = 1$), and it is nilpotent if and only if $a_0 = 0$. The non-units are precisely the nilpotents, matching theorem 52.2.2, and $\mathrm{End}_A(M)/\mathfrak{m} \cong k$ is the residue division ring (here a field, since A is commutative).

The local endomorphism ring is now used to prove the main theorem. Existence of a decomposition into indecomposables is easy, by induction on length; the content is uniqueness. The classical route to uniqueness is an *exchange argument*: given two decompositions of the same module, one shows that each indecomposable summand of the first can be swapped into the second, one at a time, without changing the ambient module, and the local endomorphism rings are exactly what make each swap possible. The theorem is due to Krull and Schmidt for finite groups and finite-length modules, with Azumaya's extension to any module that is a direct sum of submodules with local endomorphism rings.

Theorem 52.2.4: Krull-Schmidt(-Azumaya)

Let M be a nonzero A-module of finite length. Then:

1. M is a finite direct sum of indecomposable submodules,
$$M = M_1 \oplus M_2 \oplus \cdots \oplus M_r$$
with each M_i indecomposable.
2. This decomposition is unique up to isomorphism and reordering: if
$$M = M_1 \oplus \cdots \oplus M_r = N_1 \oplus \cdots \oplus N_s$$
are two decompositions into indecomposable submodules, then $r = s$ and there is a permutation σ of $\{1, \ldots, r\}$ with $M_i \cong N_{\sigma(i)}$ for every i.

***Proof*:**

1. *Existence.* Argue by induction on the length $\ell(M)$. If M is indecomposable, then $M = M$ is already such a decomposition, with one summand. Otherwise $M = M_1 \oplus M_2$ with both M_i nonzero, and then $\ell(M_1), \ell(M_2) < \ell(M)$ because length is additive over direct sums and both summands are nonzero (hence of positive length). By the inductive hypothesis each M_i is a finite direct sum of indecomposables, and concatenating the two lists expresses M as a finite direct sum of indecomposables. The base case $\ell(M) = 1$ is a simple, hence indecomposable, module. This proves existence.
2. *Uniqueness.* Suppose
$$M = M_1 \oplus \cdots \oplus M_r = N_1 \oplus \cdots \oplus N_s$$
with all M_i and N_j indecomposable of finite length, so each $\mathrm{End}_A(M_i)$ and $\mathrm{End}_A(N_j)$ is local by theorem 52.2.2. Induct on r. The strategy is to exchange M_1 for one of the N_j, peel it off both sides, and apply the inductive hypothesis to what remains.

   Let $\iota_i \colon M_i \hookrightarrow M$ and $\pi_i \colon M \twoheadrightarrow M_i$ be the inclusion and projection for the first decomposition, and $\iota'_j \colon N_j \hookrightarrow M$, $\pi'_j \colon M \twoheadrightarrow N_j$ those for the second. These satisfy
$$\sum_{i=1}^{r} \iota_i \pi_i = \mathrm{id}_M \qquad \sum_{j=1}^{s} \iota'_j \pi'_j = \mathrm{id}_M$$
   Restricting the second identity to M_1 and projecting back to M_1 gives, in $\mathrm{End}_A(M_1)$,
$$\mathrm{id}_{M_1} = \pi_1 \Big(\sum_{j=1}^{s} \iota'_j \pi'_j \Big) \iota_1 = \sum_{j=1}^{s} (\pi_1 \iota'_j)(\pi'_j \iota_1)$$
   Now $\mathrm{End}_A(M_1)$ is local, so its non-units form an ideal and cannot sum to the unit id_{M_1}; at least one summand $(\pi_1 \iota'_j)(\pi'_j \iota_1)$ must be a unit of $\mathrm{End}_A(M_1)$. After reindexing the N_j

we may assume this happens for $j = 1$: the composite

$$\theta = (\pi_1 \iota_1')(\pi_1' \iota_1) \colon M_1 \longrightarrow M_1$$

is an automorphism of M_1, where $\pi_1' \iota_1 \colon M_1 \to N_1$ and $\pi_1 \iota_1' \colon N_1 \to M_1$.

Exchange step. Consider the maps

$$f = \pi_1' \iota_1 \colon M_1 \to N_1 \qquad g = \pi_1 \iota_1' \colon N_1 \to M_1$$

so $gf = \theta$ is an automorphism of M_1. Then f is a split monomorphism, with left inverse $\theta^{-1} g$, since $(\theta^{-1} g) f = \theta^{-1}(gf) = \mathrm{id}_{M_1}$. The endomorphism $e = f\theta^{-1} g \colon N_1 \to N_1$ is then idempotent:

$$e^2 = f\theta^{-1}(gf)\theta^{-1} g = f\theta^{-1}\theta\theta^{-1} g = f\theta^{-1} g = e$$

and its image is $\mathrm{im}(f)$ (from $ef = f\theta^{-1} gf = f$), so $N_1 = \mathrm{im}(e) \oplus \ker(e) = \mathrm{im}(f) \oplus \ker(e)$ is the splitting associated to the idempotent e. But N_1 is indecomposable and $\mathrm{im}(f) \neq 0$ (since f is injective and $M_1 \neq 0$), which forces $\mathrm{im}(f) = N_1$, making f surjective as well. Hence $f \colon M_1 \to N_1$ is an isomorphism, and in particular

$$M_1 \cong N_1$$

Peeling off the summand. It remains to remove M_1 and N_1 from the two decompositions and match the rest. Set $M' = M_2 \oplus \cdots \oplus M_r$, so $M = M_1 \oplus M'$ and M' is the kernel of the projection $\pi_1 \colon M \to M_1$. The claim is

$$M = N_1 \oplus M'$$

viewing $N_1 = \iota_1'(N_1) \subseteq M$ as the submodule it names in the second decomposition. The key observation is that the restriction of π_1 to N_1 is an isomorphism onto M_1: on N_1 this restriction is $\pi_1 \iota_1' = g$, and $g = \theta f^{-1}$ is a composite of the automorphism θ with the isomorphism f^{-1}, hence itself an isomorphism $N_1 \to M_1$. Granting that $\pi_1|_{N_1} \colon N_1 \to M_1$ is an isomorphism, the claim follows:

- *Trivial intersection.* If $y \in N_1 \cap M'$, then $\pi_1(y) = 0$ because $M' = \ker(\pi_1)$, and $\pi_1|_{N_1}$ is injective, so $y = 0$. Thus $N_1 \cap M' = 0$.
- *Spanning.* Given $z \in M$, set $a = \pi_1(z) \in M_1$. Since $\pi_1|_{N_1}$ is onto M_1, choose $y \in N_1$ with $\pi_1(y) = a$. Then $\pi_1(z - y) = a - a = 0$, so $z - y \in \ker(\pi_1) = M'$, and $z = y + (z - y) \in N_1 + M'$.

Hence $M = N_1 \oplus M'$, establishing the claim.

Induction. Quotienting $M = N_1 \oplus M'$ by the summand N_1 gives $M/N_1 \cong M'$, and quotienting the original $M = N_1 \oplus N'$ by the same submodule N_1 gives $M/N_1 \cong N'$. Therefore

$$M' \cong N'$$

Now M' carries the decomposition $M_2 \oplus \cdots \oplus M_r$ into $r - 1$ indecomposables, and the isomorphism $M' \cong N'$ transports the decomposition $N_2 \oplus \cdots \oplus N_s$ onto M' as a second decomposition into indecomposables. Applying the inductive hypothesis to M', whose first decomposition has $r - 1$ summands, yields $r - 1 = s - 1$, so $r = s$, together with a bijection matching $M_2, \ldots, M_r$ against $N_2, \ldots, N_s$ up to isomorphism. Combined with $M_1 \cong N_1$ from the exchange step, this produces the permutation σ with $M_i \cong N_{\sigma(i)}$ for all i. The base case $r = 1$ has $M = M_1$ indecomposable, forcing $s = 1$ and $N_1 = M$, completing the induction and the proof.

The theorem says that the finite-length representation theory of *any* algebra, semisimple or not, has canonical building blocks: the indecomposable modules. Over a semisimple algebra these are the simple modules and Krull-Schmidt recovers the decomposition of lemma 51.1.7, but the statement here needs no semisimplicity. What it does need is finite length, and the two places that hypothesis enters are worth marking. Finite length gave the Fitting decomposition (via the ascending and descending chain conditions), which produced the local endomorphism rings; and finite length is what let “injective endomorphism” upgrade to “automorphism” at several points. Drop finiteness and uniqueness can fail. A concrete failure: over the ring $R = \mathbb{R}[x, y, z]/(x^2 + y^2 + z^2 - 1)$ of real polynomial functions on the 2-sphere, the module R^3 splits both as $R \oplus P$, where P is the (indecomposable, non-free) module of tangent vector fields, and as $R \oplus R \oplus R$; the two decompositions have non-isomorphic summands, so uniqueness is lost once the summands are no longer of finite length. Krull-Schmidt is thus not a formality but a theorem with content tied to its hypotheses.

The exchange argument also explains *why* the answer is unique, not just *that* it is. The reason each M_i has a unique isomorphism partner is that when the identity of M_1 is written as a sum of composites through the N_j, locality of $\mathrm{End}_A(M_1)$ forbids the sum from being “spread out” among non-units; one composite must already be invertible, and that single composite pins down the partner. Locality is doing the work that a division ring did in the simple case, and it is the exact amount of structure required.

Reading off the multiplicities gives the invariant form of the theorem that is used in practice.

Corollary 52.2.5: Uniqueness of Multiplicities

Let M be a nonzero A-module of finite length. For each isomorphism class of indecomposable module I, the number of summands isomorphic to I appearing in a decomposition of M into indecomposables is independent of the decomposition. That is, writing

$$M \cong I_1^{\oplus m_1} \oplus I_2^{\oplus m_2} \oplus \cdots \oplus I_t^{\oplus m_t}$$

with the I_j pairwise non-isomorphic indecomposables, the classes $I_1, \ldots, I_t$ and the multiplicities $m_1, \ldots, m_t$ are uniquely determined by M.

***Proof*:**
By theorem 52.2.4, any two decompositions of M into indecomposables have the same number of summands and are matched by a permutation σ respecting isomorphism type. Grouping the summands of a decomposition by isomorphism class, the multiplicity of a class I is the number of indices i with $M_i \cong I$. Since σ carries each M_i to an $N_{\sigma(i)} \cong M_i$ and is a bijection, it restricts to a bijection between the summands isomorphic to I in the first decomposition and those isomorphic to I in the second. Hence the two decompositions assign I the same multiplicity, and this holds for every isomorphism class I. The set of classes that occur and their multiplicities are therefore invariants of M, completing the proof.

The multiplicities m_j are the numbers one computes when decomposing a representation, and the corollary is what guarantees the computation has a well-defined answer regardless of the method used to obtain it. In the language of the Grothendieck-style count, M determines a formal $\mathbb{N}$-linear combination $\sum_j m_j[I_j]$ of indecomposable classes, and two modules are isomorphic if and only if these combinations agree. This is the precise sense in which the indecomposables are a basis for the finite-length modules of A.

The full classification is transparent for $A = k[x]/(x^n)$, where the indecomposables can be listed and the uniqueness of multiplicities checked against an explicit computation.

Example 52.2.6: Modules over the Truncated Polynomial Algebra $k[x]/(x^n)$

Fix $n \geq 1$ and let $A = k[x]/(x^n)$. A finite-dimensional A-module is the same datum as a finite-dimensional k-vector space V together with a k-linear operator T, the action of the class of x, satisfying $T^n = 0$, so that T is nilpotent of nilpotency index at most n. Being finite-dimensional over k, every such module has finite length, so Krull-Schmidt applies.

The indecomposables. Since A is a quotient of the principal ideal domain $k[x]$, the structure theorem for finitely generated modules over $k[x]$ describes every finite-length A-module as a direct sum of cyclic modules $k[x]/(x^m)$. Only the exponents $1 \leq m \leq n$ occur, because x^n annihilates the module. Each

$$J_m := k[x]/(x^m) \qquad 1 \leq m \leq n$$

is indecomposable: as in example 52.2.3, its submodules form the single chain $0 \subseteq (x^{m-1}) \subseteq \cdots \subseteq (x) \subseteq J_m$, which admits no splitting into two nonzero summands. So the indecomposable A-modules are exactly

$$J_1, J_2, \ldots, J_n$$

up to isomorphism, with $\dim_k J_m = m$; these are the Jordan blocks for the nilpotent operator, J_m being a single Jordan block of size m with eigenvalue 0. There are precisely n of them.

A decomposition and its uniqueness. Take $n = 3$ and the module $M = A \oplus J_1$, that is, $V = k^4$ with the operator

$$T = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

a single Jordan block of size 3 in the top-left together with a 1×1 zero block. As an A-module,

$$M \cong J_3 \oplus J_1$$

with multiplicities $m_3 = 1$, $m_1 = 1$, and $m_2 = 0$. corollary 52.2.5 asserts these multiplicities are forced by M, and they can be read off invariantly from the ranks of powers of T, which do not depend on any chosen decomposition. The number of Jordan blocks of size at least j equals $\operatorname{rank}(T^{j-1}) - \operatorname{rank}(T^j)$, so the multiplicity of J_m is

$$m_m = \operatorname{rank}(T^{m-1}) - 2\operatorname{rank}(T^m) + \operatorname{rank}(T^{m+1})$$

Here $\operatorname{rank}(T^0) = \operatorname{rank}(\mathrm{id}) = 4$, $\operatorname{rank}(T) = 2$, $\operatorname{rank}(T^2) = 1$, and $\operatorname{rank}(T^3) = 0$. Substituting,

$$m_1 = 4 - 2 \cdot 2 + 1 = 1, \qquad m_2 = 2 - 2 \cdot 1 + 0 = 0, \qquad m_3 = 1 - 2 \cdot 0 + 0 = 1$$

recovering $M \cong J_3 \oplus J_1$. Since the ranks $\operatorname{rank}(T^j)$ are intrinsic to the operator T (hence to the module M), the multiplicities are intrinsic too, exactly as Krull-Schmidt predicts. Any presentation of M as a direct sum of J_m's, arrived at by any change of basis, must yield one copy of J_3, one copy of J_1, and no copy of J_2.

52.3 Idempotents, Projective Covers, and the Regular Representation

The Artin–Wedderburn theorem told us how to read off the simple modules of a semisimple algebra: they are exactly the summands of the regular module A, because a semisimple A splits as a direct sum of minimal left ideals and each minimal left ideal is simple. Once A is not semisimple this picture breaks. The regular module A still decomposes into indecomposable summands (the algebra is finite-dimensional, so a dimension count forces any module to be a finite direct sum of indecomposables), but those summands are no longer simple. They are the *indecomposable projective modules*, and the simple modules sit one level down, as their tops. This section builds the dictionary that replaces the semisimple one: the summands of A are cut out by a decomposition $1 = e_1 + \cdots + e_n$ of the identity into primitive orthogonal idempotents, each summand Ae_i is an indecomposable projective covering a single simple module, and the whole configuration is governed, through the quotient $A/\mathrm{Jac}(A)$, by the semisimple theory of chapter 51.

Throughout this section A is a finite-dimensional algebra over a field k (so in particular A is left Artinian and $\mathrm{Jac}(A)$ is nilpotent). Modules are left modules. The tool that transports information from the semisimple quotient $A/\mathrm{Jac}(A)$ back up to A is the lifting of idempotents, so that is where we begin.

The projection $\pi\colon A \to A/\mathrm{Jac}(A)$ collapses the radical. A decomposition of $A/\mathrm{Jac}(A)$ into a sum of simple summands is a statement about idempotents in $A/\mathrm{Jac}(A)$, and to pull such a decomposition back to A we need to produce idempotents in A that reduce to the given ones. The obstruction is that a preimage of an idempotent need not be idempotent. The nilpotence of $\mathrm{Jac}(A)$ removes the obstruction: a Newton-style correction converts any element that is idempotent modulo $\mathrm{Jac}(A)$ into a genuine idempotent lying over it.

Theorem 52.3.1: Lifting Idempotents Modulo the Radical

Let A be a finite-dimensional k-algebra and write $J = \mathrm{Jac}(A)$. Let $\pi\colon A \to A/J$ be the quotient map.

1. If $\bar{e} \in A/J$ satisfies $\bar{e}^2 = \bar{e}$, then there exists an idempotent $e \in A$ with $\pi(e) = \bar{e}$.
2. If $\bar{e}_1, \ldots, \bar{e}_m \in A/J$ are pairwise orthogonal idempotents with $\bar{e}_1 + \cdots + \bar{e}_m = \bar{1}$, then there exist pairwise orthogonal idempotents $e_1, \ldots, e_m \in A$ with $\pi(e_i) = \bar{e}_i$ and $e_1 + \cdots + e_m = 1$.

***Proof*:**
Since A is left Artinian, $J = \mathrm{Jac}(A)$ is nilpotent by theorem 52.1.8; fix N with $J^N = 0$.

Step 1: Lifting a single idempotent. Choose any $a \in A$ with $\pi(a) = \bar{e}$. Then $a^2 - a \in J$, since $\pi(a^2 - a) = \bar{e}^2 - \bar{e} = 0$. The idea is to correct a inside the coset $a + J$ until the error $a^2 - a$ is pushed into higher and higher powers of J, where it eventually vanishes. Set

$$e = 3a^2 - 2a^3$$

which lies in $a + J$, since $e - a = (3a^2 - 2a^3) - a = -(2a - 1)(a^2 - a) \in J$, so $\pi(e) = \bar{e}$. A direct computation gives

$$e^2 - e = (3a^2 - 2a^3)^2 - (3a^2 - 2a^3) = (a^2 - a)^2\,(4a^2 - 4a - 3)$$

Writing $u = a^2 - a \in J$, this says $e^2 - e \in (u^2) \subseteq J^2$. Thus the operation $a \mapsto 3a^2 - 2a^3$ sends an element whose defect $a^2 - a$ lies in J^r to an element whose defect lies in J^{2r}, while staying in the same coset modulo J. Starting from $a_0 = a$ with defect in J^1 and iterating,

$$a_{t+1} = 3a_t^2 - 2a_t^3$$

produces $a_t \in a + J$ whose defect $a_t^2 - a_t$ lies in J^{2^t}. Once $2^t \geq N$ we have $a_t^2 - a_t \in J^N = 0$, so $e := a_t$ is a genuine idempotent with $\pi(e) = \bar{e}$. This proves (1).

Step 2: Lifting an orthogonal family. We argue by induction on m. For $m = 1$ the statement is $e_1 = 1$, which is immediate. Suppose the result holds for families of size $m-1$, and let $\bar{e}_1, \ldots, \bar{e}_m$ be pairwise orthogonal idempotents summing to $\bar{1}$. Apply the inductive hypothesis to the shorter orthogonal family $\bar{e}_1, \ldots, \bar{e}_{m-2}, \bar{e}_{m-1} + \bar{e}_m$ (its members are pairwise orthogonal idempotents summing to $\bar{1}$, since $\bar{e}_{m-1}$ and $\bar{e}_m$ are orthogonal). This yields pairwise orthogonal idempotents $e_1, \ldots, e_{m-2}, f \in A$ lifting them, with $e_1 + \cdots + e_{m-2} + f = 1$ and $\pi(f) = \bar{e}_{m-1} + \bar{e}_m$.

It remains to split f. Consider the algebra fAf, which has identity element f. Its radical is $\mathrm{Jac}(fAf) = fJf$, and the reduction $fAf \to fAf/fJf$ identifies with the corner $\bar{f}(A/J)\bar{f}$ of the semisimple algebra A/J, where $\bar{f} = \bar{e}_{m-1} + \bar{e}_m$. In that corner, $\bar{e}_{m-1}$ and $\bar{e}_m$ are orthogonal idempotents summing to the identity $\bar{f}$. Applying part (1) inside the finite-dimensional algebra fAf to the idempotent $\bar{e}_{m-1} \in fAf/fJf$ produces an idempotent $e_{m-1} \in fAf$ with $\pi(e_{m-1}) = \bar{e}_{m-1}$. Set $e_m = f - e_{m-1}$. Then e_m is idempotent, since

$$e_m^2 = (f - e_{m-1})^2 = f - 2e_{m-1} + e_{m-1} = f - e_{m-1} = e_m$$

using $fe_{m-1} = e_{m-1}f = e_{m-1}$ (because $e_{m-1} \in fAf$) and $e_{m-1}^2 = e_{m-1}$; moreover $\pi(e_m) = \bar{f} - \bar{e}_{m-1} = \bar{e}_m$, and $e_{m-1}e_m = e_{m-1}f - e_{m-1}^2 = e_{m-1} - e_{m-1} = 0$, with $e_m e_{m-1} = 0$ symmetrically. Finally $e_{m-1}, e_m \in fAf$ are orthogonal to each of $e_1, \ldots, e_{m-2}$, since f is, and $e_1 + \cdots + e_{m-2} + e_{m-1} + e_m = e_1 + \cdots + e_{m-2} + f = 1$. This completes the induction and the proof.

The polynomial $3a^2 - 2a^3$ is the second Newton iterate for the equation $x^2 - x = 0$; the quadratic doubling of the exponent is exactly Newton's quadratic convergence, made to terminate by nilpotence rather than to converge by a metric. The content of the theorem is that the arithmetic of idempotents in A is completely controlled by the arithmetic of idempotents in the semisimple quotient $A/\mathrm{Jac}(A)$: any way of splitting the identity in $A/\mathrm{Jac}(A)$ lifts to a way of splitting it in A, so the summand structure of the regular module is governed from below by Artin–Wedderburn. The next result turns this into a decomposition of A itself.

Before stating it, recall the mechanism from example 51.2.10: an idempotent $e \in A$ produces a direct sum decomposition $A = Ae \oplus A(1-e)$ of the regular module, because every $a \in A$ writes uniquely as $a = ae + a(1-e)$ with $ae \in Ae$ and $a(1-e) \in A(1-e)$. More generally an orthogonal decomposition $1 = e_1 + \cdots + e_n$ gives $A = Ae_1 \oplus \cdots \oplus Ae_n$. The summand Ae_i is indecomposable precisely when e_i cannot be split further, which is the meaning of *primitive*. Pushing the splitting as far as it will go decomposes the regular module into indecomposables.

Theorem 52.3.2: Primitive Idempotent Decomposition of the Regular Module

Let A be a finite-dimensional k-algebra. Then the identity admits a decomposition

$$1 = e_1 + e_2 + \cdots + e_n$$

into pairwise orthogonal primitive idempotents, and correspondingly the regular module decomposes as

$$A = Ae_1 \oplus Ae_2 \oplus \cdots \oplus Ae_n$$

where each Ae_i is an indecomposable projective left A-module. For an idempotent $e \in A$, the summand Ae is indecomposable if and only if e is primitive, if and only if the corner algebra eAe has no idempotents other than 0 and e.

***Proof*:**
Step 1: Idempotent decompositions correspond to direct-sum decompositions. Let $e \in A$ be an idempotent. Direct summands of the module Ae correspond to idempotents of its endomorphism ring: if $Ae = P \oplus Q$, the projection onto P along Q is an idempotent $\varepsilon \in \mathrm{End}_A(Ae)$, and conversely an idempotent $\varepsilon \in \mathrm{End}_A(Ae)$ splits $Ae = \varepsilon(Ae) \oplus (1-\varepsilon)(Ae)$. By the same computation as in lemma 51.2.3, the map $eAe \to \mathrm{End}_A(Ae)$ sending eae to right multiplication $x \mapsto x(eae)$ is a ring isomorphism

$$\mathrm{End}_A(Ae) \cong (eAe)^{\mathrm{op}}$$

The idempotents of $(eAe)^{\mathrm{op}}$ are the idempotents of eAe. So Ae decomposes nontrivially if and only if eAe has an idempotent other than 0 and $e = 1_{eAe}$. Writing such an idempotent as g and its complement $e - g$ (which is idempotent and orthogonal to g, by the computation in Step 2 of theorem 52.3.1), the decomposition $Ae = Ag \oplus A(e-g)$ corresponds to the refinement $e = g + (e-g)$ of e into orthogonal idempotents. Thus e is primitive (cannot be written as a sum of two nonzero orthogonal idempotents) if and only if eAe has no idempotent besides $0, e$, if and only if Ae is indecomposable. This proves the final three-way equivalence.

Step 2: The decomposition terminates. Start from 1. If 1 is primitive, take $n = 1$. Otherwise $1 = f + f'$ with f, f' nonzero orthogonal idempotents, giving $A = Af \oplus Af'$ with both summands nonzero. Since A is finite-dimensional and the summands Af, Af' are proper (each has strictly smaller k-dimension than A, as the other is nonzero), repeating the splitting on any summand that is still decomposable strictly decreases dimension at each step and so must stop. When it stops, every summand Ae_i is indecomposable, so by Step 1 each e_i is primitive. The resulting $e_1, \ldots, e_n$ are pairwise orthogonal (an idempotent split off from a corner Ae is orthogonal to every idempotent orthogonal to e) and sum to 1.

Step 3: Projectivity. Each Ae_i is a direct summand of the free module A, hence projective. A direct summand of a free module is projective because the splitting $A = Ae_i \oplus A(1-e_i)$ exhibits Ae_i as a retract of A, and retracts of free modules satisfy the lifting property defining projectivity; the general statement is proved in the companion volume `NateCoreAlgebra` [25] on projective modules. This gives the decomposition of A into indecomposable projectives, completing the proof.

The decomposition $A = \bigoplus_i Ae_i$ is the non-semisimple replacement for the Wedderburn splitting of a semisimple algebra into minimal left ideals. In the semisimple case each Ae_i was already simple, and the e_i were the matrix units picking out columns of the matrix blocks (proposition 51.2.5). In general each Ae_i is only indecomposable, and it will turn out to have a whole composition series rather than length one. The indecomposable summands that appear are the objects the rest of the section studies, so they deserve a name.

Definition 52.3.3: Indecomposable Projective Module

Let A be a finite-dimensional k-algebra and $1 = e_1 + \cdots + e_n$ a decomposition of the identity into primitive orthogonal idempotents. The indecomposable projective left A-modules are the summands

$$P_i = Ae_i$$

Its *radical* is $\mathrm{rad}(P_i) = \mathrm{Jac}(A)\, P_i$, and its *top* (or *head*) is the quotient

$$\mathrm{top}(P_i) = P_i/\mathrm{rad}(P_i) = Ae_i/\mathrm{Jac}(A)Ae_i$$

The module P_i is called the *projective cover* of its top; the top is a simple module.

The claim that the top is simple is the hinge of the whole correspondence, so we verify it at once. Reducing modulo $\mathrm{Jac}(A)$ turns the primitive idempotent e_i into a primitive idempotent $\bar{e}_i \in A/\mathrm{Jac}(A)$, and over the semisimple algebra $A/\mathrm{Jac}(A)$ a primitive idempotent cuts out a simple module.

Example 52.3.4: The Top of Ae_i

Let $A = k[x]/(x^3)$, a local algebra with $\mathrm{Jac}(A) = (x)/(x^3)$. Here 1 is the only nonzero idempotent (a commutative local ring has no idempotents besides 0 and 1), so the identity decomposition is trivial, $n = 1$ and $e_1 = 1$, giving a single indecomposable projective $P_1 = A$. Its radical is $\mathrm{rad}(P_1) = \mathrm{Jac}(A)\, A = (x)/(x^3)$, and its top is

$$P_1/\mathrm{rad}(P_1) = \big(k[x]/(x^3)\big)\big/\big((x)/(x^3)\big) \cong k[x]/(x) = k$$

a one-dimensional, hence simple, module. So the single projective $P_1 = A$ (of dimension 3) covers the single simple module k (of dimension 1); the two extra dimensions live in the radical $\mathrm{rad}(P_1)$, whose composition factors are again copies of k. This is the smallest example in which a projective indecomposable is strictly larger than the simple it covers.

The passage $P_i \mapsto \mathrm{top}(P_i)$ from indecomposable projectives to simple modules, and its reverse, is the organizing principle of non-semisimple representation theory. Simple modules are visible in the semisimple quotient $A/\mathrm{Jac}(A)$, where Artin–Wedderburn counts them; primitive idempotents in A are the summands of the regular module; and lifting idempotents connects the two. The following theorem assembles these into a single correspondence.

Theorem 52.3.5: Simples, Indecomposable Projectives, and Primitive Idempotents

Let A be a finite-dimensional k-algebra, and let $1 = e_1 + \cdots + e_n$ be a decomposition of the identity into primitive orthogonal idempotents. There are mutually inverse bijections among the following three finite sets:

1. isomorphism classes of simple left A-modules;
2. isomorphism classes of indecomposable projective left A-modules;
3. conjugacy classes of primitive idempotents of A, where e and e' are conjugate if $e' = ueu^{-1}$ for a unit $u \in A^\times$.

The bijection from (2) to (1) sends $P_i \mapsto S_i := P_i/\mathrm{rad}(P_i)$; the bijection from (3) to (2) sends the class of e_i to $P_i = Ae_i$. If A is split (for instance $k = \bar{k}$), the number of classes equals the number of blocks in the Artin–Wedderburn decomposition of $A/\mathrm{Jac}(A)$, and

$$A/\mathrm{Jac}(A) \cong M_{d_1}(k) \times \cdots \times M_{d_r}(k), \qquad d_i = \dim_k S_i$$

where $S_1, \ldots, S_r$ are the simple modules and P_i appears $d_i = \dim_k S_i$ times in $A = \bigoplus_i P_i^{\oplus m_i}$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$ and $\bar{A} = A/J$, which is semisimple by theorem 52.1.9.

Step 1: Simple modules are the same for A and $\bar{A}$. A simple A-module S is annihilated by J: the submodule $JS \subseteq S$ is either 0 or S, and $JS = S$ is impossible by Nakayama's lemma (lemma 52.1.7, applied to the cyclic module S: $JS = S$ would force $S = 0$). Hence $JS = 0$ and S is an $\bar{A}$-module; conversely every $\bar{A}$-module is an A-module through $\pi\colon A \to \bar{A}$. Since a submodule for A is the same as a submodule for $\bar{A}$ on a module killed by J, simplicity is preserved in both directions. Thus the simple A-modules are exactly the simple $\bar{A}$-modules, and by corollary 51.1.12 there are finitely many, one for each Wedderburn block of $\bar{A}$.

Step 2: $\mathrm{top}(P_i)$ is simple, and $P_i \mapsto \mathrm{top}(P_i)$ lands in (1). Reducing the decomposition $1 = e_1 + \cdots + e_n$ modulo J gives $\bar{1} = \bar{e}_1 + \cdots + \bar{e}_n$, a decomposition into orthogonal idempotents of $\bar{A}$. Applying the right-exact functor $\bar{A} \otimes_A -$ (equivalently reducing mod J) to $P_i = Ae_i$ gives

$$P_i/JP_i = Ae_i/JAe_i \cong \bar{A}\bar{e}_i$$

as $\bar{A}$-modules. Now $\bar{e}_i$ is primitive in $\bar{A}$: an orthogonal splitting $\bar{e}_i = \bar{g} + \bar{h}$ in $\bar{A}$ would lift, by theorem 52.3.1 applied inside the corner e_iAe_i, to an orthogonal splitting of e_i in A, contradicting primitivity of e_i. Over the semisimple algebra $\bar{A}$ a primitive idempotent generates a simple module, since $\bar{A}\bar{e}_i$ is an indecomposable summand of the semisimple module $\bar{A}$ and indecomposable semisimple means simple. Hence $\mathrm{top}(P_i) = P_i/\mathrm{rad}(P_i) = \bar{A}\bar{e}_i =: S_i$ is simple.

Step 3: The map (2) $\to$ (1) is a bijection. Distinct indecomposable projectives have distinct tops: if $Ae_i \cong Ae_j$ as A-modules then reducing mod J gives $\bar{A}\bar{e}_i \cong \bar{A}\bar{e}_j$, so $S_i \cong S_j$; conversely if $S_i \cong S_j$ then the two primitive idempotents $\bar{e}_i, \bar{e}_j$ generate isomorphic simple summands of $\bar{A}$, hence are conjugate in $\bar{A}$ (two primitive idempotents of a semisimple algebra generating isomorphic simples lie in the same Wedderburn block and differ by an inner automorphism), and a conjugating unit lifts to a unit of A because $\pi\colon A^\times \to \bar{A}^\times$ is surjective (an element of A mapping to a unit of $\bar{A}$ is itself a unit, since J is nilpotent: if $\bar{a}$ is invertible then a has a left and right inverse modulo the nilpotent ideal J, and $1+J \subseteq A^\times$). Conjugate idempotents give isomorphic projectives $Ae_i \cong Ae_j$ via right multiplication by the conjugating unit. So $P_i \cong P_j$ if and only if $S_i \cong S_j$, giving a bijection between (2) and (1). Every simple module arises as some S_i: a simple $\bar{A}$-module is a summand of $\bar{A} = \bigoplus_i \bar{A}\bar{e}_i$, hence isomorphic to some $\bar{A}\bar{e}_i = S_i$.

Step 4: Conjugacy classes of primitive idempotents. By the last paragraph, $Ae_i \cong Ae_j$ as modules if and only if e_i and e_j are conjugate in A: one direction lifts a conjugation, the other reduces an isomorphism to a conjugation via $\mathrm{End}_A(A) \cong A^{\mathrm{op}}$ (lemma 51.2.3), under which a module isomorphism $Ae_i \to Ae_j$ is right multiplication by an element u with $ue_iu^{-1} = e_j$. Thus the class of e_i under conjugacy corresponds to the isomorphism class of P_i, giving the bijection between (3) and (2).

Step 5: The split case. If A is split, Artin–Wedderburn over the semisimple $\bar{A}$ (corollary 51.2.20) gives $\bar{A} \cong \prod_{i=1}^r M_{d_i}(k)$ with r the number of simple modules and $d_i = \dim_k S_i$, since the simple module of the block $M_{d_i}(k)$ is k^{d_i}. The multiplicity of P_i in $A = \bigoplus_j Ae_j$ equals the number of j with e_j conjugate to e_i, which reducing mod J equals the multiplicity of the column module k^{d_i} inside the block $M_{d_i}(k)$, namely d_i; so $m_i = d_i$. This gives the stated dimension bookkeeping, as we sought to show.

The correspondence is the reason the count of simple modules is finite and computable: it equals the number of Wedderburn blocks of $A/\mathrm{Jac}(A)$, which Artin–Wedderburn hands us. In the semisimple case the three sets coincide with the columns of the matrix blocks and the map $P_i \mapsto S_i$ is the identity; the passage to a general finite-dimensional algebra keeps the same indexing set but separates the projective P_i from the simple S_i it covers. The word "cover" is precise, and the next definition makes it so. A cover should be the most economical projective surjecting onto a module, with no wasted projective sitting over the radical.

Definition 52.3.6: Superfluous Submodule and Projective Cover

Let A be a ring and M an A-module. A submodule $L \subseteq M$ is *superfluous* (or *small*) if for every submodule $N \subseteq M$ the equality $L + N = M$ forces $N = M$. A surjection $f\colon P \to M$ is *essential* if $\ker f$ is superfluous in P.
A *projective cover* of M is a projective module P together with an essential surjection $f\colon P \to M$; that is, f is surjective, P is projective, and $\ker f$ is superfluous in P.

The condition that $\ker f$ be superfluous is what pins the cover down. Any module has a surjection from a projective (a free module surjects onto it), but without the superfluous condition one could pad the source with a free summand mapping to zero and never have a canonical choice. Superfluousness forbids exactly this padding: no proper submodule of P maps onto M, so P is as small a projective as can surject onto M. Over a finite-dimensional algebra the radical supplies a ready source of superfluous submodules, and this makes covers exist and be unique.

Theorem 52.3.7: Existence of Projective Covers

Let A be a finite-dimensional k-algebra and M a finitely generated (equivalently, finite-length) left A-module. Then M has a projective cover $f\colon P \to M$, unique up to isomorphism over M. For a simple module $S = S_i$, the projective cover is the indecomposable projective $P_i = Ae_i$ with its quotient map $P_i \twoheadrightarrow P_i/\mathrm{rad}(P_i) = S_i$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

Step 1: JP is superfluous in a finitely generated P. Let P be finitely generated and suppose $JP + N = P$ for a submodule $N \subseteq P$. Then $J \cdot (P/N) = (JP + N)/N = P/N$, so the finitely generated module P/N satisfies $J \cdot (P/N) = P/N$. Nakayama's lemma (the module form, lemma 52.1.7; concretely, using the nilpotence of J: if $J^N = 0$ and $JQ = Q$ then $Q = JQ = J^2Q = \cdots = J^N Q = 0$) forces $P/N = 0$, i.e. $N = P$. Hence JP is superfluous in P.

Step 2: Construction of the cover. The top $\bar{M} = M/JM$ is a module over the semisimple algebra $\bar{A} = A/J$, hence semisimple: $\bar{M} \cong \bigoplus_i S_i^{\oplus c_i}$ for multiplicities $c_i \geq 0$. Set

$$P = \bigoplus_i P_i^{\oplus c_i}$$

with each $P_i = Ae_i$ the indecomposable projective covering S_i. Then $P/JP = \bigoplus_i (P_i/JP_i)^{\oplus c_i} = \bigoplus_i S_i^{\oplus c_i} = \bar{M}$, so the projection $P \to P/JP = \bar{M}$ agrees with $M \to \bar{M}$ on tops. Because P is projective, the surjection $M \twoheadrightarrow \bar{M}$ lifts through $P \to \bar{M}$ to a homomorphism $f\colon P \to M$ with $M \to \bar{M}$ equal to $P \xrightarrow{f} M \to \bar{M}$. The image $f(P)$ satisfies $f(P) + JM = M$ (their images in $\bar{M}$ agree and equal all of $\bar{M}$), and JM is superfluous in M by Step 1 applied to M; hence $f(P) = M$ and f is surjective.

Step 3: f is essential. Let $K = \ker f$. Suppose $K + N = P$ for a submodule N. Then $f(N) = f(P) = M$, so $N + JP \supseteq N + \ker(P \to \bar{M})$ surjects onto $\bar{M} = P/JP$, giving $N + JP = P$; since JP is superfluous (Step 1), $N = P$. Thus K is superfluous and $f\colon P \to M$ is a projective cover.

Step 4: Uniqueness. Let $f\colon P \to M$ and $f'\colon P' \to M$ be two projective covers. Projectivity of P' lifts f' through f to $g\colon P' \to P$ with $fg = f'$. Then $f(g(P')) = f'(P') = M$, so $g(P') + \ker f = P$; since $\ker f$ is superfluous, $g(P') = P$ and g is surjective. As P' is projective, the surjection g splits, $P' = \ker g \oplus P''$ with $P'' \cong P$; but $\ker g \subseteq \ker f' = \ker(fg)$ is superfluous in P' and a superfluous direct summand is zero (a summand L with complement C satisfies $L + C = P'$, forcing $C = P'$ hence $L = 0$). So g is an isomorphism over M.

Step 5: The simple case. For $M = S_i$ the top $\bar{M} = S_i$ has $c_i = 1$ and all other multiplicities 0, so the construction returns $P = P_i$ with $f\colon P_i \twoheadrightarrow P_i/\mathrm{rad}(P_i) = S_i$, the stated cover, completing the proof.

The theorem certifies the terminology in definition 52.3.3: $P_i \to S_i$ really is *the* projective cover, and every finite-length module is covered by an explicit direct sum of the P_i read off from its top. Uniqueness makes the assignment $M \mapsto P(M)$ well defined and turns the correspondence of theorem 52.3.5 into a computational tool: to find the projective cover of any module, compute its top $M/\mathrm{Jac}(A)M$, decompose that semisimple module into simples, and sum the corresponding P_i. What the projective P_i contributes beyond the simple top S_i is recorded in its composition series, and tabulating those multiplicities across all i produces the central numerical invariant of the algebra.

Definition 52.3.8: Cartan Matrix of an Algebra

Let A be a finite-dimensional k-algebra with simple modules $S_1, \ldots, S_r$ and indecomposable projectives $P_1, \ldots, P_r$, indexed so that $P_i/\mathrm{rad}(P_i) = S_i$. The *Cartan matrix* of A is the $r \times r$ matrix $C = (C_{ij})$ of nonnegative integers

$$C_{ij} = [P_i : S_j]$$

the multiplicity of the simple module S_j among the composition factors of a composition series of P_i.

The multiplicities $[P_i : S_j]$ are well defined by the Jordan–Hölder theorem, which guarantees the composition factors of a finite-length module are independent of the chosen composition series. The Cartan matrix measures how far A is from semisimple in a single array: when A is semisimple every $P_i = S_i$ has length one, so $C_{ij} = \delta_{ij}$ is the identity matrix, and any off-diagonal or large diagonal entry records simples fused together by the radical. The diagonal entry $C_{ii} = [P_i : S_i]$ is at least 1 (the top contributes one copy of S_i), and $C_{ii} > 1$ signals a self-extension living in the radical. The next example computes the whole apparatus of this section for the smallest non-semisimple algebra with two non-isomorphic simple modules, so that the Cartan matrix is not diagonal.

Before the example, one further point for completeness: the entire theory has a dual half. Everything above was built from the regular module A as a source of projectives; dualizing over k turns projectives into injectives and covers into envelopes.

52.3.9 Remark: The Dual Theory of Injective Envelopes Dual to a projective cover is an *injective envelope*: an injective module E with an essential injection $M \hookrightarrow E$, meaning every nonzero submodule of E meets the image of M nontrivially. Over a finite-dimensional algebra A these exist and are unique, and the duality $D = \mathrm{Hom}_k(-, k)$ carries left A-modules to right A-modules (equivalently left A^{op}-modules), exchanging projective covers of A-modules with injective envelopes of A^{op}-modules. The indecomposable injective A-modules are thus $D(e_i A)$, and each has a simple *socle* (its largest semisimple submodule) rather than a simple top; the socle plays for injectives the role the top plays for projectives. The general theory of injective and projective modules over a ring, including existence of injective envelopes via injective hulls, is developed in the companion volume `NateCoreAlgebra` [25]; the present section uses only the projective side.

Example 52.3.10: Projective Covers over the Upper-Triangular Algebra $T_2(k)$

Let

$$A = T_2(k) = \left\{ \begin{pmatrix} a & b \\ 0 & c \end{pmatrix} : a, b, c \in k \right\}$$

the algebra of 2×2 upper-triangular matrices over a field k, a three-dimensional k-algebra. We work out its idempotents, indecomposable projectives, simple modules, projective covers, and Cartan matrix.

Idempotents. The matrix units

$$e_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad e_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$$

are orthogonal idempotents with $e_1+e_2=1$. Each is primitive: the corner algebra $e_1Ae_1 = k\,e_1 \cong k$ has no idempotents but $0, e_1$, and likewise $e_2Ae_2 \cong k$, so by theorem 52.3.2 both Ae_1 and Ae_2 are indecomposable. Thus $1 = e_1 + e_2$ is a primitive orthogonal decomposition and there are two indecomposable projectives.

The radical. The Jacobson radical is the strictly upper-triangular part,

$$\mathrm{Jac}(A) = \begin{pmatrix} 0 & k \\ 0 & 0 \end{pmatrix}$$

a one-dimensional nilpotent ideal with $\mathrm{Jac}(A)^2 = 0$, and the quotient is

$$A/\mathrm{Jac}(A) \cong \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \cong k \times k$$

a product of two copies of k, confirming via theorem 52.3.5 that there are exactly two simple modules, both one-dimensional.

The indecomposable projectives. Left multiplication by A on e_i gives, with $E_{12} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$,

$$P_1 = Ae_1 = \begin{pmatrix} k & 0 \\ 0 & 0 \end{pmatrix}, \qquad P_2 = Ae_2 = \begin{pmatrix} 0 & k \\ 0 & k \end{pmatrix}$$

so $\dim_k P_1 = 1$ and $\dim_k P_2 = 2$, and indeed $\dim_k A = 1 + 2 = 3 = \dim_k P_1 + \dim_k P_2$, consistent with $A = P_1 \oplus P_2$.

The simple modules and covers. The tops are

$$S_1 = P_1/\mathrm{rad}(P_1) = P_1/\mathrm{Jac}(A)P_1 = P_1 \cong k, \qquad S_2 = P_2/\mathrm{rad}(P_2) = P_2/\mathrm{Jac}(A)P_2 \cong k$$

Here $\mathrm{Jac}(A)P_1 = 0$, so $P_1 = S_1$ is already simple and is its own projective cover, an essential surjection $P_1 \xrightarrow{\cong} S_1$. For P_2, the radical $\mathrm{Jac}(A)P_2 = \left(\begin{smallmatrix} 0 & k \\ 0 & 0 \end{smallmatrix}\right)$ is one-dimensional, and

$$\mathrm{rad}(P_2) = \begin{pmatrix} 0 & k \\ 0 & 0 \end{pmatrix} \cong S_1, \qquad P_2/\mathrm{rad}(P_2) \cong S_2$$

So P_2 is a length-two module with a nonsplit exact sequence

$$0 \to S_1 \to P_2 \to S_2 \to 0$$

and the quotient map $P_2 \twoheadrightarrow S_2$ is the projective cover of S_2, with kernel $\mathrm{rad}(P_2) = S_1$ superfluous in P_2 (it lies inside $\mathrm{Jac}(A)P_2$). The two simple modules S_1 and S_2 are not isomorphic, since e_1 and e_2 act as 1 on one and 0 on the other; the algebra is not semisimple, as $\mathrm{Jac}(A) \neq 0$.

The Cartan matrix. Reading off composition factors: P_1 has the single factor S_1, while P_2 has factors S_2 (its top) and S_1 (its radical). Hence

$$[P_1 : S_1] = 1, \quad [P_1 : S_2] = 0, \quad [P_2 : S_1] = 1, \quad [P_2 : S_2] = 1$$

and the Cartan matrix is the upper-triangular integer matrix

$$C = \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

Its determinant is 1 and its off-diagonal entry $C_{21} = 1$ records the single copy of S_1 that the radical of P_2 contributes: the exact numerical trace of the failure of $T_2(k)$ to be semisimple, where the Cartan matrix would have been the identity.

53

Representation of Finite Groups

All modules will be left R-modules for a not necessarily commutative ring R. Furthermore, all actions will be non-trivial actions unless specified otherwise.

53.1 Representations of Finite Groups

Similarly to how we studied groups and by how they acted on themselves through group-actions (ex. how a group acted on itself by conjugation gave us Sylow's Theorem), we will now try to study groups using *linear algebra*. Many really difficult results in classical group theory will become much easier when studied through this new "representation" of groups (and hence why it's called *represenation theory*). Furthermore, vector-spaces afford many more structures than a module structures (ex. a complex vector-space is the starting point for the Nullstellensatz, Complex Geometry, Analysis, and much more!) Hence, one large advantage of Representation theory will be the intersection of many mathematical diciplines which contribute towards our study (an they all feedback on each other)

In this part of the group, G will always be a finite group[1], k will always be a field (usually $\mathbb{C}$, but can be any field of any character), $\mathrm{Aut}_{k\text{-}\mathbf{Vect}}(V) = \mathrm{GL}(V)$ represents all automorphisms from the k-vector space V to itself, which when $\dim(V) < \infty$ is equivalent to the group of all nonsingular linear transformations from V to itself $\mathrm{GL}_n(k)$ where $n = \dim(V)$.

Definition 53.1.1: Representation

Let G be a finite group and V a vector space over k. Then a *linear representation* is any homomorphism $\varphi : G \to \mathrm{GL}(V)$. The *degree* of the representation is the dimension of V. A *matrix representation* of G is any homomorphism $\varphi : G \to \mathrm{GL}_n(k)$

[1] Not sure about where to address infinite groups

Usually, when we say representation we will mean *linear representation.* If a vector-space V has a representation of G, we will often call it a G-representation. To be as rigorous as possible we would say we have a representation of G on V over k, if the context requires it. Furthermore, most of the time we will have map from G to $\mathrm{GL}(V)$ to be *injective*; non-injective representations will be more common when representing infinite groups that are "trivial" on some subgroup (see [20]). Just like for group actions, A representation is *faithful* if it is injective.

As usual, we can curry or uncurry an action[2]: we can take $\varphi : G \to \mathrm{GL}(V)$ and make it $G \times V \to V$ where $g : V \to V$ with $v \mapsto g \cdot v$ is linear over k for all g. It is left for the curious to see that this is indeed the proper uncurrying of this action.

Using the definition of $\varphi : G \to \mathrm{GL}(V)$, it is easy to define a representation homomorphism mirroring the definition of group-actions and modules (which are ring actions on abelian groups):

Definition 53.1.2: Representation Homomorphism

Let V, W be two vectors spaces over k with a linear representation by G. Then $\varphi : V \to W$ a *representation homomorphism* if φ k-linear and for any $g \in G$:

$$\varphi(g \cdot v) = g \cdot \varphi(v)$$

such a homomorphism will be called G-linear.

From this perspective, it might be hard to see how our previous discussion on semi-simple rings might give us any insight. We thus introduce a perspective better suited to the results of chapter 51: every representation of G on V over k is in bijective correspondence with all $k[G]$-modules over V, where $k[G]$ represents the *group ring* as seen in section 9.2. This second perspective will also make it easier to define a couple of examples, and so we will delay giving examples till the correspondence has been established. As a reminder, a group ring $k[G]$ over a ring k (which in our case will always be a field) is the set of all formal sums:

$$\sum_{g_i \in G} a_i g_i$$

where addition and multiplication are defined in the natural way[3]:

$$\sum_{i}^{n} a_i g_i + \sum b_i g_i = \sum_{i} (a_i + b_i) g_i$$

$$\left(\sum_{i}^{n} a_i g_i \right) \left(\sum b_i g_i \right) = \sum_{k}^{n} \left(\sum_{\substack{i,j \\ g_i g_j = g_k}} a_i b_j \right) g_k$$

Another common notation for groups rings is kG, where the brackets are dropped. A couple of important acts about group rings should be recalled (or the excises ref:HERE can be completed)

1. The group G naturally injects into $k[G]$ by identifying g_i with $1 g_i$ which is the formal sum $\sum_j \delta_{ij} g_i$ (where δ_{ij} is the Kronecker delta).

[2] See remark 4.1.3

[3] A word on this really being a natural way?

2. The field k naturally injects in $k[G]$ by corresponding an element $a \in k$ with $ag_1 = ae$ where $g_1 = e$ is the identity. If it is clear from context, we will sometimes simply write $a \in k[G]$ if it is understood $a = ae = ag_1$.

3. There is a natural k action on $k[G]$ defined by

$$b \cdot \left(\sum_i a_i g_i \right) = \sum_i (ba_i) g_i$$

due to this, $k[G]$ is a vector space over k with the elements of G as a basis, and hence is finite dimensional if $|G| < \infty$.

4. By definition, The elements of k identified as kg_1 commute with all the elements of $k[G]$, hence it is in the center of $k[G]$: $k \subseteq Z(k[G])$. Thus, $k[G]$ is in fact a k-algebra.

5. A group ring the adjoint given by the forgetful functor from **Ring** to **Grp**, hence is free with respect to groups, justifying the name “formal sum” for it’s elements.

Using these, we show how representations of G on V over k correspond to $k[G]$-modules: let $\varphi : G \to \mathrm{GL}(V)$ be a representation, with $G = \{g_1, g_2, ..., g_n\}$. Thus, each $\varphi(g_i)$ is linear transformation (in particular an automorphism). Define the $k[G]$ action on V by defining:

$$\left(\sum_i^n a_i g_i \right) \cdot v = \left(\sum_i^n a_i \varphi(g_i) \right)(v) = \sum_i^n a_i \varphi(g_i)(v)$$

Then this defines a $k[G]$-module (as should be verified if it doesn’t seem like it). A particular reminder for those who are checking that $\varphi(g_i g_j) = \varphi(g_i) \circ \varphi(g_j)$, since φ is a group homomorphism onto $\mathrm{GL}(V)$ under composition. Notice how this action in fact extends the action of k on $k[G]$ since $a \cdot v = av$ (similarly to how the $F[x]$ action extended the action of F on V in section 14.3).

Conversely, let’s say V is an $k[G]$-module. Seeking to make V a vector space over k and finding a group homomorphism $\varphi : G \to \mathrm{GL}(V)$, the first thing is that V is already a K vector-space by limiting to the action of $k \subseteq k[G]$. Furthermore, for each $g \in G$, we can obtain a map $\varphi : V \to V$ by defining:

$$\varphi(g)(v) = g \cdot v$$

Then it is easy to check that $\varphi(g)$ is a linear transformation: for $\alpha, \beta \in k$, $v, w \in V$

$$\begin{aligned} \varphi(g)(\alpha v + \beta w) &= g \cdot (\alpha v + \beta w) \\ &= \alpha(g \cdot v) + \beta(g \cdot w) \\ &= \alpha\varphi(g)(v) + \beta\varphi(g)(w) \end{aligned}$$

and by the associativity axiom of modules, we get

$$\varphi(g_i g_j)(v) = (\varphi(g_i) \circ \varphi(g_j))(v)$$

Thus, $\varphi : G \to \mathrm{GL}(V)$ is indeed a group homomorphism, and we have:

$$\left\{ V \text{ an } k[G]\text{-module} \right\} \rightleftarrows \left\{ \begin{array}{c} V \text{ a vector space over } k \\ \text{and} \\ \varphi : G \to \mathrm{GL}(V) \text{ a representation} \end{array} \right\}$$

Note that this also means that this also shows that linear representations also have kernel objects, since modules have kernels. Hence, the kernel of a G-representation homomorphism between V and W is G-invariant.

Definition 53.1.3: Affording Representation

Let V be a $k[G]$-module. Then given the previous discussion, we say that V *affords* the representation φ of G.

Given this new perspective, we can also characterize sub-actions. If we have a $k[G]$-module V, then a $k[G]$-submodule $W \subseteq V$ would have to be a k-submodule, and hence a subspace, but it also has to be closed under the action of g on W, i.e. $g \cdot W \subseteq W$. Hence, any $k[G]$-submodule is a G-stable subspace of V. Conversely, if $W \subseteq V$ is G-stable, then it is closed under the action of G and is a subspace, and hence a $k[G]$-submodule. Hence

$$\left\{ W \subseteq V \text{ a } k[G]\text{-submodule} \right\} \rightleftarrows \left\{ W \subseteq V \text{ a } G\text{-stable subspace} \right\}$$

Next, we should know when two representations are equivalent. Recall that when studying a linear transformation T on V to itself, a basis for V can be found that gives a "canonical form" to the matrix representation of T. Changing basis for V kept V the same, but changed the matrix representation of T up to similarity (i.e. changed the isomorphism from $\mathrm{GL}(V)$ to $\mathrm{GL}_n(k)$). The following is the analogous term:

Definition 53.1.4: Equivalent Representation

Let φ and ψ be two representations of G over k. Then we say these two represetnations are *equivalent* (or *similar*) if the $k[G]$-module affording them are isomorphic as modules. If two representations are not equivalent, they are called *inequivalent* (or *not similar*).

When the field is known[a], if V and W are equivalent (i.e. isomorphic as $k[G]$-modules), then we write $V \cong_G W$.

[a]In most cases, the field will be $\mathbb{C}$

Note that two different representations can mean two different vector-spaces over k. If $\varphi : G \to \mathrm{GL}(V)$ and $\psi : G \to \mathrm{GL}(W)$ are equivalent representations, it would make sense if there is a relation between V and W. If $T : V \to W$ is the $k[G]$-module isomorphism between them, It is a k-module isomorphism, and hence $V \cong W$ as vector spaces, implying $\dim(V) = \dim(W)$. Furthermore, by definition of T, $T(g \cdot v) = g \cdot T(v)$. By definition of the action, we have that $T(\varphi(g)(v)) = \psi(g)(T(v))$, i.e.

$$T \circ \varphi(g) = \psi(g) \circ T \quad \Leftrightarrow \quad T \circ \varphi(g) \circ T^{-1} = \psi(g) \qquad \forall g \in G$$

That is, T is the *simultaneous change of basis* for all $\varphi(g)$, $g \in G$. In terms of matrices, there must exist a fixed invertible matrix P such that for all $g \in G$,

$$P\varphi(g)P^{-1} = \psi(g)$$

The function T (or matrix P) are said to *intertwine* φ and ψ (it gives the rules on how to relate φ and ψ).

Example 53.1.5: Representations

1. Let G be any finite group, V any 1 dimensional vector-space over k. Define the $k[G]$-module structure on V by
$$g \cdot v = v$$
for all $g \in G$, $v \in V$. This called the *trivial representation* of G. This module affords the representation $\varphi : G \to \mathrm{GL}(V)$ by $\varphi(g) = I$ (the corresponding matrix representation from G to $\mathrm{GL}_1(k)$ sends $g \mapsto I$).

2. Let G be any finite group and k any field. Let $V = k[G]$ and consider it as a $k[G]$-module over itself. Then $\dim_k(V) = |G| = n$, with the basis being the elements of G. Then we see that each $g \in G$ permute the basis elements:
$$g \cdot g_i = gg_i = g_j \in G$$
Thus, the matrix representation for the action by the element g is an $n \times n$ matrix with 1 in the ij component if $g \cdot g_j = g_i$ (hence n 1's) and zero everywhere else. This representation of g is called the *regular representation* of G. Note how the underlying field didn't matter: the coefficients in the matrices can only ever by 1 or 0, and we would simply say "Let φ be the regular representation of G" without specifying which field the group-ring is.

3. Let $G = S_n$ ($n \in \mathbb{N}_{>0}$) and k be any field. Then let V be a vector-space over k of dimension n, $(e_1, e_2, ..., e_n)$ a basis for V, and define the action:
$$\sigma \cdot e_i = e_{\sigma(i)}$$
that is, σ permute the basis of V. Through this, we see that we afford a faithful representation $\varphi : S_n \hookrightarrow \mathrm{GL}(V)$. Furthermore, since any finite group is a subgroup of S_n for an appropriate n, we see that a group of order n we can define $\varphi : G \to S_n \to \mathrm{GL}(V)$, giving another perspective on how to embed any finite group into a matrix group. Notice too how we made a $k[G]$-module given the action of a $k[S_n]$-module. This is called the *permutation representation* of G.

   Note that this means that *any* finite groups acts on a vector space, and by using this construction we see that any finite group G of size n can be embedded into $\mathrm{GL}_n(k)$ showing how much structure the matrix groups embody.

4. Generlizing the last result, if $\psi : H \to \mathrm{GL}(V)$ is any representation and $\varphi : G \to H$ is a group homomorphism, then $\psi \circ \varphi$ is a representation of G on V.

5. Recall that in section 20.1.3 we defined a *group character* to be a homomorphism from G to $L^\times$. This is in fact a 1-dimensional representation of G, since $\mathrm{GL}_1(L) = L^\times$. For a concrete example, let $G = C_n$ be the cyclic group of order n and $\zeta_n \in \mathbb{C}^\times$ the nth root of unity. Then the map:
$$\chi : G \to \mathbb{C}^\times \qquad a^i \mapsto \zeta_n^i$$
is a faithful representation of G.

6. Let $G = D_8$. We already have the regular represenation of dimension 8 and premutation represetntation of dimension 8, but can we do better? In fact we can. In order to see this, let's first write out D_8 in terms of generators and relations:
$$D_8 = \langle r, s \mid r^4 = s^2 = 1,\ rs = sr^{-1} \rangle$$

Let $k = \mathbb{R}$ and consider $\mathrm{GL}_2(\mathbb{R})$. If we can find matrices that satisfy these relations, than we would have a faithful representation of degree 2. This can be laborious, but with some work we can find:

$$r \mapsto \begin{pmatrix} \cos(2\pi/n) & -\sin(2\pi/n) \\ \sin(2\pi/n) & \cos(2\pi/n) \end{pmatrix} \qquad s \mapsto \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

Let $G = Q_8$. We will show how different fiels can produce different represetnations. First, recall the following two generator and relation set for Q_8:

$$Q_8 = \langle i, j \mid i^4 = j^4 = 1,\ i^2 = j^2,\ i^{-1}ji = j^{-1} \rangle$$

$$Q_8 = \langle i, j, k \mid i^2 = j^2 = k^2 = ijk = 1 \rangle$$

If $k = \mathbb{C}$, and we work over $\mathrm{GL}_2(\mathbb{C})$ we can use the first representation an find:

$$i \mapsto \begin{pmatrix} \sqrt{-1} & 0 \\ 0 & -\sqrt{-1} \end{pmatrix} \qquad j \mapsto \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

can you find one if $k = \mathbb{R}$ and $\mathrm{GL}_4(\mathbb{R})$? (Hint: think of the Hamiltonian's $\mathbb{H}$)

7. Let $H \trianglelefteq G$ which is further an abelian p-group for some prime p. Then $V = H$ is a vector-space over $\mathbb{F}_p$ with the action of $a \cdot v = v^a$. Then define the action of G on H by conjugation: $g \cdot h = ghg^{-1}$. This action is well-defined since $gh^a g^{-1} = (ghg^{-1})^a$. The kernel of this action is $C_G(H)$. Such an action is called a *module representation*.

8. Let V be the $k[S_n]$-module which affords the permutation representation. We will find 2 S_n-invariant subspaces: Let $N \subseteq V$ be the subspace defined by:

$$N = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 = \cdots = \alpha_n\}$$

Then this a subspace that is also S_n-invariant. As practice, show that if $n \geq 3$, then N is the unique 1-dimension subspace which is S_n-stable. This submodule is called the *trace* submodule of V.

Another natural S_n-stable subspace is the following: take $I \subseteq V$ such that

$$I = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 + \cdots + \alpha_n = 0\}$$

notice that $I = \ker(\varphi)$ where $\varphi : V \to \mathbb{C}$, $\varphi(\alpha_1 e_1 \alpha_2 e_2 \cdots \alpha_n e_n) = \sum_i \alpha_i$, and so I is $n-1$ dimensional. Since φ is called the *augmentation map* (was in section 7.3 of D&F), I is called the *augmentation module*.

9. If V is a regular representation of G so that $V = k[G]$, then V has the same two natural G-invariant subspaces:

$$\begin{aligned} N &= \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 = \cdots = \alpha_n\} \\ I &= \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 + \cdots + \alpha_n = 0\} \end{aligned}$$

these are both in fact *two-sided ideals*, even if G is not abelian. Since they appear naturally, they are usually given a name: N is called the *trace ideal* and I is called the *augment ideal*.

Corollary 53.1.6: Schur's Lemma For Representations

Let V, W be irreducible G-representations (over $\mathbb{C}$) with represetnations ρ_V and ρ_W. Then:

1. If $V \not\cong_G W$, then there does not exist a non-trivial G-linear map between V and W
2. Let's say $V = W$, are finite dimensional vecor-spaces with $\rho_V = \rho_W$, then the only non-trivial G-linear maps from V to W are scalars: $\lambda I : V \to W$, $\lambda I(v) = \lambda v$.

***Proof*:**

1. Since V and W are irreducible G-representations, they are simple $k[G]$-modules, and hence we apply the original Schur's lemma.
2. Let $V = W$ of the same dimension with matching actions $\rho_V = \rho_W$, and let $f : V \to W$. Since f is a linear transformation over $\mathbb{C}$, there always exists an eigenvalue, say λ so that $f(x) = \lambda x$. Consider:
$$\varphi = f - \lambda I$$
so that $\varphi(x) = 0$. Since the difference of two G-linear maps is G-linear, then $\ker(\varphi)$ is a G-invariant subspace. But V is irreducible, and $\ker(\varphi)$ is non-empty, and hence must be all of V, and so $\varphi(V) = 0$, telling us that $0 = f(x) - \lambda I(x)$, i.e.
$$f(x) = \lambda x$$
completing the proof.

Recall that if V is a simple R-module over a semi-simple ring R, then $\text{End}_R(V) \cong_{\mathbf{Ring}} D^{\text{op}}$ is a division ring, and that any finite-dimensional division $\mathbb{C}$-algebra is in fact equal to $\mathbb{C}$. This lemma now gives an explicit isomorphism between these two!

Since we are working over a vector-space, it is often convenient when possible to bring in an inner product that give further relations between our objects. The key the following inner product is that it is invariant on G-actions:

Definition 53.1.7: G-Invariant Inner Product

Let V be $k[G]$-module. Then a *G-invariant inner product* is an inner product $\langle \cdot, \cdot \rangle$ along with the additional property of:
$$\langle g \cdot v, g \cdot w \rangle = \langle v, w \rangle$$

Instead of giving examples of this inner product, we will soon show if V is a semi-simple $k[G]$-module, we can transform any inner product into a G-invariant inner product (hint: can you see how to use the "averaging" idea in Machke's Theorem to do so? The answer is given in corollary 53.1.12, page 1475).

Now, the study of linear representations in themseves can difficult; we are essentially studying all possible $\mathbb{C}[G]$-module. We would rather be able to decompose them into smaller pieces, and show that any represetnation of G is some how build form these simpler pieces (similarly to our exploration of semi-simple modules). The rest of this chapter is dedicated to seeing if we can bring

Artin-Wedderburn's theorem and all of it's consequences to understanding linear representations of finite groups:

Definition 53.1.8: Decomposing Representations

A representation is called *simple, reducible, indecomposable, decomposable*, or *semisimple* if the $k[G]$-module affording it has the corresponding property

Recall that indecomposable in general does not imply irreducible. The example under definition 51.1.1 could is in fact a representation of $\mathbb{Z}$ defined by:

$$n \mapsto \begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$$

which is reducible (since it is in block upper-triangular form) but not indecomposable (since it's not in block-diagonal form). Notice that any 1-dimensional representation is automatically an irreducible, since any $k[G]$-submodule of k would be a k-subspace of k, but k is already irreducible as vector-space over k.

To get an idea of how $k[G]$-submodules interact with the definitions above, let V be an n-dimensional representation of G affording the represetnation ρ, and $W \subseteq V$ an m-dimensional $k[G]$-submodule (i.e. m-dimensional G-invariant subspace) with $0 \neq m \neq n$. Then choosing a basis $\{w_1, w_2, ..., w_m\}$ for W, we can extend it to a basis $\{w_1, w_2, ..., w_m, v_{m+1}, ..., v_n\}$. Since W is G-invariant, for any $w \in W$, $\rho(g)(w) \in W$. In matrix represetntation, $\varphi(g)(w^i) = \rho^i_j w^j$, and the coefficeints of $v^{m+1}, ..., v_n$ are zero. Hence we get the matrix representation of $\rho(g)$ as:

$$\begin{pmatrix} \alpha(g) & \beta(g) \\ 0 & \gamma(g) \end{pmatrix}$$

Notice too that:

$$\begin{aligned}
\begin{pmatrix} \alpha(gh) & \beta(gh) \\ 0 & \gamma(gh) \end{pmatrix} &= \rho(gh) \\
&= \rho(g)\rho(h) \\
&= \begin{pmatrix} \alpha(g) & \beta(g) \\ 0 & \gamma(g) \end{pmatrix} \begin{pmatrix} \alpha(h) & \beta(h) \\ 0 & \gamma(h) \end{pmatrix} \\
&= \begin{pmatrix} \alpha(g)\alpha(h) & \alpha(g)\beta(h) + \beta(g)\gamma(h) \\ 0 & \gamma(g)\gamma(h) \end{pmatrix}
\end{aligned}$$

which shows the the converse is also true: if we find a basis so that the matrices are block upper triangular, then the subspace spanned by the first m are G-invariant. As an example of this, let V be the permutation representation of S_3. Then the set of all vectors that are invariant to the action of $G = S_3$ is $V^G = \text{span}(e_1 + e_2 + e_3)$. Let $W = \text{span}(e_1 + e_2 + e_3)$. Since $G \curvearrowright W$ is of the form $g \cdot w = w$, we see that W is in fact the *trivial representation*. Since V is semi-simple, we have that $V = V^G \oplus V^{\perp}$. Making some new basis for V, say $(e_1 + e_2 + e_3, e_2, e_3)$, we see that $S_3 \curvearrowright V$ will have matrix representations that are of the above form:

$$\begin{pmatrix} 1 & * & * \\ 0 & * & * \\ 0 & * & * \end{pmatrix}$$

If V were irreducible, then no such basis would exist. If $V = U \oplus W$, then we would get a block diagonal form. It turns out that all representations of groups over either a character zero ring or fields where $|G| \nmid \text{char}(k)$ are block-diagonal, i.e. are semisimple!

Theorem 53.1.9: Maschkle's Theorem

Let G be a finite group and let k be a field whose characteristic does not divide $|G|$ or $\text{char}(k) = 0$. Then if V is a $k[G]$-module, it is a semi-simple $k[G]$-module.

The condition that $|G| \nmid \text{ch}(k)$ is equivalent to $|G| \in k^{\times}$. Note how this theorem is "surprising" as a finite group G certainly cannot be reduced to a direct sum of irreducible (or simple) groups, but as extensions of simple groups, but furthermore (as of writing this book) we do not know how to construct all finite group via extensions of simple groups. Hence, having a very computable decomposition into irreducible representations provides a very potent tool to analyze the structure of finite groups.

***Proof*:**
We will use lemma 51.1.7[3] to show that for any $U \subseteq V$, there exists a compliment W such that $V = U \oplus W$

We will find a projection onto U: $\pi : V \to U$. Thus, we need to show it has the following properties:

1. $\pi(u) = u$ for all $u \in U$
2. $\pi(\pi(v)) = \pi(v)$ for all $v \in V$ [a]

As a reminder on why this is sufficient[b], let π be such that the function defined on the $k[G]$-module that satisfies these properties. Let $W = \ker(\pi)$. Then $W \subseteq V$ is a submodule, and W is the comliment of U. First, let $v \in U \cap W$. Then since $v \in U$, $\pi(v) = v$ and since $v \in W$, $\pi(v) = 0$, hence $v = 0$, meaning $U \cap W = 0$. Next, let $v \in V$ be an arbitrary element, and write $v = \pi(v) + (v - \pi(v))$. By definition, $\pi(v) \in U$, and by the 2nd property:

$$\pi(v - \pi(v)) = \pi(v) - \pi(\pi(v)) = \pi(v) - \pi(v) = 0$$

and hence $v - \pi(v) \in W$. Hence $v \in U + W$, and so $V = U + W$, hence $V \cong U \oplus W$. Hence, it suffices to find an $k[G]$-module projection π.

Let $U \subseteq V$ be a $k[G]$-submodule. Then it is already a k-subspace, and so it has a vector-space direct sum compliment $W_0 \subseteq V$ (take a basis β for U, extend it to a basis $\mathcal{B}$ for V, then take $\mathcal{B} - \beta$) Thus, $V = U \oplus W_0$ as a vector-space. However, W_0 need not be G-stable (i.e. a $k[G]$-submodule), for example $G = C_2$ on $\mathbb{R}^2$ with the refection across $y = x$ which has the G-subspace $y = x$ and compliment spanned by $(1, 0)$ which is certainly not G-invariant. We will show how to find such the appropriate $k[G]$-module given W_0. First, let $\pi_0 : V \to U$ be the vector-space projection map:

$$\pi_0(u + w_0) = u$$

Here is the key to finding a proper compliment: we will "average" π_0 over G as follows:

$$g\pi_0 g^{-1} : V \to U \qquad g\pi_0 g^{-1}(v) = g \cdot \pi_0(g^{-1} \cdot v)$$

Since π_0 maps V to U, and U is a $k[G]$-submodule, U is stable under this G-action, hence $g\pi_0 g^{-1}$ is well-defined. Note that both g and g^{-1} act as k-linear transformations, so $g\pi_0 g^{-1]}$

is a k-linear transformation. Furthermore, if $u \in U$, then so must $g^{-1}u$, so by definition of π_0, $\pi_0(g^{-1}u) = g^{-1}u$. Thus, for all $g \in G$:

$$g\pi_0 g^{-1}(u) = u$$

hence, $g\pi_0 g^{-1}$ is also a vector-space projection of V onto U!

Let $n = |G|$, and viewing n as an element of k $(n = 1 + \cdots + 1)$, since $\mathrm{ch}(k) \nmid |G|$ $n \neq 0$, i.e. $n \in k^\times$. Thus, n has an inverse in k, meaning we can define:

$$\pi = \frac{1}{n} \sum_{g \in G} g\pi_i g^{-1}$$

We can immediately deduce that π has the following properties:

1. By definition, π is still k-linear from V to U.
2. Restricting π to U would restrict each summand in the definition of π, and so as we've pointed out earlier each summand would be the identity map. Hence, we get $1/n$ times n copes of u, meaning $\pi|_U = \mathrm{id}$
3. π is well-defined, hence $\pi(v) \in U$, so $\pi(v)^2 = \pi(v)$

It remains to show that π is in fact a $k[G]$-module homomorphism (i.e. is $k[G]$ linear). It suffices to show that for any $h \in G$, $\pi(hv) = h\pi(v)$. This is simply a computation:

$$\begin{aligned}
\pi(hv) &= \frac{1}{n} \sum_{g \in G} g\pi_0(g^{-1}hv) \\
&= \frac{1}{n} \sum_{g \in G} h(h^{-1}g)\pi_0(g^{-1}hv) \\
&= \frac{1}{n} \sum_{\substack{k=h^{-1}g \\ g \in G}} h(k\pi_0(k^{-1}v)) \\
&\overset{!}{=} h\frac{1}{n} \sum_{\substack{k=h^{-1}g \\ g \in G}} (k\pi_0(k^{-1}v)) \\
&= h\pi(v)
\end{aligned}$$

where $\overset{!}{=}$ comes form the fact that as g goes over all elements of G, then so will $k = h^{-1}g$ (i.e. groups acting on themselves are always transitive actions). Hence, π is indeed a $k[G]$-homomorphism, and so it is a projection map, completing the proof.

[a] In fact, this is implied by 1

[b] see ref:HERE for the original development of this

Thus, if we take any representation V over k of G, and consider the $k[G]$-module, then we know through $k[G]$ and G being finite and k a field (so V is a vector-space) that there are only *finitely many* simple $k[G]$-modules (i.e. finitely many irreducible representations of G), meaning we only have a finite number of "building blocks" from which we can build) any representation for G! Even better, the way we put together irreducible representation is through direct sums the simplest of ways of putting together algebraic objects! Then through the Artin-Wedderburn decomposition of V, we can find all *irreducible* representations that make up the representation V of G, giving us a simple finite list of irreducible representations per finite group! Note that if $p = \text{ch}(k) > 0$ and $p \big| |G|$, then $k[G]$ is *not* semisimple, or if G is infinite, it need not be semi-simple

Example 53.1.10: Non-Simple Group-Ring

For the infinite case, we've presented $\mathbb{Z} \curvearrowright \mathbb{Z}^2$ above. For the finite case where $p \big| |G|$,

1. let $G = C_n$ be the cyclic group of order n. Show that $k[C_p] \cong k[a]/(a^n - 1)$
2. Show that if char$k \nmid |G|$, then $k[C_n]$ is isomorphic product of fields. Since $M_1(k) = k$, by the uniqueness of Artin Wedderburn, this is the Artin-Wedderburn decomposition. Conclude that since $k[C_n]$ is abelian, any Artin-Wedderburn decomposition *has* to be a product of fields.
3. Show that if $\text{char}(k) = p$, then $k[C_p]$ has nilpotent elements, and hence cannot be a product of fields.

If $k = \mathbb{C}$, then Maschkle's Theorem always applies, and we can further use Artin Wedderburn over closed k-algebras (corollary 51.2.20) to deduce a relatively simple structure! Hence, from now on, we will always have $k = \mathbb{C}$, meaning all of our representations of finite groups will be over the complex vector-field of finite dimension.

Corollary 53.1.11: Matrix Representation Consequences

Let $\rho : G \to \text{GL}(V)$ be a representation over a field k where $\text{char}(k) \nmid |G|$. Then there exists a basis for V such that for all $g \in G$, the matrix $\rho(g)$ is of block-diagonal form:

$$\begin{pmatrix} \rho_1(g) & & & \\ & \rho_2(g) & & \\ & & \ddots & \\ & & & \rho_m \end{pmatrix}$$

where ρ_i is an irreducible representation of G, $1 \leq i \leq m$.

***Proof*:**
Let V be the $k[G]$-module representing ρ. By Maschkle's Theorem, we may write $V = U_1 \oplus \cdots \oplus U_m$. where U_i is simple $k[G]$-module. For each U_i, choose a basis β_i. Let $\beta = \bigcup_i^m \beta_i$. then each matrix representation of $\rho(g)$ is of the form in the corollary, with $\rho(g)|_{U_i} = \rho_i(g)$, completing the proof.

Corollary 53.1.12: Defining G-Invariant Inner Product

Let V be a $k[G]$-module and $\langle \cdot, \cdot \rangle$ be an inner product. Then this inner product induces a G-invariant inner product

***Proof*:**
If $\langle \cdot, \cdot \rangle$ is an inner product, then:

$$\langle v, w \rangle_G = \frac{1}{|G|} \sum_{g \in G} \langle gv, gw \rangle$$

is a well-defined inner product (as can be checked), and for any $h \in G$

$$\begin{aligned}\langle hv, hw \rangle_G &= \frac{1}{|G|} \sum_{g \in G} \langle ghv, ghw \rangle \\ &= \frac{1}{|G|} \sum_{k = gh \in G} \langle kv, kw \rangle \\ &= \langle v, w \rangle_G\end{aligned}$$

In other words, there is always an inner product on our space in which the group actions keeps all elements of the same length and the same angle between them, showing how we can interpret a group as somehow rotating and reflecting an object in a vector-space. Now that we know any represetnation of G is composed in some way by finitely many irreducible representations, it would be useful to be able to quickly deduce the Artin-Wedderburn decomposition of $\mathbb{C}[G]$:

Proposition 53.1.13: Properties Of Representations

Let $k = \mathbb{C}$ and G be finite. Let $S_1, S_2, ..., S_r$ be the irreducible G-representations (up to isomorphism). Then:

1. the number of irreducible G-representations is equal to the number of conjugacy classes in G
2. For every representation V of G,
$$V \cong S_1^{\oplus \ell_1} \oplus \cdots \oplus S_r^{\ell_r}$$
where $\ell_i > 0$ and is unique
3. $\mathbb{C}[G] \cong \bigoplus_{i=1}^n \left(S_i^{\oplus \dim_k S_i} \right)$ as regular representation
4. $|G| = \sum (\dim_k S_i)^2$

***Proof*:**
part (3) and (4) come from corollary 51.2.20.

For part (1), we first use Artin-Wedderburn to conclude that $Z(\mathbb{C}[G]) = \prod_i^r \mathbb{C}$, so $\dim_{\mathbb{C}}(Z(\mathbb{C}[G])) = r$, so the dimension of the center is equal to the number of irreducible G-representations.

Now, let $\mathcal{K}_1, ..., \mathcal{K}_s$ represent the conjugacy classes (recall they partition G). Define:

$$\sigma_i = \sum_{g \in \mathcal{K}_i} g$$

Note that any pair of elements σ_i and σ_j have no common terms since the conjugacy classes partition G. Furthermore, by definition, for any $g \in G$, $g\sigma_i g^{-1} = \sigma_i$, and so $\sigma_i \in Z(\mathbb{C}[G])$. If the σ_i's form a basis for $Z(\mathbb{C}[G])$, then we would have $s = t$. As a $\mathbb{C}$-vector-space, they are already linearly independent since the group elements from a basis, so it suffices to show they span. If $\sum_{g \in G} \lambda_g a_g \in Z(\mathbb{C}[G])$. Then by definition for all $h \in G$,

$$\begin{aligned}
\Leftrightarrow\ h\left(\sum_{g\in G}\lambda_g g\right) &= \left(\sum_{g\in G}\lambda_g g\right)h \\
\Leftrightarrow \left(\sum_{g\in G}\lambda_g g\right) &= h^{-1}\left(\sum_{g\in G}\lambda_g g\right)h \\
\Leftrightarrow \sum_{g\in G}\lambda_g g &= \left(\sum_{g\in G}\lambda_g (h^{-1}gh)\right) \\
\overset{!}{\Leftrightarrow} \sum_{g\in G}\lambda_g g &= \sum_{g\in G}\lambda_{hgh^{-1}} g \\
\Leftrightarrow \lambda_{hgh^{-1}} &= \lambda_g \qquad \forall g \in G
\end{aligned}$$

since h arbitrary, we see that the coefficients of elements in the same conjugacy class remain with an element that's in that conjugacy class. Equivalently, the function $G \to \mathbb{C}$, $g \mapsto \lambda_g$ is constant on conjugacy classes. Thus:

$$Z(\mathbb{C}[G]) = \operatorname{span}\left\{\sum_{g\in G} f([g])g\right\}$$

where f is a function from the conjugacy classes of G to $\mathbb{C}$. Hence $s = t$.

for (2), Since $\mathbb{C}[G]$ is a semi-simple ring, V is a semi-simple $\mathbb{C}[G]$-module, giving us existence of the decomposition by AW. For uniqueness, first note that:

$$\operatorname{End}_{\mathbb{C}[G]}(S_i) = \mathbb{C}$$

since $\mathbb{C}$ is the only [finite-dimensional?] division $\mathbb{C}$-algebra. Then, we get by Schur's lemma:

$$\operatorname{Hom}_{\mathbb{C}[G]}(S_i, V) \overset{\text{Schur}}{\cong} \operatorname{Hom}_{\mathbb{C}[G]}(S_i, S_i)^{\oplus l_i} \cong \mathbb{C}^{l_i}$$

Corollary 53.1.14: Abelian Groups And Degree 1 Decomposition

1. If A is an abelian group, then every irreducible complex representation of A is 1-dimensional (i.e. a homomorphism from A to $\mathbb{C}^\times$), and A has $|A|$ inequivalent irreducible complex representations.
2. The number of inequivalent (irreducible) 1-dimensional complex representations of any finite group G is equal to $|G/G'|$

***Proof*:**

1. Since A is abelian, so is $\mathbb{C}[A]$. By the Artin-Wedderburn decomposition, it must be a product of matrices, which since $\mathbb{C}[A]$ abelian is so must each matrix ring, which is only true if and only if $n_i = 1$. Then, by corollary 51.2.20, $\mathbb{C}[A]$ is a product of fields. It follows that any irreducible representation (i.e. simple $\mathbb{C}[A]$-module) is 1-dimensional. Conversely, if A were not abelian, $\mathbb{C}[A]$ cannot be a product of fields, hence one of the dimensions of the matrix rings *must* be greater than 1

2. Let G be an arbitrary group. We want to show that there is a bijective correspondence between the 1-dimension representations of G and the 1-dimensional representations of G/G'. $\rho : G/G' \to \mathbb{C}^\times$ is a 1-dimensional representations of G/G', then we have the natural map $G \to G/G'$, which shows that each 1-dimensional representations of G/G' is also a 1-dimensional representations of G. Convexly, if f $\rho : G \to \mathbb{C}^\times$ is a 1-dimensional representations of G, then by the universal property, this factors through:

$$\begin{tikzcd} G/G' \arrow[r] & \mathbb{C}^\times \\ G \arrow[u] \arrow[ur] & \end{tikzcd}$$

showing that any 1-dimensional representation of G is associated to a 1-dimensional representations of G/G', showing there can't be more 1-dimensional representations of G than there are of G/G', completing the proof.

A more general technique can be adopted from this proof: If $H \trianglelefteq G$ and V is an irreducible representation of G/H, then V is an irreducible representation of G.

Example 53.1.15: Decomposition Of Modules

1. DnF p. 847, and a bit about $\dim(V) = 1$ example right under definition

Finally, for those who read chapter 50, the following results are a glimpse at how representation theory is a "generalization" of number theory. First, if $H \leqslant G$ is a subgroup and (ρ, V) is an irreducible representation, $\rho|_H$ breaks up into the direct sum of representations, not necessarily of the same size or multiplicity. This is similar to how for a prime $\mathfrak{p} \subseteq F$ it may split to multiple primes with varying inertia degree and ramification numbers in a finite separable extension L/F. If L/F is furthermore normal (and hence Galois) then all the inertia degree's and ramification numbers match. In a similar vein:

Theorem 53.1.16: Clifford's Theorem

G be a group, $N \trianglelefteq G$ a normal subgroup, K a field, $\pi : G \to \mathrm{GL}_n(K)$ be an irreducible representation. Then the restriction $\pi|_N$ breaks up into a direct sum of irreducible representations of N of equal dimensions (i.e. it is semisimple and each representation is of the same dimension). These irreducible representations of N lie in one orbit for the action of G by conjugation on the equivalence classes of irreducible representations of N (i.e. they are isotypic components with the same multiplicity).

***Proof*:**
Let W be an irreducible subrepresentation of $V|_H$. Since H is normal in G, for $g \in G$, H acts irreducibly on gW by $(h, gw) \mapsto hgh^{-1}hw$. The subspace $\sum_{g \in G} gW$ is a nonzero subrepresentation of V. Since V is irreducible, it is equal to V. Since a representation which is a sum of irreducible sub-representations is semisimple, $V|_H$ is semisimple. A similar argument follows for the 2nd assertion, completing the proof.

Exercise 53.1.1

1. If χ_1 and χ_2 are both 1 dimensional representations, then $\chi_1 \cong \chi_2 \Leftrightarrow \chi_1 = \chi_2$. Use the property of equivalent representations to see this.
2. Let V be a non-trivial irreducible G-representation (i.e. not $\chi(g) = 1$ for all $g \in G$). Show that there are $\dim_{\mathbb{C}}(V^G) = 0$
3. By Caley's Theorem, all finite groups are linear. Do there exists infinite non-linear groups? (Hard: Do there exists finitely generated non-linear groups?)
4. Show that if ρ is irreducible and $N \trianglelefteq G$ is normal, if N fixes a point v, N acts trivially on all of V.

53.2 Character Theory

We know now we can decompose a G-representation V into the direct sum of r different types of irreducible G-modules. How do we know proceed to find these? These can be quite unwiedly: if we have a 10 or 100-dimensional represenation of a group G, then we have a matrix with 100 and $10'000$ entries! We'd then have to multiply these and figure out what relation's they have between each other, quite a hassle! Furthermore, how do we do this in such way that is independent of equivalent representations? A convinient basis might be nice, but to find a nice basis for every $\rho(g) \in \rho(G)$, we'd have to find a basis that can *simultaneously* diagonalize every element in $\rho(G)$! If there was some invariant we can find on a representation that we can use to keep track of the decomposition information between representations that is invariant of representation, that would be useful to this endevaour. The following does exactly this (Move the discussion of trace here to build-up to it? Give some of D&F examples to demonstrate it does get quite ugly sometimes?)

Definition 53.2.1: Class Function and Character

Let V be a representation of G over an arbitrary field F. Then

1. A function $f : G \to F$ that is constant on conjugacy classes is called a *class function* of G

2. If φ is a representation of G afforded by the $F[G]$-module V, then a function:

$$\chi_V : G \to \mathbb{C} \qquad g \mapsto \operatorname{tr}(g : V \to V) = \operatorname{tr}(\varphi(g))$$

   is called the *character* of φ, where $\operatorname{tr}(\varphi(g))$ is the trace of φ with respect to some basis for V. A character is called *irreducible* if φ is irreducible (and reducible oherwise). The *degree* of a character is the degree of any representation affording it.

For ease of reference, recall these properties of the trace:

1. $\operatorname{tr}(A+B) = \operatorname{tr}(A) + \operatorname{tr}(B)$ an $\operatorname{tr}(cA) = c\operatorname{tr}(A)$
2. $\operatorname{tr}(A) = \operatorname{tr}(A^t)$
3. $\operatorname{tr}(AB) = \operatorname{tr}(BA)$

Note that in general, a character is *not* a homomorphism from G into the additive or multiplicative structure of k. Since $\operatorname{tr}(AB) = \operatorname{tr}(BA)$, $\operatorname{tr}(ABA^{-1}) = \operatorname{tr}(B)$, we see that the trace (and hence the character) is independent of choice of basis, and so equivalent representations have the same character, meaning the character is indeed an invariant. Furthermore, for any representation φ of G,

$$\varphi(g^{-1}xg) = \varphi(g)^{-1}\varphi(x)\varphi(g)$$

hence, we can take the trace and use the 3rd property above to show that characters an an example of *class functions*. Furthermore, since the trace is linear, we can extend the domain of a character to be the trace over any element in $\mathbb{C}[G]$. If $F = \mathbb{C}$, then the collection of class function's form a complex vector-space, since the sum of two class functions is a class function, and multiplying by a scalar $z \in \mathbb{C}$ does not change that a class function is invariant.

Example 53.2.2: Character

1. Given the trivial representation of G (i.e. any 1-dim vector space where $g \mapsto I$), then if φ is the representating affording the trivial representation, it has $\chi_\varphi(g) = 1$ for all g. This is called the *trivial character*.

2. If we have a degree 1-representation, then the character and the representation are the same. Thus for abelian group, complex representations and their characters are the same. For example, take the representation $\varphi : C_p \to \mathbb{C}^\times$, $\varphi(a^i) = \zeta_p^i$. Then:

$$\chi(a^i) = \zeta_p^i$$

3. Let $\Pi : G \to S_n$ be a permutation representation of G and φ the linear of G of degree n on V where:

$$\varphi(g)(e_i) = e_{\Pi(g)(i)}$$

with respect to the given basis, $\varphi(g)$ has 1 in the ii-entry if $\Phi(g)$ fixes i, and zero otherwise. Thus, we can say that the character χ is:

$$\chi(g) = \#\{\text{number of fixed points of } g \text{ on } \{1, 2, ..., n\}\}$$

If in particular the permuation representation of G into S_n is by left multiplication, then the character is called the *pemutation character*.

4. Consider any regular representation of G, φ. Then the character is:

$$\chi(g) = \begin{cases} 0 & g \neq 1 \\ |G| & g = 1 \end{cases}$$

This character is called the *regular character* of G (note how this character is not a group homomorphism into k or $k^\times$)

5. Take the representation $\varphi : D_n \to \mathrm{GL}_2(\mathbb{R})$ from example 53.1.5. Then:

$$\chi(r) = 2\cos(2\pi/n) \qquad \chi(s) = 0 \qquad \chi(1) = 2$$

where the last one is since $1 \in G$ must map to the identity matrix $I \in \mathrm{GL}_2(\mathbb{R})$.

From now on, all our representation will be complex.

Lemma 53.2.3: Properties Of Character

Let $\rho_V : G \to \mathrm{GL}(V)$ be a complex representation. Then:

1. $\chi_V(1) = \dim_{\mathbb{C}}(V)$
2. $\rho_V(g)$ is diagonalizable for all $g \in G$ and $\chi(g)$ is integral over the integers: $\chi(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$
3. If $g \in G$ has order n, then $\chi_V(g)$ is a sum of $\dim(V)$ number of nth roots of 1
4. $|\chi_V(g)| \leq \chi_V(1)$ for all $g \in G$
5. $\chi_V(g^{-1}) = \overline{\chi_V(g)}$

***Proof*:**

1. We showed this in the above examples.
2. The criterion we need from linear algebra is that $A \in M_n(\mathbb{C})$ is diagonlizable if and only if the minimal polynomial has no repeated roots, which can be implied if $M^k = I$ for some k, which it certainly is in our case since every element is finite.
3. If $g^n = 1$, then $\rho_V(g)^n = 1$, so by (2)

$$\rho_V(g) \sim \begin{pmatrix} z_1 & & \\ & \ddots & \\ & & z_k \end{pmatrix}$$

where $z_i^n = 1$ for all $1 \leq i \leq k$. Furthermore, this shows that these trace values in the matrix representation are always integral over the integers, being the sum of integral elements.

4.
$$|\chi_V(g)| = \left|\sum z_i\right| \leq \sum |z_i| = \dim(\chi_V(1))$$

5. Since $\rho_V(g^{-1}) = \rho_V(g)^{-1}$ and

$$\rho_V(g)^{-1} \sim \begin{pmatrix} z_1^{-1} & & \\ & \ddots & \\ & & z_k^{-1} \end{pmatrix}$$

$\chi_V(g^{-1}) = \sum_i z_i^{-1}$, but $\|z_i\| = 1$, so $z_i^{-1} = \overline{z_i}$, so

$$\chi_V(g^{-1}) = \sum_i z_i^{-1} = \sum_i \overline{z_i} = \overline{\chi_V(g)}$$

Now, if we have some G-representation V, it has some character χ. In the following, we will show how we can always break-down a character to be the sums of characterse on the irreducible G-representations:

Proposition 53.2.4: Linearly Independent Characters

Let G be a finite group and V a semi-simple $k[G]$-module, and φ the representation that V affords. Then:

1. The character of V is the sum of the characters of the componens appearing in the direct sum decomposition.
2. The irreducible characters of G are linearly independent set in the set of class functions. Furthermore, the irreducible characters of G form a basis of the vector-space of class functions.

***Proof*:**
For the 1st point, By the Artin-Wedderburn decoposition, we have:

$$V \cong (S_1)^{n_1} \oplus \cdots \oplus (S_k)^{n_k}$$

where S_i are simple $k[G]$-modules (irreducible G-representations). If we focus on the case where $M = S_1 \oplus S_2$, then we can choose a basis for S_1 and S_2 which will give us:

$$\varphi(g) = \begin{pmatrix} \varphi_1(g) & 0 \\ 0 & \varphi_2(g) \end{pmatrix}$$

where φ_1, φ_2 are the representations afforded by M_1 and M_2 respectively. Then if ψ_1 and ψ_2 are the characters of φ_1 and φ_2 an χ is the character of φ then we get:

$$\chi = \psi_1 + \psi_2$$

using induction get's us the result.

For the 2nd point, first notice that the class functions defined by being 1 on a conjugacy class and 0 otherise forms a basis for class functions of dimension r. It thus suffices to sho that the r irreducible characters are independent. To that end, define:

$$\widetilde{\chi_V} : \mathbb{C}[G] \to G \qquad x \mapsto \mathrm{tr}(x : V \to V)$$

Note that this map is $\mathbb{C}$-linear since $\mathbb{C}$ commutes with $\mathbb{C}[G]$, and $\widetilde{\chi_V}|_G = \chi_V$. Now, say $S_1, ..., S_r$ are simple $\mathbb{C}[G]$-modules and:

$$\sum_i^r \lambda_i \chi_{S_i} = 0 \qquad \lambda_i \in \mathbb{C}$$

Then this is equivalent to:

$$\sum_i^r \lambda_i \widetilde{\chi_{S_i}}(g) = 0 \qquad \forall g \in G$$

and since the maps are $\mathbb{C}$-linear, by linearity:

$$\sum_i^r \lambda_i \widetilde{\chi_{S_i}}(x) = 0 \qquad \forall x \in \mathbb{C}[G]$$

which by plugging into the definition we get:

$$\sum_i^r \lambda_i \mathrm{tr}(x : S_i \to S_i) = 0 \qquad \forall x \in \mathbb{C}[G]$$

Next, by Artin Wederburn, we have the decomposition:

$$C[G] \cong M_{n_1}(\mathbb{C}) \times \cdots \times M_{n_r}(\mathbb{C})$$

where each $M_{n_i}(\mathbb{C}) \cong S_i^{\oplus n_i}$, with $S_i = \mathbb{C}^{\oplus n_i}$. Using this, take the element:

$$x_i = (0, ..., I, ..., 0)$$

where I is the identity matrix[a]. Then $x_i : S_j \to S_j$ is 0 if $i \neq j$, and the identity marix if $i = j$. Thus, the trace is:

$$\mathrm{tr}(x_j : S_j \to S_j) = \begin{cases} 0 & i \neq j \\ n_i & i = j \end{cases}$$

and since n_j is at least 1, we must have that

$$\lambda_1 = \cdots = \lambda_r = 0$$

where we took advantage of the fact we are in characeristic 0

[a] If the field had finite characteristic, it is better to take the elementary matrix E_{11}

53.2.5 Remark We can prove this directly without using Artin-Wedderburn, which we will

Corollary 53.2.6: Detecting Isomorphic Representations Using Characters

Let V_1, V_2 be representations that are semi-simple modules.

1. Every character of G is uniquely of the form

$$\sum_{i}^{r} \lambda_i \chi_i \qquad \lambda_i \geq 0$$

where χ_i are irreducible characters.

2. the representations V_1 and V_2 are isomorphic if and only if $\chi_{V_1} = \chi_{V_2}$

***Proof*:**

1. This comes straight from the fact that irreducible characters form a basis, and that any G-representation V will be some direct sum of a finite list of known simple G-modules

2. If $V_1 \cong_G V_2$, there is a matrix P that simultaneously diagonalizes so that if A and B are basis matrices, $A = PBP^{-1}$. But the trace is independent of conjugation, and so the characters are the same. For the othe way around, treating a representation as a $k[G]$-module, then by Machke's theorem, we *know* the list simple $k[G]$-modules and the actions of $k[G]$ on them. Since any $k[G]$-module can be broken down into a direct summand of simlpe $k[G]$-modules, and the two chracters are the same, the list of $k[G]$-modules and their multiplicity are the same.

Thus, we have translated the problem of finding the irreducible representations of a group G to finding the irreducible characters of G! Since a character of a representation is determined by the irreducible characters, we give a way to systematize the tracking of irreducible characters:

Definition 53.2.7: Character Table

Let $\varphi : G \to \mathrm{GL}(V)$ be a representaiton of G an χ_V it's character. Then we call the *character table* a table with the rows being irreducible characters and columns being an element in the conjugacy class. Common practice is to make the first column the identity conjugacy class and the first row the trivial representation

Example 53.2.8: Character Table

Consider $G = S_3$ Then we can start creating it's character table:

	e	$(1\ 2)$	$(1\ 2\ 3)$
1	1	1	1
χ_{sgn}	1	-1	1
$\vdots$	$\vdots$	$\vdots$	$\vdots$

Since G has 3 conjugacy classes, exactly 3 irreducible characters of G. How would we go about finding it? The comning propositions work towards this.

To be able to find the missing character, and more generally find new characters for a character table, we may look to construct new character given old one, and hope that we break down those characters into a linear combination of irreducible characters. In a sense, we are finding a way to create represetnations without doing it "by hand". We will do this in two way: the first is by taking advatange of group-actions, since are relatively easy to define and their representations are matrices with 1's and 0's. Since all groups embedd into a symmetric group, this can be done systematically. We then see how to work directly with known representation to create new represenations.

Definition 53.2.9: Precaution Representation

Let G act on a finite set X. Define $\mathbb{C}X$ to be the set of formal sums:

$$\mathbb{C}X = \left\{ \sum_{x \in X} \lambda_x x \;\middle|\; \lambda_x \in \mathbb{C} \right\}$$

So that we get a $\mathbb{C}$-algebra with $\dim_{\mathbb{C}}(\mathbb{C}X) = |X|$. Then we can make this a G-represetnation by defining:

$$g \cdot \left(\sum \lambda_x x \right) = \sum \lambda_x (g \cdot x)$$

The 3 usual premutation representations is $G \curvearrowright G$ by left multiplication (which gives the regular representation) or conjugation, and $G \curvearrowright \{*\}$ trivially (which gives the trivial representation).

Lemma 53.2.10: Character Of Permutation Representation

Let G act on X, $G \curvearrowright X$. Then

$$\chi_{\mathbb{C}X}(g) = \# \{ x \in X \mid gx = x \}$$

***Proof*:**
FIx $g \in G$. Then the set of x's is a basis for the representation. To make the computation simpler, we will find a convinient order for them. In particular, by choosing any $x_1 \in X$, we can find the orbit of the element:

$$\begin{tikzcd} x_1 \arrow[r, "g"] & x_2 \arrow[r] & \cdots \arrow[r] & x_k \arrow[lll, bend left] & x_{k+1} \arrow[r, "g"] & \cdots \end{tikzcd}$$

so the basis representation will look like:

$$\begin{pmatrix} 0 & & & \\ 1 & 0 & & \\ 0 & 1 & \ddots & \\ & & 1 & 0 \end{pmatrix}$$

so we get that the trace is 0 if the order of the orbit is greater than 1, hence:

$$\chi_{\mathbb{C}X}(g) = \#\{g\text{-orbits of size } 1\}$$

An immediate consequence of this is that we have another way of computing the character of the regular representation

$$\chi_{\mathbb{C}G}(g) = \begin{cases} |G| & g = e \\ 0 & g \neq e \end{cases}$$

which makes sense, since the $\dim_{\mathbb{C}}(\mathbb{C}G) = |G|$.

Next, we turn towards a more systematic way of constructing characters by creating them out of pervious ones, that is, given some representations V and W of a group G, we can make new representations by creating new representations from V and G:

Definition 53.2.11: Constructing Representations from smaller ones

Let V, W be G-representations. Then

1. we can make a $V \oplus W$ representation by:
$$g \cdot (v, w) = (g \cdot v, g \cdot w) \; [(\rho_V(g)v, \rho_W(g)w)]$$
2. we can make $V \otimes_{\mathbb{C}} W$ a representations by:
$$g \cdot (v \otimes w) \mapsto (gv) \otimes (gw)$$
3. we can make $\mathrm{Hom}_{\mathbb{C}}(V, W)$ a representations by:
$$g \cdot f : V \to W \quad v \mapsto g \cdot f(g^{-1} \cdot v)$$
4. we can make $V^* = \mathrm{Hom}_{\mathbb{C}}(V, \mathbb{C})$ a representaiton by:
$$g \cdot f : V \to \mathbb{C}, \; v \mapsto f(g^{-1} \cdot v)$$

Note that the last construction is the same as the 3rd if we take $\mathbb{C}$ as the trivial representation. Before we show what the character's of these new representations are, we first find a relatively simpler way of representing the hom representation of V and W:

Lemma 53.2.12: Hom-Tensor Representation Dual

Let V, W be G representations. Then:

$$\mathrm{Hom}_{\mathbb{C}}(V, W) \cong_G V^* \otimes_{\mathbb{C}} W$$

as G-representations.

Note that this is not true in general, even for vector-spaces. It is important that the spaces are finite-dimensional. In this way, this is a stronger result then the hom-tensor adjoint presented in theorem 15.3.9 for the case of finite-dimensional vector-spaces.

Proof:
By the universal property:

$$\theta : V^* \otimes_{\mathbb{C}} W \to \mathrm{Hom}_{\mathbb{C}}(V, W) \qquad \lambda \otimes w \mapsto (v \mapsto \lambda(v)w)$$

you should check that this is well-define (note that it is bilinear).

Now, pick basis $e_1, e_2, ..., e_n$ for V, $f_1, f_2, ..., f_m$ for W, and the natural dual $e_1^*, ..., e_n^*$ for V^*. Then we get a basis for $V^* \otimes W$:

$$(e_i^* \otimes f_j) \qquad 1 \leq i \leq n,\ 1 \leq j \leq m$$

Now, notice that:

$$\theta(e_i^* \otimes f_j) \qquad v \mapsto e_i^*(v) f_j \sim \begin{pmatrix} 0 & \cdots & 0 & \cdots & 0 \\ \vdots & & \vdots & & 0 \\ 0 & & 1 & & 0 \\ \vdots & & \vdots & & \vdots \\ 0 & \cdots & 0 & \cdots & 0 \end{pmatrix} = E_{ij}$$

which is a matrix with 1 in the ij position and zero evywehre else. This is clearly a basis, hence θ sends a basis to a basis, and hence θ is a vector-space isomorphism. We next check that θ is G-linear:

$$\begin{aligned} \theta(g \cdot (\lambda \otimes w)) &= \theta(g\lambda \otimes gw) \\ &\equiv v \mapsto (g\lambda)(v) gw \\ &= v \mapsto (g\lambda)(g^{-1}v) w \\ &= g(\lambda(g^{-1}v)w) \\ &\equiv g(\theta(\lambda \otimes w) g^{-1} v) \\ &= g \cdot \theta(\lambda \otimes w) \end{aligned}$$

Lemma 53.2.13: Creating New Characters

1. $\chi_{V \oplus W} = \chi_V + \chi_W$
2. $\chi_{V \otimes W} = \chi_V \cdot \chi_W$
3. $\chi_{\mathrm{Hom}_{\mathbb{C}}(V,W)} = \overline{\chi_V} \chi_W$
4. $\chi_{V^*} = \overline{\chi_V}$

Proof:

1. obvious

2. It is enough to show that if $f : V \to V$ and $g : W \to W$ are linear functions, then:

$$\mathrm{tr}(f \otimes h) = \mathrm{tr}(f)\mathrm{tr}(h)$$

Now if we pick basis (e_i) for V and (f_j) for W, then $f(e_i) = \sum a_{ij}e_j$ and $h(f_k) = \sum b_{lk}f_l$. Then:

$$(f \otimes h)(e_i \otimes f_j) = \left(\sum_j a_{ij}e_j\right) \otimes \left(\sum_l b_{kl}f_l\right) = \sum_{j,l} a_{ij}b_{lk}(e_j \otimes f_l)$$

Notice the cofficient of $e_i \otimes f_j$ is $\sum_{i,k} a_{ii}b_{kk} = (\sum_i a_{ii})(\sum_k b_{kk}) = \mathrm{tr}(f)\mathrm{tr}(h)$

3. Recall that for $f \in V^*$,

$$(gf)(v) = f(g^{-1} \cdot v)$$

that is

$$\rho_{V^*}(g)(f) = f \circ \rho_V(g^{-1})$$

that is, it is the transpose:

$$\rho_{V^*}(g) = (\rho_V(g^{-1}))^t$$

So, since the transpose matrix has the same trace, we have

$$\chi_{V^*}(g) = \chi_V(g^{-1}) = \overline{\chi_V(g)}$$

we then apply lemma 53.2.12 and part (3)to get:

$$\chi_{\mathrm{Hom}_{\mathbb{C}}(V,W)} = \overline{\chi_V} \cdot \chi_W$$

4. $\chi_{V^*} = \chi_{\mathrm{Hom}(V,\mathbb{C})} = \overline{\chi_V} \cdot 1 = \overline{\chi_V}$.

With this, we can create new characters! However, we have yet to establish how we may find the irreducible components of these chracters. For example, if we take $V \otimes V$, we may find that $\chi_{V \otimes V}$ is a linear combination of some characters already present in our table, but then we have a left-over part. How would we determine if the left-over is irreducible? We will show this by defining an *inner product* on the vector-space of class equations, and show that the irreducible form an *orthogonal basis*!

Definition 53.2.14: Inner Product On Class functions

Let $\chi_1, \chi_2 : G \to \mathbb{C}$ be class functions. Then define:

$$\langle \chi_1, \chi_2 \rangle = \frac{1}{|G|} \sum_{g \in G} \chi_1(g)\overline{\chi_2(g)} \in \mathbb{C}$$

Then this is a [Hermitian] *inner product.*

It should be verified that this is indeeed an inner product. Since class functions are by definition constant on conjugacy classes, we only need to run through representatives of conjgacy classe times the order of each conjugacy class:

$$\langle \chi_1, \chi_2 \rangle = \frac{1}{|G|} \sum_{\substack{\mathcal{K} \in \mathrm{conj}(G) \\ g \in \mathcal{K}}} |\mathcal{K}| \chi_1(g) \overline{\chi_2(g)} \in \mathbb{C}$$

where we pick a single represetnative $g \in \mathcal{K}$ and sum over the number of conjugacy classes, i.e. $|\mathrm{conj}(G)|$. Looking a the inner product like this is desirable to make computation easier (ex. if taking the inner product of a character with itself, we would simply take the squrae of each element in a row multiplied by the size of it's conjugcay class). Notice how this inner product mirrors the G-invariant inner product we induced in corollary 53.1.12 if we let $\langle, \cdot, \cdot \rangle$ be the usual conjugate dot product on $\mathbb{C}^n$. (TBD)

Lemma 53.2.15: Inner Product With Trivial Character

Let V be a G-representation. Then if $\mathbb{1}$ is the trivial representation,

$$\langle \chi_V, \chi_{\mathbb{1}} \rangle = \dim_{\mathbb{C}}(V^G)$$

where $V^G = \{v \in V \mid g \cdot v = v \; \forall g \in G\}$ is the subspace fixed by G.

***Proof*:**
Define the linear map $\pi : V \to V$ where

$$v \mapsto \frac{1}{|G|} \sum_{g \in G} g \cdot v$$

then:

$$\pi|_{V^G} = \mathrm{id}$$

and

$$\mathrm{im}(\pi) \subseteq V^G$$

which implies $\pi^2 = \pi$, i.e. a projection. By linear linear algebra:

$$V = \ker(\pi) \oplus \mathrm{im}(\pi)$$

where on the kernel, $\pi = 0$, and on the image $\pi = \mathrm{id}$. Thus,

$$\frac{1}{|G|} \sum_g \chi_V(g) = \frac{1}{|G|} \sum_g \mathrm{tr}(g : V \to V) = \mathrm{tr}(\pi) = \dim_{\mathbb{C}}(V^G)$$

but the left hand side is $\langle \chi_V, \chi_{\mathbb{1}} \rangle$, completing the proof.

Corollary 53.2.16: Row Orthogonality

If V and W are any representations of G, then

$$\langle \chi_V, \chi_W \rangle = \dim_{\mathbb{C}}(\hom_{\mathbb{C}[G]}(W, V))$$

In particualr, if V an W are irreducible, then

$$\langle \chi_V, \chi_W \rangle = \begin{cases} 1 & V \cong W \\ 0 & \text{otherwise} \end{cases}$$

that is, irreducible character's are orthogonal to each other.

***Proof*:**
We reduce to the previous lemma:

$$\begin{aligned}
\langle \chi_V, \chi_W \rangle &= \frac{1}{|G|} \sum_{g \in G} \chi_V(g) \overline{\chi_W(g)} \\
&= \frac{1}{|G|} \sum_{g \in G} \chi_{\mathrm{Hom}_{\mathbb{C}}(W,V)}(g) \\
&= \langle \chi_{\mathrm{Hom}_{\mathbb{C}}(W,V)}, 1 \rangle \\
&= \dim_{\mathbb{C}}(\mathrm{Hom}_{\mathbb{C}}(W, V)^G)
\end{aligned}$$

Note that $f \in \mathrm{Hom}_{\mathbb{C}}(W, V)$ is G-invariant, so $g \cdot f = gfg^{-1} = f$ for all $g \in G$ (recall the definition of $g \cdot f$ on $\mathrm{Hom}_{\mathbb{C}}(W, V)$). Thus this is true iff

$$gf = fg$$

Thus

$$gf(w) = f(gw) \qquad \forall g \forall w \in W$$

so f is $\mathbb{C}[G]$-linear so f is in the $\mathrm{Hom}_{\mathbb{C}[G]}(W, V)$.

There is also a more concrete proof worth remarking: since characters are linear combination's of irreducible characters, the direct product of irreducible modules translates to the sum of an irreducible character with the multiplicity of the irreducible module afording the representation being the multiplicity of the ireducibile characters. Hence:

$$\begin{aligned}
\langle \chi_V, \chi_W \rangle &= \langle \sum_i m_i \chi^{(i)}, \sum_j m_j \chi^{(j)} \rangle \\
&= \sum_{i,j} m_i m_j \langle \chi^{(i)}, \chi^{(j)} \rangle
\end{aligned}$$

where we have now reduced it to $\langle \chi^{(i)}, \chi^{(j)} \rangle$. Expanding the inner product and using the hom-set definition, we can apply Schur's Lemma and get:

$$\langle \chi^{(i)}, \chi^{(j)} \rangle = \delta_{ij}$$

Thus, our formula becomes:

$$\begin{aligned}\langle \chi_V, \chi_W \rangle &= \langle \sum_i m_i \chi^{(i)}, \sum_j m_j \chi^{(j)} \rangle \\ &= \sum_{i,j} m_i m_j \langle \chi^{(i)}, \chi^{(j)} \rangle \\ &= \sum_{i,j} m_i m_j \delta_{ij}\end{aligned}$$

To find $\langle \chi^{(i)}, \chi^{(i)} \rangle$ for an irreducible character, seeing it through multiplicites, then we know that an irreducible character corresponds to an irreducible representation, which necessarily has to then have multiplicity one, so if in particular:

$$\langle \chi^{(i)}, \chi^{(i)} \rangle = m_i^2 = 1 \cdot 1 = 1$$

Thus, the irreducible character produce and orthogonal basis of class functions!

Corollary 53.2.17: Consequence of Orthogonality

Let $V = \bigoplus_i^r S_i^{l_i}$ where each S_i irreducible and $S_i \ncong S_j$. Then

1. the multipliity of l_i of S_i is: $l_i = \langle \chi_V, \chi_{S_i} \rangle$
2. $\langle \chi_V, \chi_V \rangle = \sum_i l_i^2$
3. $\hom_G(W, V) \cong \hom_G(V, W)^*$

***Proof*:**

1. Use the Artin-Wedderburn decomposition and the fact that direct sums of modules becomes sums of characters
2. this is just taking advantage of the summing formula
3. This is taking advantage of the fact that $\langle \chi, \psi \rangle = \overline{\langle \psi, \chi \rangle}$.

The second line is useful enough to be given it's own name:

Definition 53.2.18: Character Norm

Let V be a G-representation and let $\langle \cdot, \cdot \rangle$ be the inner product on the class functions of G. Then for any class function $\psi = \sum_i \lambda_i \chi_i$,

$$\|\psi\| = \left(\sum_i \lambda_i^2 \right)^{1/2}$$

We will use all this informaiton to deduce new characters:

Example 53.2.19: Orthogonality Relation

Let's go back to our table for S_3:

	e	(1 2)	(1 2 3)
1	1	1	1
χ_{sgn}	1	-1	1
$\vdots$	$\vdots$	$\vdots$	$\vdots$

Since S_3 has 3 conjugacy classes, it can at most have one more irreducible character. What can this character be? We may start by looking at the regular represetnation of S_3 and take it's character χ_V. Then:

$$\langle \chi_V, 1\rangle = 1$$
$$\langle \chi_V, \chi_{\text{sng}}\rangle = 0$$

showing the regular character χ_V has one copy of the trivial representation (which makes sense, since $\chi_V(e) = 1$). Since

$$\chi_V(e) = 3 \qquad \chi_V((1\ 2)) = 1 \qquad \chi_V((1\ 2\ 3)) = 0$$

then we can take a "compliment" character by subtracting the trivial character, which defines a character which gives:

$$\chi^{\perp}(e) = 2 \qquad \chi^{\perp}(1\ 2) = 0 \qquad \chi^{\perp}(1\ 2\ 3) = -1$$

So, if there were to be another irreducible character, it would be of this form. But does there exist a degree 2 irreducible representation with this character? In fact, there has to: we saw that the number of irreducible representations is equal to the number of conjugacy classes, meaning the number of characters must be equal to the number of irreducible representations.

More generally, there can be a few approaches to finding it. One is to tensor two characters we know and see if it is irreducible, or one of it's linear components is irreducible. Another is to find the compliment of a represetnation of an existing character (since $k[G]$-modules are semi-simple). This compliment method is in general less desirable, and usually harder, but is managable if working with permutation representations.To demonstrate, let V be the degree three permutation representation of S_3[a] with basis $\{e_1, e_2, e_3\}$. Then if $\mathbb{1}$ is the trivial action, $V^{\mathbb{1}} = \text{span}(e_1+e_2+e_3)$, Thus, by Machke's theorem, $V^{\mathbb{1}}$ has a compliment. To see it, we simply have to extend $e_1+e_2+e_3$ to an orthogonal basis for V, for example, choose $(e_1+e_2+e_3, e_2-e_1, e_3-e_1)$. Then we can calculate what the action ρ does on this basis. For example:

$$\begin{aligned}\rho(1\ 2)(e_1+e_2+e_3) &= e_1+e_2+e_3\\ \rho(1\ 2)(e_2-e_1) &= e_1-e_2 = -(e_2-e_1)\\ \rho(1\ 2)(e_3-e_1) &= e_3-e_2 = -(e_2-e_1)+(e_3-e_1)\end{aligned}$$

If we write out ρ for an element in each conjugacy class, we will find that it's trace will be

$$\chi^{\perp}(e) = 2 \qquad \chi^{\perp}((1\ 2)) = 0 \quad \chi^{\perp}((1\ 2\ 3)) = -1$$

showing we have found the desired irreducible representation! Finally, by Artin-Wedderburn, we have that $\mathbb{C}S_3 \cong \mathbb{1} \oplus \text{sgn} \oplus V^{\perp}$

Now that we know the character table for S_3, we can construct any other character of representations of S_3, and hence any other representation of S_3. For example, we know that $V^\perp \otimes V^\perp$ has as character $\chi_{V^\perp} \cdot \chi_{V^\perp}$. Using this, we can compute that:

$$\langle V^\perp \otimes V^\perp, \mathbb{1} \rangle = 1$$
$$\langle V^\perp \otimes V^\perp, \mathrm{sgn} \rangle = 1$$
$$\langle V^\perp \otimes V^\perp, V^\perp \rangle = 1$$

showing that

$$\chi_{V^\perp \otimes V^\perp} = \chi_{\mathbb{1}} + \chi_{\mathrm{sgn}} + \chi_{V^\perp}$$

[a]Which in this case, is just the regular representation

Recall from linear algebra that if the rows are orthogonal in a square matrix, then so would be the column (and vice-versa). We bring to light this relation for the character table. As in linear algebra, it comes down to proper normalizing of a different basis: recall that the class equations of the form $\delta_{\mathcal{K}} : G \to \mathbb{C}^\times$ where:

$$\delta_{\mathcal{K}}(g) = \begin{cases} 1 & g \in \mathcal{K} \\ 0 & \text{otherwise} \end{cases}$$

this naturally forms a basis for the class equations too. The following theorem will also show how to go between this basis and the irreducible character basis:

Theorem 53.2.20: Column Orthogonality

If $\chi_1, \chi_2, ..., \chi_r$ are the irreducible characters of G and $g_1, g_2, ..., g_r$ represent the conjugacy classes of G, then

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \delta_{st}\frac{|G|}{|\mathrm{conj}(g_s)|}$$

which by Orbt-stabalizer,

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \delta_{st}|C_G(g_s)|$$

If $g_s, g_t \in \mathrm{conj}(g)$, then we get that

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \sum_i |\chi_i(g_s)|^2 = |C_G(g_s)|$$

in particular, we must have:

$$\sum_i |\chi_i(e)|^2 = |G|$$

***Proof*:**
Define $f_s : G \to \mathbb{C}$,

$$g \mapsto \begin{cases} 1 & g \in \mathrm{conj}(g_s) \\ 0 & \text{otherwise} \end{cases}$$

which is natural basis for the class functions. since it's a class function, we know we can write it as the sum of orhtogonal ireducibile characters:

$$f_s = \sum_i^r \lambda_{is}\chi_i \qquad \lambda_{is} \in \mathbb{C}$$

since these are orthornormal, we know that:

$$\lambda_{is} = \langle f_s, \chi_i \rangle$$

so computing:

$$\begin{aligned}\lambda_{is} &= \langle f_s, \chi_i \rangle \\ &= \frac{1}{|G|}\sum_{g\in G} f_s(g)\overline{\chi_i(g)} \\ &= \frac{1}{|G|}\sum_{g\in \mathrm{conj}(g_s)} \overline{\chi_i(g)} \\ &= \frac{|\mathrm{conj}(g_s)|}{|G|}\overline{\chi_i(g_s)}\end{aligned}$$

so

$$f_s = \frac{\mathrm{conj}(g_s)|}{|G|}\sum_i^r \overline{\chi_i(g_s)}\chi_i$$

we know evaluate at g_t.

Since both the rows and columns of a character table are all orthogonal to each other, the character table is in fact invertible!

Example 53.2.21: Using Column Orthogonality

Let $G = S_4$. We want to find it's character table. We first pick what conjugacy classes to index the columns by, say:

conj. class	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
size	1	6	8	3	6

Next, we can immediately deduce that $\chi_{\mathbb{1}}$ and χ_{sgn} are irreducible characters, giving us the current begining of a character table:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1

To find more characters, we can first take the pemutation character of $\mathbb{C}X$. The character of each conjugacy class is the number of fixed points, giving us:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{C}X}$	4	2	1	0	0

We can see that the trivial character is part of linear decomposition of $\chi_{\mathbb{C}X}$, since:

$$\langle \chi_{\mathbb{C}X}, \chi_{\mathbb{1}} \rangle = (1(4 \cdot 1) + 6(2 \cdot 1) + 8(1 \cdot 1))/24 = 24/2 = 1$$

and so $\chi_{\mathbb{C}X} - \chi_{\mathbb{1}}$ is a 3 dimensional character, let's label this χ_3. Then $\|\chi_3\|^2 = 1$, showing that it's irreducible, hence we expand our table:

	1 1	6 (1 2)	8 (1 2 3)	3 (1 2)(3 4)	6 (1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
$\chi_{\mathbb{C}X} - \chi_{\mathbb{1}} = \chi_3$	3	2	0	-1	-1

To find the next character, we can multiply χ_{sgn} and χ_3 (note we can do χ_3 with itself, but it will be 9 dimensional, which we'll show in the next proposition cannot be an irreducible representation). Let$\chi_4 = \chi_{\text{sgn}} \cdot \chi_3$. Then $\|\chi_4\|^2 = 1$, meaning it's irreducible, and so we add another row to our table:

	1 1	6 (1 2)	8 (1 2 3)	3 (1 2)(3 4)	6 (1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	2	0	-1	-1
$\chi_{\text{sng}} \cdot \chi_3 = \chi_4$	3	-1	0	-1	1

Finally, since $|G| = \sum_i \chi_i(e)^2$, we can deduce that $\chi_5(e) = 2$. We can't do this same trick exactly for the other columns since we will get the value up to a complex number z with $\|z\| = 1$. To find the rest of the character values, we can either use column orthogonality For example, to find $\chi_5(1\ 2)$, noticet that the inner product of the first and second column is:

$$1 \cdot 1 + (-1) \cdot 1 + 3 \cdot 1 + 3 \cdot (-1) = 0$$

and so $\chi_5(2)$ must be 0. For the next column, we'd get :

$$1 \cdot 1 + 1 \cdot 1 + 3 \cdot 0 + 3 \cdot 0 = 2$$

and so, since $2 \cdot -1 = -2$, we get that $\chi_5(1\ 2) = -1$. Continuing this way, we get that the rest of the table will be:

	1 1	6 (1 2)	8 (1 2 3)	3 (1 2)(3 4)	6 (1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	2	0	-1	-1
χ_4	3	-1	0	-1	1
χ_5	2	0	-1	2	0

We can verify this is indeed irreducible by taking $\|\chi_5\|^2 = 1$.

Another method would be to use the regular representation, where we get:

$$\chi_{\mathbb{C}[G]} = \sum_i \chi_i(1)\chi_i$$

These can be verified by taking advantage of the fact that the "column norm" should give you $C_G(g)$ (i.e. the number on top of the table).

As a fun aside, it can be shown that the represetned by χ_4 is the action of the rotation of a cube that is, if $C \subseteq \mathbb{R}^3$ are the vertex points of the cube, then χ_3 is the character of $S_4 \curvearrowright \mathrm{GL}_3(\mathbb{R})$ of all rotations C.

Notice how the dimension of each irreducible representation divided the order of the group. This is in fact true in general. It is not a trivial fact, the only "order" information we've shown so far is that the sums of the squares of the dimensions of the ireducibile representation sum to $|G|$. It is also relatively eays to show that if $W \subseteq V$ is an irreducible $k[G]$-module then the dimension of W is $< |G|$. The following is thus a much stronger result:

Proposition 53.2.22: Dimension Theorem of Irreducible Representations

Let V be an irreducible G-representation. Then:

$$\dim_{\mathbb{C}}(V) \,\big|\, |G|$$

that is, the dimension of V divides the order of G.

***Proof*:**
Let $g_1, g_2, ..., g_r$ be representatives of the conjugacy class. Recall the following trick from proposition 53.1.13:

$$e_i = \left(\sum_{g \in \mathrm{conj}(g)} g \right) \in Z(\mathbb{C}[G])$$

Note that e_i in fact lies in $e_i \in Z(\mathbb{Z}[G])$, since $ge_ig^{-1} = e_i$ (by definition), and so extending linearly all $xe_ix^{-1} = e_i$. Now we have a commutative ring that is a finitely generated $\mathbb{Z}$-module (one way to see this is as we've done in proposition 53.1.13, another way is to notice that $\mathbb{Z}[G]$ is a finitely generated $\mathbb{Z}$-module and $\mathbb{Z}$ is Noetherian, so the center is finitely generated)

Thus, by proposition 26.1.4, $\mathbb{Z} \subseteq Z(\mathbb{Z}[G])$ is an *integral extension*. Next, we have a ring homomorphism:

$$\varphi : Z(\mathbb{C}[G]) \to \mathrm{End}_{\mathbb{C}[G]}(V) \overset{!}{\cong} \mathbb{C} \qquad z \mapsto (z : V \to V)$$

where $\overset{!}{=}$ comes from corollary 51.2.19 and Schur's lemma, and $z(v) = zv$. Hence, each element of $\varphi(Z(\mathbb{C}[G]))$ is $\mathbb{C}$-linear, and must be invertible, and so φ is in fact a map from $Z(\mathbb{C}[G]) \to \mathrm{Aut}_{\mathbb{C}}(V) = \mathrm{GL}(V)$, which is simply a restriction of the origional G-action ρ to $Z(\mathbb{C}[G])$. Hence $\rho(e_i) = \lambda_i I$ for appropriate $\lambda_i = \varphi(e_i)$, meaning $\chi(e_i) = \mathrm{tr}(e_i : V \to V) = n\varphi(e_i)$ where $n = \dim(V)$ since by what we've just shown, $\varphi(e_i)$ acts as scalar multiplication on the representation V.

Now, since $e_i \in Z(\mathbb{C}[G])$ is integral over $\mathbb{Z}$, $\varphi(e_i) \in \mathbb{C}$ is integral over $\mathbb{Z}$, that is $\varphi(e_i) \in \overline{\mathbb{Z}}^{\mathbb{C}} \subseteq \mathbb{C}$ (i.e. $\varphi(e_i)$ is algebraic). Next, we can express $\chi(e_i)$ in a different way:

$$\sum_{g \in \mathrm{conj}(g_i)} \chi_V(g) = |\mathrm{conj}(g_i)| \cdot \chi_V(g_i) = \chi(e_i)$$

so:

$$\frac{\text{conj}(g_i)}{n}\chi_V(g_i) = \varphi(e_i) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

which is telling us that if we divide it by n, we still get an algebraic integer! Taking a nice linear combination and multiplying by $\overline{\chi_V(g_i)}$ we get:

$$\sum_i^r \frac{\text{conj}(g_i)}{n}\chi_V(g_i)\overline{\chi_V(g_i)}$$

Then we've just shown that $\frac{\text{conj}(g_i)}{n}\chi_V(g_i)$ is an algebraic integer, and $\overline{\chi_V(g_i)}$ is an algebraic integer (being the sum of roots of unity). Now, notice this is the form of the inner product, giving us:

$$\frac{|G|}{n}\langle\chi_V,\chi_V\rangle = \frac{|G|}{n} \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

as a V irreducible. Thus, we have that $\frac{|G|}{n}$ is some algebraic integer. We further have that it is certainly a rational number ($|G|, n \in \mathbb{N}$), but then we have:

$$\frac{|G|}{n} \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} \overset{!}{=} \mathbb{Z}$$

where $\overset{!}{=}$ comes from the fact that if R is a Unique Factorization Domain, $\alpha \in \text{Frac}(R)$, α is integral over R if and only if $\alpha \in R$, completing the proof.

This will make the computation of characters of abelian groups paticularly simple! (see rep theory of finite groups: An introductory Appraoch p. 47!)

Exercise 53.2.1

1. Let G act on the n-dimensional vector-space V by basis permutation. Show that $\dim(V^G)$ equals the number of orbits of G.

53.2.1 More Character Tables

In this section, we go over a few more exmaples of character tables in order to see some techniques used to find them. For any abelian, group, the character table is straight forward. As a really simple example, consider $\mathbb{Z}/3\mathbb{Z}$:

	1	1	1
	1	2	3
χ_1	1	1	1
χ_2	1	ζ_3	ζ_3^2
χ_3	1	ζ_3^2	ζ_3

If we take $\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$, we will get a 9 by 9 table. The table bellow fills in a few of the characters (note that these were found by taking $\chi_i(g_i)\chi_j(g_j)$)

	1	1	1	1	1	1	1	1	1
$\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$	$(1,1)$	$(2,1)$	$(3,1)$	$(1,2)$	$(2,2)$	$(3,2)$	$(1,3)$	$(2,3)$	$(3,3)$
$\chi_{(1,1)}$	1	1	1	1	1	1	1	1	1
$\chi_{(2,1)}$	1	ζ_3	ζ_3^2	1	ζ_3	ζ_3^2	1	ζ_3	ζ_3^2
$\chi_{(2,2)}$	1	ζ_3	ζ_3^2	ζ_3	ζ_3^2	1	ζ_3^2	1	ζ_3
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$

Note that the root ζ_3 might change if we take the direct product of cyclic groups of differnet orders, for example the character table of $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$ has roots of unity of order 3 and 6 (as you can verify).

More generally, if G is abelian, we break G down into a product of cyclic groups and construct the table like above. Thus, we focus on non-abelian groups. We have already found the character table for S_3:

S_3	e	$(1\ 2)$	$(1\ 2\ 3)$
$\chi_{\mathbb{1}}$	1	1	1
χ_{sgn}	1	-1	1
χ_3	2	0	-1

and the character table for S_4:

	1	6	8	3	6
S_4	1	$(1\ 2)$	$(1\ 2\ 3)$	$(1\ 2)(3\ 4)$	$(1\ 2\ 3\ 4)$
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	2	0	-1	-1
χ_4	3	-1	0	-1	1
χ_5	2	0	-1	2	0

Next, let $G = D_4$. Then: $D' = \{e, r^2\}$, so G has 4 degree 1-irreducible representations. We also found in example 53.1.5 that D_4 has a degree 2 irreducible representation. These are all of the representations, sinc $1+1+1+1+2^2 = 8$. To find the 1-dimensional irreducible representations, notice that $D_4/D_4' \cong \mathbb{Z}_2 \times \mathbb{Z}_2$, meaning we can find the irreducible representations of $\mathbb{Z}/2\mathbb{Z}$, which are:

$\mathbb{Z}/2\mathbb{Z}$	0	1
χ_0	1	1
χ_1	1	-1

and take the tensor product to create:

$\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$	$(0,0)$	$(1,0)$	$(0,1)$	$(1,1)$
$\chi_{(0,0)}$	1	1	1	1
$\chi_{(1,0)}$	1	-1	1	-1
$\chi_{(0,1)}$	1	-1	-1	1
$\chi_{(1,1)}$	1	1	-1	-1

and using this, we can complete the table for D_4:

D_4	e	r	r^2	σ	σr
χ_1	1	1	1	1	1
χ_2	1	1	1	-1	-1
χ_3	1	-1	1	1	-1
χ_4	1	1	1	-1	1
χ_5	2	0	-2	0	0

More generally, for D_n, the character table will conssite of characters of degree 1 and 2.

Let's now let $G = Q_8$. Taking the presentation:

$$Q_8 = \langle i, j | i^4 = 1,\ i^2 = j^2,\ i^{-1}ji = j^{-1} \rangle$$

with $k = ij$ and $i^2 = -1$, we get the conjugacy classes can be represented by $1, -1, i, j, k$, with sizes 1, 1, 2, 2, 2. Since $Q_8/Q_8' \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$, there are 4 degree 1 characters. The final irreducible character thus *must* have degree 2; let's label if χ_5. We have in fact explicitely found this character before in example 53.1.5, but we can find it without actually manually finding a representation. Let φ be an irreducible representation of degree 2. Since $-1 \in Z(Q_8)$, by Schur's lemma $\varphi(-1)$ is a 2×2 scalar matrix of order 2, hence it is $\pm I$, and so $\chi_5(-1) = \pm 2$. Next, if $\chi_5(i) = a$, $\chi_5(j) = b$, and $\chi_5(k) = c$, then since χ_5 is orthogonal, we have that:

$$1 = \langle \chi_5, \chi_5 \rangle = \frac{1}{8}(2^2 + (\pm 2)^2 + 2a\overline{a} + 2b\overline{b} + 2c\overline{c})$$

and since $a\overline{a}, b\overline{b}, c\overline{c} \in \mathbb{R}^+$, they must all be zero. Furthermore, we must have that:

$$0 = \langle \chi_1, \chi_5 \rangle = \frac{1}{8}(2(\pm 2) + 0 + 0 + 0 + 0)$$

implying that $\chi_5(-1) = -2$. Thus, we have that the character table is:

Q_8	1	i	-1	j	k
χ_1	1	1	1	1	1
χ_2	1	1	1	-1	-1
χ_3	1	-1	1	1	-1
χ_4	1	1	1	-1	1
χ_5	2	0	-2	0	0

Notice that this character table is identical to the character table of D_8. Hence, identical character tables does not imply isomorphic groups! Finally, we could have found the last row of the above table by applying column orthogonality to find the missing values, once we knew $\chi_5(1) = 2$.

Next, let $G = A_4$. Since we found the character table for S_4, we can use it it to find the character table of A_4. We first note that A_4 has 4 conjugacy classes (represented by 1, (1 2)(3 4), (1 2 3) and (1 3 2)), and $[A_4 : A_4'] = 3$, meaning A_4 has 3 chacacters of degree 1, and the only other character must be of degree 3. Next, using the orthogonality relation, notice that χ_3 in the table for S_4 when restricted to A_4 is still irreducible (this is certainly not generally the case, for ex. the degree 2 representaiton of S_3 will become reducible since any proper subgroup of S_3 is abelian). Overall, we get:

A_4	1	(1 2)(3 4)	(1 2 3)	(1 3 2)
χ_1	1	1	1	1
χ_2	1	1	ζ_3	ζ_3^3
χ_3	1	1	ζ_3^2	ζ_3
χ_5	3	-1	0	0

Finally, we will do the character table for S_5:

S_5	1	(1 2)	(1 2 3)	(1 2 3 4)	(1 2 3 4 5)	(1 2)(3 4)	(1 2)(3 4 5)
χ_1	1	1	1	1	1	1	1
χ_2	1	-1	1	-1	1	1	-1
χ_3	4	2	1	0	-1	0	-1
χ_4	4	-2	1	0	-1	0	1
χ_5	5	-1	-1	1	0	1	-1
χ_6	5	1	-1	-1	0	1	1
χ_7	6	0	0	0	1	-2	0

TBD

53.2.2 Burnside's Theorem

We now move towards Burnside's Theorem, which shows that any group of order $p^a q^b$ for primes p, q and numbers $a, b \in \mathbb{N}$ is a solvable group! This proof is relatively simple in the context of representation theory, but it took over 70 years before a proof was found using just group theory! This is a good example of the power perspective: simply switching to the context of representation theory and seeing groups as embedded into $GL(V)$ let us prove a claim that from another perspective is much much harder!

Lemma 53.2.23: Burnside build-up Lemma

Suppose that V is an irreducible representation is of dimensin n (i.e. $\chi_1(V) = n$). If $\gcd(n, |\text{conj}(g)|) = 1$, then:

$$|\chi_V(g)| = 0 \text{ or } n$$

***Proof*:**
By the above proof, we have:

$$\frac{\text{conj}(g)}{n}\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

where $\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$ as well, so by Bézout $(1 = am + b|\text{conj}(g)|)$

$$\frac{1}{n}\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

Let $\alpha = \frac{1}{n}\chi_V(g)$. Furthermore, notice that:

$$|\alpha| = \left|\frac{\chi_V(g)}{\chi_V(1)}\right| \leq 1$$

Now, let N be the Galois closure of $\mathbb{Q}(\alpha)/\mathbb{Q}$ so that $G = \text{Gal}(N/\mathbb{Q})$ is the glaois group of N. Let

$$\beta = \prod_{\sigma \in G} \sigma(\alpha)$$

Then certainly β is in the fixed field of the galois group, $\beta \in N^G = \mathbb{Q}$. Notice that each $\sigma(\alpha)$ satisfies the same monic polynomials as that of α, and so $\sigma(\alpha) \in \overline{\mathbb{Z}}^{\mathbb{C}}$, and so $\beta \in \overline{\mathbb{Z}}^{\mathbb{C}}$, but then $\beta \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} = \mathbb{Z}$.

Now, recall that:

$$\alpha = \frac{\chi_V(g)}{n} = \frac{\zeta_1 + \zeta_2 + ... + \zeta_n}{n}$$

which are roots of unity, which means that:

$$\sigma(\alpha) = \frac{\sigma(\zeta_1) + \cdots + \sigma(\zeta_n)}{n}$$

so $|\sigma(\zeta_1)| \leq 1$, so $|\beta| \leq 1$. Since β is an integer, we either get that $|\beta| \in \{0, 1\}$, If $|\beta| = 0$, then $\alpha = 0$, and if $|\beta| = 1$, then $|\alpha| = 1$, and so plugging back into our original equation we get that:

$$\chi_V \in \{0, n\}$$

as we sought to show.

We can also treat this lemma as another check that we have given the correct character table (verify it for the character table of S_4 we found in example 53.2.21).

Theorem 53.2.24: Burnside's Theorem

Let $p \neq q$ be prime numbers, $a, b \in \mathbb{N}$. If $|G| = p^a q^b$, then G is solvable.

Notice how this immedaitely implies that the smallest possible order of a non-abelian simple group is 30, since $30 = 2 \cdot 3 \cdot 5$, which matches with the fact that the smallest non-abelian group is A_5 which has order 60! Recall also that if $|G| = p^a$, then we would need that $a = 1$ (namely, any p-group has a non-trivial center)

***Proof*:**
Take the composition series:

$$1 = G_0 \trianglelefteq G_1 \trianglelefteq \cdots \trianglelefteq G_k = G$$

where G_i/G_{i-1}. Then we'll show that if G is simple, then G is *abelian*. For the sake of contradiction, suppos that G is non-abelian and simple with order $p^a q^b$ (where we may as well assume $a, b \in \mathbb{N}_{>0}$). Let $\chi_1, \chi_2, ..., \chi_r$ be the irreducible representation for the group G, and $\chi_1 = \chi_{\mathbb{1}}$. Let $Z_i = \{g \in G \mid |\chi_i(g)| = \chi_i(1),\ \forall i\}$. The condition in side doesn't happen so often, we can equivanelty say that $\rho_i(g)$ is a scalar by using the triangle inequality. Thus,

$$Z_i \trianglelefteq G$$

If $Z_i = G$, then G acts by scalars on V_i. But then every subspace of V_i is a subrepresentation, so the dimension of all the irreducible is 1. And so each character is of the form:

$$\chi_i : G \to \mathbb{C}^\times$$

Since G is simple, each each i is injective or trivial. If each i is injective, then G is abelian, a contradiction, and if it is trivial we get $i = 1$ (the trivial representation). Thus, it must be that:

$$Z_i = 1 \qquad \forall i > 1$$

Now, take the sylow q-subgroup Q: (notice we are using that $a, b > 0$)

$$1 \subsetneq Q \subsetneq G$$

So Q is a p-group, and so has a non-trivial center: $Z(Q) \neq 1$. Take $h \in Z(Q) \setminus \{e\}$. Hence $Q \leqslant C_G(h)$. , so $[G : C_G(h)] \big| [G : Q] = p^a$, where $[G : C_G(h)] = |\text{conj}(h)$. Now recall we've shown that:

$$\chi_1 \big| |G| = p^a q^b$$

Now, if $p \nmid \chi_i(1)$, then by the previous line we have that $\chi_1(1) \big| q^b$. So, $\gcd(\chi_i(1), |\text{conj}(h)) = 1$, and so by lemma 53.2.23

$$\chi_i(h) = 0 \qquad \text{or} \qquad \chi_i(1)$$

But if $|\chi_i(h)| = \chi_i(1)$, $h \in Z_i$, and so $i = 1$

So, if $p \nmid \chi_i(1)$ and $i > 0$, then $\chi_i(h) = 0$. Using this, we can get our contradiction: as h is not the trivial element, we get:

$$\begin{aligned} 0 &= \sum_i \overline{\chi_i(h)} \chi_i(1) \\ &= \sum_i \chi_i(h) \chi_i(1) \\ &\stackrel{!}{=} 1 + \sum_{\substack{i>1 \\ p \big| \chi_i(1)}} \underbrace{\chi_i(1)}_{\in p\mathbb{Z}} \underbrace{\chi_i(h)}_{\in \overline{\mathbb{Z}}^{\mathbb{C}}} \\ &= 1 + p\alpha && \text{some } \alpha \in \overline{\mathbb{Z}}^{\mathbb{C}} \end{aligned}$$

where the one in the $\stackrel{!}{=}$ equality came from when $i = 1$. Thus,

$$a = -1/p \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} = \mathbb{Z}$$

a contradiction, completing the proof.

(huge list of character tables: commented)

53.3 Induced Representation

This is another way of constructing representations. We saw that if $H \leqslant G$ and V is a G representation, then we can make V an H-representation through the inclusion map $H \hookrightarrow G \to \text{GL}(V)$. We may ask if we may go the other way: given an H representation W, can we find a G-representation? If φ is the representations afforded by H, can we find a Φ such that $\Phi|_H = \varphi$? It turns out we cannot: take $A_3 \subseteq S_3$ and consider a faithful representation of degree 1 (recall it's a cyclic group). Then notice that any 1 dimensional representations of S_3 will have to have A_3 in it's kernel, meaning we can't extend the action of A_3 to an action of S_3. A little more generally, if we let G be a simple group, $H \leqslant G$, and φ a representation of H where $\ker(\varphi)$ is a proper nontrivial subgroup of H, then if we somehow extend the representation φ of H to Φ of G, then $\ker(\Phi)$ would have a proper kernel too, contradicting that G is simple. So instead, we will not be extending representation from H to G, but *inducing* a representation in a natural way. This method of inducing a representation will work even in the two above cases, meaning an induced representation will not always be an extension.

Let $H \leqslant G$, and consider some H-representation V, which can be represented as a $k[H]$-module V.

Recall that we can "extend scalars" and define a new $k[G]$-module:

$$k[G] \otimes_{k[H]} V$$

This is (the outer tensor product for representatives, which I haven't talked about yet, but probably should have it here to motivate the idea)

Definition 53.3.1: Induced Representation

Let $H \leqslant G$ of a finite group G and let V be a $k[H]$-module affording the representation φ. Then the $k[G]$-module $k[G] \otimes_{k[H]} V$ is called the *induced module* of V, the representation is called the *induced representation*, and if χ is the character of φ, then the character of the induced representation is called the *induced character*, and is written as $\mathrm{Ind}_H^G(\psi)$.

Another intuition behind defining the induced module is the following: If W is an H-representation, then let our new module be:

$$\mathrm{Ind}_H^G(W) = \{f \in \mathrm{Hom}_{\mathbf{Set}}(G, W) \mid f(hg) = h \cdot f(g),\ \forall g \in G, h \in H\}$$

Then $\mathrm{Ind}_H^G(W)$ is clearly a complex vector space under pointwise addition and scalar multiplication, and the G-action on this space would be:

$$\gamma \cdot f : G \to W \qquad g \mapsto f(g\gamma)$$

It should be verified that this is indeed G-linear. In this case, we get that:

$$\mathrm{Ind}_H^G(W) = \mathrm{Hom}_{\mathbb{C}[H]}(\mathbb{C}[G], W)$$

where we may use a variant of lemma 53.2.12 to show that this is the same thing as we've just defined. It is also easy to see the dimension of $\mathrm{Ind}_H^G(W)$, namely:

$$\dim_{\mathbb{C}}(\mathrm{Ind}_H^G(W)) = [G : H] \dim_{\mathbb{C}}(W)$$

with the $\mathbb{C}$-vector space isomorphism being:

$$\mathrm{Ind}_H^G(W) \to W^{\oplus[G:H]} \qquad f \mapsto f(g_1), ..., f(g_{[G:H]})$$

where we treat $G = \coprod_i Hg_i$ for the cosets Hg_i. By letting $g_1 = e$ being the identity, there is a natural canonical map:

$$\mathrm{Ind}_H^G(W) \to W \qquad f \mapsto f(e)$$

This motivates the following adjoint of the restriction functor:

Theorem 53.3.2: Frobenius Reciprocity

Let $H \leqslant G$. Then if V is a G-representation and W and H-representation, then:

$$\mathrm{Hom}_G(V, \mathrm{Ind}_H^G W) \cong_{\mathbb{C}} \mathrm{Hom}_H(V|_H, W)$$

where $V|_H$ is the restriction of the action to H

***Proof*:**
We will explicitly construct inverse bijections Φ from left to right and Θ from right to left. Let $\alpha : \mathrm{Ind}_H^G(W) \to W$, $f \mapsto f(1)$. Then α is H-linear. Then let

$$\Phi(f) = \alpha \circ f$$

Then $\Phi(f)$ is H-linear (check $\mathbb{C}$-linearity of Φ). For the other way, let $\psi : V|_H \to W$ be H-linear,

$$\Theta(\psi) : V \to \mathrm{Ind}_H^G(W) \qquad v \mapsto (g \mapsto \psi(gv))$$

Then this is well-defined. What's left is to check they are inverses of each other

53.3.3 Left Vs Right Adjoint This proof shows that induction is right-adjoint to restriction. It can be shown to also be *left adjoint*. A pair of functors (F, G) where the functor F is both left and right adjoint to a functor G (and hence G is also right/left adjoint to F) is sometimes called a *Frobenius pairing*. The functor Ind is usually only right-adjoint to the restriction restriction functor when G is infinite (The *compact induction* functor is usually left-adjoint to the restriction functor, see [20]).

Corollary 53.3.4: Frobenius Reciprocity On Characters

Let $H \leqslant G$, χ be the character of a G representation and ψ a character of an H-representation. Then:

$$\langle \chi|_H, \psi \rangle_H = \langle \chi, \mathrm{Ind}_H^G(\psi) \rangle_G$$

***Proof*:**
https://unapologetic.wordpress.com/2010/12/03/dual-frobenius-reciprocity/

Example 53.3.5: Induced Representations

1. $\mathrm{Ind}_G^G(W) = W$
2. $\mathrm{Ind}_{\mathbb{1}}^G(\mathbb{C}) = \mathbb{C}[G]$
3. $\mathrm{Ind}_H^G(\mathbb{1}) = \mathbb{C}[G/H]$

Another way of thinking of this result is that if V is an irreducible representation of G and W is an irreducible representation of W, then the number of times W occurs in $\mathrm{Ind}_H^G(W)$ is equal to the number of times W occurs in $V|_H$.

Proposition 53.3.6: Properties Of Induced Representation

Let $K \leqslant H \leqslant G$, W be an K-representation, $\operatorname{Ind}_K^H(W)$ the induced H representation, $\operatorname{Ind}_H^G(\operatorname{Ind}_K^H(W))$ the induced G-representation. Then:

1. If χ, χ' are two characters of W,
$$\operatorname{Ind}_K^H(\chi + \chi') = \operatorname{Ind}_K^H(\chi) + \operatorname{Ind}_K^H(\chi')$$
2. Induction is transitive:
$$\operatorname{Ind}_H^G(\operatorname{Ind}_K^H(W)) = \operatorname{Ind}_K^G(W)$$

***Proof*:**

Theorem 53.3.7: Computing Induced Representation

Let $H \leqslant G$ of a finite group G, and $g_1, g_2, ..., g_m$ be representatives for distinct left cosets of H in G. Let V be an H-representation of degree n. Then the induced G-representation $W = k[G] \otimes_{k[H]} V$ is an nm degree representation, and if Φ repersented the induced representation, then there exists a basis for W such that W affords the matrix representation defined for each $g \in G$ by:
$$\Phi(g) = \begin{pmatrix} \varphi(g_1^{-1}gg_1) & \cdots & \varphi(g_1^{-1}gg_m) \\ \vdots & \vdots & \cdots \\ \varphi(g_m^{-1}gg_1) & \cdots & \varphi(g_m^{-1}gg_m) \end{pmatrix}$$
where each $\varphi(g_i^{-1}gg_j)$ is an $n \times n$ block, with $\varphi(g_i^{-1}gg_j) = 0$ if $g_i^{-1}gg_j \notin H$.

***Proof*:**
First, $k[G]$ is a free right $k[H]$-module with decomposition:
$$k[G] = g_1k[H] \oplus \cdots \oplus g_mk[H]$$
Since tensor products commute with direct sums, we get:
$$W = k[G] \otimes_{k[H]} V \cong (g_1 \otimes V) \oplus \cdots \oplus (g_m \otimes V)$$
Since k is in the center of $k[G]$, the above isomorphism is also a k-vector space isomorphism. Thus, if $v_1, v_2, ..., v_n$ is a basis for V, then $\{g_i \otimes v_j \mid 1 \leq i \leq m,\ 1 \leq j \leq m\}$ is a basis for W, and hence $\dim_k(W) = nm$.

To show $\Phi(g)$ is of the given form, order the basis into m of size n as:
$$g_1 \otimes v_1, g_1 \otimes v_2, ..., g_1 \otimes v_n, g_2 \otimes v_1, ..., g_m \otimes v_n$$
Using this order, we can compute the matrix $\varphi(g)$ for each g acting on W given this basis. Fixing j and g, let $g_j = g_ih$ for some index i and $h \in H$. Then for every k:
$$g(g_j \otimes v_k) = (gg_j \otimes v_k) = g_i \otimes v_k = \sum_{t=1}^{n} a_{tk}(h)(g_i \otimes v_t)$$

where a_{tk} is the t, k coefficient of the matrix h acting on V with respect to the basis $v_1, v_2, ..., v_n$. Notice that the action of g on W maps the jth block of n basis vectors of W to the ith block of basis vectors, and then has the matrix $\varphi(h)$ as that block. Since $h = g_i^{-1} g g_j$, this fully describes $\Phi(g)$, as we sought to show.

Corollary 53.3.8: Computing The Induced Character

Let $H \leqslant G$ where G is a finite group, V be an H-representation with character χ, and $\mathrm{Ind}_H^G(\chi)$ the induced character. Then:

$$\mathrm{Ind}_H^G(\chi) = \sum_{i=1}^{m} \chi(g_i^{-1} g g_i)$$

where $\chi(g_i^{-1} g g_i) := 0$ if $g_i^{-1} g g_i \notin H$. Hence, $\mathrm{Ind}_H^G(\chi)(g) = 0$ if g is not conjugate of some element in H in G, in particular if $H \trianglelefteq G$ then $\mathrm{Ind}_H^G(\chi)$ is zero on all elements $G - H$.

Proposition 53.3.9: Induced Index Two Induced Representation

Let $H \leqslant G$ where $[G : H]$ has index two[a] (ex. $A_n \leqslant S_n$ or $C_n \leqslant D_{2n}$). Then if V is a finite-dimensional irreducible representation of G, either $V|_H$ is irreducible or $V|_H = W_1 \oplus W_2$ where $W_1 \not\cong W_2$, are both ireducibile, and have the same dimension. Moreover, the second option implies that $V \cong V \otimes \chi$ where $\chi : G \twoheadrightarrow G/H \cong \{\pm 1\}$ (i.e. a 1-dimensional representation)

[a] Recall that this makes H a normal subgroup

In the case where $V|_H$ is not irreducible, we can imagine it splitting into a diagram like so:

$$\begin{tikzcd}
& W_1 \\
V \arrow[ur, dash] \arrow[dr, dash] & \\
& W_2
\end{tikzcd}$$

while in the case where $V|_H$ is irreducible, what we actually have (and didn't have time to prove), is that we have *two* irreducible representation's of G (V and V') that both get restricted to W:

$$\begin{tikzcd}
V \arrow[dr, dash] & \\
& W \\
V' \arrow[ur, dash] &
\end{tikzcd}$$

and then the induced representation of W is the direct sum of V and V'.

***Proof*:**
Let $W \subseteq V|_H$ be an irreducible H-representation. Then Since $H \trianglelefteq G$, gW is is an H-stable space: gW is some subspace of V (it satisfies the subspace axioms since the action is linear), and for any $h \in H$, $h \cdot gW = hgW = g'hW$ that is $gW = hg'h^{-1}W$, and since $hg'h^{-1} \in H$, we have that $h \cdot gW = gW$. Now, gW is irreducible: since W is irreducible and $\varphi_g(W) = gW$ is a G-linear isomorphism (with inverse$\varphi_{g^{-1}}(gW) = W$), gW is irreducible. Finally, the structure of gW only depends on that of the coset gH

Thus, fix $\gamma \in G \setminus H$ so that

$$\sum_{g \in G} gW = W + \gamma W \subseteq V$$

where the $\subseteq$ comes from the fact that this is a sum of two subspaces. Now, notice that the left hand side is a G-stable space, but V is irreducible meaning it does not have a G-stable subspace, and therefore, we actually have the equality:

$$W + \gamma W = V$$

meaning the $H + gH = G$ is parallelled in the action! We know have two possibilities: either $W = \gamma W$, and so $V|_H = W$, and we have $\dim V = \dim W$ (which is case (a)).

on the otherhand, if $W \neq \gamma W$, then $W \cap \gamma W = (0)$ (since they are both irrreducible), and so $V = W \oplus \gamma W$ (i.e. direct sum as H-representations), and so V is the direct sum of two irreducible H-representations.

Now, by Frobeinus reciprocity, we get:

$$\langle W, V|_H \rangle_H = \langle \mathrm{Ind}_H^G(W), V \rangle_G$$

Since W occurs in $V|_H$ by definition, we get that $1 \leq \langle W, V|_H \rangle_H$, while since V is irreducible, meaning by a dimension argument we get $\langle \mathrm{Ind}_H^G(W), V \rangle_G \leq 1$, and hence:

$$1 = \langle W, V|_H \rangle_H = \langle \mathrm{Ind}_H^G(W), V \rangle_G = 1$$

Thus, from the first one, we get that $W \ncong \gamma W$ (or else the left hand side would be equal to 2), and we must have $V = \mathrm{Ind}_H^G(W)$ (or else the right hand side would be equal to something greater than 1)

If part (b) holds, then

$$V \oplus \chi|_H \cong V|_H$$

and

$$V \cong \mathrm{Ind}_H^G(W) \cong V \oplus \chi$$

Conversely, if $V \cong V \oplus \chi$, then $\chi_V(g) = \chi_V(g)\chi(g)$ for all $g \in G$. Thus, by simple arithmetics we see that $\chi(g) = 0$ for all $g \notin H$. And so:

$$\|\chi_{V|_H}\|_H^2 = 2\|\chi_V\|_G^2$$

and so it is a direct sum of irreducibles, as we sought to show.

53.4 *Application to Harmonic Analysis

In this section, we take a brief moment to explore the representation of locally compact abelian groups, such as $\mathbb{R}$. This section will assume some understanding of topological groups, and is mainly to motivate for the reader the connection between the representation theory of this chapter with *Fourier analysis* and more broadly *Harmonic analysis*.

Every group G is always a topological group with the discrete topology (see appendix C.4). The group G is finite iff it is a compact discrete group. Many groups of interest are either compact (like the torus or compact lie groups), or locally compact (like the real line). The representation theory of these groups rely on the correct framing of the representation in the finite case. For the case of infinite dimension *non-abelian* groups, the build-up is a good deal too complicated for this expository section[4], however many of the major ideas for the abelian are simple enough to exposit, and even better naturally motivate the Fourier transform and abstract harmonic analysis through the lens of representation theory.

Let G be a finite abelian group so that all complex irreducible representations are 1-dimensional, and hence characters and necessarily a homomorphism. As G is finite, say $n = |G|$, then $\chi(g^n) = \chi(e) = 1$ for all $g \in G$, and so $\chi^n = \text{id}$, showing that $\chi : G \to \mathbb{C}^*$ restricts to a map $\chi : S^1$. This shows that all characters are *unitary representations*. All characters for a finite group are necessarily unitary representations, while for non-finite groups there can be non-unitary representations[5]. Such groups which have a (general) representation theory that doesn't generalize as well as infinite unitary representations (many representation are indecomposable but not irreducible, for the details see the companion Lie groups notes). Thus, for this sections we stick to maps to S^1 with the natural multiplication structure as the subgroup of $\mathbb{C}^*$: label this collection $\hat{G} = \text{Hom}_{\mathbf{Ab}}(G, S^1)$. As the codomain is a group, $\hom_{\mathbf{Ab}}(G, S^1)$ has a group structure given by point-wise multiplication.

Definition 53.4.1: Pontryagin Group

Let G be locally compact abelian group. Then the *Pontryagin dual* of G is the group:

$$\text{Hom}_{\text{Top}}(G, S^1)$$

with the operation being point-wise multiplication.

This is just another way of representing the characters of the group. Let us stick to the special case where G is a finite abelian group and re-frame the previous theory using the Pontryagin group:

[4] see [26] for the EYNTKA series on geometric representation theory

[5] $\text{SL}_2(\mathbb{R})$ acting on $\mathbb{R}^2$ need not be unitary

Proposition 53.4.2: Pontryagin Dual

Let G be a finite abelian group, $\hat{G} = \mathrm{Hom}_{\mathbf{Ab}}(G, S^1)$ the group of characters under point-wise multiplication. Then there is an isomorphism:

$$G \cong \widehat{G}$$

Furthermore, there is a natural isomorphism:

$$G \cong \hat{\hat{G}}$$

If G is infinite, it is rarely the case that $G \cong \widehat{G}$ (think $\widehat{L^p} \cong L^q$). Even when G is compact this G need not be isomorphic to $\widehat{G}$. What is most important is that $\widehat{G}$ contains the necessary information to recover G, as the double-dual recovers G. We can think of $\widehat{(-)}$ as an operation that goes back and forth from a group to a unitary representation, and as we are working with unitary representations this collection also forms a group[6]. We can thus imagine going back and forth between these two:

$$\text{Group} \overset{\widehat{(-)}}{\rightleftarrows} \text{Unitary Rep.}$$

***Proof*:**
As G is finite abelian,

$$G \cong \mathbb{Z}/n_1\mathbb{Z} \times \mathbb{Z}/n_2\mathbb{Z}/ \times \cdots \times \mathbb{Z}/n_k\mathbb{Z}$$

where $n_1 \big| n_2 \big| \cdots \big| n_k$. Choose generators, $a_1, ..., a_k$. Define the indicator characters on the generators:

$$\chi_i(a_j) = \begin{cases} e^{\frac{2\pi i}{n_i}} & i = j \\ 1 & i \neq j \end{cases}$$

These certainly generate $\hat{G}$. Define the map on the generators:

$$\Phi(a_i) = \chi_i$$

This is an isomorphism.

For the double-dual, take the natural map:

$$\Phi(g_i) = \mathrm{ev}_{g_i}$$

where as usual $\mathrm{ev}_{g_i}(\chi) = \chi(g_i)$. This is easy to check that is an isomorphism, completing the proof.

Now, when studying spaces we study all (continuous) functions on a space. In our case, our space is finite abelian groups. Let G have the discrete topology so that the set of continuous functions from G to $\mathbb{C}$ is all set functions. We want a $\mathbb{C}$-algebra isomorphism between $\mathbb{C}[G]$ and $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$.

[6] the collection of representations also form a ring called the *representation ring* and has fascinating ties to K-theory and intersection theory, but it is again too much for this section and the connections are discussed in [5, Part II] of the EYTNKA series

These two sets are clearly bijective via the natural mapping:

$$\sum_i a_i g_i \mapsto (g_i \mapsto a_i)$$

And this map preserves addition if addition is defined point-wise in the hom-set:

$$\begin{aligned}
&\Phi\left(\sum_i a_i g_i + \sum_i b_i g_i\right)\\
&= \Phi\left(\sum_i (a_i + b_i) g_i\right)\\
&\mapsto (g_i \mapsto a_i + b_i)\\
&= (g_i \mapsto a_i) + (g_i \mapsto b_i)\\
&= \Phi\left(\sum_i a_i g_i\right) + \Phi\left(\sum_i b_i g_i\right)
\end{aligned}$$

But it does *not* preserve multiplication if the operation is pointwise multiplication:

$$\begin{aligned}
&\Phi\left(\sum_{g\in G} a_i g \sum_{g\in G} b_i g\right)\\
&= \Phi\left(\sum_{g\in G} \sum_{g_k g_\ell = g} (a_k b_\ell) g\right)\\
&\mapsto (g_i \mapsto \sum_{g_k g_\ell = g_i} (a_k b_\ell))\\
&\neq (g_i \mapsto a_i b_i)\\
&\neq (g_i \mapsto a_i) \cdot (g_i \mapsto b_i)\\
&= \Phi\left(\sum_i a_i g_i\right) \cdot \Phi\left(\sum_i b_i g_i\right)
\end{aligned}$$

This is because the points g_i act on each other. There is a natural multiplication function defined on $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ called *convolution*:

Definition 53.4.3: Convolution

Let $p, q \in \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$. Then their *convolution* is define pointwise as:

$$(p * q)(g) = \sum_{g_i g_j = g} p(g_i) q(g_j) = \sum_{h \in G} p(h) q(h^{-1} g)$$

Lemma 53.4.4: Isomorphism With Convolution

Let G be a finite abelian group. Then:

$$(\mathbb{C}[G], +, \cdot) \cong_{k\text{-}\mathbf{Alg}} (\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$$

where the left hand side is the usual group ring and the right hand side has convolution as multiplication

***Proof*:**
refer to the above calculations.

Now, $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$ is a $|G|$-dimensional $\mathbb{C}$ vector-space with the natural basis given by the indicator function:

$$\delta_h(g) = \begin{cases} 1 & g = h \\ 0 & g \neq h \end{cases}$$

Namely for any $f : G \to \mathbb{C}$ there is a unique decomposition given the functionals defined by each $g \in G$:

$$f = \sum_{h \in G} f(h)\delta_h \qquad \text{so that} \qquad f(g) = \sum_{h \in G} f(h)\delta_h(g) = f(g) \cdot 1 = f(g)$$

The key feature of this basis is that it acts like evaluation when taking the inner product. Define:

$$\langle f, g \rangle = \sum_{h \in G} f(h)\overline{g(h)}$$

Then $\{\delta_g\}_{g \in G}$ is an orthogonal basis and:

$$\langle f, \delta_{g_i} \rangle = f(g_i) \cdot \overline{\delta_{g_i}(g_i)} = f(g_i) \cdot 1 = f(g_i) = a_i$$

This is a special case of the Riesz representation theorem: every linear functional here is inner-product representable using these δ_{g_i}. This inner product can be thought as expressly chosen so that the collection δ_{g_i} forms an orthonormal basis, or conversely given this standard inner product, the indicator function will always be an orthonormal basis. By Pontryagin duality, $G \cong \hat{G}$, but this group isomorphism does not *a-priori* preserve the orthogonality of the basis given by G. The key insight of Fourier analysis is that it does!

Proposition 53.4.5: Character Form Orthogonal Basis: Fourier Basis

The characters $\widehat{G}$ form an orthogonal basis for $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$. Normalizing by $1/\sqrt{|G|}$ forms an orthonormal basis.

***Proof*:**
If $i = j$:

$$\begin{aligned}\langle \chi_i, \chi_i \rangle &= \sum_{g \in G} \chi_i(g)\overline{\chi_i(g)} \\ &= \sum_{g \in G} |\chi_i(g)|^2 \\ &= \sum_{g \in G} 1^2 \\ &= |G|\end{aligned}$$

if $i \neq j$, Then as $\overline{\chi_j} = \chi_j^{-1}$ (as we are mapping to the unit circle), we get that $\chi' = \chi_i \chi_j^{-1}$ is a non-trivial character, so there is some h such that $\chi'(h) \neq 1$. Let

$$\langle \chi_i, \chi_j \rangle = S = \sum_{g \in G} \chi'(g)$$

Then:

$$\chi'(h)S = \chi'(h) \sum_{g \in G} \chi'(g) = \sum_{g \in G} \chi'(h)\chi'(g) = \sum_{g \in G} \chi'(h + g)$$

As $h + G = G$, this is just a re-arranging of terms, hence:

$$\chi'(h)S = \sum_{g \in G} \chi'(g) = S \qquad \text{so} \qquad S(\chi'(h) - 1) = 0$$

Now, by assumption $\chi'(h) \neq 1$, so $\chi'(h) - 1 \neq 0$, so as $\mathbb{C}$ is an integral domain it must be that $S = 0$, implying:

$$\langle \chi_i, \chi_j \rangle = 0$$

as we sought to show.

This inner product can be thought of as extracting the "phase" information.

Example 53.4.6: Phase-Space Basis
Let $G = \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z} = \{(0,0), (1,0), (0,1), (1,1)\}$. A character $\chi : G \to \mathbb{C}^*$ is determined by its values on the generators $g_1 = (1,0)$ and $g_2 = (0,1)$. Since both generators have order 2, we must have $\chi(g_1)^2 = \chi(g_1^2) = \chi(0,0) = 1$ and likewise for g_2. Thus, the character's values on the generators must be either 1 or -1. This gives $2 \times 2 = 4$ possible characters, which we can index by pairs $(k_1, k_2) \in \{0,1\}^2$.

The four characters χ_{k_1,k_2} are defined by their values on the generators:

$$\chi_{k_1,k_2}(1,0) = (-1)^{k_1} \qquad \text{and} \qquad \chi_{k_1,k_2}(0,1) = (-1)^{k_2}$$

From this, the value for any element $(a,b) \in G$ is $\chi_{k_1,k_2}(a,b) = (-1)^{k_1 a + k_2 b}$.

This gives the following character table, which explicitly lists the functions that form our new "basis":

$\hat{G}$	**(0,0)**	**(1,0)**	**(0,1)**	**(1,1)**
χ_{00}	1	1	1	1
χ_{10}	1	-1	1	-1
χ_{01}	1	1	-1	-1
χ_{11}	1	-1	-1	1

We can verify the orthogonality relation from proposition 53.4.5 directly. Let us compute $\langle \chi_{10}, \chi_{11} \rangle$:

$$\begin{aligned}\langle \chi_{10}, \chi_{11} \rangle &= \sum_{g \in G} \chi_{10}(g)\overline{\chi_{11}(g)} \\ &= \chi_{10}(0,0)\chi_{11}(0,0) + \chi_{10}(1,0)\chi_{11}(1,0) + \chi_{10}(0,1)\chi_{11}(0,1) + \chi_{10}(1,1)\chi_{11}(1,1) \\ &= (1)(1) + (-1)(-1) + (1)(-1) + (-1)(1) \\ &= 1 + 1 - 1 - 1 = 0\end{aligned}$$

Using the above example, let us change perspectives on how to interpret this change of basis. The function $f : G \to \mathbb{C}$ takes the "points" $g \in G$ and maps them (continuously) to the complex numbers, and those points are evaluated by the Riesz representation of f against the indicator functions that form an orthonormal basis. But we have just found another orthonormal basis for $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ against which we can take the inner product. We may thus think of the characters $\chi \in \hat{G}$ as points in their own right: points carrying "phase" information rather than the "location" information that the indicator functions carry. This motivates the following definition:

Definition 53.4.7: Fourier Transform (Gelfand Transform)

Let G be a finite abelian group with the discrete topology. Then the *Fourier transform* is:

$$\widehat{(-)} : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \mapsto \mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C}) \qquad f \mapsto (\chi \mapsto \langle f, \chi \rangle)$$

where the image of f is often written as:

$$\hat{f}(\chi) = \langle f, \chi \rangle = \sum_{g \in G} f(g)\overline{\chi(g)}$$

The name *Gelfand transform* comes from the fact that the Fourier transform is traditionally about real periodic functions, or Legesgue measurable functions. It wasn't until later where mathematicians like Folland and Gelfand generalized it to the context of locally compact abelian groups, where the above is the special case where G is finite.

Now, certainly as vector spaces $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \cong_{\mathbb{C}} \mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C})$ mapping:

$$(g \mapsto \langle f, \delta_g \rangle) \mapsto (\chi \mapsto \langle f, \chi \rangle)$$

But does this map preserve the inner product, and more so can the convolution product of $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ be preserved given the appropriate choice of product on $\mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C})$? The answer is yes, and can be thought of as the corner-stone result of harmonic analysis on discrete abelian groups:

Theorem 53.4.8: Fourier Reciprocity

The map given in definition 53.4.7 is a unitary $\mathbb{C}$-algebra isomorphism,

$$(\mathrm{Hom}_{\mathbf{Top}}(G,\mathbb{C}),+,*) \cong (\mathrm{Hom}_{\mathbf{Top}}(\hat{G},\mathbb{C}),+,\cdot)$$

with $\cdot$ in $(\mathrm{Hom}_{\mathbf{Top}}(\hat{G},\mathbb{C}),+,\cdot)$ being point-wise multiplication.

Recall that unitary means $\langle \hat{f},\hat{g}\rangle = \langle f,g\rangle$. In a conventional real analysis course:

- the $\mathbb{C}$-algebra homomorphism is called the *Convolution Theorem*,
- the unitary property is called *Plancherel's Theorem*,
- invertibility (i.e. bijectivity) is called the *Fourier Inversion Theorem*.

***Proof*:**

1. *1. Linearity:* Let $f,h \in \mathrm{Hom}_{\mathbf{Top}}(G,\mathbb{C})$ and $a,b\in\mathbb{C}$.

$$\begin{aligned}
\widehat{af+bh}(\chi) &= \langle af+bh,\chi\rangle && \text{by definition}\\
&= \sum_{g\in G}(af+bh)(g)\overline{\chi(g)}\\
&= a\sum_{g\in G} f(g)\overline{\chi(g)} + b\sum_{g\in G} h(g)\overline{\chi(g)} && \text{by linearity of sums}\\
&= a\langle f,\chi\rangle + b\langle h,\chi\rangle\\
&= a\hat{f}(\chi)+b\hat{h}(\chi)
\end{aligned}$$

Since this holds for all $\chi\in\hat{G}$, the transform is a linear map.

2. $\mathbb{C}$-algebra Homomorphism (The Convolution Theorem): We must show that the Fourier transform converts convolution into pointwise multiplication.

$$\begin{aligned}
\widehat{f*h}(\chi) &= \langle f*h,\chi\rangle\\
&= \sum_{k\in G}(f*h)(k)\overline{\chi(k)} && \text{by definition of inner product}\\
&= \sum_{k\in G}\left(\sum_{g\in G} f(g)h(g^{-1}k)\right)\overline{\chi(k)} && \text{by definition of convolution}\\
&= \sum_{g\in G} f(g)\sum_{k\in G} h(g^{-1}k)\overline{\chi(k)} && \text{swapping order of summation}
\end{aligned}$$

Let $\ell = g^{-1}k$, so $k=g\ell$. As k runs over G, so does ℓ. The inner sum becomes:

$$\sum_{\ell\in G} h(\ell)\overline{\chi(g\ell)} = \sum_{\ell\in G} h(\ell)\overline{\chi(g)\chi(\ell)} = \overline{\chi(g)}\sum_{\ell\in G} h(\ell)\overline{\chi(\ell)} = \overline{\chi(g)}\hat{h}(\chi)$$

Substituting this back into the main expression:

$$\begin{aligned}\widehat{f*h}(\chi) &= \sum_{g\in G} f(g)\left(\overline{\chi(g)}\hat{h}(\chi)\right)\\ &= \hat{h}(\chi)\sum_{g\in G} f(g)\overline{\chi(g)}\\ &= \hat{h}(\chi)\hat{f}(\chi)\end{aligned}$$

Thus, $\widehat{f*h} = \hat{f}\cdot\hat{h}$, proving the map is an algebra homomorphism.

3. Isomorphism (The Fourier Inversion Theorem): We show the map is invertible by constructing its inverse. Let $\mathcal{F}(f) = \hat{f}$. We claim the inverse is given by $\mathcal{F}^{-1}(\hat{f})(g) = \frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi(g)$.

$$\begin{aligned}\frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi(g) &= \frac{1}{|G|}\sum_{\chi\in\hat{G}}\left(\sum_{h\in G} f(h)\overline{\chi(h)}\right)\chi(g) && \text{by definition of } \hat{f}\\ &= \frac{1}{|G|}\sum_{h\in G} f(h)\sum_{\chi\in\hat{G}}\chi(g)\overline{\chi(h)} && \text{swapping order of summation}\\ &= \frac{1}{|G|}\sum_{h\in G} f(h)\sum_{\chi\in\hat{G}}\chi(gh^{-1})\end{aligned}$$

The inner sum is an example of the *Second Orthogonality Relation* and is a standard exercise the reader should do. In particular, the sum of all characters evaluated at a group element (giving all powers of a certain root of unity) is $|G|$ if $x = e$ and 0 otherwise. Thus $\sum_{\chi\in\hat{G}}\chi(gh^{-1}) = |G|\delta_{g,h}$.

$$\frac{1}{|G|}\sum_{h\in G} f(h)(|G|\delta_{g,h}) = \sum_{h\in G} f(h)\delta_{g,h} = f(g)$$

Since we can recover f uniquely from $\hat{f}$, the map is an isomorphism.

4. Unitary Property (Plancherel's Theorem): Note that here is where it is important for the inner product to be normalized. Let us calculate the inner product for the given definition.

$$\begin{aligned}
\langle \hat{f}, \hat{h} \rangle_{\hat{G}} &= \sum_{\chi \in \hat{G}} \hat{f}(\chi)\overline{\hat{h}(\chi)} \\
&= \sum_{\chi \in \hat{G}} \left(\sum_{g \in G} f(g)\overline{\chi(g)} \right) \overline{\left(\sum_{k \in G} h(k)\overline{\chi(k)} \right)} \\
&= \sum_{\chi \in \hat{G}} \left(\sum_{g \in G} f(g)\overline{\chi(g)} \right) \left(\sum_{k \in G} \overline{h(k)}\chi(k) \right) \\
&= \sum_{g \in G} \sum_{k \in G} f(g)\overline{h(k)} \sum_{\chi \in \hat{G}} \chi(k)\overline{\chi(g)} && \text{re-arranging terms} \\
&= \sum_{g \in G} \sum_{k \in G} f(g)\overline{h(k)}(|G|\delta_{g,k}) && \text{by Second Orthogonality} \\
&= |G| \sum_{g \in G} f(g)\overline{h(g)} \\
&= |G|\langle f, h \rangle_G
\end{aligned}$$

This proves *Plancherel's Theorem.* To make the map strictly unitary, one must normalize the transform. If we define the unitary transform $\mathcal{U}(f) = \frac{1}{\sqrt{|G|}}\hat{f}$, then it follows immediately that $\langle \mathcal{U}(f), \mathcal{U}(h) \rangle = \langle f, h \rangle$, completing the proof.

Example 53.4.9: Fourier Transform

Take $G = \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ form example 53.4.6. Let us now compute the Fourier transform of a concrete function. Let $f = \delta_{(1,0)}$, so that $f(1,0) = 1$ and is zero elsewhere. This is a basis vector in the standard "position" basis. We find its coordinates in the character basis by computing $\hat{f}(\chi) = \langle f, \chi \rangle$ for each character.

$$\begin{aligned}
\hat{f}(\chi) = \langle \delta_{(1,0)}, \chi \rangle &= \sum_{g \in G} \delta_{(1,0)}(g)\overline{\chi(g)} \\
&= 1 \cdot \overline{\chi(1,0)} + 0 + 0 + 0 = \chi(1,0)
\end{aligned}$$

Using the character table, we can compute this value for each χ:

- $\hat{f}(\chi_{00}) = \chi_{00}(1,0) = 1$
- $\hat{f}(\chi_{10}) = \chi_{10}(1,0) = -1$
- $\hat{f}(\chi_{01}) = \chi_{01}(1,0) = 1$
- $\hat{f}(\chi_{11}) = \chi_{11}(1,0) = -1$

Thus, the original function $f = \delta_{(1,0)}$, which is a spike at one point in the "position" basis, has been transformed into a new function $\hat{f}$ on $\hat{G}$ with values $(1, -1, 1, -1)$.

Recall the inversion formula from the proof of theorem 53.4.8: $f(g) = \frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi(g)$ (here $|G| = 4$). Let's check the value at $g = (1, 0)$:

$$\begin{aligned}
f(1,0) &= \frac{1}{4}\left(\hat{f}(\chi_{00})\chi_{00}(1,0) + \hat{f}(\chi_{10})\chi_{10}(1,0) + \hat{f}(\chi_{01})\chi_{01}(1,0) + \hat{f}(\chi_{11})\chi_{11}(1,0)\right)\\
&= \frac{1}{4}\left((1)(1) + (-1)(-1) + (1)(1) + (-1)(-1)\right)\\
&= \frac{1}{4}(1+1+1+1) = 1
\end{aligned}$$

Now let's check the value at $g = (0, 1)$, where we expect 0:

$$\begin{aligned}
f(0,1) &= \frac{1}{4}\left(\hat{f}(\chi_{00})\chi_{00}(0,1) + \hat{f}(\chi_{10})\chi_{10}(0,1) + \hat{f}(\chi_{01})\chi_{01}(0,1) + \hat{f}(\chi_{11})\chi_{11}(0,1)\right)\\
&= \frac{1}{4}\left((1)(1) + (-1)(1) + (1)(-1) + (-1)(-1)\right)\\
&= \frac{1}{4}(1-1-1+1) = 0
\end{aligned}$$

Let us now connect this to Representation Theory. So far, we have established that for a finite abelian group G, the Fourier transform is a unitary $\mathbb{C}$-algebra isomorphism between the algebra of functions on G with convolution, $(\mathrm{Hom}_{\mathbf{Top}}(G,\mathbb{C}), *)$, and the algebra of functions on the dual group $\hat{G}$ with pointwise multiplication. The representation theory perspective shows that Fourier analysis is the simplest case of a Artin-Wedderburn decomposition. The key is to view the $\mathbb{C}$-group algebra $\mathbb{C}[G]$ with the natural G-action given by left multiplication (convolution), namely $\rho : G \to \mathrm{GL}(\mathbb{C}[G])$ given by:

$$\rho(g) : f \mapsto g * f$$

From this viewpoint, the study of the $\mathbb{C}$-algebra $(\mathbb{C}[G], +, *)$ and the $\mathbb{C}[G]$-module $\mathbb{C}[G]$ is the same thing that is the study of the regular representation of G. Now, this representation can be broken down into the direct sum of 1-dimensional irreducible representations. Namely, for a finite abelian group, the set of irreducible representations is exactly the dual group: $\mathrm{Irr}(G) = \widehat{G}$ and so we get:

$$\mathbb{C}[G] \cong \bigoplus_{\chi\in\widehat{G}} V_\chi$$

where each V_χ is a 1-dimensional subspace corresponding to the character χ.

This decomposition is made concrete by the Fourier transform. The Fourier Inversion Formula, $f = \frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi$, is the literal expression of this decomposition. It writes the function f as a sum of components, where each term $\hat{f}(\chi)\chi$ is the projection of f onto the 1-dimensional irreducible subspace V_χ. Then the fourier coefficient $\hat{f}(\chi)$ is the coordinate of f in the irreducible component corresponding to χ.

Note that we can define projection functions $p_\chi = \frac{1}{|G|}\sum_{g\in G}\overline{\chi(g)}g$ that we can construct in $\mathbb{C}[G]$ that project onto the irreducible subspace V_χ. Convolving any function f with p_χ annihilates all other "frequency components", leaving the part of f that lies in V_χ.

Hence, the Fourier basis *the* unique basis that diagonalizes the natural action of the group on its own algebra of functions.

If G is a *non-abelian* finite group, the concept of a dual group $\hat{G}$ and a simple transform onto it ceases to be useful (it is now a set with no natural group structure). However, the representation theory perspective remains: the generalized Fourier transform (given by the *Peter-Weyl Theorem*) decomposes a function f on the group into a sum of *matrix coefficients* corresponding to these higher-dimensional matrix representations.

53.4.1 Generalization to Locally Compact Abelian Groups

What happens when we wish to analyze functions on abelian groups like $(\mathbb{R}, +)$, $(\mathbb{Z}, +)$, or the circle group $(S^1, \cdot)$? These are examples of *Locally Compact Abelian (LCA)* groups. Moving from the finite to the infinite setting requires us to replace our finite sums with integrals, but to integrate on an arbitrary group, we first need a notion of "volume" or "measure". The shape of the answer is already visible in the finite case: read the delta functions δ_h as *measures*, and every f becomes a sum of weighted point masses. What we want, then, is a measure on the group that the group operation cannot see. The essential new ingredient is the *Haar measure*. For any LCA group G, there exists a measure μ that gives a consistent way to integrate functions on the group.

Definition 53.4.10: Haar Measure

A *Haar measure* on an LCA group G is a measure μ on the Borel σ-algebra of G that is left-translation-invariant. That is, for any measurable set $E \subseteq G$ and any element $g \in G$:

$$\mu(gE) = \mu(E)$$

This measure is unique up to a positive scaling constant. For abelian groups, it is also right-translation-invariant.

See [22] for details on how to construct such a measure on any LCA that is unique up to scaling. This measure is the direct generalization of taking the order of the group.

Example 53.4.11: Haar Measure

1. For a finite group with the discrete topology, the Haar measure is the counting measure, and $\mu(G) = |G|$.
2. For $(\mathbb{R}, +)$, the Haar measure is the standard Lebesgue measure dx.
3. For $(S^1, \cdot)$, the Haar measure can be taken as $d\theta$.
4. For $(\mathbb{Z}, +)$, the Haar measure is again the counting measure.

Note that in the infinite case we can no longer represent points by indicator functions; the *Dirac delta distributions* take on that role instead. See [42] for the theory of distributions.

With the Haar measure, we can redefine our main objects of study by replacing every sum over G with an integral with respect to $d\mu$.

1. *The Group Algebra $L^1(G)$:* The space of all functions becomes too large. The natural replacement for the convolution algebra $\mathbb{C}[G]$ is the space of absolutely integrable functions, $L^1(G, d\mu)$. For

two functions $f, h \in L^1(G)$, their convolution is defined by the integral:

$$(f * h)(g) = \int_G f(x)h(x^{-1}g)d\mu(x)$$

This space $(L^1(G), +, *)$ forms a Banach algebra.

2. *The Dual Group $\widehat{G}$:* It was proven that the correct codomain should be S^1. The dual group is the set of all *continuous* group homomorphisms into S^1.

$$\widehat{G} = \mathrm{Hom}_{\mathbf{Top}}(G, S^1)$$

The dual group $\widehat{G}$ is itself an LCA group. It is crucial to note that, unlike the finite case, it is rarely true that $G \cong \widehat{G}$. For example:

$$\widehat{\mathbb{R}} \cong \mathbb{R}, \qquad \widehat{\mathbb{Z}} \cong S^1, \qquad \widehat{S^1} \cong \mathbb{Z}$$

This highlights why it is essential to treat $\hat{G}$ as a distinct space. The theory that governs this relationship is *Pontryagin Duality*, which states that the double-dual is canonically isomorphic to the original group: $\widehat{\widehat{G}} \cong G$.

3. *The Fourier Transform:* The definition of the Fourier transform is the direct analogue of the finite case, replacing the sum with an integral. For a function $f \in L^1(G) \cap L^2(G)$, its Fourier transform is a function $\hat{f}$ on the dual group $\hat{G}$:

$$\hat{f}(\chi) = \int_G f(g)\overline{\chi(g)}d\mu(g)$$

Similarly, the inner product that defines the Hilbert space structure on $L^2(G)$ is:

$$\langle f, h \rangle = \int_G f(g)\overline{h(g)}d\mu(g)$$

With these definitions, the entire suite of theorems proven in the finite case carries over:

Theorem 53.4.12: Fourier Reciprocity on LCA Groups

Let G be an LCA group with Haar measure μ. Then there exists a unique Haar measure ν on the dual group $\widehat{G}$ such that the Fourier transform, appropriately normalized, is a unitary $\mathbb{C}$-algebra isomorphism. The main results are:

1. *The Fourier Inversion Theorem:* For a sufficiently well-behaved function f (e.g., $f \in L^1 \cap L^2$ such that $\hat{f} \in L^1$), the original function can be recovered by an integral over the dual group:
$$f(g) = \int_{\widehat{G}} \hat{f}(\chi)\chi(g)d\nu(\chi)$$
2. *Plancherel's Theorem:* The Fourier transform extends uniquely from $L^1 \cap L^2$ to a unitary isomorphism of Hilbert spaces, $\mathcal{F} : L^2(G, \mu) \to L^2(\widehat{G}, \nu)$. This means it preserves the inner product:
$$\langle \hat{f}, \hat{h} \rangle_{L^2(\widehat{G})} = \langle f, h \rangle_{L^2(G)}$$
3. *The Convolution Theorem:* For $f, h \in L^1(G)$, the Fourier transform maps convolution to pointwise multiplication:
$$\widehat{f * h}(\chi) = \hat{f}(\chi) \cdot \hat{h}(\chi)$$

***Proof*:**
This is the Pontryagin duality theorem; a full proof via the Gelfand transform belongs to the harmonic analysis of locally compact abelian groups and is not reproduced in this starred section.

The correspondence between the finite and general LCA settings can be summarized as follows:

Finite Abelian Case	**LCA Case**
Group G	LCA Group G
Order $\lvert G\rvert$	Haar Measure μ
Group Algebra $\mathbb{C}[G]$	Banach Algebra $L^1(G, \mu)$
Hilbert Space $\mathrm{Hom}(G, \mathbb{C})$	Hilbert Space $L^2(G, \mu)$
Summation $\sum_{g \in G}$	Integration $\int_G d\mu(g)$
Dual Group $\widehat{G} = \mathrm{Hom}(G, \mathbb{C}^\times)$	Dual Group $\widehat{G} = \mathrm{Hom}_{\mathbf{Top}}(G, S^1)$
Inner Product $\sum f(g)\overline{h(g)}$	Inner Product $\int f(g)\overline{h(g)}d\mu(g)$
Fourier Transform $\sum f(g)\overline{\chi(g)}$	Fourier Transform $\int f(g)\overline{\chi(g)}d\mu(g)$

53.4.2 The Algebraic-Geometric Meaning of the Dual Group

In algebraic geometry, a fundamental principle is that the geometry of a space can be recovered from its algebra of functions. For an affine space k^n, the corresponding algebra is the polynomial ring $k[x_1, \dots, x_n]$. The points of the space correspond to the maximal ideals of this algebra. Specifically, for any point $p = (a_1, \dots, a_n) \in k^n$, the evaluation map:
$$\mathrm{ev}_p : k[x_1, \dots, x_n] \to k \qquad f \mapsto f(p)$$

is an algebra homomorphism whose kernel, $m_p = (x_1 - a_1, \ldots, x_n - a_n)$, is a maximal ideal. The quotient $k[x_1, \ldots, x_n]/m_p \cong k$ recovers the value of the function at that point.

We have established a similar setup for a finite abelian group G, with the convolution algebra $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), *, +)$ taking the role of the function algebra. A natural question arises: can we recover the "points" of our space from the maximal ideals of this algebra? Let's first attempt a direct analogy. We might assume the points are the elements of the group G itself. For a point $g_i \in G$, we can define the point-evaluation map, which is a linear map:

$$\mathrm{ev}_{g_i} : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \to \mathbb{C} \qquad f \mapsto f(g_i)$$

The kernel of this map is the vector subspace of functions that are zero at g_i. However, for this subspace to be an ideal, it must be closed under convolution. Let $f \in \ker(\mathrm{ev}_{g_i})$ (so $f(g_i) = 0$) and let h be any function in our algebra. Consider their convolution:

$$(h * f)(g_i) = \sum_{k \in G} h(k) f(k^{-1} g_i)$$

Just because $f(g_i) = 0$ does not imply that the sum on the right-hand side is zero. The value of f at other points, $f(k^{-1} g_i)$, can be non-zero. Therefore, the kernel of the point-evaluation map is *not* an ideal with respect to convolution. This implies the points of G do not correspond to the maximal ideals of its convolution algebra.

The key insight is that the correct "geometric points" for the convolution algebra are not the elements of G, but the characters of the dual group $\widehat{G}$.

Proposition 53.4.13: Characters and Maximal Ideals

Let G be a finite abelian group. The maximal ideals of the convolution algebra $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$ are in bijective correspondence with the characters $\chi \in \widehat{G}$.

***Proof*:**

For each character $\chi \in \widehat{G}$, define a Fourier evaluation map:

$$\widehat{\mathrm{ev}}_\chi : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \to \mathbb{C} \qquad f \mapsto \hat{f}(\chi)$$

This map takes a function and returns its Fourier coefficient at the frequency χ. By 53.4.8 $\widehat{\mathrm{ev}}_\chi$ is a $\mathbb{C}$-algebra homomorphism. Since $\widehat{\mathrm{ev}}_\chi$ is a surjective algebra homomorphism onto a field ($\mathbb{C}$), its kernel, which we denote by I_χ, is a maximal ideal:

$$I_\chi = \ker(\widehat{\mathrm{ev}}_\chi) = \{f \in \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \big| \hat{f}(\chi) = 0\}$$

By the First Isomorphism Theorem for rings, we have:

$$\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})/I_\chi \cong \mathbb{C}$$

This shows that every character $\chi \in \widehat{G}$ defines a maximal ideal. Conversely, After applying the Fourier transform we get the usual multiplication and ring structure, and then an approach similar to the Gelfand-Kolmogorov theorem gives the desired result.

For the infinite case, the maximal ideals of the Banach algebra $L^1(G, \mu)$ arise in this same way from homomorphisms into $\mathbb{C}$ (see the *Gelfand-Mazur Theorem*).

Thus, with the convolution algebra $\mathbb{C}[G]$ as our primary object, the natural geometric space that emerges is not the group G itself, but its Pontryagin dual, $\widehat{G}$. The Fourier transform is the mechanism that allows us to evaluate the functions of our algebra at the points of this "true" underlying space. This perspective, generalized by Gelfand, is the foundation of non-commutative geometry.

Concepts	**Classical Algebraic Geometry**
Algebra	Polynomial Ring $(k[x_1, \ldots, x_n], \cdot)$
Product	Polynomial Multiplication
Geometric Space	Affine Space k^n
A "Point" p	A tuple $(a_1, \ldots, a_n) \in k^n$
Evaluation Map	$\mathrm{ev}_p : f \mapsto f(p)$
Maximal Ideal for p	$\ker(\mathrm{ev}_p) = (x_i - a_i)$

Concepts	**Harmonic Analysis on G**
Algebra	Group Algebra $(\mathbb{C}[G], *)$
Product	Convolution
Geometric Space	The Dual Group $\widehat{G}$
A "Point" p	A character $\chi \in \widehat{G}$
Evaluation Map	Fourier "Evaluation" $\widehat{\mathrm{ev}}_\chi : f \mapsto \hat{f}(\chi)$
Maximal Ideal for p	$\ker(\widehat{\mathrm{ev}}_\chi) = I_\chi$

54

Quiver Representations and Path Algebras

(Currently, this chapter really focuses on Quiver theory. I will put my exploration of Lie Algebra Representations here)

(This motivation is if you know some differential geometry) Quiver's have their origin in the classification of Lie groups. A Lie group is a group $(G, \cdot)$ G is a *smooth manifold* and $\cdot : G \times G \to G$ is a *smooth map*. The classification of these types of groups (in particular, the continuous ones, since discrete lie groups is just the classification of all groups) is a problem completed by Killing. Out of his classification, there came out 5 exotic Lie groups lying outside of the other classifications. Why did these Lie groups come up? The answer of this question might come from a change in perspective: Any Lie group has a Lie Algebra – the tangent space at the identity of the group which also has an extra operation called the *lie braked* which allows to capture in some of the smooth properties of G into T_eG. These Lie brackets allow us to define a linear map $\text{ad}_x : T_eG \to \mathbb{C}$, $\text{ad}_x(y) = [x, y]$. The image of these operations are called the *ideals* of a lie algebra (not unlike rings, since an ideal $I \subseteq L$ is the set of all elements where for all $x \in L$ and $a \in I$, $[x, a] \in I$). Using this fact, we can ask for the classification of *simple lie algebras*. As an example of one:

$$\text{sl}(3, \mathbb{C}) = \left\{ \begin{matrix} a & b & c \\ d & e & f \\ g & h & i \end{matrix} \middle| \, a + e + i = 0 \right\}$$

which is closed under Lie braked $[A, B] = AB - BA$ (but not closed under multiplication). Now, since these are linear maps, they can be diagonalized. If we take $h_1, ..., h_k \in \text{sl}(3, \mathbb{C})$ to be diagonal elements (elements that are zero everywhere except possibly the diagonal), then $\text{ad}_{h_1}, ..., \text{ad}_{h_k}$ are all simultaneously diagonalizable. This leads us to be able to define *root systems*, which allows for *root decomposition* and *root systems*. This leads to two important theorems for classification of *complex lie algebras*:

(Cartan's Thorems)

1. Up to isomorphism, there is just one complex semisimple Lie algebra for each root system
2. With 5 exceptions, every finite dimensional semisimple Lie algebra over $\mathbb{C}$ is isomorphic to one of the classical Lie Algebras:

$$\mathrm{sl}(n, \mathbb{C}) \quad \mathrm{so}(n, \mathbb{C}) \quad \mathrm{sp}(2n, \mathbb{C})$$

and 5 excpetional Lie algebras, labeled: e_6, e_7, e_8, f_4, g_2

54.1 Quiver's and their Decomposition

The following is just an accumulation of common terms in graph theory that we will need. The one notable exception is that we will rename oriented graphs to *quivers*

Definition 54.1.1: Quiver

A *quiver* Q is an oriented graph (V, E, s, t) where V represents the vertices (the vertex set), E is the set of edges (the "arrows") and $s : E \to V$ with $t : E \to V$ represents the orientation (s for source, t for terget), that is for any $e \in E$, if we have:

$$\overset{i}{\bullet} \xrightarrow{e} \overset{j}{\bullet}$$

then $s(e) = i$ and $t(e) = j$.

Usually, we will abuse notation say $Q = (V, E)$ is a quiver and ommit s and t. Most of the time, we will draw quivers instead of explicitely define them through a 4-tuple or 2-tuple

Example 54.1.2: Quivers

1. If $V = \{1\}$, $E = \{e\}$, and $s(e) = t(e) = 1$, then we can draw this quiver as

$$\begin{tikzcd} 1 \arrow[loop above] \end{tikzcd}$$

2. If $V = \{1, 2\}$, $E = \{e\}$, $s(e) = 1$, and $t(e) = 2$, then we can draw this quiver as

$$1 \xrightarrow{e} 2$$

3. If $V = \{1, 2\}, E = \{e, f\}$, with $s(e) = 1$, $t(e) = 2$ and $s(f) = 2$, $t(f) = 1$, then we can draw this quiver as

$$\begin{tikzcd} 1 \arrow[r, bend left, "e"] & 2 \arrow[l, bend left, "f"] \end{tikzcd}$$

If you are still uncomfortable, with quivers, try to come up with some as a challenge.

Definition 54.1.3: Path and Cycle

Let Q be a quiver.

1. A path γ is a sequence of edges
$$\gamma = e_k e_{k-1} \cdots e_1$$
where $t(e_i) = s(e_{i+1})$. for $1 \leq i \leq k-1$.
2. If γ is a path where $s(e_1) = a$ and $t(e_k) = b$, then we say that γ is a path from a to b, and we write $s(\gamma) = a$, $t(\gamma) = b$.
3. The number of number of edges in a path is called the *length* of he path.
4. If γ is a path and $s(\gamma) = t(\gamma)$, we call γ a *cycle*.
5. A cycle of length 1 is called a *loop*

Definition 54.1.4: Sink And Source

Let Q be a quiver

1. Let $e \in E$ and $i \in V$. We say that e *contains* i if $s(e) = i$ or $t(e) = i$. We say that e is *incoming at* i if $t(e) = i$ and that e is *outgoing at* i if $s(e) = i$
2. We say a vertex $i \in V$ is a *sink* if all edges containing i are incoming. Intuitvely, this can be visualized as:
$$\begin{tikzcd} {} \arrow[dr] & {} \arrow[d] & {} \arrow[dl] \\ {} \arrow[r] & i & {} \arrow[l] \\ {} \arrow[ur] & {} \arrow[u] & {} \arrow[ul] \end{tikzcd}$$
3. We say a vertex $i \in V$ is a *source* if all edges containing i are outgoing. Intuitvely, this can be visualized as:
$$\begin{tikzcd} {} & {} & {} \\ {} & i \arrow[ul] \arrow[u] \arrow[ur] \arrow[l] \arrow[r] \arrow[dl] \arrow[d] \arrow[dr] & {} \\ {} & {} & {} \end{tikzcd}$$
4. Let s be a sink or a source. Then define sQ to be a new quiver where all the arrows at s are reversed.

54.1.1 Quiver Representation and Varieties

Definition 54.1.5: Quiver Representation

Let Q be a quiver. Then a *quiver representation* V *of* Q consists of

1. a vector space $V(i)$ over a fixed field $\mathbb{F}$ for each vertex of Q
2. a linear transofmration $T_e : V(i) \to V(j)$ for each $e \in E$

Let $\text{Rep}_{\mathbb{F}}(Q)$, or $\text{Rep}(Q)$ be the collection of all quiver representations of Q.

Example 54.1.6: Quiver Representations

1. Let

$$1 \xrightarrow{e} 2$$

be a quiver. Then any linear transformation $T : V \to W$ is a representation of this quiver

2. Let

$$\begin{tikzcd} 1 \arrow[r, "e"] & 2 \arrow[loop above, "f"] \end{tikzcd}$$

be a quiver. Then we can take any linear transformation $T : V \to W$ and an identity map $\text{id} : W \to W$. Note that f need not be represented by the identity: any linear transformation from W to itself is valid.

3. Take

$$1 \xrightarrow{e} 2 \xrightarrow{f} 3$$

Then one class of possible representations of this quiver consits of vector-spaces $V(1)$, $V(2)$, $V(3)$ where the sequence is exact at $V(2)$. Another representation can have T_e and T_f be scalar multiplications. Yet another can be the set of vector spaces and linear transformations T_e and T_f where $T_e, T_f \neq \text{id}$ but $T_f \circ T_e = \text{id}$. There are many more possibilities

Since each vertex has a representation, we can capture a notion of dimension of a quiver representation

Definition 54.1.7: Quiver Dimension

Let Q be a quiver and V a representation of Q. Then the *dimension* or *quiver dimension* of V is the tuple that is denoted:

$$\dim_Q V = (\dim V(i))_{i \in I}$$

where each i is a vertex. If there are finitely many vertices, then we can biject them to natural numbers and have:

$$\dim_Q V = (\dim V(1), \dim V(2), ..., \dim V(n))$$

Definition 54.1.8: Quiver Subrepresentation

Let Q be a quiver and V be a quiver representation. Then a *subrepresentation* W of V consists of a subspace $W(i) \subseteq V(i)$ for each $i \in V$ and a linear transformations restricted to the new domain, $T_e|_{W(i)} = S_e$ for each $e \in E$, such that each S_e, $S_e(W_i) \subseteq W_j$

the last condition is so that each T_e is still well-defined. As an exercise, see if you can come up with quivers and subrepresentations (you can keep it simple and consider a quiver $\bullet \to \bullet$).

Definition 54.1.9: Quiver Morphisms

Let Q be a quiver and let V and V be representations of Q. Then we say that $\varphi : V \to W$ is a *quiver morphism* if for every edge e with representation $T_e : V(i) \to V(j)$ in V and representation $S_e : W(i) \to W(j)$ in W, there exists linear transformations $\varphi(i)$ and $\varphi(j)$ such that the following diagram commutes:

$$\begin{tikzcd} V(i) \arrow[r, "T_e"] \arrow[d, "\varphi(i)"] & V(j) \arrow[d, "\varphi(j)"] \\ W(i) \arrow[r, "S_e"] & W(j) \end{tikzcd}$$

collection of all quiver morphisms between V and W is denoted $\text{Hom}_{\mathbf{Q}}(V, W)$ or $\text{Hom}(V, W)$ if it is unambiguous in context.

Proposition 54.1.10: Structure Of $\text{Hom}(V, W)$

Let $V, W \in \text{Rep}(Q)$. Then $\text{Hom}(V, W)$ forms a vector-space structure over the base field $\mathbb{F}$.

***Proof*:**
left as an exercise

Example 54.1.11: Quiver Morphism

1. Let $V = \overset{\mathbb{F}^1}{\bullet} \xrightarrow{1} \overset{\mathbb{F}^1}{\bullet}$ and $W = \overset{\mathbb{F}^1}{\bullet} \xrightarrow{0} \overset{\{0\}}{\bullet}$ be two quiver representations. Then we can define a morphism:

$$\begin{tikzcd} V \arrow[d, "\varphi"] & \mathbb{F} \arrow[r, "1"] \arrow[d, "1"] & \mathbb{F} \arrow[d, "0"] \\ W & \mathbb{F} \arrow[r, "0"] & \{0\} \end{tikzcd}$$

Does there exist a nonzero morphism $\varphi : W \to V$?

2. Let $V = \overset{\mathbb{R}}{\bullet} \xrightarrow{1} \overset{\mathbb{R}}{\bullet} \xrightarrow{1} \overset{\mathbb{R}}{\bullet}$ and $W = \overset{\mathbb{R}^2}{\bullet} \xrightarrow{\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}} \overset{\mathbb{R}^2}{\bullet} \xrightarrow{\begin{pmatrix} 1 & 1 \end{pmatrix}} \overset{\mathbb{R}}{\bullet}$. Then: (commented to compile) is a quiver morphism. Does there exist a nonzero morphism $\varphi : W \to V$?

What we have technically defined is a *quiver representation morphism.* A quiver morphisms would usually be between two direct graphs where if $Q = (V, E, s, t)$ and $R = (V', E', s', t')$ are two quivers, then a quiver morphism would consit two functions $m_v : V \to V'$ and $m_e : E \to E'$ such that $m_v \circ s = s' \circ m_e$ and $m_v \circ t = t' \circ m_e$. This is ostensibly the same concept with different objects. All mosrphisms between Q and R would be represented as $\mathrm{Hom}_{\mathbf{Quiv}}(Q, R)$. Most of the time, we will care about the representation of quivers, and hence leaving the name of "quiver morphism" to representations. In either case, the collection of all quivers along with the just-defined quiver morphism defines a category **Quiv**, and the collection of all representations of a quiver $\mathrm{Rep}(Q)$ along with the previously-defined quiver morphism defines a category **Quiv(Q)** (you can check these as exercises)

The category **Quiv(Q)** has a a 0, namely the representation where all vertices are assigned the zero vector-sapces and the linear transformations are the identity. Since 0 exists, we can define kernels. Images also exist in this category:

Definition 54.1.12: Kernels And Images

Let $\varphi : V \to W$ be a quiver morphism. Then $\ker(\varphi)$ is the subrepresetnation of V consisting of $\ker(\varphi(i)) \subseteq V(i)$, and $\mathrm{im}(\varphi)$ is the subrepresentation of W consisting of $\mathrm{im}(V(i)) \subseteq W_i$

Note that $\ker(\varphi)$ and $\mathrm{im}(\varphi)$ are indeed subrepresentations: the fact that the vertices exist is a direct consequence of linear algebra. It remains to show that the diagram still commutes.

Definition 54.1.13: Quiver Isomorphisms

Let $V, W \in \mathrm{Rep}(Q)$. Then V is isomorphic to W if there exists a quiver morphism $\varphi : V \to W$ and $\psi : W \to V$. We denote two isomorphic quivers as $V \cong W$

Example 54.1.14: Quiver Isomorphism

In Jamail's notes. Some pretty cool ones. In parituclar, the classification of quiver representations of the form $\bullet \xrightarrow{e} \bullet$ with each vector-space being finite dimensional.

Next, we define the dual of sub-representations. Since for every subspace of a vector space $W \subseteq V$ we can define V/W, the notion of a quotient quiver is defined similarly

Definition 54.1.15: Quotient Quiver

Let $V \in \mathrm{Rep}(Q)$ and $W \subseteq V$ a subrepresentation. Then V/W is defined as a new quiver where every vertex of V is replaced by the quotient of $V(i)/W(i)$.

Proposition 54.1.16: 1st Isomorphism for Quivers

Let $V, W \in \mathrm{Rep}(Q)$ and $\varphi : V \to W$ be a quiver morphism. Then:

$$\mathrm{im}(\varphi) = V/\ker(\varphi)$$

***Proof*:**
left as an exercise

Definition 54.1.17: Product Quiver

Let $V, W \in \text{Rep}(Q)$. Define $V \oplus W \in \text{Rep}(Q)$ as

1. $(V \oplus W)(i) = V(i) \oplus W(i)$
2. $T_e : (V \oplus W)(i) \to (V \oplus W)(j)$ is given by $T_e = T_{e,v} \oplus T_{e,w}$ (recall that $T \oplus S(a,b) = (T(a), S(b))$)

Definition 54.1.18: Quiver Variety

Let $Q = (I, E, s, t)$ be a finite quiver. and $\underline{d} \in \mathbb{N}^n$. Then a *quiver variety* is:

$$\text{Rep}(\underline{d}, Q) := \prod_{e \in E} M_{d_j, d_i}(\mathbb{F})$$

where $i = s(e)$ and $j = t(e)$. Every point in $\text{Rep}(\underline{d}, Q)$ is a representation of Q with dimension vector $\underline{d}$.

A quiver variety let's us reduce a quiver where each vertex can have a different dimension (i.e. any possible total dimension) to only thinking about quivers with the same total dimension

Proposition 54.1.19: Action On Quiver Variety

Let $Q = (I, E, s, t)$ be a finite quiver with $I = \{1, ..., n\}$ and $E = \{e_1, ..., e_n\}$. Let $\underline{d} = (d_1, ..., d_n) \in \mathbb{N}^n$, and define the group $G(\underline{d}) = \prod_i GL_{d_i}(\mathbb{F})$. Then define the $G(\underline{d})$ action on $\text{Rep}(Q, \underline{d})$ as follows:

$$g = (\varphi_1, ..., \varphi_n)$$
$$(g \cdot V)_e = (\varphi_j A_e \varphi_i^{-1})_e$$

where $s(e) = i$ and $t(e) = j$.

***Proof*:**
If $g = (I)_e$ for each edge, then

$$(g \cdot V)_e = (I_j A_e I_i)_e = (A_e)_e$$

showing that $I \cdot V = V$. Associativity comes for free from assocaitivty of composition of linear maps.

I think the group in the theorme is called a *Weyl Group*.

Theorem 54.1.20: Isomorphism Equivalence

Let $\text{Rep}(Q, \underline{d})$ be a quiver variety and $G(\underline{d})$ be the group as defined in proposition 54.1.19. Then two representations $V, W \in \text{Rep}(Q, \underline{d})$ are isomorphic if and only if there exists a $g \in G(\underline{d})$ such that $g \cdot V$. That is, two quivers are isomorphic if they lie in the same orbit:

$$\{G(\underline{d})\text{-orbit of } \text{Rep}(Q, \underline{d})\} \rightleftarrows \{\text{iso classes of rep with dim } \underline{d}\}$$

***Proof*:**

As we've seen in example 54.1.14, two quiver represenations (of the same dimension) of $\bullet \xrightarrow{e} \bullet$ are equivalent if T_e and S_e are equivalent, i.e., their range is of the same dimension, i.e. $\varphi_j A_e \varphi_i^{-1} = B_e$ for two invertible matrices φ_i and φ_j. However, this is exactly the condition for the orbits of this group-actions.

54.1.2 Decomposing Quivers

Similarly to all other algebraic structures we've encountered, we have a notion of simple objects:

Definition 54.1.21: Simple Representation

Let Q be a quiver. Then $V \in \text{Rep}(Q)$ is called a *simple* or *irreducible* representation if the only subrepresentations of V are $\{0\}$ and V

The notion of simple objects is essentially trivial for vectorspaces since $V \cong \mathbb{F}^n$. In other words, every vector-space is decomposable into simple vector-spaces. The analogous notion of decomposability exists for quivers, however, they can be more complicated for quivers

Definition 54.1.22: Indecomposable Quiver

Let Q be a quiver. Then $V \in \text{Rep}(V)$ said to be *decomposable* if there exists non-trival subrepresentation $V_1, V_2 \subseteq V$ such that:

$$V \cong V_1 \oplus V_2$$

and is said to be *indecomposable* otherwise

Example 54.1.23: Simple Quivers and decomposability

Let $Q = \bullet \xrightarrow{e} \bullet$. Then:

$$0 \xrightarrow{\ 0\ } \mathbb{F} \qquad \mathbb{F} \xrightarrow{\ 0\ } 0$$

are both simple representations. Note that the left quivers is a subrepresentations of $V = \mathbb{F} \xrightarrow{\text{id}} \mathbb{F}$, and along with $\mathbb{F} \xrightarrow{\text{id}} \mathbb{F}$ and $0 \xrightarrow{0} 0$, $\mathbb{F} \xrightarrow{\text{id}} \mathbb{F}$ has 3 sub-quivers. Thus, V is not a simple quiver. However, V is *indecomposable*. To see this, notice that if V were decomposable, then we get:

$$\dim_Q(V_1 \oplus V_2) = \dim_Q(V_1) + \dim_Q(V_2)$$

and for the representation to be nontrival, we would have that one representation would have dimension $(1, 0)$, while the other has $(0, 1)$. However,V has no representation of dimension $(1, 0)$.

This means that the extension of quivers will be more elaborate than split exact sequences.

Theorem 54.1.24: Quiver Representation Decomposition

Let Q be a quiver and V be a representaiton where $\sum_i \dim V(i) < \infty$. Then there exists a finite set of indecomposable subrepesentations I_1, ..., I_n such that

$$V = I_1 \oplus I_2 \oplus \cdots \oplus I_n$$

***Proof*:**
Define the *total dimension* $\mathrm{Tdim}(V) = \sum_i \dim V(i)$. If $\mathrm{Tdim}(V) = 1$, then V must be only contain one vector-space $\mathbb{F}$ with all other vecor-spcaes being the trivial vector spaces. Assume for a moment that V has no oriented cycles. Then all maps from edges that are being the trivial map. Clearly, V is indecomposable, and so it is it's own decomposition.

On the other hand, if V has an oriented cycle, then without loss of generality we can consider

$$T = T_n \circ T_{n-1} \circ \cdots \circ T_1$$

so that we have $T : \mathbb{F} \to \mathbb{F}$. Since $\mathbb{F}$ has no non-trival subspace (being an indecomposable vector-space over $\mathbb{F}$), V is still indecomposable, and so is it's own decomposition.

Using strong induction, assume that all vector-spaces of total dimension $\mathrm{Tdim}(V) = n$ can be decomposed into a direct sum of indecomposable representations, and consider a representation of total dimension $n + 1$. If V is indecomposable, then we're done, so let's assume V is decomposableso that there exists two non-trival subrepresentations V_1, V_2 such that

$$V = V_1 \oplus V_2$$

Then since V_1, V_2 are both non-trivial, their total dimension must be strictly greater than and strictly less than that of V and nonzero. But then, by the inductive hypothesis, V_1 and V_2 can de decomposed into a finite direct sum of indecomposable modules. Hence:

$$V = V_1 \oplus V_2 = (I_{1,1} \oplus \cdots \oplus I_{1,n_1}) \oplus (I_{2,1} \oplus \cdots \oplus I_{2,n_2})$$

completing the proof.

Example 54.1.25: Decomposing Representations

1. Let $Q = \bullet \xrightarrow{e} \bullet$ be a quiver. Find all simple and indecomposable representations of Q. Using this knowledge, decompose any representation $V \xrightarrow{T_e} W$.

2. Let $Q = \bullet \xrightarrow{e} \bullet \xrightarrow{f} \bullet$. Find all simple and indecomposable representation of Q. Using this knoweldge, decompose any representation $V \xrightarrow{T_e} W \xrightarrow{T_f} L$.

3. Let $Q = \begin{tikzcd} \bullet \arrow[loop above] \end{tikzcd}$ be a quiver. Given $\mathbb{F}$ is algebraically closed, find all simple and indecomposable representations of Q (this is heavily reliant on Jordan canonical forms from chapter 14). Using this knowledge, decompose any representation $T : V \to V$.

54.1.3 Root Systems

Recall that if $(V, \langle \cdot, \cdot \rangle)$ ia an inner product space and $v \in V$, then

$$\frac{\langle w, v\rangle}{\langle v, v\rangle} v$$

is the projection of w onto v. Furthermore, define:

$$s_v(w) = w - 2\frac{\langle w, v\rangle}{\langle v, v\rangle} v$$

which reflects w across the hyperplane orthogonal to v.

Definition 54.1.26: Root System

Let V be an inner product space over $\mathbb{R}$. Then a *(reduced) root system* $R \subseteq V$ is a finite collection of non-zero vectors such that

1. $\operatorname{span}(R) = V$
2. For all $\alpha, \beta \in R$, $\eta_{\alpha,\beta} = \frac{2\langle \alpha, \beta\rangle}{\langle \beta, \beta\rangle} \in \mathbb{Z}$. In terms of angles, recall that $\theta = \cos^{-1}\left(\frac{\langle \alpha, \beta\rangle}{\|\alpha\|\|\beta\|}\right)$, so $n_{\alpha\beta} = \|\alpha\| \cos(\theta)$
3. For each $\alpha \in R$, the corresponding reflection $s_\alpha : V \to V$ has the property that for all $\beta \in R$, $s_\alpha(\beta) \in R$, i.e., R is symmetric under all α reflections.
4. If both $\alpha, c\alpha \in R$ then $c = \pm 1$ (this is true for reduced systems only)

Example 54.1.27: Root Systems

Let $V = \{(x, y, z) \in V \mid x + y + z = 0\}$, where V inherits the usual inner product from $\mathbb{R}^3$. Let

$$R = \{\pm(e_1 - e_2), \pm(e_2 - e_3), \pm(e_1, e_3)\} = \{\alpha, \beta, \gamma\}$$

Then R is a reduced root system. This set spans V because HERE.

Furthermore:

$$\eta_{\pm\alpha,\pm\beta} = \frac{2\langle \pm(e_1 - e_2), \pm(e_2 - e_3)\rangle}{\pm\langle (e_2 - e_3), \pm(e_2 - e_3)\rangle}$$

(finish rest later)

Include these

Notice that any root system can be simplified:

Definition 54.1.28: Polarization And Simple

Let R be a root sytem. Then if there exists a vector v such that $\langle v, \alpha \rangle \neq 0$ for all $v \in R$ then $R_+ = \{\alpha \in R \mid \langle v, \alpha \rangle > 0\}$ along with $R_+ = \{\alpha \in R \mid \langle v, \alpha \rangle < 0\}$ is called the *polarization of* R, and $R = R_+ \sqcup R_-$. The elements of R_+ are called *positive roots*. A positive root is called *simple* if it cannot be expressed as the sume of other positive roots.

Example 54.1.29: Simple Roots

homework, exercise 8 in Jimails notes

Theorem 54.1.30: Simple Root Decomposition

Let R, V be a (reduced) root system with polarization $R = R_+ \sqcup R_-$. Let Π denote the set of simple roots for this polarization. Then:

1. Every $\alpha \in R_+$ is a sum of simple roots
2. If $\alpha, \beta \in R_+$, then $\langle \alpha, \beta \rangle \leq 0$
3. The set Π of simple roots froms a basis for V

***Proof*:**

exercise 9

(words about root systems being isomorphic, which I'm guessing is a map from one vec sp from another s.t. all the properties of root systems are preserved)

Definition 54.1.31: Cartan Matrix

Let R, V be a (reduced) root system with polarization $R = R_+ \sqcup R_-$, let Π denote the set of simple roots for this polarization, and let $r = |\Pi|$. Then define *Cartan matrix* A to be the $r \times r$ matrix defined by:

$$A_{ij} = n_{\alpha_j \alpha_i} = \frac{2\langle \alpha_i, \alpha_j}{\alpha_i, \alpha_i}$$

Example 54.1.32: Cartan Matrix

exercise 10

(word to motivate the following visualization)

Definition 54.1.33: Dynkin Diagrams

Let R, V be a (reduced) root system with polarization $R = R_+ \sqcup R_-$, let Π denote the set of simple roots for this polarization, and identify Π with the set $\{1, ..., k\}$. Then we can construct a graph following these steps:

1. The vertices are given by simple roots Π (or equivalently, by indices $i \in \{1, ..., k\}$)
2. We join a vertex i and j by n_{ij} edges, which depends on the angle θ where

$$\theta = \frac{\pi}{2} \Rightarrow n_{ij} = 0 \qquad \theta = \frac{2\pi}{3} \Rightarrow n_{ij} = 1 \qquad \theta = \frac{3\pi}{4} \Rightarrow n_{ij} = 2 \qquad \theta = \frac{5\pi}{6} \Rightarrow n_{ij} = 3$$

3. Roots joined by a single edge have the same length. Roots joined by muliple edges have an arrowhead ">" on the edge pointing towards the root with sorther length (imagine this as an inequality between the length of the roots)

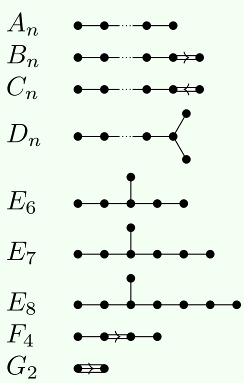
Example 54.1.34: Dynkin Diagrams

1. finding dynkin diagram for many root systems

We know proceed to classify root systems. As with other definition, if R is a root system and $R = R_1 \sqcup R_2$ where R_1, R_2 are proper subsets of R that are root systems, we say that R is reducible, and irreducible otherwise.

Theorem 54.1.35: Classification of Root Systems

Let R be a (reduced) irreducible root system. Then it's dynkin Diagram is one of the following:



***Proof*:**
here

(representing root systems via it's symmetries)

Definition 54.1.36: Weyl Group

Let $R \subseteq V$ be a root system. Let $W \subseteq \mathrm{GL}(V)$ be the group generated by the reflections s_α, $\alpha \in R$. Then W is called the *Weyl group* of R.

Since it is a group generated by reflections, every element acts linearly on V. Furthermore, it perserves lengths and angles, and so it is an element of $O(V)$ (definition 1.2.32)

Example 54.1.37: Weyl Group
p. 11 Jimail

Definition 54.1.38: Simple Reflection

Let $R \subseteq V$ be a root system with Weyl group W, and $R = R_+ \sqcup R_-$ is a polarizatoin with simple roots Π.
Then for each $\alpha_i \in \Pi$, the corresponding reflection $s_i = s_{\alpha_i} \in W$ is called a *simple reflection.*

Theorem 54.1.39: Weyl Groups Representing Root Systems

Let $R \subseteq V$ be a root system with Weyl group W, and $R = R_+ \sqcup R_-$ a polarization with simple roots Π. Then:

1. The simple roots s_i (for $i \in \Pi$) generate W
2. $W(\Pi) = R$. Hence, the root system can be recovered from the simple roots; we apply all Weyl group elements to Π to produce the full list of possible roots

***Proof*:**
exercise?

(reduced expressions and longest elements)

Definition 54.1.40: Length Of Weyl Group Elements

Let W be the Weyl group of a root system R, and Π the simple roots. Then the *length* of $w \in W$ is the shortest length of word for w as a product of simple reflections. We denote the length of w by $l(w)$.

In other words, if $w = s_{i_\ell} \cdots s_{i_1}$ and no shorts sequence exists, then $l(w) = \ell$.

Theorem 54.1.41: Generating Roots Using Weyl Group

Let W be the Weyl group of a root system R with polarization $R = R_+ \sqcup R_-$ and Π the corresponding simple roots.

1. There exists a unique element $w_0 \in W$ such that $\ell(w_0) = |R_+|$
2. The element w_0 has the property that $w_0(R_+) = R_-$
3. If $w = s_{i_k} \cdots s_{i_1}$ is an expression for w_0 of length $l(w_0)$, then
$$\begin{aligned} \gamma_1 &= \alpha_{i_1} \\ \gamma_2 &= s_{i_1}(\alpha_{i_2}) \\ &\vdots \\ \gamma_k &= s_{i_k} \cdots s_{i_1}(\alpha_{i_k}) \end{aligned}$$
is an enumeration of the positive roots
4. The elements γ_j defined above satisfy the propety that the roots γ_j, $s_{i_1}(\gamma_j)$, ..., $s_{i_1}(\gamma_j) \in R_+$ are positive, but the roots $s_{i_j} s_{i_{j-1}} \cdots s_{i_1}(\gamma_j) \in R_-$ are negative.

***Proof*:**
Jimail didn't prove – we don't have enough tools yet

Now that we have a better undersatnding of Weyl groups, we seek to link some of their structure to structure of simple roots. As we saw, the relations between simple roots can be captured via Dynkin Diagrams. We will seek for elements of the Weyl group which are "compatible" with the Dynkin diagrams. (for some reaosn), let Γ be a dynkin diagram of type A, D, or E (i.e. a Dynkin diagram with no multiple edges). Let R denote the corresponding root system. For any orientation Ω of Γ, Let (γ, Ω) represent the correspondign quiver. Recall that if i is a sink or source in Ω, we have an operator $s_i^{\pm}$ that reverses the arrows at i. Denote thie operation by

$$(\Gamma, \Omega) \mapsto (\Gamma, s_i^{\pm}\Omega)$$

where we would put a $+$ if it is a sink-to-source operation, and a $-$ if it is a source-to-sink operation

Definition 54.1.42: Adapted Word

Let Γ be a Dynkin diagram of type A, D, or E (i.e. a diagram with no multiple edges, or "simply laced"), W the corresponding Weyl group, and Ω an orientation of Γ. Let $w \in W$. Then the reduced expression $w = s_{i_k} \cdots s_{i_1}$ for w is *adapted for* Ω if

1. The verex i_1 is a sink for (Γ, Ω)
2. The verex i_2 is a sink for $(\Gamma, s^+_{i_1}\Omega)$

   $\vdots$

3. The verex i_k is a sink for $(\Gamma, s^+_{i_{k-1}} \cdots s^+_{i_1}\Omega)$

i.e. at each step, we can apply the operator $s^+_{i_j}$ to the quiver $(\Gamma, s^+_{i_{j-1}} \cdots s^+_{i_1}\Omega)$

Example 54.1.43: Adapted Dynkin Diagrams
p. 15 Jaimal

Theorem 54.1.44: Lusztig's Theorem

Let R be an A, D, or E root system with dynkin diagram Γ and Weyl group W. For any orientation Ω of Γ, there exists an expession for the longest element $w_0 \in W$ which is adapted for Ω

***Proof*:**
exercise 19

54.1.4 Gabriel's Theorem

In this section, we come back to Quiver's. Recall in example 54.1.25 it was asked to show how find the indecomposable quivers with underlying graphs of type A_1, A_2, and a cyclic quiver. The result was that A_2 and A_3 (with the given orientation) reduced to finitely many indecomposable representations. However, if there is a cycle, the quiver did not afford such a representation. A quiver which has finite decomposition is naturally much easier to study (TBD). The question then becomes:

> Which quivers Q can be decomposed into finitely many indecomposable representations?
> Can we classify all such quivers?

The answer of this question is *Gabriel's Theorem*; the goal of this section is to prove this result. Gabriel's Theorem is the key result linking the representation of quivers to Lie algebras, a pivotal tool in studying manifolds with group structures.

(a,b) To make the connection more precise, some terms need to be defined:

Definition 54.1.45: Collection Of Indecomposables

Let Q be a quiver, and let $\text{Rep}(Q)$ be it's representations. Then the set $\text{Ind}(Q) = \{[X] \mid X \in \text{Rep}(Q) \text{ is indecomposable }\}$ is the set of isomrophism classes of indecomposable quivers of $\text{Rep}(Q)$.
We say that a quiver is of *finite type* if $\text{Ind}(Q)$ is finite.

Before continuing with proving he result, it is useful to at least see how such a connection might even be hypothesized:

Example 54.1.46: Motivating Connection

Consider the quiver $\overset{1}{\bullet} \longrightarrow \overset{2}{\bullet} \longrightarrow \overset{3}{\bullet}$. The underlying graph is A_3, so let α_1, α_2, and α_3 denote the simple roots for the root system A_3. Using these, we can deduce the positive roots are:

$$\{\alpha_1, \alpha_2, \alpha_3, \alpha_1 + \alpha_2, \alpha_2 + \alpha_3, \alpha_1 + \alpha_2 + \alpha_3\}$$

We furthermore saw in example 54.1.25 that the indecomposable representations are:

$$\mathbb{F} \xrightarrow{0} 0 \xrightarrow{0} 0 \qquad \mathbb{F} \xrightarrow{1} \mathbb{F} \xrightarrow{0} 0$$

$$0 \xrightarrow{0} \mathbb{F} \xrightarrow{0} 0 \qquad 0 \xrightarrow{0} \mathbb{F} \xrightarrow{1} \mathbb{F}$$

$$0 \xrightarrow{0} 0 \xrightarrow{0} \mathbb{F} \qquad \mathbb{F} \xrightarrow{1} \mathbb{F} \xrightarrow{1} \mathbb{F}$$

Here is the key insight: notice we can correspond the *dimension vector* of these repesenations to the positive roots!

Theorem 54.1.47: Gabriel's Theorem

Let Q be a quiver. then Q is of finite type if and only if the underlying graph of Q is a Dynkin Diagram of type A, D, or E. In this case, the dimension vector:

$$\dim_Q : \text{Ind}(Q) \to R_+ \qquad [I] \mapsto \dim_Q(I)$$

bijects the indecomposable representations (up to isomorphism) and positive roots in the corresponding root system.

The proof will be relegated to page pageref:HERE

The theorem hints to us that indecomposable quivers somehow relate to the simple reflections of a Weyl group. However, a Dynkin Diagram is inherently unoriented, while Quivers are by definition an oriented graph. The first thing we need to do to fix is find the equivalent of a "reflection" for quivers.

The idea for the following definition is as follows: Take the quiver and the reflection

$$\overset{1}{\bullet} \xrightarrow{e} \overset{2}{\bullet} \qquad \overset{1}{\bullet} \xleftarrow{f} \overset{2}{\bullet}$$

Now, given a representation assigning $V(1)$, $V(2)$, and T_e, how should we assign values to the reflection? One way of doing it is by taking $T_e : V(1) \to V(2)$, and mapping it to $S_f : \ker(T_e) \to V(1)$ where $S_f(x) = 0$. Visually, we see that:

$$\left(\overset{V(1)}{\bullet} \xrightarrow{T_e} \overset{V(2)}{\bullet} \right) \mapsto \left(\overset{V(1)}{\bullet} \xleftarrow{S_f} \overset{\ker(T_e)}{\bullet} \right)$$

this map considers what happens at a sink. Another approach maps by considering the source:

$$\left(\overset{V(1)}{\bullet} \xrightarrow{T_e} \overset{V(2)}{\bullet} \right) \mapsto \left(\overset{\operatorname{coker}(T_e)}{\bullet} \xleftarrow{S_f} \overset{V(2)}{\bullet} \right)$$

hwere $S_f(x) = \overline{T_e(x)}$. Both of these asignements are in fact functorial, If we have a quiver morphism $\varphi : V \to W$ represented by:

$$\begin{tikzcd} V(1) \arrow[r, "T_e"] \arrow[d, "\varphi(1)"] & V(2) \arrow[d, "\varphi(2)"] \\ W(1) \arrow[r, "S_e"] & W(2) \end{tikzcd}$$

Then the appropriate morphim φ maps to is represented in these diagrams:

$$\begin{tikzcd} V(1) \arrow[d, "\varphi(1)"] & \ker(T_e) \arrow[l, "T_f|_{\ker(T_e)}"'] \arrow[d, "\varphi(1)|_{\ker(T_e)}"] \\ W(1) & \ker(S_e) \arrow[l, "S_f|_{\ker(S_e)}"'] \end{tikzcd} \qquad \begin{tikzcd} \operatorname{coker}(T_e) \arrow[d, "\overline{\varphi(2)}"] & V(2) \arrow[l, "\overline{T_f}"'] \arrow[d, "\varphi(2)"] \\ \operatorname{coker}(S_e) & W(2) \arrow[l, "\overline{S_f}"'] \end{tikzcd}$$

which both commute (where it was shown that $\varphi|_{\ker(T_e)}(\ker(T_e)) \subseteq \ker(S_e)$ when we showed the cateogry of quivers contains kernels). This will essentially represent how a reflection functor between two quivers will be defined – locally.

The different between these two functors is where there is a sink or a source. If i is a sink, then for any given quiver representatin $V \in \operatorname{Rep}(Q)$, let

$$\Psi_i : \bigoplus_{e:i \to j} V(j) \to V(i)$$

represent the collection of all linear transformation, where for each summand we have $T_e : V(i) \to V(j)$. If i is a source, then let:

$$\Phi_i : V(i) \to \bigoplus_{e:i \to j} V(j)$$

where each summand is mapped to T_e.

Definition 54.1.48: Reflection Functor

Let Q be a quiver. Define a functor from $\text{Rep}(Q)$ to $\text{Rep}(s_i^{\pm}Q)$ as follows:

1. For any $V \in \text{Rep}(Q)$, define $S(V)_i^+ \in \text{Rep}(s_i^+(Q))$ for a sink i, where at each vertex k,

$$S_i^+(V)(k) = \begin{cases} V(k) & i \neq k \\ \ker(\Psi_i) & i = k \end{cases}$$

and for each linear transformation T_e:

$$S_i^+(T_e) = \begin{cases} T_e & s(k) \neq i \\ \pi_k \circ \iota_i & \text{if } f : i \to k \text{ is in } s_i^+(Q) \end{cases}$$

where $\iota_i : \ker(\Psi) \to \bigoplus_{e:j\to i} V(j)$ is the inclusion map and $\pi_k : \bigoplus_{e:j\to i} V(j) \to V(k)$ is the projection map onto the kth component.

2. For any $V \in \text{Rep}(Q)$, define $S(V)_i^- \in \text{Rep}(s_i^n(Q))$ for a source i, where at each vertex k,

$$S_i^+(V)(k) = \begin{cases} V(k) & i \neq k \\ \text{coker}(\Phi_i) & i = k \end{cases}$$

and for each linear transformation T_e:

$$S_i^+(T_e) = \begin{cases} T_e & s(k) \neq i \\ q_k \circ \iota_i & \text{if } f : i \to k \text{ is in } s_i^+(Q) \end{cases}$$

where $\iota_i : V(k) \to \bigoplus_{e:j\to i} V(j)$ is the inclusion map and $q : \bigoplus_{e:j\to i} V(j) \to \text{coker}(\Phi_i)$ is the quotient map

Then these two functors, $S_i^{\pm} : \text{Rep}(Q) \to \text{Rep}(s_i^{\pm}Q)$ are called the *Bernstein-Gelfand-Ponomarev reflection functor*, or *reflection functor* for short.

Example 54.1.49: Reflection Functor

p. 70 Jaimal. The key idea is that these functors give different quiver representations, even if it on A_2 with the only orientation and doing S_1^+ then S_2^-.

A couple of properties of the functors needs to be established. For notational simplicity, let $\text{Rep}^{i,-}(Q)$ denote the full subcategory consisting of representations of Q for which the map

$$\Psi_i : \bigoplus_{e:j\to i} V(j) \to V(i)$$

is surjective, while $\text{Rep}^{i,+}(Q)$ denotes the full subcategory consisting of representations of Q for which the map

$$\Phi_i : V(i) \to \bigoplus_{e:i\to j} V(j)$$

is injective.

Proposition 54.1.50: Properties Of Reflection Functor

Let Q be a quiver.

1. If i is a sink, then for any $V \in \mathrm{Rep}(Q)$, $S_i^+ \in \mathrm{Rep}^{i,+}(s_i^+(Q))$ (similarly for source)
2. If i a sink, then for any $V \in \mathrm{Rep}(Q)$, $S_j^- S_i^+ \in \mathrm{Rep}^{i,-}(Q)$ (similarly for source)
3. The restriction of the reflection functors are inverse equivalences (adjoints?)
$$S_i^+ : \mathrm{Rep}^{i,-}(Q) \to \mathrm{Rep}^{i,+}(s_i^+ Q)$$
$$S_i^- : \mathrm{Rep}^{i,+}(Q) \to \mathrm{Rep}^{i,-}(s_i^- Q)$$
4. If V is simple at vertex i, then $S_i^{\pm}(V) = 0$.
5. If V is a non-zero indecomposable representation of Q that is not simple at i, then $S_i^{\pm}(V)$ is a nonzero indecomposable representation of $s_i^{\pm}(Q)$, and $V \cong S_j^{\mp} S_i^{\pm}(V)$.
6. $S_i^{\pm}(V)$ is a nonzero indecomposable representation of $s_i^{\pm}(V)$ if and only if $s_i(\dim_Q(V)) \geq 0$
7. If $V \in \mathrm{Rep}^{i,\pm}(Q)$ is a nonzero indecomposable representation, then $\dim_Q(S_i^{\pm}(V)) = s_i \dim_Q(V)$

***Proof*:**
exercise

Finally, we define a new object with purpose HERE (Apparently, these definitions can be given if we use some homological algebra. Perhaps revamp this after you do the homological algebra section, or keep it at this level with the mention of the version of greater generality for those who want to skip Hom Alg)

Definition 54.1.51: Root Lattice

Let Q be a quiver with vertex set I. Then if the underlying graph of Q is a dynkin diagram, $\mathbb{Z}^I$ is called the *root lattice*. For $(v_i)_{i\in I} \in \mathbb{Z}^I$, we say that $v \geq 0$ if $v_i \geq 0$ for all $i \in I$. Furthermore, we let $\mathbb{Z})+^I := \left\{v \in \mathbb{Z}^I \;\middle|\; v \geq 0\right\}$

(The following theorem seems to make more sense with some homological algebra, where the domain of the function should actually be the Grothendieck group of a $\mathrm{Rep}(Q)$) (Are objects in the following theorem representations?)

Theorem 54.1.52: Root Lattice Map

here exists a map $\dim_Q : \{\text{iso classes of Rep's}\} \to \mathbb{Z}_+^I$

***Proof*:**
not proved

Definition 54.1.53: Euler And Tits Form

Let $Q = (I, E)$ be a quiver. Define a bilinar form on $\mathbb{Z}^I$ as follows: for any $v, w \in \mathbb{Z}^I$:

$$\langle v, w\rangle_Q = \sum_i v_i w_i - \sum_e v_{s(e)} w_{t(e)}$$

This is called the *Euler form* of Q. The *symmetrized Euler form* of Q is given by

$$(v, w)_Q = \langle v, w\rangle_Q + \langle w, v\rangle_Q$$

Finally, the *tits form* of Q is the quadratic form $q_Q(v) = \langle v, v\rangle = \frac{1}{2}(v, v)$

Example 54.1.54: Euler And Tits Forms

Let $Q = \overset{1}{\bullet} \xrightarrow{e} \overset{2}{\bullet} \xrightarrow{f} \overset{3}{\bullet}$. Then the Euler's form is:

$$\langle v, w\rangle_Q = \sum_{i=1}^{3} v_i w_i - v_1 w_2 - v_2 w_3$$

$$q_Q(v) = \sum_{i=1}^{3} v_i v_i - v_1 v_2 - v_2 v_3$$

The tits form is also positive definite, since if it weren't, we would be able to pick 3 positive integer's satisfying:

$$v_2(v_1 + v_3) > v_1^2 + v_2^2 + v_3^2$$

However, this is no possible (we can show this with elementary calculus and optimization, or take a couple of space cases and induction).

Now let $Q' = \overset{1}{\bullet} \xleftarrow{e} \overset{2}{\bullet} \xrightarrow{f} \overset{3}{\bullet}$. Then:

$$\langle v, w\rangle_Q = \sum_{i}^{3} v_i w_i - v_2 w_1 - v_2 w_3$$

and:

$$q_Q(v) = \sum_{i}^{3} v_i v_i - v_2 v_1 - v_2 v_3$$

then we see that the tits form of Q and Q' agree.

Theorem 54.1.55: Positive Definite Forms And Dynkin Diagrams

Let Γ be a connected graph. The Tits form q_Γ is positive definite if and only if Γ is a Dynkin diagram of type A, D, or E

Proof:
ommited by Jimail

(exercise showing not true for not A, D, E)

Finally, we will state one more theorem we need for the proof

Theorem 54.1.56: Coxeter Element Lemma

Let R be a root system, $\Pi = \{\alpha_1, \alpha_2, ..., \alpha_n\}$ a set of simple roots and W its Weyl group. Let $s_i = s_{\alpha_i}$ denote the simple reflections corresponding to the simple root α_i. let $C = s_{i_n} \cdots s_{i_1}$ where $i_1, i_2, ..., i_n$ is some ordering of the simple roots (such an element is called a *Coxeter element*).

Then for any $v \in \mathbb{Z}^I$, there exists a $m \geq 0$ such that $C^m(v) \ngeq 0$

Proof:
ommited

Proof:
(of Gabriels theorem) here

54.1.5 Path Algebra of Quivers

(there are some really important insights that feel like they should actually be the priority of this section!! Essentially, we build-up more on how to think about algebras in terms of quotients of free modules, build-up how "path algebras" naturally come into play in representing quivers, and finish off with the Morita equivalence between R-Mod and R/I-Mod where $I = \text{Ann}_R(M)$).

Let $Q = (V, E)$ be a quiver. For vertices i, j of Q, Define the set $\text{Path}(i, j) = \text{span}\{\text{paths } \gamma \text{ from } i \text{ to } j\}$ (i.e. consider the path as a basis to generate a vector-space over k, where k is usually understood), which we will call the *path space*. the length of a particular path is the number of edges between each point. The length of the path from i to i is zero. If γ is a path, and if we let i, j represent a path from it to itself, then if γ is a path from i to j, we will say that γi and $j\gamma$ are the same path.

Lemma 54.1.57: Properties Of Path

here

***Proof*:**

1. We want to show that P_i has the structure of a representation $\text{Rep}(Q)$, which consists of a collection of vector-spaces and linear transformation's between them. First, each $P_i(j)$ is a vector-space, as pointed out earlier. Next, we may define a "linear" map $T_e : P_i(j) \to P_i(k)$ to be $\gamma \mapsto e\gamma$ (i.e. append another edge to the path). Notice that since we are treating paths as basis elements to some freely generated vector-space $P_i(j)$, then we get by construciton that $T_e(c \cdot \gamma) = ec \cdot \gamma = ce\gamma = cT_e(\gamma)$. Next, taking $\gamma + \epsilon$ to be a formal sum of two paths, we can naturally extend the action of concatinating to the formal sum:

$$e(\gamma + \epsilon) = e\gamma + e\epsilon$$

   which will mirror the linear maps within a represetnation $\text{Rep}(Q)$. Furthermore, if e, f are neigbhouring edges, then $T_{ef} = T_e T_f$. This now mirrors how $\text{Rep}(Q)$ is both a collection of vector-spaces and a collection of maps between them.

2. We are now going to treat P_i as a representation, since we considered them to be related to them in the above example. We want to prove that the collection of vector-spces P_i along with the linear transformations T_e are indecomposable, that is we cannot find subrepresentations. This comes from the construction of our map, in particular that we have that for any collection of paths that form a basis for $P_i(j)$, we have that they are eached mapped to by some paths through the appropriate T_e for an appropriate edge e. To make it more intuitive to see, consider for example P_i of the bellow quiver with a "cycle":

$$\begin{tikzcd} & j \arrow[dr, "b"] & \\ i \arrow[ur, "a"] \arrow[rr, "c"'] & & k \end{tikzcd}$$

   Then $\dim(V(i)) = 1$, $\dim(V(j))) = 1$, and $\dim(V(k)) = 2$, with the path i mapping to ci in $V(k)$ and mapping to bi in $V(j)$, while the path bi of $V(j)$ maps to ibc, in $V(k)$. Then notice that $V(k)$ is "surjected" upon by both $V(i)$ and $V(j)$ combined, and all the maps are injective. If the above quiver were to split, then either the dimension of $V(i)$ or $V(j)$ would have to get smaller (since $V(k)$ would have to diminish a dimension): if $\dim(V(j)) = 0$, then that would break the surejctivity of T_a, while if $\dim(V(i)) = 0$, then the map $T_c \neq T_c|_A \oplus T_c|_B$ for the two subquivers A and B.

   If the quiver has a proper cycle (i.e. $P_i(i)$ has more than $\{i\}$ as a basis), then since every map must be injective (mapping onto the appropriate basis) we have that each vector-space is 1-dimensional and an isomorphism, which we've shown in chapter 1 with a dimension argument that this representation is indecomposable.

   If The quiver does not have a cycle:

$$\begin{tikzcd} j & & k \\ & i \arrow[ul, "a"] \arrow[ur, "b"'] & \end{tikzcd}$$

   Then if for the sake of contradiction P_i were decomposable, then if $\dim(V(i)) = 0$ in one of the decomposibition, so would $V(j)$ and $V(k)$, making it a trivial decomposition, while if $\dim(V(i)) = 1$, both $\dim(V(j))$ and $\dim(V(k))$ would have to be 1 or else the map wouldn't be well-defined, and hence this quiver is indecomposable.

More generally, any quiver Q can be broken down into one of these two cases: If the quiver has a "cycle", then since every map is injective and must surject onto the vertex where two edges meet, we can repeat the above argument to show that the two scenarios which we may have while trying to decompose a quiver lead to a contradiction, and if the quiver has no cycles, we repeat the argument we've done for the above quiver.

3. If P_i were not a sink, then if e is an edge where that makes i not a sink, say $s(e) = i$ and $t(e) = j$, then we can take a subquiver where the vector-space at $P_i(i) = 0$, and we have a zero-map from $P_i(i)$ to $P_i(j)$, giving us a subquiver.

   Conversely, if P_i were a sink, the only path from i would be to i, and so all other vertices would have a 0 dimensional vector-space, while $P_i(i)$ would be 1-dimensional, which makes P_i into a simple representation

4. For notational simplicity, if $\gamma = k_n k_{n-1} \cdots k_1$ is some path, let

$$f_\gamma(v) = f_{k_n}(f_{n-1}(\cdots f_1(v)))$$

   so that $f_{ab}(v) = f_a(f_b(v))$.

   For the proof, pick any $v \in V(i)$, and consider the following commutative diagram:

$$\begin{tikzcd} P_i(a) \arrow[r, "T_e"] \arrow[d, "\varphi_a"] & P_i(b) \arrow[d, "\varphi_b"] \\ V(a) \arrow[r, "S_e"] & V(b) \end{tikzcd}$$

   Then define $\varphi^v : P_i \to V$, $\varphi^v(\gamma) = S_\gamma(v)$. Then

$$S_e(\varphi_a^v(\gamma)) = S_e S_\gamma(v) = S_{e\gamma}(v) = \varphi_b^v(e\gamma) = \varphi_b^v(T_e(\gamma))$$

   proving commutativity of the diagram. If $v \neq w$, then since $\varphi_i^v(i) = v \neq w = \varphi_i^w(i)$, $\varphi^v \neq \varphi^w$. Next, if $\varphi \in \mathrm{Hom}_Q(P_i, V)$, then if $(\gamma_1, \gamma_2, ..., \gamma_n)$ is a basis for $V(i)$, consider

$$(\varphi_i(\gamma_1), ..., \varphi_i(\gamma_n)) = (v_1, ..., v_n)$$

   and define $v = \sum_i v_i$. Then extending linearly we get that $\varphi_i\left(\sum_i c_i\gamma_i\right) = \sum_i c_i v_i$, and then extending φ_i to any other φ_j through a chain of commutative diagrams, we get that all of φ is determined by where v maps to in any path in V. Thus, $\varphi = \varphi^v$, and so $\mathrm{Hom}(P_i, V)$ and $V(i)$ are in bijective correspondence. Finally, By linearly of each map in φ, and each map assigned to an edge in P_i and $V(i)$, it we see that:

$$\varphi^{v+cw} = \varphi^v + c\varphi^w \in \mathrm{Hom}(P_i, V)$$

   giving us that the map is in fact a linear map, completing the proof.

Definition 54.1.58: Path Algebra

Let $Q = (V, E)$ be a quiver. Then the *path algebra* $P(Q)$ is defined as follows:

1. As a vector-space $P(Q) = \text{span}\{\text{paths in } Q\}$, where each vertex $i \in V$ we include an element e_i representing the constant path $i \to i$
2. multiplication is defined via concatenation when legal, that is:

$$p \cdot q = \begin{cases} pq & \text{if } t(q) = s(p) \\ 0 & \text{otherwise} \end{cases}$$

54.2 Bound Quiver Algebras

The path algebra of definition 54.1.58 takes a combinatorial object, a quiver, and turns it into an associative algebra whose modules are exactly the quiver representations of definition 54.1.5. This is already a bridge between two worlds, but it runs in only one direction: every quiver produces an algebra. The converse question is the one that completes the picture. Given an abstract finite-dimensional algebra A over a field k, is there a quiver Q whose path algebra is A, or close enough to A that the two have the same representation theory? A path algebra is rarely finite-dimensional (any quiver with a cycle has paths of every length), so one cannot hope for equality on the nose. The fix is to impose relations, cutting the path algebra down by an ideal, and the content of this section is that this always suffices: over an algebraically closed field, every finite-dimensional algebra is, up to the coarsening supplied by Morita equivalence, a path algebra modulo relations. This is the structure theorem of Gabriel, and it makes the theory of quivers the universal combinatorial model for finite-dimensional representation theory.

The route to this statement passes through three reductions. First we cut a path algebra by an *admissible* ideal, which is what makes it finite-dimensional while keeping its arrows intact. Then we isolate the class of algebras for which the reconstruction is cleanest, the *basic* algebras, and show via Morita theory that restricting to them loses nothing. Finally we read a quiver directly off an abstract algebra A (its *Gabriel quiver*) using the Jacobson radical of chapter 52, and prove that A is the path algebra of that quiver modulo an admissible ideal. Throughout, A denotes a finite-dimensional algebra over k, modules are left modules, and $\text{Jac}(A)$ is the Jacobson radical. We write kQ for the path algebra $P(Q)$ of definition 54.1.58, following the standard notation, and recall its multiplication convention: for paths p and q the product $p \cdot q$ is the concatenation "q then p", nonzero exactly when $t(q) = s(p)$. In particular a path γ from i to j satisfies $e_j \gamma e_i = \gamma$, so it lives in $e_j(kQ)e_i$; this ordering of the idempotents matters when counting arrows.

The first task is to identify, inside kQ, the piece built from arrows of positive length. The constant paths e_i span a semisimple part, a product of copies of k, and everything else is generated by the arrows. Collecting the arrow-generated part into an ideal gives the object that measures "length at least one", and its powers measure length.

Definition 54.2.1: Arrow Ideal and Admissible Ideal

Let Q be a finite quiver and kQ its path algebra over k.

1. The *arrow ideal* $R_Q \subseteq kQ$ is the two-sided ideal generated by the arrows (the paths of length 1).

2. A two-sided ideal $I \subseteq kQ$ is *admissible* if there exists an integer $m \geq 2$ with

$$R_Q^m \subseteq I \subseteq R_Q^2$$

Two facts make this definition run, both immediate from the way paths concatenate. First, R_Q^ℓ is spanned by the paths of length at least ℓ: a product of ℓ arrows is a path of length ℓ (when the concatenation is legal) and zero otherwise, and every path of length ℓ factors as such a product. Consequently $kQ = kQ_0 \oplus R_Q$ as vector spaces, where $kQ_0 = \bigoplus_i ke_i$ is the span of the constant paths, and more generally the paths of a fixed length span a complement to $R_Q^{\ell+1}$ inside R_Q^ℓ. Second, the sandwiching $R_Q^m \subseteq I \subseteq R_Q^2$ has a concrete meaning at each end. The lower bound $R_Q^m \subseteq I$ forces I to contain all sufficiently long paths, which is exactly what truncates kQ/I to finite dimension. The upper bound $I \subseteq R_Q^2$ forbids relations of length 0 or 1: no relation may involve a constant path or set a single arrow equal to a combination of other arrows. This is the condition that keeps the arrows of Q visible in the quotient, so that Q can be recovered from the algebra kQ/I rather than being partly erased by the relations.

Definition 54.2.2: Bound Quiver Algebra

Let Q be a finite quiver and $I \subseteq kQ$ an admissible ideal. The quotient

$$kQ/I$$

is called the *bound quiver algebra* (or the path algebra of Q *bound by* the relations I). The pair (Q, I) is called a *bound quiver*.

Because $R_Q^m \subseteq I$, the quotient kQ/I is spanned by the images of the paths of length less than m, of which there are finitely many when Q is finite; so a bound quiver algebra is always finite-dimensional. The constant paths e_i descend to a complete set of orthogonal idempotents summing to 1, and R_Q/I is a nilpotent ideal with $(R_Q/I)^m = 0$. In fact R_Q/I is precisely the Jacobson radical of kQ/I: the quotient by it is $kQ_0 = \prod_i k$, a product of copies of k, which is semisimple, and a nilpotent ideal is always contained in the radical, so the two coincide. This last observation is the seed of the reconstruction theorem: the arrows of Q will be recovered from $\mathrm{Jac}(kQ/I)/\mathrm{Jac}(kQ/I)^2$.

Example 54.2.3: Loops, Truncation, and the A_2 Quiver

We compute three bound quiver algebras from the ground up.

1. *The dual numbers as a bound one-loop quiver.* Let Q be the quiver with one vertex 1 and one loop $\alpha \colon 1 \to 1$:

$$\begin{tikzcd} 1 \arrow[loop above, "\alpha"] \end{tikzcd}$$

The paths in Q are $e_1, \alpha, \alpha^2, \alpha^3, \ldots$, so as a vector space $kQ = k[\alpha]$ is the polynomial ring in one variable (identifying e_1 with 1 and concatenation of the loop with multiplication). The arrow ideal is $R_Q = (\alpha)$, and $R_Q^m = (\alpha^m)$. Take $I = (\alpha^2) = R_Q^2$, which is admissible with $m = 2$ (indeed $R_Q^2 \subseteq I \subseteq R_Q^2$). Then

$$kQ/I = k[\alpha]/(\alpha^2)$$

is the algebra of *dual numbers*, two-dimensional over k with basis $\{e_1, \alpha\}$ and the single relation $\alpha^2 = 0$. Its radical is $R_Q/I = (\alpha)$, one-dimensional, with square zero, and kQ/I modulo its radical is k: there is exactly one simple module, and it is one-dimensional. This is the smallest example of a bound quiver algebra that is not itself a path algebra, the relation $\alpha^2 = 0$ being unavoidable if one wants a finite-dimensional quotient of $k[\alpha]$.

2. *Truncating a longer loop.* Keeping the same one-loop quiver but taking instead $I = (\alpha^3) = R_Q^3$ gives $kQ/I = k[\alpha]/(\alpha^3)$, three-dimensional with basis $\{e_1, \alpha, \alpha^2\}$. Here $m = 3$; the admissibility bound $I \subseteq R_Q^2$ holds because $\alpha^3 \in R_Q^3 \subseteq R_Q^2$, and the relation still involves no constant path and no bare arrow. More generally $k[\alpha]/(\alpha^n)$ is the one-loop quiver bound by (α^n) for each $n \geq 2$, and these exhaust the local algebras arising from a single loop.

3. *The A_2 quiver, hereditary case.* Let Q be the quiver

$$1 \xrightarrow{\alpha} 2$$

with two vertices and a single arrow $\alpha \colon 1 \to 2$. The only paths are e_1, e_2, and α, so kQ is already three-dimensional and $R_Q^2 = 0$ (there is no legal concatenation of two arrows). The only admissible ideal is therefore $I = 0$: admissibility requires $I \subseteq R_Q^2 = 0$, so nothing may be quotiented, and $R_Q^2 = 0 = I$ supplies the lower bound with $m = 2$. Thus $kQ/I = kQ$, a path algebra with no relations. An algebra whose only admissible bound is the zero ideal, equivalently one whose radical squares to zero and imposes no relations, is called *hereditary*; the A_2 path algebra is the prototype.

Concretely kQ is isomorphic to the lower-triangular matrix algebra

$$\begin{pmatrix} k & 0 \\ k & k \end{pmatrix}$$

via $e_1 \mapsto E_{11}$, $e_2 \mapsto E_{22}$, and $\alpha \mapsto E_{21}$, where E_{ij} is the elementary matrix with a 1 in position (i, j). Lower- rather than upper-triangular is forced by the multiplication convention: the arrow $\alpha \colon 1 \to 2$ satisfies $e_2 \alpha e_1 = \alpha$, so its image must land in position $(2, 1)$, the strictly lower-triangular slot. The check is direct on the multiplication table: $e_2 \cdot \alpha \cdot e_1 = \alpha$ matches $E_{22}E_{21}E_{11} = E_{21}$, and every other product of basis elements is forced to zero on both sides. (The upper-triangular algebra is the opposite algebra, the A_2 path algebra with the arrow reversed to $2 \to 1$; we recover it from the radical in example 54.2.9.) We return to this identification once we have located the indecomposable projectives.

The dual-numbers example already shows the shape of the reconstruction: a local algebra with radical square zero came out as a single loop bound by α^2, and the loop is exactly a basis vector of $\mathrm{Jac}/\mathrm{Jac}^2$. Before making this into a theorem, one must decide which algebras to reconstruct. Not every finite-dimensional algebra is a bound quiver algebra on the nose. The matrix algebra $M_2(k)$, for instance, is simple, so its only simple module is two-dimensional, whereas a bound quiver algebra always has all its simples one-dimensional over k when k is algebraically closed (they are the vertex simples S_i). The class for which the reconstruction is exact is singled out by demanding that the semisimple quotient $A/\mathrm{Jac}(A)$ be as small as possible: a product of division rings, with no matrix blocks of size larger than one.

Definition 54.2.4: Basic Algebra

A finite-dimensional k-algebra A is *basic* if the quotient $A/\mathrm{Jac}(A)$ is a product of division rings,

$$A/\mathrm{Jac}(A) \cong D_1 \times \cdots \times D_n$$

with each D_i a division k-algebra. Equivalently, in the Artin–Wedderburn decomposition of $A/\mathrm{Jac}(A)$ (corollary 51.2.18) every matrix block $M_{n_i}(D_i)$ has $n_i = 1$.

When k is algebraically closed the finite-dimensional division k-algebras collapse to k itself (corollary 51.2.20), so a basic algebra over such a k has

$$A/\mathrm{Jac}(A) \cong k \times \cdots \times k$$

a product of n copies of k. Two consequences are worth stating plainly. First, the simple A-modules are the n simple modules of this product, each one-dimensional over k; a basic algebra over an algebraically closed field has *all simple modules one-dimensional*. Second, the number n of simple modules equals the number of factors, and it becomes the number of vertices of the reconstructed quiver. The condition "every matrix block has size one" is precisely the condition that the regular representation of $A/\mathrm{Jac}(A)$ contains each simple exactly once, so that A is, in the language of idempotents, a sum of pairwise non-isomorphic indecomposable projectives.

Example 54.2.5: Basic and Non-Basic Algebras

The bound quiver algebras of example 54.2.3 are all basic: for $k[\alpha]/(\alpha^2)$ the radical quotient is k, and for the A_2 path algebra it is $k \times k$, both products of copies of k. The upper-triangular algebra of 2×2 matrices is basic for the same reason. By contrast $M_2(k)$ is *not* basic: it is already semisimple, so $\mathrm{Jac}(M_2(k)) = 0$ and $M_2(k)/\mathrm{Jac}(M_2(k)) = M_2(k)$ is a single 2×2 block. The group algebra $k[S_3]$ over $k = \mathbb{C}$ is not basic either, since by Maschke's theorem it is semisimple and Artin–Wedderburn gives $\mathbb{C} \times \mathbb{C} \times M_2(\mathbb{C})$, a product with a 2×2 block coming from the two-dimensional irreducible representation of S_3. These non-basic examples are not pathological; they are the reason the theorem is stated up to Morita equivalence rather than isomorphism.

The point of Morita equivalence is that it does not see the difference between an algebra and its basic model. Two algebras are Morita equivalent when their module categories are equivalent, and Morita's theorem identifies exactly which algebras share a module category with a given one: they are the endomorphism algebras of progenerators. That theory, including generators, progenerators, and the classification of Morita equivalences by bimodules, is developed in *Core Algebra* [25, Morita theory]; what is used here is the criterion for a corner ring, that Ae is a progenerator exactly when the idempotent e is full, in which case A and eAe are Morita equivalent. The block structure of the radical quotient is this book's own and is settled below.

Proposition 54.2.6: Reduction to the Basic Case

Let A be a finite-dimensional k-algebra. Then there is a basic finite-dimensional k-algebra A^b, the *basic algebra of* A, that is Morita equivalent to A: the categories of left modules A**-Mod** and A^b**-Mod** are equivalent. The algebra A^b is unique up to isomorphism, and A and A^b have the same number of simple modules and the same radical quotient block *data* in the sense that $A^b/\mathrm{Jac}(A^b) \cong D_1 \times \cdots \times D_n$ where $M_{n_i}(D_i)$ are the Artin–Wedderburn blocks of $A/\mathrm{Jac}(A)$.

***Proof*:**
Step 1: the idempotent. Write $1 = e_1 + \cdots + e_r$ as a sum of primitive orthogonal idempotents, following theorem 52.3.2, so that $A = \bigoplus_j Ae_j$ expresses the regular module as a direct sum of indecomposable projectives $P_j = Ae_j$. Two of these are isomorphic exactly when the corresponding simples $P_j/\mathrm{rad}(P_j)$ and $P_{j'}/\mathrm{rad}(P_{j'})$ agree, so grouping the e_j by the isomorphism class of P_j and choosing one representative from each class produces an idempotent

$$e = e_{i_1} + \cdots + e_{i_n}$$

with n the number of simple modules. It is idempotent because the e_{i_j} are orthogonal. Set $A^b := eAe$.

Step 2: e is full. Each e_{i_j} satisfies $e_{i_j}e = e_{i_j}$, again by orthogonality, so $Ae_{i_j}A = Ae_{i_j}eA \subseteq AeA$. For an arbitrary l the projective Ae_l is isomorphic to Ae_{i_j} for some j by the choice of representatives, and isomorphic projectives generate the same two-sided ideal, so $Ae_lA = Ae_{i_j}A \subseteq AeA$. Summing,

$$1 = \sum_{l=1}^{r} e_l \in \sum_{l=1}^{r} Ae_lA \subseteq AeA$$

so $AeA = A$ and e is full.

Step 3: the equivalence. By theorem 18.3.6, a full idempotent makes Ae a progenerator with $\mathrm{End}_A(Ae)^{\mathrm{op}} \cong eAe$, so A and $A^b = eAe$ are Morita equivalent. The equivalence is $\mathrm{Hom}_A(Ae, -)$, which sends an A-module M to eM.

Step 4: A^b is basic, with the stated radical quotient. The equivalence carries the indecomposable projectives of A to those of A^b and preserves isomorphism, and $Ae = \bigoplus_j Ae_{i_j}$ retains exactly one indecomposable projective from each isomorphism class. So the regular representation of A^b contains each simple exactly once, which is what it means for A^b to be basic, and its radical quotient has all blocks of size one. The division rings are unchanged: the equivalence induces a bijection on simple modules and a ring isomorphism on their endomorphism rings, so the blocks are over the same $D_i = \mathrm{End}_A(S_i)^{\mathrm{op}}$ furnished by Schur's lemma (lemma 51.1.5). Uniqueness of A^b up to isomorphism follows because any two choices of representatives give isomorphic modules Ae, hence isomorphic endomorphism rings, completing the proof.

The reduction lets us prove the structure theorem only for basic algebras and inherit it for all finite-dimensional algebras through the equivalence of module categories: whatever we say about the representations of $A^b = kQ_A/I$ transfers verbatim to the representations of A. From now on A is basic, and to make the reconstruction concrete assume k is algebraically closed, so that all simple modules are one-dimensional and the radical quotient is a product of copies of k. This is the setting of Gabriel's theorem, and it is where the assumption $k = \overline{k}$ earns its place: over a non-closed field the division algebras D_i reappear and the vertices of the quiver would have to be weighted by them.

The quiver attached to an abstract algebra can now be defined. Its vertices are the simple modules; its arrows count how simples fail to split off one another, measured either homologically by Ext^1 or internally by the radical filtration. That these two counts agree is the bridge between the abstract and combinatorial descriptions.

Definition 54.2.7: Ext-Quiver (Gabriel Quiver)

Let A be a basic finite-dimensional algebra over an algebraically closed field k, with simple modules $S_1, \dots, S_n$ up to isomorphism and a complete set of primitive orthogonal idempotents $e_1, \dots, e_n$ with $S_i = Ae_i/\mathrm{rad}(Ae_i)$. The *Ext-quiver* (or *Gabriel quiver*) Q_A is the quiver with

1. vertex set $\{1, \dots, n\}$, one vertex for each simple module S_i, and
2. exactly
$$\dim_k \mathrm{Ext}^1_A(S_i, S_j) = \dim_k\, e_j\big(\mathrm{Jac}(A)/\mathrm{Jac}(A)^2\big)e_i$$
arrows from i to j.

The order of the idempotents in the formula is fixed by the multiplication convention of definition 54.1.58 and is worth pausing on, since it is easy to get backwards. In the path algebra a would-be arrow from i to j satisfies $e_j \alpha e_i = \alpha$, so it lives in $e_j(kQ)e_i$; matching this, the arrows from i to j in Q_A are counted by $e_j(\mathrm{Jac}/\mathrm{Jac}^2)e_i$, with e_j on the left and e_i on the right. A source using the opposite (left-to-right) convention for path multiplication would write $e_i(\mathrm{Jac}/\mathrm{Jac}^2)e_j$ instead; the two conventions transpose the quiver, so one must commit to one. Here the commitment is to the book's convention throughout. The equality of the two counts, homological and idempotent-theoretic, is the following lemma, proved here because it is what makes the definition well-posed: the arrow count must not depend on the choice of description.

Lemma 54.2.8: Arrows Count Radical Extensions

Let A be a finite-dimensional k-algebra with primitive orthogonal idempotents $e_1, \dots, e_n$ and simple modules $S_i = Ae_i/\mathrm{rad}(Ae_i)$, and assume k is algebraically closed. Then for all i, j,
$$\mathrm{Ext}^1_A(S_i, S_j) \cong e_j\big(\mathrm{Jac}(A)/\mathrm{Jac}(A)^2\big)e_i$$
as k-vector spaces. In particular the two are equidimensional.

***Proof*:**
Write $J = \mathrm{Jac}(A)$ and $P_i = Ae_i$, the indecomposable projective with top $S_i = P_i/\mathrm{rad}(P_i)$; recall from definition 52.3.3 that $\mathrm{rad}(P_i) = Je_i$, so that $S_i = Ae_i/Je_i$.

Step 1: A projective presentation of S_i. The surjection $P_i \twoheadrightarrow S_i$ has kernel $\mathrm{rad}(P_i) = Je_i$, giving the short exact sequence
$$0 \to Je_i \to P_i \to S_i \to 0$$
Applying $\mathrm{Hom}_A(-, S_j)$ produces the exact sequence
$$0 \to \mathrm{Hom}_A(S_i, S_j) \to \mathrm{Hom}_A(P_i, S_j) \to \mathrm{Hom}_A(Je_i, S_j) \to \mathrm{Ext}^1_A(S_i, S_j) \to 0$$

where the last term is $\mathrm{Ext}^1_A(S_i, S_j)$ and not $\mathrm{Ext}^1(P_i, S_j)$ because P_i is projective, so $\mathrm{Ext}^1_A(P_i, S_j) = 0$ and the connecting map surjects onto $\mathrm{Ext}^1(S_i, S_j)$. The definition and basic properties of Ext^1 as the obstruction to lifting homomorphisms along a projective presentation are developed in the companion volume on core algebra, `NateCoreAlgebra` [25]; we use only that a projective resolution computes it and that projectives have no higher self-extensions.

Step 2: Evaluating the outer terms. For any simple S_j and any module M, a homomorphism $M \to S_j$ factors through $M/\mathrm{rad}(M)$ because $\mathrm{rad}(M)$ maps into $\mathrm{rad}(S_j) = 0$. Applying this to P_i gives $\mathrm{Hom}_A(P_i, S_j) = \mathrm{Hom}_A(S_i, S_j)$, so the first two terms of the sequence in Step 1 cancel and the map between them is an isomorphism. The sequence therefore collapses to

$$0 \to \mathrm{Hom}_A(Je_i, S_j)/\big(\text{image of } \mathrm{Hom}_A(P_i, S_j)\big) \to \mathrm{Ext}^1_A(S_i, S_j) \to 0$$

but the image of $\mathrm{Hom}_A(P_i, S_j)$ in $\mathrm{Hom}_A(Je_i, S_j)$ is zero: a homomorphism $P_i \to S_j$ vanishes on $\mathrm{rad}(P_i) = Je_i$ by the factoring just noted. Hence the connecting map is an isomorphism

$$\mathrm{Ext}^1_A(S_i, S_j) \cong \mathrm{Hom}_A(Je_i, S_j)$$

Step 3: The Hom into a simple is a radical layer. Again by the factoring through the top, any homomorphism $Je_i \to S_j$ kills $\mathrm{rad}(Je_i) = J^2 e_i$, so

$$\mathrm{Hom}_A(Je_i, S_j) = \mathrm{Hom}_A\big(Je_i/J^2e_i,\ S_j\big)$$

The module Je_i/J^2e_i is semisimple, being a module over the semisimple algebra A/J, and S_j is simple, so by Schur's lemma (lemma 51.1.5) and $\mathrm{End}_A(S_j) = k$ (from $k = \overline{k}$) the space $\mathrm{Hom}_A(Je_i/J^2e_i, S_j)$ has dimension equal to the multiplicity of S_j in Je_i/J^2e_i. That multiplicity is $\dim_k e_j(Je_i/J^2e_i)$, since for a semisimple module N over $A/J = \prod_\ell k$ the multiplicity of S_j in N is $\dim_k e_jN$: the idempotent e_j projects N onto its S_j-isotypic part, which over an algebraically closed field is a sum of copies of S_j each one-dimensional. Therefore

$$\dim_k \mathrm{Ext}^1_A(S_i, S_j) = \dim_k e_j(Je_i/J^2e_i) = \dim_k e_j(J/J^2)e_i$$

the last equality because $e_j(J/J^2)e_i = e_j(Je_i)/e_j(J^2e_i)$ and right-multiplication by e_i identifies Je_i/J^2e_i with the e_i-column of J/J^2. Assembling the three isomorphisms gives $\mathrm{Ext}^1_A(S_i, S_j) \cong e_j(J/J^2)e_i$, as we sought to show.

The lemma says the arrows of Q_A have two readings. Homologically, an arrow $i \to j$ records a one-dimensional worth of non-split extension of S_i by S_j: a module of length two with S_j as a submodule and S_i on top that does not break as $S_i \oplus S_j$. Internally, the same arrow is a basis vector of the (j, i) block of the first radical layer $\mathrm{Jac}/\mathrm{Jac}^2$. The first reading is the reason the quiver is called the Ext-quiver and explains why it is an invariant of the module category, hence of the Morita equivalence class; the second reading is the one to compute with, because $\mathrm{Jac}/\mathrm{Jac}^2$ is a finite matrix of idempotent-sandwiched subspaces. The running examples compute it.

Example 54.2.9: Gabriel Quivers of the Running Algebras

Reading off Q_A for two algebras confirms it recovers the starting quiver.

1. *The dual numbers.* Let $A = k[\alpha]/(\alpha^2)$. This is local: its only maximal ideal is (α), so $\mathrm{Jac}(A) = (\alpha)$ and there is a single simple module $S_1 = A/(\alpha) = k$, giving one vertex. The first radical layer is $\mathrm{Jac}/\mathrm{Jac}^2 = (\alpha)/(\alpha^2)$, one-dimensional with basis the image of α, and

with $e_1 = 1$ the block $e_1(\mathrm{Jac}/\mathrm{Jac}^2)e_1$ is all of it. So Q_A has one vertex and one arrow, a loop:

$$\begin{tikzcd} 1 \arrow[loop above, "\alpha"] \end{tikzcd}$$

exactly the quiver we bound in example 54.2.3. The relation to be imposed will be $\alpha^2 = 0$, recovering A.

2. *The upper-triangular algebra.* Let $A = \begin{pmatrix} k & k \\ 0 & k \end{pmatrix}$, the 2×2 upper-triangular matrices. Its radical is the strictly upper-triangular part, $\mathrm{Jac}(A) = kE_{12}$, one-dimensional with square zero. The idempotents $e_1 = E_{11}$ and $e_2 = E_{22}$ are primitive orthogonal with $e_1 + e_2 = 1$, and $A/\mathrm{Jac}(A) \cong k \times k$, so there are two vertices with simples S_1, S_2. Since $\mathrm{Jac}^2 = 0$ we have $\mathrm{Jac}/\mathrm{Jac}^2 = kE_{12}$, and we locate E_{12} by its idempotent sandwich:

$$e_1 E_{12} e_2 = E_{11} E_{12} E_{22} = E_{12}, \qquad e_2 E_{12} e_1 = E_{22} E_{12} E_{11} = 0$$

so the one basis vector of $\mathrm{Jac}/\mathrm{Jac}^2$ sits in the block $e_1(\mathrm{Jac}/\mathrm{Jac}^2)e_2$. By definition 54.2.7 the block $e_j(\cdots)e_i$ counts arrows $i \to j$, so with $j = 1$, $i = 2$ this is one arrow $2 \to 1$:

$$2 \xrightarrow{\alpha} 1$$

Under the identification $\alpha \mapsto E_{12}$ this is the A_2 quiver of example 54.2.3, up to relabelling the vertices, and $\mathrm{Jac}^2 = 0$ forces the admissible ideal to be $I = 0$. The algebra is hereditary, and Q_A carries no relations: the upper-triangular algebra *is* its own path algebra kQ_A.

The two examples describe the same three-dimensional hereditary algebra, once as a bound quiver algebra and once reconstructed from its radical, and the indecomposable projectives match under the identification. Take the bound-quiver presentation of example 54.2.3, the A_2 path algebra with arrow $\alpha\colon 1 \to 2$ realized as the lower-triangular matrices via $e_1 \mapsto E_{11}$, $e_2 \mapsto E_{22}$, $\alpha \mapsto E_{21}$. The indecomposable projective $P_i = kQ \cdot e_i$ is spanned by the paths starting at i: P_1 has basis $\{e_1, \alpha\}$, the trivial path at 1 together with the arrow out of 1, and is two-dimensional with top S_1 and socle S_2, while P_2 has basis $\{e_2\}$ and is the simple S_2 itself. On the matrix side these are the column modules AE_{11} and AE_{22}: the first column of the lower-triangular algebra is two-dimensional, spanned by E_{11} and E_{21} (the entries in rows 1 and 2 of column 1), and the second column is one-dimensional, spanned by E_{22}. So the indecomposable projectives read off from the primitive idempotents of theorem 52.3.2 are exactly the projective quiver representations P_i of the path algebra. The Gabriel reconstruction of example 54.2.9 applied instead the upper-triangular representative, whose radical kE_{12} sits in the opposite corner and so produces the arrow $2 \to 1$; the two matrix algebras are opposite to one another (transpose exchanges upper and lower triangular), which is exactly the transposition of the quiver that the two multiplication conventions differ by. Either way the representation theory of A_2 is the same, and the two constructions coincide.

Everything is now in place for the structure theorem. It asserts that the passage from a basic algebra to its Gabriel quiver and back to a bound quiver algebra is a round trip: A is isomorphic to kQ_A modulo an admissible ideal. The proof builds a surjection $kQ_A \twoheadrightarrow A$ by sending vertices to the primitive idempotents and arrows to a lift of the radical layer, then shows the kernel is admissible using that $\mathrm{Jac}(A)$ is nilpotent.

Theorem 54.2.10: Structure of Basic Algebras (Gabriel)

Let A be a basic finite-dimensional algebra over an algebraically closed field k, with Gabriel quiver Q_A (definition 54.2.7). Then there is an admissible ideal $I \subseteq kQ_A$ and an isomorphism of k-algebras

$$A \cong kQ_A/I$$

Consequently, by the reduction to the basic case (proposition 54.2.6), every finite-dimensional k-algebra over an algebraically closed field is Morita equivalent to a bound quiver algebra kQ/I.

The quiver Q_A is determined by A, but the ideal I is not: different admissible ideals can present isomorphic algebras, so the theorem produces *some* admissible presentation rather than a canonical one. This is the one point where the correspondence between algebras and bound quivers fails to be a clean bijection, and it is the reason bound quiver algebras are studied through their quiver plus a choice of relations rather than through the quiver alone.

***Proof*:**
Write $J = \mathrm{Jac}(A)$, and recall J is nilpotent, say $J^m = 0$ for some $m \geq 2$, because A is finite-dimensional (a nilpotent radical is the Artinian case established in theorem 52.1.8). Let $e_1, \dots, e_n$ be the complete set of primitive orthogonal idempotents underlying Q_A, with $1 = e_1 + \cdots + e_n$ and $S_i = Ae_i/Je_i$.

Step 1: Send vertices to idempotents and arrows to a radical lift. For each vertex i of Q_A set the constant path $\varepsilon_i \in kQ_A$ to map to $e_i \in A$. For the arrows, fix for each pair (i, j) a k-basis of the block $e_j(J/J^2)e_i$; by definition 54.2.7 and lemma 54.2.8 the arrows of Q_A from i to j are in bijection with this basis. For each arrow $\alpha\colon i \to j$ choose a lift $x_\alpha \in e_jJe_i \subseteq A$ of the corresponding basis vector of $e_j(J/J^2)e_i$; such a lift exists because $e_j(J/J^2)e_i$ is a quotient of e_jJe_i. Note $x_\alpha \in e_jJe_i$ means $e_jx_\alpha e_i = x_\alpha$, which is the algebra image of the path relation $e_j\alpha e_i = \alpha$, so the assignment respects the idempotent bookkeeping.

Step 2: Extend to an algebra homomorphism. Because kQ_A is free on paths, an algebra homomorphism out of it is determined by the images of the vertices and arrows, subject only to the relations $\varepsilon_i\varepsilon_{i'} = \delta_{ii'}\varepsilon_i$, $\sum_i \varepsilon_i = 1$, and the source-target matching for arrows. The chosen images e_i and x_α satisfy all of these: the e_i are orthogonal idempotents summing to 1, and $x_\alpha \in e_jAe_i$ matches the source i and target j of α. Extend multiplicatively, sending a path $\alpha_r \cdots \alpha_1$ to the product $x_{\alpha_r} \cdots x_{\alpha_1} \in A$ (in the algebra's own multiplication, so a path from i to j lands in e_jAe_i). This defines a k-algebra homomorphism

$$\varphi\colon kQ_A \to A$$

Step 3: φ is surjective. The image contains all e_i and, since each x_α together with the x_α-products spans, it contains a lift of a basis of J/J^2. We show $\mathrm{im}\varphi = A$ by showing it contains all of $A = A/J^0 \supseteq J \supseteq J^2 \supseteq \cdots \supseteq J^m = 0$ layer by layer. The images $\varphi(\varepsilon_i) = e_i$ generate $A/J = \prod_i ke_i$ over k, so $\mathrm{im}\varphi + J = A$. Next, the products of length one, $x_\alpha = \varphi(\alpha)$, form lifts of a basis of J/J^2, so $\mathrm{im}\varphi + J^2 \supseteq J$, hence $\mathrm{im}\varphi + J^2 = A$. Inductively suppose $\mathrm{im}\varphi + J^\ell = A$; then J^ℓ is spanned modulo $J^{\ell+1}$ by products of ℓ elements of J, each of which may be taken from the spanning set $\{x_\alpha\}$ of J modulo J^2, so products $\varphi(\alpha_\ell \cdots \alpha_1)$ of ℓ arrows span J^ℓ modulo $J^{\ell+1}$. Thus $\mathrm{im}\varphi + J^{\ell+1} = A$. Since $J^m = 0$, after m steps $\mathrm{im}\varphi = \mathrm{im}\varphi + J^m = A$, so φ is surjective.

Step 4: The kernel is admissible. Let $I = \ker\varphi$, so $A \cong kQ_A/I$. It remains to check $R_Q^{m'} \subseteq I \subseteq$

R_Q^2 for some m', where R_Q is the arrow ideal of kQ_A.

For the lower bound, $\varphi(R_Q^m) \subseteq J^m = 0$: a path of length at least m is a product of at least m arrows, and each arrow maps into J, so a length-$\geq m$ path maps into $J^m = 0$. Hence $R_Q^m \subseteq \ker \varphi = I$, giving the lower bound with $m' = m$.

For the upper bound $I \subseteq R_Q^2$, suppose $u \in I$ and write $u = u_0 + u_1 + u_2$ where $u_0 \in kQ_{A,0}$ is the constant-path part, u_1 is the arrow part (length exactly one), and $u_2 \in R_Q^2$ collects the length-≥ 2 paths. We must show $u_0 = 0$ and $u_1 = 0$. Applying φ and reducing modulo J: $\varphi(u_1) \in J$ and $\varphi(u_2) \in J^2 \subseteq J$, so $0 = \varphi(u) \equiv \varphi(u_0) \pmod{J}$. But φ restricted to constant paths is the isomorphism $kQ_{A,0} = \prod_i k\varepsilon_i \xrightarrow{\sim} \prod_i ke_i = A/J$ (the e_i are linearly independent modulo J because they are orthogonal idempotents with distinct simple tops), so $\varphi(u_0) \equiv 0 \pmod{J}$ forces $u_0 = 0$. Now reduce modulo J^2: with $u_0 = 0$ we have $0 = \varphi(u) = \varphi(u_1) + \varphi(u_2)$, and $\varphi(u_2) \in J^2$, so $\varphi(u_1) \equiv 0 \pmod{J^2}$. But $\varphi(u_1)$ is the image in J/J^2 of a linear combination of arrows, and the arrows were chosen to map to a *basis* of J/J^2; a linear combination of basis vectors that is zero in J/J^2 has all coefficients zero, so $u_1 = 0$. Therefore $u = u_2 \in R_Q^2$, proving $I \subseteq R_Q^2$.

Combining the two bounds, $R_Q^m \subseteq I \subseteq R_Q^2$, so I is admissible and $A \cong kQ_A/I$ is a bound quiver algebra. The final clause on general algebras follows by composing with the Morita reduction of proposition 54.2.6: an arbitrary finite-dimensional A is Morita equivalent to its basic algebra A^b, and $A^b \cong kQ_{A^b}/I$ by what was just proved, completing the proof.

Three features of the argument deserve a closing word. The surjectivity in Step 3 is a radical-filtration induction: because $\mathrm{Jac}(A)$ is nilpotent, generating $A/\mathrm{Jac}(A)$ by the idempotents and the first radical layer $\mathrm{Jac}/\mathrm{Jac}^2$ by the arrows suffices to generate all of A, since higher layers are spanned by products. The admissibility of the kernel in Step 4 is the exact counterpart of the two bounds in definition 54.2.1: the lower bound $R_Q^m \subseteq I$ is nilpotence of the radical, and the upper bound $I \subseteq R_Q^2$ is the choice of arrows as a basis of $\mathrm{Jac}/\mathrm{Jac}^2$, which is precisely why an admissible ideal is forbidden to contain constant paths or bare arrows. And the theorem is the structure theorem of Gabriel, to be kept distinct from Gabriel's other theorem in this chapter (theorem 54.1.47), which classifies the quivers of finite representation type as the simply-laced Dynkin diagrams A, D, E. The two results are complementary: the present one says every finite-dimensional algebra is a bound quiver algebra, and the Dynkin classification says which of the unbound path algebras have only finitely many indecomposable modules.

Part XI

Homological Algebra

Throughout this book, the reader has encountered many functors, some notable examples being $\operatorname{Hom}_R(-, N)$, $\operatorname{Hom}_R(M, -)$ and $M \otimes_R -$ among many others. Each of these functors give some information about the objects and the morphisms passing through the functor. As we saw for the Hom and $M \otimes_R -$ functors, certain appropriate objects preserve exactness, while most preserve it only partially. Perhaps a crowning achievement of mid 20th century mathematics is to be able to quantify this lack of exactness, and rather spectacularly use the information given by this quantification to extract a (sometimes copious) amount of information about the objects of study. The great effectiveness with which homological algebra can produce interesting information may seem surprising at first, for example, using homological algebra the notion of *dimension* as it is understood in geometry is readily translatable to algebra, or that we may measure how far away a module is from being a vector-space (details are in K-theory)[1] How this is the case is perhaps best motivated by going through learning the subject to see for oneself, but it may be helpful for some readers to have some of my (the authors) intuition presented to stand on some ground before proceeding.

If we have two objects M_1 and M_2, we may wish to consider a way of constructing a new object M given M_1 and M_2. Ideally, we may form a short exact sequence like so:

$$0 \to M_1 \to M \to M_2 \to 0$$

More generally, we may have a collection of objects $\{M_i\}_{i \in I}$ which we use to construct an object via a long exact sequence. However, it is often not the case that such an exact sequence is too strong, that is, it is not the case that $\operatorname{im}(\varphi_i) = \ker(\varphi_{i+1})$. Even if such a construction exists, we often then want to "transform" this information via a functor which shall then lose us exactness (one can think of a functor as asking some sort of "question" whose output is the answer). In this case, it has been eerily common that the image of φ_i is contained in the kernel of φ_{i+1}:

$$\operatorname{im}(\varphi_i) \subseteq \ker(\varphi_{i+1}) \tag{54.1}$$

Conceptually, this can be thought as the object "being obstructed" from fully being an extension. This new type of sequence is called a *cochain complex.* The reader with a good memory may recall definition 12.2.11 where it was given that another name for a long exact sequence is an exact cochain complex. In this way, the condition given by equation 54.1 is a generalization of the exact condition. The theoretical heart of homological algebra can be thought of how to extract "quantitatively" how a cochain complex *fails* to be an exact cochain complex. For example, in chapter 17⋆ it was have eluded that through the use of homology theory, the Ext functor gives us all the ways two modules M_1, M_2 may be extended. In this case, the failure of $\operatorname{Hom}(M, -)$ or $\operatorname{Hom}(-, N)$ preserving injectivity or surjectivity (equivalently, the "obstruction" to these functors being exact) gave rise to the Ext functor and the study of its homology.

The term "algebraic object" has been is a bit ambiguous. What type of algebraic objects can be used to in the theory of homological algebra? As it turns out, not all algebraic objects satisfy the right conditions for the theory of homological algebra (for example, **Grp** and **Fld** will be shown to be inappropriate for a theory of homology). However, there are non-algebraic objects for which a homological theory can be induced (famously, topological spaces and smooth manifolds admit a theory of homological algebra). This spurred the need to generalize the theory of homological algebra to the categorical level, where homological theory is well-defined on *abelian categories.* We thus shall start homological algebra with an overview of abelian categories. For those who are already familiar with some homological algebra, they may have studied homological algebra within the category of

[1] This is overviewed in chapter 57

R-**Mod**, which is a concrete abelian category. Doing so will in fact not loose any generality due to Freyd-Mitchell Theorem (theorem 55.1.15) which states that any [small] abelian category A admits a fully faithful exact functor to a category R-**Mod** for a suitable ring R. Working with the concrete category R-**Mod** brings it benefits as it may be easier to conceptualize the manipulation of elements, and so the reader may ask for the benefit in sticking to working with general abelian categories. As the author, I believe the benefits comes in being comfortable with more advanced category theory. Future algebraists are going to encounter more complicated problems involving category theory (higher order categories, topoi's, and stacks, are all examples the reader may see in the not too distant future). Hence, introducing a categorical perspective will familiarize the reader for more complicated categorical notions in their not too distant future[2].

The reader may wonder why a cochain complex is not called a chain complex. This is because we can work in the dual category, where all arrows are flipped. In the dual category, we shall get chain complexes. Homological algebra in the dual category is theoretically the same, however we shall see that cohomology is often computationally easier to work in, permitting more useful algebraic structures we can use to study. It is for this reason that most mathematicians work with cohomology rather than homology, even though every theorem we shall show for homology translates directly to cohomology[3]. In this book, we shall start with homology, and switch to cohomology when starting to work with more computational parts of the theory to get the reader accustomed to both modes of thinking.

Goal

Chapter 55 shall introduce the theory of abelian categories which shall be the types of categories in which homological algebra is well-defined.

The main result Chapter 56 of the book is trying to convey is what information from R-modules give rise to certain properties in its respective chain complex(es), and conversely what information from it's chain complex(es) gives us information about modules. A (co)chain complex need not be exact, and (co)homology shall be the algebraic object quantifying this failure of exactness. We shall see that given an object M within an abelian category, there are in general an infinite number of ways we may associate a [co]chain complex to it. Thus, there will have to be a way to either associate a canonical [co]chain complex (in a natural functorial manner), or we assign [co]chain complexes to an object up to appropriate notion of isomorphism. The latter shall be the approach in this book, where we shall see that we will want to consider [co]chain complexes up to something called *quasi-isomorphism* of [co]chain complexes. We shall then see what cohomological information we may deduce given different choices of functors and how they transform [co]chain complexes.

After having developed the ground work for extracting cohomological information, in Chapter 57 we shall put this knowledge to good use and apply cohomology theory to G-invariant functors and see what this this can tell us about groups. This shall also finally address what was foreshadowed in box 20.4.5 where it was said the units of a Galois field form a trivial 1st homology group. We shall define the notion of homological dimension which shall line up with the results presented in the section on commutative algebra. Finally, we present an interesting technical result to check flatness of a module over a local ring that builds on the same intuitions the Nakayama lemma (lemma 52.1.7)

[2]assuming, naturally, that the reader holds great interest in algebra and shall keep pursuing branches within the field

[3]there is even an equivalent algebraic structure for the additional algebraic structure that is induced in cohomology, however it is less useful

presented.

Finally, this Part concludes with the introduction to spectral sequences in chapter 58, which are the quintessential tool for many concrete computations in homological algebra and any serious work in many disciplines of algebra and geometry. The main idea is that most object of study can be broken down into a filtration of simpler objects whose cohomology is more computed. The spectral sequence will put piece together this cohomological information.

Connection to Singular Homology/Cohomology

For readers familiar with algebraic topology and the theory of (co)homology, the connection between the above abstraction and the homology theory of topological spaces comes from noticing that singular (co)homology on a manifold can be interpreted as taking the projective resolution $C_n(X) = \mathrm{Hom}_{\mathbf{Top}}(\Delta^n, X)$. In particular, given M, we can apply $C_*(-)$ to it and get a projective (even free) resolution from which we extract homological information. This should also motivate the use of $\mathrm{Hom}_R(M, -)$ and $\mathrm{Hom}_R(-, N)$ as the "right" functors to be considering when generalizing classical algebraic topology to the algebraic setting. As the tensor product it adjoint (theorem 15.3.9) it is another natural candidate.

54.2.11 Foreshadowing: Yoneda's Lemma The Hom is very useful as it is "represented" by an element (either in the domain or codomain). Even more is true: it can be used to represent other functors. In theorem 60.2.1 this is studied *representable functors* which are functors where $F(-) \Rightarrow \mathrm{Hom}_C(A, -)$ for natural transformation $\Rightarrow$, category C, object $A \in C$, and $F : C \to \mathbf{Set}$. The Yoneda lemma will give a way of representing objects using Hom.

Historical Origins

While modern homological algebra is phrased in the language of categories, its machinery evolved from two distinct 19th-century sources which converged in the mid-20th century.

The algebraic lineage begins around 1890 with David Hilbert's Invariant Theory. To prove the Basis Theorem, Hilbert studied the relations ("syzygies") between generators of an ideal. He constructed a chain of free modules to resolve these relations:

$$0 \to F_n \to \cdots \to F_1 \to F_0 \to M \to 0$$

Hilbert proved the *Syzygy Theorem*, showing that for polynomial rings, this chain of relations eventually terminates in an exact sequence of free modules. However, this theory encountered a significant obstruction when applied to rings with singularities (such as coordinate rings of singular curves). In these non-regular settings, Hilbert's resolutions do not terminate but continue infinitely. This failure shifted the mathematical focus from simply computing invariants to essentially classifying the severity of a singularity by the infinite length of its resolution.

Parallel to this, in the 1930s, number theorists like Emmy Noether, Richard Brauer, and Helmut Hasse were attempting to classify division algebras (generalizations of the quaternions) over number fields. They classified these algebras using "Crossed Products," which relied on complex systems of functions called "Factor Sets" ($c : G \times G \to K^\times$). While they successfully defined the *Brauer Group* of a field to organize these algebras, the calculations were notoriously opaque. The "Factor Sets" satisfied a messy algebraic identity that seemed arbitrary, acting as a computational blocker that obscured the underlying structure of the fields they were studying.

Simultaneously, from 1895 onwards, the topological roots of the subject were forming as Henri Poincaré classified manifolds. He decomposed spaces into simplices and represented their boundaries using incidence matrices. He defined Betti numbers as the ranks of these matrices. However, Poincaré's numerical approach had a blind spot: rank obliterates "torsion." A twisted shape like the projective plane appeared numerically identical to a trivial one (both have rank 0 in dimension 1).

In 1925, Emmy Noether revolutionized this view. She realized that the matrices topologists were diagonalizing were actually presentations of abelian groups. By shifting focus from the numerical rank to the *Homology Group* itself ($\ker \partial / \operatorname{im} \partial$), she captured the torsion information, effectively "algebraizing" the topology. She showed that the matrix was not just a calculator for a number, but a presentation of a structure.

The convergence of these fields occurred in the 1940s when algebraists attempted to classify *Group Extensions*. Saunders Mac Lane and Samuel Eilenberg attempted to classify these extensions and rediscovered the same "Factor Sets" used by Brauer and Hasse. They discovered that the algebraic identity these functions satisfied was *identical* to the boundary formula for a 2-simplex in topology; essentially they realized they were calculating $H^2(G, N)$ (see [13] for this computation in the EYNTKA series). This was the turning point: it proved that "cohomology" was not just a property of geometric shapes, but a fundamental algebraic structure that arose whenever one tried to "extend" one object by another, whether in topology, group theory, or number theory.

The grand unification arrived in 1956 when Cartan and Eilenberg realized that the topological concept of "boundaries" and the algebraic concept of "extensions" were instances of the same phenomenon: the *failure of exactness*. They observed that while Hilbert's resolution is exact, applying a functor (like the tensor product or Hom) usually destroys that exactness. They realized that the "homology" groups were simply the mathematical terms required to repair this broken exactness. This birth of the *Derived Functor* (Tor and Ext) transformed the field from the study of static objects to the study of how functors distort structure. To build this machinery, they faced a technical blocker: Hilbert's reliance on "Free Modules." While free modules worked for Homology (Tor), they failed for the dual theory of Cohomology (Ext), as the dual of a free module is rarely free. To achieve the necessary symmetry, they replaced the specific condition of "Freeness" with the categorical properties of *Projectivity* and *Injectivity*. This allowed them to define derived functors for any ring, regardless of whether a basis existed.

With this machinery established, the period from 1955 to 1980 saw these newly developed tools being used to solving the original obstructions in geometry and number theory. In geometry, Jean-Pierre Serre proved that a local ring is regular (non-singular) if and only if it has finite global homological dimension (theorem 57.2.8). This transformed the "problem" of infinite resolutions into a precise detection tool: the non-terminating resolution was effectively the algebraic signature of a geometric singularity. Alexander Grothendieck later introduced *Local Cohomology* ($H^i_{\mathfrak{m}}$) to quantify the depth and severity of these singularities, eventually leading to Intersection Homology which restored Poincaré Duality to singular spaces.

In number theory, the mysterious "Factor Sets" of the 1930s were identified as elements of the second Galois Cohomology group, $H^2(\mathrm{Gal}(L/K), L^\times)$. This realization allowed Emil Artin and John Tate to rewrite Class Field Theory entirely in the language of cohomology. The obscure identities of the past were revealed to be standard cohomological relations, and the *Tate Cohomology* groups ($\hat{H}^i$) were developed specifically to handle the arithmetic of finite groups, solving the classification problems that had stalled the previous generation (see [39] for the EYNTKA series exposition of modern class field theory).

55

Abelian Categories

This chapter focuses on the category in which we may define "cohomological theories" as not all categories are well-suited for this endeavor

55.1 Definitions and Properties

We have extensively worked with categories which have a multitudes of different properties. Some important terms to recall are the following:

- *zero-object*: an object 0 in a category C $0 \in \mathrm{Obj}(C)$ that is both the initial and final object. Such an object is also called a terminal object. Similarly, a zero morphism is a morphism $f : X \to Y$ such that for any other morphisms $g, h : X \to Y$, $fg = fh$ and $hf = gf$.
- *Products* and *Coproducts*: Given two objects $a, b \in \mathrm{Obj}(C)$, if there exists an object $c \in \mathrm{Obj}(C)$ that is the limit (resp. colimit) of the diagram:

$$\overset{A}{\bullet} \qquad \overset{B}{\bullet}$$

  then c is the product (resp. coproduct) of a and b, and is usually written as $a \times b$ (resp. $a \amalg b$)
- *kernels* and *cokernels*: Given a morphism $f : a \to b$, the kernel (resp. cokernel) of f is an object k and a morphism $\iota : k \to a$ such that k is the limit (resp. colimit) of the diagarm:

$$\overset{a}{\bullet} \xrightarrow{f} \overset{b}{\bullet}$$

  with the added restriction that the map $\varphi : k \to y$ must be the zero morphism (namely, by commutativity, $f\iota = 0_{kb}$ must be the zero morphism). In terms of diagrams, we get that that for any $\iota' : K \to A$ such that $f\pi\iota' = 0$, that there exists a morphism φ st the following diagram commutes:

$$\begin{tikzcd}
K' \arrow[r, "\iota'"'] \arrow[rr, bend left, "0"] \arrow[dr, dashed, "\varphi"'] & A \arrow[r, "\varphi"'] & B \\
& K \arrow[u, "\iota"'] &
\end{tikzcd}$$

and simmilarly for cokernels:

$$\begin{tikzcd}
& K' \arrow[d, "\pi'"] \arrow[dr, dashed, "\psi"] & \\
A \arrow[r, "\varphi"] \arrow[rr, bend right, "0"'] & B \arrow[r, "\pi"] & K
\end{tikzcd}$$

Kernels and cokernels do not necessarily exist in a category, or not all morphisms have kernels (ex. the category of finitely generated R-modules for any ring R need has morphisms without kernels). Furthermore, monomorphism need not be kernels (not all subgroups are normal) and epimorphisms need not be cokernels (recall $\mathbb{Z} \to \mathbb{Q}$ is an epimorphism in **Ring**)

Not all categories we have worked with have these properties. For example, **Fld** doesn't have products (what would be the characteristic of the product of $\mathbb{F}_p$ and $\mathbb{F}_q$ for $p \neq q$?), some categories don't have zero morphisms (set being an example), some have monomorphisms/epimorphisms that do not correspond to kernels (as showed above). We first limit our attention to categories which have these nice properties:

Definition 55.1.1: Additive Category

Let $\mathbf{A}$ be a category. Then $\mathbf{A}$ is said to be *additive* if it has a zero-object, has both finite products and coproducts, and each $\text{Hom}_A(X, Y)$ can be given an abelian group structure such that the composition of maps:

$$\text{Hom}_A(X, Y) \times \text{Hom}_A(Y, Z) \to \text{Hom}_A(X, Z)$$

is bilinear. A functor between additive categories is *additive* if it is a group homomorphism on hom-sets.

A functor between two additive categories is called an *additive functor* if the maps between the hom-sets is a homomorphism.

The term "additive" comes froms the fact that we may interpret the additive category as a monoidal category (a category which we may add a functor $\otimes : C \times C \to C$ that is given the property of a monoid operation, for an additive category this would be the direct product), where the hom-sets are "enriched" to also be abelian groups. Another way of looking at additive categories is in which the algebra of matrices is well-defined.

Example 55.1.2: Additive Categories

1. The category of R-modules is an example of an additive category.

2. **Grp** is not additive, for $\mathrm{Hom}_{\mathbf{Grp}}(A, B)$ doesn't have an abelian group strucuture satisfying the above condition.

3. The category of matrices over a ring is an additive category.

4. The category of finitely generated R-modules is an additive category

A key realisation is that in the absence of kernels and cokernels as objects monomorphisms and epimorphisms take their place:

Lemma 55.1.3: Additive Categories: Monomorphisms and Kernels I

Let A be an additive category. Then kernels are monomorphisms and cokernels are epimorphisms

***Proof*:**
Let $k\colon K \to A$ be a kernel of $\varphi\colon A \to B$, and let $f, g\colon X \to K$ satisfy $k \circ f = k \circ g$. Because the hom-sets of an additive category are abelian groups and composition is bilinear, this says $k \circ (f - g) = 0$.

Now apply the universal property of the kernel to the zero morphism $0\colon X \to A$. It satisfies $\varphi \circ 0 = 0$, so there is a *unique* morphism $u\colon X \to K$ with $k \circ u = 0$. Both $f - g$ and the zero morphism $X \to K$ have this property, so uniqueness forces $f - g = 0$, that is $f = g$. Hence k is a monomorphism.

The statement for cokernels is the same argument in the opposite category: a cokernel of φ in A is a kernel of φ in A^{op}, an additive category, and a monomorphism there is an epimorphism in A, completing the proof.

Note that kernels and cokernels need not exist in an additive category, hence the converse of each accession need not be the case (in a vacuous way). If a morphism φ has a kernel then we may identify exactly what this kernel is:

Lemma 55.1.4: Additive Categories: Monomorphisms and Kernels II

Let A be an additive category and $\varphi : X \to Y$ a morphism. Then:

1. If φ has a kernel, then φ is a monomorphism if and only if $0 \to X$ is its kernel

2. If φ has a cokernel, then φ is an epimorphism if and only if $Y \to 0$ is its cokernel

***Proof*:**

1. Suppose first that the zero morphism $0 \to X$ is a kernel of φ, and let $f, g\colon Z \to X$ satisfy $\varphi \circ f = \varphi \circ g$. Then $\varphi \circ (f - g) = 0$, so $f - g$ factors through the kernel: there is $u\colon Z \to 0$ with $f - g = 0 \circ u = 0$. Hence $f = g$ and φ is a monomorphism.

   Conversely suppose φ is a monomorphism and let $k\colon K \to X$ be a kernel of φ. From

$\varphi \circ k = 0 = \varphi \circ 0$ and φ monic it follows that $k = 0$. But k is itself a monomorphism by lemma 55.1.3, and $k \circ \mathrm{id}_K = 0 = k \circ 0$, so $\mathrm{id}_K = 0$. An object whose identity is the zero morphism is a zero object, so $K \cong 0$ and the kernel is $0 \to X$.

2. This is the statement of (1) in the opposite category, where kernels and monomorphisms become cokernels and epimorphisms.

This completes the proof.

As mentioned, it is not guaranteed that kernels and cokernels exist. We shall shortly axiomatically add them to our category by adding them into the definition of a new category that supersedes additive categories, but first we show a few more important results about abelian categories. Namely, in an additive category, products and coproducts are equivalent:

Lemma 55.1.5: Additive Categories: Products and Coproducts

Let A be an additive category and $X, Y \in \mathrm{Obj}(A)$. Then if $X \times Y$ exists, so does $X \amalg Y$, and if $X \amalg Y$ exists, so does $X \times Y$. Furthermore,

$$X \times Y \cong X \amalg Y$$

***Proof*:**
Suppose $P = X \times Y$ exists, with projections $p_X : P \to X$ and $p_Y : P \to Y$. Let $i_X : X \to P$ be the unique morphism with $p_X i_X = \mathrm{id}_X$ and $p_Y i_X = 0$, and let $i_Y : Y \to P$ be defined symmetrically; both exist by the universal property of the product.

Step 1: The key identity $i_X p_X + i_Y p_Y = \mathrm{id}_P$. Two morphisms out of P into P agree as soon as their composites with p_X and with p_Y agree, again by the universal property of the product. Compute

$$p_X(i_X p_X + i_Y p_Y) = (p_X i_X)p_X + (p_X i_Y)p_Y = \mathrm{id}_X \circ p_X + 0 \circ p_Y = p_X$$

using bilinearity of composition, and symmetrically $p_Y(i_X p_X + i_Y p_Y) = p_Y$. Since id_P has the same two composites, the identity holds.

Step 2: (P, i_X, i_Y) is a coproduct. Let $f : X \to Z$ and $g : Y \to Z$ be given and set $h = f p_X + g p_Y : P \to Z$. Then

$$h i_X = f(p_X i_X) + g(p_Y i_X) = f, \qquad h i_Y = f(p_X i_Y) + g(p_Y i_Y) = g$$

so h is a morphism with the required restrictions. For uniqueness, suppose h' also satisfies $h' i_X = f$ and $h' i_Y = g$. Then by Step 1,

$$h' = h' \mathrm{id}_P = h'(i_X p_X + i_Y p_Y) = (h' i_X)p_X + (h' i_Y)p_Y = f p_X + g p_Y = h$$

Hence P with i_X, i_Y satisfies the universal property of $X \amalg Y$, and in particular $X \times Y \cong X \amalg Y$.

If instead $X \amalg Y$ is assumed to exist, the same argument in the opposite category produces the product, completing the proof.

Hence, additive categories behave very much like abelian groups, however as we pointed out kernels and cokernels need not exist. We thus define a new category that forces these conditions:

Definition 55.1.6: Abelian Category

[Abelian Category] Let A be an additive category. Then A is an *abelian* category if

1. kernels and cokernels exist in A;
2. every monomorphism is the kernel of some morphism, and every epimorphism is the cokernel of some morphism.

The second condition is not a consequence of the first, and it is the one that does the work. An additive category satisfying only (1) is called *pre-abelian*, and there the canonical map from the coimage to the image of a morphism (theorem 55.1.9) need not be an isomorphism; the category of torsion-free abelian groups is pre-abelian but not abelian, since $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ is there both a monomorphism and an epimorphism without being an isomorphism. Condition (2) rules this out, and is what makes lemma 55.1.8 true.

Note that lemma 55.1.4 is a weaker statement, not this one: it characterizes a monomorphism by having *zero* kernel, which says nothing about whether the monomorphism is itself a kernel.

Since each kernel is associated to a monomorphism, we may intuitively think of the association:

$$\text{kernel} \;\Leftrightarrow\; \text{submodule}$$

and similarly:

$$\text{cokernel} \;\Leftrightarrow\; \text{quotient module}$$

In many ways, an abelian category should be thought of as the minimum number of conditions necessary to define exact sequence[1]. To see this, we require the following:

Lemma 55.1.7: Abelian Category: Kernels And Cokernels

Let A be an abelian category. Then every kernel is the kernel of its cokernel, and every cokernel is the cokernel of its kernel.

***Proof*:**
Let $k\colon K \to A$ be a kernel, say of $\varphi\colon A \to B$, and let $c\colon A \to C$ be a cokernel of k. The claim is that k is a kernel of c.

First, $c \circ k = 0$ holds by the definition of a cokernel. Now let $t\colon T \to A$ satisfy $c \circ t = 0$; a unique factorization of t through k is needed. Since $\varphi \circ k = 0$ and c is the cokernel of k, the morphism φ factors as $\varphi = \bar{\varphi} \circ c$ for some $\bar{\varphi}\colon C \to B$. Therefore

$$\varphi \circ t = \bar{\varphi} \circ c \circ t = 0$$

and since k is the kernel of φ, there is a unique $u\colon T \to K$ with $k \circ u = t$. Uniqueness is automatic because k is a monomorphism by lemma 55.1.3. So k satisfies the universal property of $\ker c$.

[1] Those familiar with some algebraic topology may find it insightful that an abelian category is the the category with ninimum number of condition so that the snake lemma (theorem 56.1.15) holds

The dual statement, that every cokernel is the cokernel of its kernel, is this argument in the opposite category, completing the proof.

Lemma 55.1.8: Abelian Categories: Isomorphisms

[Abelian Categories, Isomorphisms] Let $\mathcal{A}$ be an abelian category and $\varphi : A \to B$ a morphism in $\mathcal{A}$. Then if φ is a monomorphism and an epimorphism, it is an isomorphism

Note that this does not hold in additive categories, nor even in pre-abelian ones: condition (2) of definition 55.1.6 is exactly what the proof below consumes.

***Proof*:**
Since φ is an epimorphism, condition (2) of definition 55.1.6 makes it the cokernel of some morphism $\psi\colon C \to A$. By the definition of a cokernel $\varphi \circ \psi = 0$, so ψ factors through $\ker \varphi$ by the universal property of the kernel.

Now φ is also a monomorphism, so $\ker \varphi = 0$ by lemma 55.1.4. The factorization of the previous paragraph then runs through the zero object, so $\psi = 0$ outright and φ is a cokernel of the zero morphism $0 \to A$. But the identity $\mathrm{id}_A\colon A \to A$ is also a cokernel of $0 \to A$: any $f\colon A \to X$ with $f \circ 0 = 0$, which is every f, factors uniquely through id_A. Cokernels are unique up to unique isomorphism, so there is an isomorphism $A \to B$ commuting with φ and id_A, which forces φ to be that isomorphism, as we sought to show.

Theorem 55.1.9: Abelian Category: Canonical Decomposition

[Abelian Category, Canonical Decomposition] Let $\mathcal{A}$ be an abelian category and $\varphi : A \to B$ a morphism. Write $C = \operatorname{coker}(\ker \varphi)$ and $K = \ker(\operatorname{coker}\varphi)$. Then φ decomposes in the following cannonical way:

$$\begin{tikzcd} A \arrow[r, two heads] \arrow[rrr, bend left, "\varphi"] & C \arrow[r, "\tilde{\varphi}"'] & K \arrow[r, tail] & B \end{tikzcd}$$

where the first morphism is an epimorphism, the last a monomorphism, and the middle morphism $\tilde{\varphi}$ is an *isomorphism*.

***Proof*:**
Write $k\colon N \to A$ for $\ker \varphi$ and $p\colon A \to C$ for its cokernel, and $q\colon B \to Q$ for $\operatorname{coker}\varphi$ and $\iota\colon K \to B$ for its kernel. By lemma 55.1.3 the morphism p is an epimorphism and ι is a monomorphism.

Step 1: φ factors through ι. Since q is the cokernel of φ, $q \circ \varphi = 0$, and since ι is the kernel of q there is a unique $\varphi'\colon A \to K$ with $\varphi = \iota \circ \varphi'$.

Step 2: φ' factors through p. From $\iota \circ \varphi' \circ k = \varphi \circ k = 0$ and ι monic it follows that $\varphi' \circ k = 0$. As p is the cokernel of k, there is a unique $\tilde{\varphi}\colon C \to K$ with $\varphi' = \tilde{\varphi} \circ p$. Combining, $\varphi = \iota \circ \tilde{\varphi} \circ p$, which is the displayed factorization.

Step 3: ι is the smallest subobject through which φ factors. Let $m\colon V \to B$ be any monomorphism with $\varphi = m \circ \psi$ for some ψ. By condition (2) of definition 55.1.6 the monomorphism m is a kernel, so by lemma 55.1.7 it is the kernel of its own cokernel; write $d\colon B \to D$ for coker$m$, so that $m = \ker d$. Then

$$d \circ \varphi = d \circ m \circ \psi = 0$$

so d factors through the cokernel of φ, say $d = \bar{d} \circ q$. Since $\iota = \ker q$ gives $q \circ \iota = 0$, it follows that $d \circ \iota = \bar{d} \circ q \circ \iota = 0$, and therefore ι factors through $\ker d = m$.

Step 4: φ' is an epimorphism. Let $c\colon K \to W$ be the cokernel of φ' and $n\colon V \to K$ its kernel. From $c \circ \varphi' = 0$ the morphism φ' factors as $\varphi' = n \circ \psi$, whence $\varphi = \iota \circ n \circ \psi$. The composite $\iota \circ n$ is a monomorphism, being a composite of two (each is a kernel, so lemma 55.1.3 applies), so Step 3 gives a t with $\iota = \iota \circ n \circ t$. As ι is monic this yields $n \circ t = \mathrm{id}_K$, so n is a split epimorphism as well as a monomorphism, hence an isomorphism by lemma 55.1.8. Then $c \circ n = 0$ with n invertible forces $c = 0$; but c is a cokernel, hence an epimorphism by lemma 55.1.3, and $\mathrm{id}_W \circ c = 0 = 0 \circ c$ then gives $\mathrm{id}_W = 0$, so $W \cong 0$. A morphism with zero cokernel is an epimorphism, so φ' is one.

Step 5: $\tilde{\varphi}$ is an isomorphism. By Step 4 the composite $\tilde{\varphi} \circ p = \varphi'$ is an epimorphism, and if $u \circ \tilde{\varphi} = 0$ then $u \circ \tilde{\varphi} \circ p = 0$ and hence $u = 0$; so $\tilde{\varphi}$ is an epimorphism. Dually, running Steps 1 to 4 in the opposite category shows that the induced morphism $C \to B$, which is $\iota \circ \tilde{\varphi}$, is a monomorphism; and a composite $g \circ h$ can be a monomorphism only if h is, so $\tilde{\varphi}$ is a monomorphism. Being both, it is an isomorphism by lemma 55.1.8, completing the proof.

From the above, we may think of ker(coker) : $K \to B$ as representing the "image" of φ:

Lemma 55.1.10: Abelian Category: Images

Let $\varphi : A \to B$ be a morphism in an abelian category, and let $\iota : K \to B$ be the kernel of the cokernel of φ. Then:

1. ι is a monomorphism
2. φ factors through ι
3. ι is initial with these properties

***Proof*:**
Part (1) is lemma 55.1.3, since ι is a kernel. Part (2) is Step 1 of the proof of theorem 55.1.9: writing $q = \mathrm{coker}\varphi$, the identity $q \circ \varphi = 0$ makes φ factor uniquely through $\iota = \ker q$.

Part (3) is the minimality established in Step 3 of that proof: if $m\colon V \to B$ is any monomorphism through which φ factors, then ι factors through m. Concretely, m is a kernel by condition (2) of definition 55.1.6, hence the kernel of its own cokernel d by lemma 55.1.7; then $d \circ \varphi = 0$ makes d factor through q, so $d \circ \iota = 0$ and ι factors through $\ker d = m$, as we sought to show.

Definition 55.1.11: Abelian Category: Image

Let $\varphi : A \to B$ be a morphism in an abelian category. Then the *iamge* of φ is $\ker(\operatorname{coker}(\varphi))$ and is denoted $\operatorname{im}(\varphi)$. Similarly, its co-image is $\operatorname{coker}(\ker(\varphi))$ and is dentoed $\operatorname{coim}(\varphi)$.

With our intuition from working with R-modules, given a morphism $\varphi : A \to B$ with image $\iota : K \to B$, we may imagine there is an induced epimorphism $\overline{\varphi} : A \to K$. This is indeed the case:

Proposition 55.1.12: Abelian Category: sub object and quotient objects

Let $\varphi : A \to B$ be a morphism in an abelian category with image $\operatorname{im}\varphi\colon K \to B$ and coimage $\operatorname{coim}\varphi\colon A \to C$. Then the induced morphism $A \to K$ is an epimorphism and the induced morphism $C \to B$ is a monomorphism.

***Proof*:**
The induced morphism $A \to K$ is the morphism φ' of theorem 55.1.9, shown to be an epimorphism in Step 4 of that proof. The induced morphism $C \to B$ is the composite $\iota \circ \tilde{\varphi}$, a composite of a monomorphism with an isomorphism, hence a monomorphism, completing the proof.

From the cannonical decomposition, we may say that the image and coimage are "isomorphic" (which is not strictly true since these are morphisms, however by the Freyd-Mitchell Theorem this is a safe way of looking at it).

Theorem 55.1.13: Abelian Category: Exactness

Consider a sequence of objects in an abelian cateogy

$$\cdots \to A \xrightarrow{\varphi} B \xrightarrow{\psi} C \to \cdots$$

Then this sequence is *exact* if:

1. $\psi \circ \varphi = 0$
2. $\operatorname{coker}\varphi \circ \ker\psi = 0$

Example 55.1.14: Categorical Exactness

1. Aluffi p.577

Freyd-Mitchell Theorem

As mentioned, R-mod is an abelian category, and as we shall develop a bit later it the categories R-mod "represent" all abelian categories.

Theorem 55.1.15: Freyd-Mitchell Theorem

Let A be a small abelian category. Then there is a fully faithful exact functor $A \to R$-Mod for a suitable ring R. Such a functor reflects exactness: a sequence in A is exact if and only if its image in R-Mod is.

***Proof Key ideas*:**
The proof constructs R as the endomorphism ring of a suitable injective cogenerator in the category of left exact functors $A^{\mathrm{op}} \to \mathbf{Ab}$, and occupies a chapter's worth of category theory that this book does not otherwise need; it is given in full in *An Introduction to Homological Algebra* [53], §1.6. The idea is that A embeds into its category of left exact presheaves by Yoneda, that this larger category is a Grothendieck category with enough injectives, and that a single injective cogenerator there converts the whole category into modules over its endomorphism ring.

The clause about reflecting exactness is immediate from the rest and is what the theorem is used for: a fully faithful exact functor reflects kernels and cokernels, so a diagram chase valid in R-Mod transfers back to A. This is what licenses the element-based arguments in lemma 56.1.17 and throughout chapter 58.

55.2 Localization of Categories

The constructions of this book repeatedly produce morphisms that ought to be invertible but are not. The model for what to do about it is already familiar from commutative algebra: a ring R and a multiplicative set S of elements one wishes to invert are replaced by $S^{-1}R$, together with a map $R \to S^{-1}R$ that is universal among ring maps sending S into the units. Nothing in that description mentions elements of a ring rather than morphisms of a category, and the same universal property can be imposed one level up.

The payoff comes in chapter 56, where the class to be inverted is the class of quasi-isomorphisms and the resulting category is the derived category. The construction is recorded here, before it is needed, because it is a statement about categories and not about complexes.

Definition 55.2.1: Localization of a Category

Let $\mathcal{C}$ be a category and W a class of morphisms of $\mathcal{C}$. A *localization* of $\mathcal{C}$ at W is a category $\mathcal{C}[W^{-1}]$ together with a functor $Q\colon \mathcal{C} \to \mathcal{C}[W^{-1}]$ such that

1. $Q(w)$ is an isomorphism for every $w \in W$;
2. for every category $\mathcal{D}$ and every functor $F\colon \mathcal{C} \to \mathcal{D}$ carrying each element of W to an isomorphism, there is a functor $\overline{F}\colon \mathcal{C}[W^{-1}] \to \mathcal{D}$ with $\overline{F} \circ Q = F$, and $\overline{F}$ is unique with this property.

As with every universal property, the definition determines the answer up to canonical isomorphism as soon as an answer exists: two localizations receive unique comparison functors from one another whose composites must be the identity, by the uniqueness clause applied to Q itself. Existence is the substantive point, and it is settled by a construction that simply writes down the morphisms that formal inversion forces to exist.

Theorem 55.2.2: Existence of the Localization

Let $\mathcal{C}$ be a category and W a class of morphisms. Then a localization $Q\colon \mathcal{C} \to \mathcal{C}[W^{-1}]$ exists.

***Proof*:**

Step 1: The construction. Let $\mathcal{C}[W^{-1}]$ have the same objects as $\mathcal{C}$. For objects X and Y, consider finite *zigzags* from X to Y: alternating strings of morphisms of $\mathcal{C}$

$$X = X_0 \;\vdash\!\!-\; X_1 \;\vdash\!\!-\; \cdots \;\vdash\!\!-\; X_n = Y$$

in which each link $X_i \vdash\!\!- X_{i+1}$ is either a morphism $X_i \to X_{i+1}$ of $\mathcal{C}$, called a forward link, or a morphism $X_{i+1} \to X_i$ that belongs to W, called a backward link. Enlarging W to contain all identities and to be closed under composition changes neither the class of functors inverting it nor, therefore, the localization, so assume this without loss of generality; it is what makes the second move below well formed. Impose on the collection of zigzags the smallest equivalence relation generated by: replacing two consecutive forward links by their composite; replacing two consecutive backward links by their composite; deleting a forward or backward link that is an identity; and deleting a pair of adjacent links w forward followed by w backward, or w backward followed by w forward, for $w \in W$. Let $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(X, Y)$ be the collection of equivalence classes, with composition given by concatenation, which is well defined because the generating relations are local to the links they touch. Concatenation is associative and the empty zigzag is an identity, so this is a category. Let Q send an object to itself and a morphism to the one-link forward zigzag.

Step 2: Q inverts W. For $w \in W$ the backward one-link zigzag on w is a morphism in the opposite direction, and concatenating it with the forward one-link zigzag on w in either order produces a pair of adjacent links which the last generating relation deletes, leaving the empty zigzag. So $Q(w)$ is an isomorphism.

Step 3: The universal property. Let $F\colon \mathcal{C} \to \mathcal{D}$ carry W into isomorphisms. Define $\overline{F}$ to be F on objects, and on a zigzag to be the composite in $\mathcal{D}$ obtained by applying F to each forward link and $F(-)^{-1}$ to each backward link. Each generating relation is respected: composites go to composites by functoriality, identities to identities, and an adjacent pair w, w of opposite orientation goes to $F(w)F(w)^{-1}$ or $F(w)^{-1}F(w)$, both identities. So $\overline{F}$ is well defined on equivalence classes, and it is a functor because concatenation goes to composition. By construction $\overline{F} \circ Q = F$.

For uniqueness, suppose $G \circ Q = F$ for a functor G. Every morphism of $\mathcal{C}[W^{-1}]$ is a concatenation of one-link zigzags, each of which is $Q(f)$ or $Q(w)^{-1}$; a functor is determined by its values on these, and $G(Q(f)) = F(f)$ forces $G(Q(w)^{-1}) = G(Q(w))^{-1} = F(w)^{-1}$. So G agrees with $\overline{F}$ on every morphism, completing the proof.

55.2.3 Warning: Localization and Set Theory The construction above builds each $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(X,Y)$ out of *all* zigzags, and for a category $\mathcal{C}$ that is not small there is no guarantee that the result is a set rather than a proper class. The property at risk is *local smallness*: the localization of a locally small category need not be locally small.

Two remedies are standard. The first is to assume $\mathcal{C}$ small, which is of no use here since $\mathrm{Ch}(\mathbf{A})$ never is. The second is to exhibit a calculus of fractions as in theorem 55.2.5, which replaces arbitrary zigzags by roofs; note that this alone does not bound anything, since the roofs over a fixed object are indexed by a proper class. What is needed in addition is that the W-morphisms into each object admit a *set* that is cofinal among them, and a multiplicative system with that property is what makes the localization locally small.

Neither remedy applies to $\mathrm{Ch}(\mathbf{A})$ localized at quasi-isomorphisms, because the quasi-isomorphisms there are *not* a multiplicative system. Both conditions (2) and (3) of definition 55.2.4 fail: taking $C^\bullet = (\mathbb{Z} \xrightarrow{\mathrm{id}} \mathbb{Z})$ in degrees $-1, 0$, which is acyclic, and $h\colon \mathbb{Z}[0] \to C^\bullet$ the chain map that is the identity in degree 0, every chain map $t\colon X^\bullet \to \mathbb{Z}[0]$ has only a degree-zero component, so $h \circ t = 0$ forces $t = 0$, which is not a quasi-isomorphism. The standard route is instead to pass to the homotopy category first: quasi-isomorphisms *are* a multiplicative system in $K(\mathbf{A})$, and $D(\mathbf{A}) = K(\mathbf{A})[\mathrm{qis}^{-1}]$, which is how section 56.5 presents it.

The zigzag description settles existence and is useless for computation: a morphism is an equivalence class of arbitrarily long strings, and deciding when two strings agree is not something one does by hand. Under a mild hypothesis on W every zigzag collapses to a single roof, and then morphisms become genuinely manipulable.

Definition 55.2.4: Multiplicative System

A class W of morphisms in a category $\mathcal{C}$ is a *multiplicative system* if

1. W contains every identity and is closed under composition;
2. (Ore condition) for every $f\colon Z \to B$ in $\mathcal{C}$ and every $t\colon V \to B$ in W there are $t'\colon Z' \to Z$ in W and $f'\colon Z' \to V$ in $\mathcal{C}$ with $f \circ t' = t \circ f'$;
3. for every pair $f, g\colon X \to Y$ and every $s\colon Y \to Y'$ in W with $s \circ f = s \circ g$, there is $t\colon X' \to X$ in W with $f \circ t = g \circ t$.

Condition (2) is what lets two roofs be composed, and condition (3) is what makes the resulting notion of equality between roofs transitive. Both are visible in the ring case: for a commutative ring every S is a multiplicative system, and the conditions are the familiar manipulations that put two fractions over a common denominator.

Theorem 55.2.5: Calculus of Fractions

Let W be a multiplicative system in $\mathcal{C}$. Then:

1. every morphism $A \to B$ in $\mathcal{C}[W^{-1}]$ is represented by a *roof*
$$\begin{tikzcd} & Z \arrow[dl, "s"'] \arrow[dr, "f"] & \\ A & & B \end{tikzcd}$$
with $s \in W$, standing for $Q(f) \circ Q(s)^{-1}$;
2. if two roofs (s, f) and (s', f') are *commonly dominated*, meaning there are $u \colon Z'' \to Z$ and $u' \colon Z'' \to Z'$ with $su = s'u' \in W$ and $fu = f'u'$, then they represent the same morphism;
3. conversely, two roofs representing the same morphism are commonly dominated, so that roofs modulo common domination compute $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(A, B)$.

***Proof*:**

Step 1: Roofs compose. Given roofs $A \xleftarrow{s} Z \xrightarrow{f} B$ and $B \xleftarrow{t} V \xrightarrow{g} C$, apply the Ore condition to $f \colon Z \to B$ and $t \in W$ to obtain $t' \colon Z' \to Z$ in W and $f' \colon Z' \to V$ with $ft' = tf'$. Then $A \xleftarrow{st'} Z' \xrightarrow{gf'} C$ is a roof, since $st' \in W$ by closure under composition, and in $\mathcal{C}[W^{-1}]$ it represents
$$Q(g)Q(f')Q(t')^{-1}Q(s)^{-1} = Q(g)Q(t)^{-1}Q(f)Q(s)^{-1}$$
the identity following by rearranging $Q(f)Q(t') = Q(t)Q(f')$, both $Q(t)$ and $Q(t')$ being invertible. This is the composite of the two given morphisms.

Step 2: Part (2). Suppose (s, f) and (s', f') are commonly dominated by u, u'. Since $su = s'u'$ lies in W and $Q(s)$ is invertible, $Q(u)$ is invertible too, and then
$$Q(f)Q(s)^{-1} = Q(fu)Q(su)^{-1} = Q(f'u')Q(s'u')^{-1} = Q(f')Q(s')^{-1}$$
so the two roofs represent the same morphism.

Step 3: Common domination is an equivalence relation. Reflexivity and symmetry are immediate. For transitivity, suppose Z_1 dominates (s, f) and (s', f') through u_1, v_1 with $\sigma_1 := su_1 = s'v_1 \in W$, and Z_2 dominates (s', f') and (s'', f'') through u_2, v_2 with $\sigma_2 := s'u_2 = s''v_2 \in W$. Apply the Ore condition to $\sigma_1 \colon Z_1 \to A$ and $\sigma_2 \in W$ to get $t' \colon Z_3 \to Z_1$ in W and $w \colon Z_3 \to Z_2$ with $\sigma_1 t' = \sigma_2 w$. Then
$$s'(v_1 t') = \sigma_1 t' = \sigma_2 w = s'(u_2 w)$$
so condition (3) of definition 55.2.4, applied to the parallel pair $v_1 t', u_2 w \colon Z_3 \rightrightarrows Z'$ and to $s' \in W$, yields $t \colon Z_4 \to Z_3$ in W with $v_1 t' t = u_2 w t$. The roof with middle leg $\sigma_1 t' t \in W$ and legs $u_1 t' t$ and $v_2 w t$ then dominates both (s, f) and (s'', f''): the middle leg lies in W by closure, and the two outer compatibilities follow because $fu_1 = f'v_1$ and $f''v_2 = f'u_2$ both factor through f'.

Step 4: Part (1). Every morphism of $\mathcal{C}[W^{-1}]$ is a zigzag, and it suffices to show every zigzag is equivalent to one of the form backward-then-forward. Assign to a zigzag the number of pairs $i < j$ with link i forward and link j backward. Composing two adjacent links of the same orientation strictly decreases the length and does not increase this number; and given an adjacent pair $Z \xrightarrow{f} B \xleftarrow{t} V$ with $t \in W$, the Ore condition supplies $Z \xleftarrow{t'} Z' \xrightarrow{f'} V$ with $t' \in W$ and $ft' = tf'$, which represents the same morphism because $Q(t)^{-1}Q(f) = Q(f')Q(t')^{-1}$, and which strictly decreases the count. The count cannot decrease forever, so the process terminates at a zigzag with no forward link preceding a backward one; composing along each run leaves a single roof.

Step 5: Part (3). What remains is the converse of Step 2. The standard route builds the category whose morphisms are roofs modulo common domination, with composition as in Step 1, and checks that this is well defined on classes, associative and unital, and that it satisfies the universal property of definition 55.2.1; comparing with $\mathcal{C}[W^{-1}]$ through that universal property then forces the two to agree, which is exactly the converse. Those verifications are bookkeeping of the same kind as Steps 1 and 3, carrying no further idea, and they are carried out in full in *An Introduction to Homological Algebra* [53]. This completes the proof.

The construction now applies verbatim to the situation this book treats, and it is recorded as a corollary so that later chapters may cite existence rather than assume it.

Corollary 55.2.6: Existence of the Derived Category

Let $\mathbf{A}$ be an abelian category and let qis denote the class of quasi-isomorphisms in $\mathrm{Ch}(\mathbf{A})$. Then the localization

$$D(\mathbf{A}) := \mathrm{Ch}(\mathbf{A})[\mathrm{qis}^{-1}]$$

exists, and the canonical functor $Q\colon \mathrm{Ch}(\mathbf{A}) \to D(\mathbf{A})$ is universal among functors carrying quasi-isomorphisms to isomorphisms.

***Proof*:**
Apply theorem 55.2.2 with $\mathcal{C} = \mathrm{Ch}(\mathbf{A})$ and $W = \mathrm{qis}$; no hypothesis on W is needed for existence. The universal property is clause (2) of definition 55.2.1.

The construction says nothing about local smallness, and by box 55.2.3 neither remedy applies here, so $D(\mathbf{A})$ is produced only as a possibly non-locally-small category. The route that repairs this, and the one section 56.5 follows, is to localize $K(\mathbf{A})$ rather than $\mathrm{Ch}(\mathbf{A})$, where the quasi-isomorphisms do form a multiplicative system and theorem 55.2.5 applies, as we sought to show.

56

Complexes and (co)Homology

Let $\mathbf{A}$ be a fixed abelian category, which by theorem 55.1.15 may without loss of generality it can be considered ${}_R\mathrm{Mod}$. In this chapter, we shall focus on studying (co)chains of such modules, that is sequence of modules that respect equation (54.1):

$$\mathrm{im}(d^n) \subseteq \ker(d^{n+1})$$

The collection of all chains shall be denoted $\mathrm{Ch}(\mathbf{A})$. We shall see that $\mathrm{Ch}(\mathbf{A})$ is an abelian category, the notion of extensions (and snakes lemma) is well defined, which will be explored. In the right categories, it is relatively easy to construct a concrete complex given the category has enough objects, for example $M \in \mathrm{Obj}(R\text{-}\mathbf{Mod})$ always has a complex known as a *free resolution* (see definition 12.3.27). There will be many different ways of creating complexes given an object, giving us different types of resolutions. We shall see that when a category has enough projective objects (resp. Injective objects), then "up to homotopy equivalence", projective resolutions shall be *initial* (resp. final) in the category of complexes $\mathrm{Ch}(A)$. Thus, we shall take the time to develop the homology theory in categories with enough projective or injective objects. We shall see that under appropriate circumstances, taking (co)homology of a projective resolution of an object can give us some important information about said object.

Homology and cohomology are duals of each other, which means on the theoretical level they are the same. As cohomology is the more computationally useful tool, we shall be focusing on cohomology on this chapter, with the idea that the reader shall be comfortable being able to switch indices when necessary. Taking the cohomology of a complex shall be shown to be an additive functorial process, meaning for a given morphism of complexes $\alpha^\bullet : A^\bullet \to B^\bullet$, we shall get a morphism each cohomology $H^i(\alpha) : H^i(A^\bullet) \to H^i(B^\bullet)$ which will be shown can be to form a new complex $H^\bullet(\alpha) : H^\bullet(A^\bullet) \to H^\bullet(B^\bullet)$.

The goal of this chapter is to show how to extract information given a complexes (co)homology. Given this, it is important to know what information a morphism of complexes preserves in cohomology, that is given a morphism of complexes, $\alpha^\bullet : A^\bullet \to B^\bullet$, when is $H^\bullet(\alpha) : H^\bullet(A^\bullet) \to H^\bullet(B^\bullet)$ an isomorphism? This shall lead us to the notion of *quasi-isomorphisms*, and their "representation" through mapping cones. As it turns out, quasi-isomorphisms do not behave nicely in general. What we shall then seek out is a stricter concept known as a *homotopy equivalence* that will still be a quasi-isomorphism, but will be invertible in the appropriate category.

56.1 Basic Definition and Properties

Starting with defining the generalization of an exact sequence:

Definition 56.1.1: Chain Complex

A *chain complex* $(C_\bullet, d_\bullet)$ is a sequence of objects and morphisms:

$$\cdots \xleftarrow{d_i} M_i \xleftarrow{d_{i+1}} M_{i+1} \xleftarrow{d_{i+2}} \cdots$$

with the indices running through $\mathbb{Z}$, such that

$$d_i \circ d_{i+1} = 0$$

and each d_i is called a *boundary map*. Similarly, a *cochain complex* $(C^\bullet, d^\bullet)$ is a sequence of objects

$$\cdots \xrightarrow{d^i} M^i \xrightarrow{d_{i-1}} M^{i-1} \xrightarrow{d^{i+2}} \cdots$$

with the indices running through $\mathbb{Z}$, such that

$$d^i \circ d^{i-1} = 0$$

where $d^\bullet$ are is called the *differential*[a].

[a]Due to it's origin's in differential geometry and algebraic topology

Chains and cochains can be interchanged by taking

$$M_i = M^{-i}$$

Working with one or the other makes essentially no difference for homological algebra. In certain cases, some structures present themselves more in the cohomological case (ex. a natural ring structure called the *cohomology ring* shall become important to us), and so we opt to work with the cohomology, even though at this stage this can be considered to be an arbitrary choice. The condition that $d^i \circ d^{i-1} = 0$ is the same as $\mathrm{im} d^{i-1} \subseteq \ker d^i$. If the complex is exact, then $\mathrm{im} d^{i-1} = \ker d^i$ for all i. We also often write $C^\bullet$ instead of $(C^\bullet, d^\bullet)$ if the mappings $d^\bullet$ are clear from context or implied. In some textbooks, even the bullet is dropped and M represents the complex. Sometime, for homology, the notation $\partial_\bullet$ shall be used instead of $d_\bullet$ due to it's connection to being the boundary map for topological spaces when creating complexes out of topological spaces[1].The condition that $d^i \circ d^{i-1} = 0$ (resp. $d_i \circ d_{i+1} = 0$) is often abbreviated to $d \circ d = 0$.

Due to historical origins in algebraic topology, the kernel and image of the differential

[1]Similarly, $d^\bullet$ stands for the *differential* due to it's link to the derivative, which would be explored in a class in algebraic topology, or see EYNTKA Algebraic Topology

Definition 56.1.2: Cycles and Boundaries

Let $C_\bullet$ (resp. $C^\bullet$) be a chain complex (resp. cochain complex). Then:

1. $\ker(d_n)$ is called the n-*cycles* of $C_\bullet$ and $\mathrm{im}(d_{n+1})$ is called the n-boundary of $C_\bullet$. The n-cycle is represented as $Z_n = Z_n(C_\bullet)$ and the n-*boundary* is represented as $B_n = B_n(C_\bullet)$
2. $\ker(d^n)$ is called the n-*cocycles* of $C^\bullet$ and $\mathrm{im}(d^{n-1})$ is called the n-*coboundary* of $C^\bullet$. The n-cocycle is represented as $Z^n = Z_n(C_\bullet)$ and the n-coboundary is represented as $B_n = B_n(C_\bullet)$

The name cycles and boundaries has it's origin in algebraic topology:

Example 56.1.3: Cycles and Boundaries

(Put that image from p.67 from alg top notes)

The collection of all complexes forms a Category:

Definition 56.1.4: Category Of Complexes

Let $\mathbf{A}$ be an abelian category. Then $\mathrm{Ch}^\bullet(\mathbf{A})$ is a new category called the *category of complexes of A* where

1. $\mathrm{Obj}(\mathrm{Ch}^\bullet(\mathbf{A})) = \{\text{cochain complexes in } \mathbf{A}\}$
2. For two complexes $C^\bullet$ and $N^\bullet$, a morphism $\alpha^\bullet \in \mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(C^\bullet, N^\bullet)$ consists of morphisms st the following diagram commute:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & M^{i-1} & \xrightarrow{d^{i-1}_{C^\bullet}} & M^i & \xrightarrow{d^i_{C^\bullet}} & M^{i+1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle \alpha^{i-1}} & & \downarrow{\scriptstyle \alpha^{i-1}} & & \downarrow{\scriptstyle \alpha^{i-1}} & & \\
\cdots & \longrightarrow & N^{i-1} & \xrightarrow{d^{i-1}_{N^\bullet}} & N^i & \xrightarrow{d^i_{N^\bullet}} & N^{i+1} & \longrightarrow & \cdots
\end{array}$$

Similarly for $\mathrm{Ch}_\bullet(\mathbf{A})$ with chain complexes.

If unambiguous, the bullet is dropped giving $\mathrm{Ch}(\mathbf{A})$. It should be checked that $\mathrm{Ch}(A)$ is indeed a category. There are many variations of $\mathrm{Ch}(A)$ which will be important:

1. $C^+(A)$ is the full subcategory of $\mathrm{Ch}(A)$ of complexes which are bounded from bellow, so that $L^i = 0$ for $i \ll 0$
2. $C^-(A)$ is the full subcategory of $\mathrm{Ch}(A)$ of complexes which are bounded from above, so that $L^i = 0$ for $i \gg 0$
3. $C^{\geq 0}(A)$ (resp. $C^{\leq 0}$) for which $L^i = 0$ for $i \leq 0$ (resp. $i \geq 0$)
4. P, I are full subcategories of A consisting of projective and injective objects in A respectively, and hence we have $\mathrm{Ch}(P)$, $\mathrm{Ch}(I)$, and all its variants

There are also a few simple functors we may immediately define:

1. Take $\iota_r : \mathbf{A} \to \mathrm{Ch}(\mathbf{A})$ that sends an object A form $\mathbf{A}$ to a complex that is zero every and A in the rth degree. We shall commonly identify A with the complex given by ι_0.
2. Take $s_r : \mathrm{Ch}(\mathbf{A}) \to \mathrm{Ch}(\mathbf{A})$ which shifts over the complex, namely
$$C^\bullet \mapsto M[r]^\bullet$$
where $M[r]^i = M^{i+r}$ and $d^i_{M[r]^\bullet} = (-1)^r d^{i+r}_{C^\bullet}$ (the $(-1)^r$ shall be explained shortly).
3. the truncation functor shall truncate the complex in the natural way.

More importantly, $\mathrm{Ch}(A)$ is an abelian category, allowing the notion of exactness between complexes to be well-defined:

Lemma 56.1.5: Complex Category Is Abelian

Let A be an abelian category and $\mathrm{Ch}(A)$ the category of complexes of A. Then $\mathrm{Ch}(A)$ is an abelian category

***Proof*:**
Left as an exercise, check that:

1. morphisms between two complexes form an abelian group, namely since $\alpha^i + \beta^i$ will be well-defined
2. Finite products and coporducts exist in $\mathrm{Ch}(A)$ as a consequence of them existing in A
3. kernels and cokernls will come from the commutativity of the diagram defining morphisms of complexes

Since it is an abelian category, we shall be able to consider sequences of complexes, and in particular exact sequences of complexes:
$$\cdots \to L^\bullet \to C^\bullet \to N^\bullet \to \cdots$$
which give a commutative diagram like so:

$$\begin{tikzcd}
 & 0 \arrow[d] & 0 \arrow[d] & 0 \arrow[d] & 0 \arrow[d] & \\
\cdots \arrow[r] & A_{n+2} \arrow[r] \arrow[d, "\iota"] & A_{n+1} \arrow[r] \arrow[d, "\iota"] & A_n \arrow[r] \arrow[d, "\iota"] & A_{n-1} \arrow[r] \arrow[d, "\iota"] & \cdots \\
\cdots \arrow[r] & B_{n+2} \arrow[r] \arrow[d, "\pi"] & B_{n+1} \arrow[r] \arrow[d, "\pi"] & B_n \arrow[r] \arrow[d, "\pi"] & B_{n-1} \arrow[r] \arrow[d, "\pi"] & \cdots \\
\cdots \arrow[r] & C_{n+2} \arrow[r] \arrow[d] & C_{n+1} \arrow[r] \arrow[d] & C_n \arrow[r] \arrow[d] & C_{n-1} \arrow[r] \arrow[d] & \cdots \\
 & 0 & 0 & 0 & 0 &
\end{tikzcd} \tag{56.1}$$

Example 56.1.6: Complexes

1. Given any object M, we may always create the trivial complex
$$\cdots 0 \to 0 \to M \to 0 \to 0 \to \cdots$$
Verify that this is indeed a complex.

2. As mentioned, In R-**Mod**, the free resolution is an example of a complex.

3. Any short exact sequence can be thought of an (exact) complex if we add 0's that extend arbitrarily to the left and right.

4. Let $C^n = \mathbb{Z}/8\mathbb{Z}$ for $n \geq 0$ and $C^n = 0$ for $n < 0$. Let each d^n be defined as:
$$\overline{x} \mapsto \overline{4x}$$
Show that this is a cochain complex.

5. Let $\{V_i, W_i\}_{i\in\mathbb{Z}}$ be a collection of vector spaces. Define:
$$A_n = V_n \oplus W_n \oplus V_{n-1}$$
Combining the projection and inclusion maps $A_n \to V_{n-1} \to A_{n-1}$, show that $A_\bullet$ forms a chain complex.

6. Let $C^\bullet$ be a cochain complex, choose an object $A \in \mathbf{A}$, and apply $\mathrm{Hom}_A(-, A)$ to each object. Show that this is a cochain complex.

Since $\mathrm{Ch}(\mathbf{A})$ is an abelian category, kernels and cokernels exist and match with monomorphisms/epimorphisms, hence giving us the following:

Definition 56.1.7: Sub-complexes And Quotient Complexes

Let $C^\bullet$ be a (co)chain complex. Then a (co)chain complex $N^\bullet$ is called a *subcomplex* if each N_n is a sub-object of C_n and the differential on B_n is the restriction of the differential in C_n (categorically, the inclusion map $\iota : N^\bullet \to C^\bullet$ is a morphism of complexes).

Furthermore, C^n/B^n is a *quotient-complex*. Furthermore, by the canonical decomposition of morphisms in abelian categories, for any complex-morphism $\alpha^\bullet$, $\{\ker(\alpha^\bullet)\}$ and $\{\mathrm{coker}(\alpha^\bullet)\}$ is a sub-complex and quotient complex respectively.

56.1.1 Homology and Cohomology

Chain complexes need not be exact. The cohomology of a complex measures how far away a complex is from being exact, that is how far away a complex is form representing a sequence of extensions

Definition 56.1.8: Homology and Cohomology Of A Complex

Let $(C^\bullet, d^\bullet)$ be a complex. Then the ith homology and cohomology of the complex at M^i is, respectively:

$$H_i(C^\bullet) = \frac{\ker d_i}{\mathrm{im} d_{i+1}} \qquad H^i(C^\bullet) := \frac{\ker d^i}{\mathrm{im} d^{i-1}}$$

Though homology and cohomology are similar, it is not necessarily the case that $H^i(C^\bullet) = H_{n-i}(C^\bullet)$ for some appropriate n around which the chain can "pivot". We shall see such examples soon, and later also show under what conditions we may compare homology and cohomology[2]

Example 56.1.9: Cohomology Of Complex

Let's compute the cohomology of sequences in example 56.1.6.

1. The homology and cohomology at the 0th entry is:

$$\frac{\ker(d_0)}{\mathrm{im}(d_1)} = \frac{\ker(d^1)}{\mathrm{im}(d^0)} = M$$

   which shows that at this position, the chain is "off" by M in being exact.

2. As we have defined exact free resolutions, they are exact, meaning $\mathrm{im}(d^i) = \ker(d^{i-1})$, hence their homology and cohomology is always 0
3. Any exact sequence has trivial homology and cohomology
4. This sequence is not exact, and yet it's homoogy/cohomology is trivial (as the reader should verify). Such a sequence is called *acyclic*.
5. The reader should calculate this cohomology as an exercise
6. This cohomology shall be calculated later in this chapter.

Lemma 56.1.10: Cohomology Functor

For every $i \in \mathbb{Z}$, there exists a functor:

$$H^i : \mathrm{Ch}(A) \to A \qquad C^\bullet \mapsto H^i(C^\bullet)$$

which is additive and covariant.

This shows that taking cohomology is indeed a way of analyzing resolutions, for it preserves enough of the structures of modules and complexes. Notice it is not necessarily an exact functor, hence it will not in general preserve extensions.

[2]The universal coefficient theorem and Poincaré duality being two famous examples the reader may have heard of if they took algebraic topology

***Proof*:**
Let $\alpha^\bullet : C^\bullet \to N^\bullet$ be a morphism of complexes and take $H^i(C^\bullet)$ and $H^i(N^\bullet)$. Let $x \in H^i(H^\bullet)$ so that $x = k + \text{im}(d_M^{i-1})$ for d^{i-1}. Since $d^i(x) = 0$, by commutativity it must be that $\alpha^i(x) \in \ker(d_N^i)$. Furthermore, by commutativity we see that $\overline{\alpha^i}$ is zero on the image of $\text{im}(d_M^{i-1})$, hence $H^i(\alpha^\bullet)$ is well-defined.

This functor is certainly covariant, and is additive since $\text{Hom}_A(H^i(C^\bullet), H^i(N^\bullet))$ is an abelian group.

Notice that each H^i takes d^i to the zero map. Hence, we may consider the following functor:

$$H^\bullet : \text{Ch}(\mathbf{A}) \to \text{Ch}(\mathbf{A})$$

by taking $H^i(C^\bullet)$ for each i and connecting them by the zero-morphism. This is the cohomology of this complex then equals that of $C^\bullet$, namely:

$$H^\bullet(H^\bullet(C^\bullet)) = H^\bullet(C^\bullet)$$

Lemma 56.1.11: Cohomology And Products

Let $\{A_\alpha^\bullet\}$ be a collection of complexes in $\mathbf{A}$, and suppose the coproduct (respectively the product) indexed by α exists and is an exact functor. Then

$$H^n\Big(\bigoplus_\alpha A_\alpha^\bullet\Big) = \bigoplus_\alpha H^n(A_\alpha^\bullet) \qquad H^n\Big(\prod_\alpha A_\alpha^\bullet\Big) = \prod_\alpha H^n(A_\alpha^\bullet)$$

The exactness hypothesis is automatic for *finite* index sets, where the two agree by lemma 55.1.5, and it holds for arbitrary index sets in R-Mod.

***Proof*:**
Treat the coproduct; the product is the same argument in the opposite category. The complex $\bigoplus_\alpha A_\alpha^\bullet$ has n-th term $\bigoplus_\alpha A_\alpha^n$ and differential $\bigoplus_\alpha d_\alpha^n$.

An exact functor preserves kernels and images, so

$$\ker\Big(\bigoplus_\alpha d_\alpha^n\Big) = \bigoplus_\alpha \ker d_\alpha^n, \qquad \text{im}\Big(\bigoplus_\alpha d_\alpha^{n-1}\Big) = \bigoplus_\alpha \text{im} d_\alpha^{n-1}$$

and it preserves the quotient of the second by the first, being exact. Hence

$$H^n\Big(\bigoplus_\alpha A_\alpha^\bullet\Big) = \frac{\bigoplus_\alpha \ker d_\alpha^n}{\bigoplus_\alpha \text{im} d_\alpha^{n-1}} = \bigoplus_\alpha \frac{\ker d_\alpha^n}{\text{im} d_\alpha^{n-1}} = \bigoplus_\alpha H^n(A_\alpha^\bullet)$$

For a finite index set the coproduct is a finite biproduct, which every additive functor preserves, so no hypothesis is needed; in R-Mod both $\bigoplus$ and $\prod$ are exact and kernels and images are computed componentwise, giving the statement for arbitrary index sets. This completes the proof.

Now, given a morphism of complexes $\alpha^\bullet : C^\bullet \to N^\bullet$, we may ask what (co)homological information such a morphism preserves. In other words, given a morphism $\alpha^\bullet$, when is $H^\bullet(\alpha^\bullet)$ an isomorphism? We give such morphisms a name:

Definition 56.1.12: Quasi-Isomorphism

Let $\alpha^\bullet : C^\bullet \to N^\bullet$ be a morphism of complexes. Then if $H^\bullet(\alpha^\bullet) : H^\bullet(C^\bullet) \to H^\bullet(N^\bullet)$ is an isomorphism, $\alpha^\bullet$ is called a *quasi-isomorphism*

One may wonder if the fact that the (co)homology is isomorphism is strong enough of a condition for the chains to be isomorphic. This turns out to be rather far from the case:

Example 56.1.13: Quasi-Isomorphism

1. The following counter example shall come up with many different minor variations, and so the reader should keep this in mind. Take the following morphism of complexes:

$$\begin{tikzcd}
\cdots \arrow[r] & 0 \arrow[r] \arrow[d] & \mathbb{Z} \arrow[r, "\cdot 2"] \arrow[d] & \mathbb{Z} \arrow[r] \arrow[d, "\pi"] & 0 \arrow[r] \arrow[d] & \cdots \\
\cdots \arrow[r] & 0 \arrow[r] & 0 \arrow[r] & \mathbb{Z}/2\mathbb{Z} \arrow[r] & 0 \arrow[r] & \cdots
\end{tikzcd}$$

   This is a quasi-isomorphism, as the reader should check, however it does not have an inverse. More generally, it is not even an equivalence relation, failing to be symmetric (show there is no morphism the other way around that is a quasi-isomorphism).

2. The natural maps $H^\bullet(C^\bullet) \to C^\bullet$ and $C^\bullet \to H^\bullet(C^\bullet)$ are quasi-isomorphisms, given the property of $H^\bullet(H^\bullet(C^\bullet)) = H^\bullet(C^\bullet)$ discussed earlier.

3. Let $\iota(A) \in \mathrm{Obj}(\mathrm{Ch}(\mathbf{A}))$ be the complex with A at the 0th position and zero's everywhere else. Say that $C^\bullet$ is a resolution such that $C^\bullet \to \iota(A)$ is a quasi-isomorphism. Show that this implies $C^\bullet$ is exact everywhere except possibly at $H^0(M^0)$

The lack of symmetry means that quasi-isomorphisms do not form an equivalence relation, but a *weak equivalence relation* (a relation that is reflective and transitive, but not symmetric). This is rather a pity, since if it did form an equivalence relation, then the equivalence class of morphisms up to weak isomorphism would hold all the necessary (co)homological information. Alas, this was not mean to be. Thus, in the pursuit of finding (co)homological invariants, it productive to ask how (co)homological information can be detected between (co)chain complexes. One idea is to map $\mathrm{Ch}(\mathbf{A})$ into another category $D(\mathbf{A})$ in which quasi-isomorphisms become isomorphisms. If quasi-isomorphisms formed equivalence relationships, we could have formed a congruence category which would satisfy this condition, however as just mentioned this cannot be the case.

Such a functor has already been encountered: the (co)homology functor is already one such example. It is more fruitful to as if this can be done in a *univerasl* way, that is if there is a category $D(\mathbf{A})$ where for any category D for which there exists an additive functor $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to D$ where every quasi-isomorphism in $\mathrm{Ch}(\mathbf{A})$ becomes an isomorphism in D, there exists a unique functor such that the following diagram commutes:

$$\begin{tikzcd} \mathrm{Ch}(\mathbf{A}) \arrow[r, "\mathscr{F}"] \arrow[d] & D \\ D(\mathbf{A}) \arrow[ur, "\exists!"'] & \end{tikzcd} \tag{56.2}$$

This category does indeed exist, by corollary 55.2.6, and is called the *derived category* (hence the $D(-)$ notation). This category shall further be explored in the coming sections. In some nice categories $\mathbf{A}$, quasi-isomorphisms will line up with the nicer notion of *homotopy-equivalence*, in which case the derived category will be eminently understandable. We shall explore these all in greater detail section 56.2.

Though quasi-isomorphisms may not be ideal in computing (co)homological invariants, they are still important as the defining concept for (co)homological information. For example, the following shows the relationship between quasi-isomorphism and exactness:

Lemma 56.1.14: Quasi-isomorphisms And Exactness

Let $C^\bullet$ be a cochain complex. Then the following are equivalent:

1. $C^\bullet$ is exact
2. $C^\bullet$ is acyclic, that is $H^\bullet(C^\bullet) = 0$
3. The morphism of complexes $0 \to C^\bullet$ is a quasi-isomorphism

***Proof*:**
(1) $\Leftrightarrow$ (2): exactness of $C^\bullet$ at degree n means $\ker d^n = \mathrm{im} d^{n-1}$, and $H^n(C^\bullet) = \ker d^n / \mathrm{im} d^{n-1}$ by definition 56.1.8. A quotient object is zero exactly when the two are equal, so $C^\bullet$ is exact at every degree if and only if $H^n(C^\bullet) = 0$ for every n.

(2) $\Leftrightarrow$ (3): the zero complex has $H^n(0) = 0$ for every n, and the unique morphism $0 \to C^\bullet$ induces the unique morphism $0 \to H^n(C^\bullet)$ in each degree. That morphism is an isomorphism precisely when $H^n(C^\bullet) = 0$. So $0 \to C^\bullet$ is a quasi-isomorphism, meaning it induces isomorphisms in every degree, if and only if $H^\bullet(C^\bullet) = 0$, completing the proof.

56.1.2 Snake Lemma

We often have multiple ways of constructions a resolution for an object M. We shall often extend resolutions using smaller resolutions. We then get cohomology of this new extended resolution by simply applying the cohomology functor. However, is is this functor exact? More generally, let's say we have a short exact sequence of complexes, then after applying cohomology do we get a short exact sequence of homology complexes? The answer is no: if

$$0 \to L^\bullet \to C^\bullet \to N^\bullet \to 0$$

is a short exact sequence, then we get the (not necessarily exact) sequence:

$$H^i(L^\bullet) \to H^i(C^\bullet) \to H^i(N^\bullet)$$

In terms of morphisms, if we have:

$$\alpha^\bullet : C^\bullet \to N^\bullet$$

Then the morphism after applying the cohomology functor $H^\bullet(\alpha^\bullet) : H^\bullet(C^\bullet) \to H^\bullet(N^\bullet)$ need not be exact, i.e. it doesn't preserve kernels and cokernels. Can we "fix" this in some way by recovering some exact sequence from this and thus allowing our analysis of building more complicated resolutions for M to be independent of cohomology. The answer is yes, Namely, if we take the cohomology of complexes, we may "snake" like in the following diagram:

$$\begin{tikzcd}
 & 0 \arrow[d, dotted] & 0 \arrow[d, dotted] & 0 \arrow[d, dotted] & 0 \arrow[d, dotted] & \\
\cdots \arrow[r, dotted] & H_{n+2}(A) \arrow[r, dotted] \arrow[d, "\iota"] & H_{n+1}(A) \arrow[r, dotted] \arrow[d, "\iota"] & H_n(A) \arrow[r, dotted] \arrow[d, "\iota"] & H_{n-1}(A) \arrow[r, dotted] \arrow[d, "\iota"] & \cdots \\
\cdots \arrow[r, dotted] & H_{n+2}(B) \arrow[r, dotted] \arrow[d, "\pi"] & H_{n+1}(B) \arrow[r, dotted] \arrow[d, "\pi"] & H_n(B) \arrow[r, dotted] \arrow[d, "\pi"] & H_{n-1}(B) \arrow[r, dotted] \arrow[d, "\pi"] & \cdots \\
\cdots \arrow[r, dotted] & H_{n+2}(C) \arrow[r, dotted] \arrow[d, dotted] \arrow[uur] & H_{n+1}(C) \arrow[r, dotted] \arrow[d, dotted] \arrow[uur] & H_n(C) \arrow[r, dotted] \arrow[d, dotted] \arrow[uur] & H_{n-1}(C) \arrow[r, dotted] \arrow[d, dotted] & \cdots \\
 & 0 & 0 & 0 & 0 &
\end{tikzcd}$$

Theorem 56.1.15: Snake Lemma

Given a short exact sequence of complexes $0 \to A \to B \to C \to 0$, we may form a long exact sequence of modules using cohomology:

$$\cdots \to H^n(A) \xrightarrow{i^*} H^n(B) \xrightarrow{\pi^*} H^n(C) \xrightarrow{\partial} H^{n+1}(A) \xrightarrow{i^*} H^{n+1}(B) \xrightarrow{\pi^*} H^{n+1}(C) \to \cdots$$

Equivalently, in homological indexing, where the differential lowers degree and H_n is written for the homology in degree n, the same statement reads

$$\cdots \to H_n(A) \xrightarrow{i_*} H_n(B) \xrightarrow{\pi_*} H_n(C) \xrightarrow{\partial} H_{n-1}(A) \xrightarrow{i_*} H_{n-1}(B) \to \cdots$$

and it is this form that the proof below constructs. The two are the same statement under $H_n = H^{-n}$, and both are used in this book.

The following proof can be found (in the Homological variant) in EYNTKA Algebraic Topology

***Proof*:**
We first define the map $\partial : H_n(C) \to H_{n-1}(A)$. We should keep in mind the following diagram:

$$\begin{tikzcd} & A_{n-1} \arrow[d, "\iota"] \\ B_n \arrow[r, "\partial"] \arrow[d, "\pi"] & B_{n-1} \\ C_n & \end{tikzcd}$$

Let $c \in C_n$ be a cycle so that $c \in \ker \partial_n$. Since π is surjective, $c = \pi(b)$ for some $b \in B_n$. Then by definition $\partial : B_n \to B_{n-1}$ so $\partial(b) \in B_{n-1}$. Then by commutativity $j(\partial(b)) = \partial(j(b)) = \partial(c) = 0$ (since c is a cycle), thus $\partial b \in \ker(\pi)$. Since $\ker j = \mathrm{im} i$, $\partial b = i(a)$ for some $a \in A_{n-1}$. Since $i(\partial a) = \partial i(a) = \partial\partial b = 0$ since i is injective, $\partial a = 0$. Thus, define $\partial : H_n(C) \to H_{n-1}(A)$ by $[c] \mapsto [a]$. This is well defined since:

1. The element a is uniquely determined by ∂b since i is injective
2. for differnet choice b' for b, we get $j(b') = j(b)$, os $b' - b \in \ker(j)$ which is equal to $\mathrm{im}(i)$. Thus, $b' - b = i(a')$ for some a', ehcen $b' = b + i(a')$. But then this means we just chanage a to another representative (a homologous element) $a + \partial a'$, namely since
$$i(a + \partial a') = i(a) + i(\partial a') = \partial b + \partial i(a') = \partial(b = i(a'))$$
3. A difference choice of c within its homology class would have hte form $c = \partial c'$. To see this, since $c' = j(b')$ for some b',
$$c + \partial c' = c\partial j(b') = c + j(\partial b') = j(b + \partial b')$$
thus b is replaced by $b = \partial b'$, which gives ∂b and thus a is unchanged.

Finally, $\partial : H_n(C) \to H_{n-1}(A)$ is a homomorphism, for if $\partial[c_1] = [a_1]$ and $\partial[c_2] = [a_2]$ via elements b_1, b_2, then
$$j(b_1 + b_2) = j(b_1) + j(b_2) = c_1 = c_2$$
and
$$i(a_1 + a_2) = i(a_1) + i(a_2) = \partial b_1 + \partial b_2 = \partial(b_1 + b_2)$$
hence
$$\partial([c_1] + [c_2]) = [a_1] + [a_2]$$
giving us the map ∂ is indeed a homomorphism. What's left to show is the following inclusions:

1. $\mathrm{im} i_* \subseteq \ker j_*$. Since $ji = 0$, $j_* i_* = 0$
2. $\mathrm{im} j_* \subseteq \ker \partial$. By definition of ∂, $\partial b = 0$ so $\partial j_* = 0$.
3. $\ker j_* \subseteq \mathrm{im} i_*$. Let $b \in B_n$ with boundary represent a homology class in $\ker j_*$, so $j(b) = \partial c'$ for some $c' \in C_{n+1}$. Since j is surjectiv,e $c' = j(b')$ for some $b' \in B_{n+1}$. Then since $\partial j(b') = \partial c' = j(b)$,
$$j(b - \partial b') = j(b) - j(\partial b') = j(b) - \partial j(b') = 0$$

Thus, $b - \partial b' = i(a)$ for some $a \in A - n$. Since $i(\partial a) = \partial i(a) = \partial(b - \partial b') = \partial b = 0$ and i is injective, a is a cycle. Thus:

$$\iota_*[a] = [b - \partial b'] = [b]$$

showing that i_* maps onto $\ker j_*$

4. $\ker \partial \subseteq \mathrm{im} j_*$. By definition of ∂, if c represents a homology class in $\ker \partial$, then $a = \partial a'$ for some $a' \in A_n$. The element $b - i(a')$ is a cycle since $\partial(b - i(a')) = \partial b - \partial i(a') = \partial b - i(\partial a') = \partial b - i(a) = 0$. Since

$$j(b - i(a')) = j(b) - ji(a') = j(b) = c$$

we get that $j_*[b - i(a')] = [c]$

5. $\ker i_* \subseteq \mathrm{im}\partial$. Given a cycle $a \in A_{n-1}$ such that $i(a) = \partial b$ for seom $b \in B_n <$ then $j(b)$ is a cycle since $\partial j(b) = j(\partial b) = ji(a) = 0$, hence $\partial[j(b)] = [a]$

Doing this shall completing the proof.

Example 56.1.16: Uses Of Snake Lemma

1. *The six-term kernel-cokernel sequence.* The classical statement that carries the name "snake" is a special case of theorem 56.1.15. Suppose given a commutative diagram with exact rows

$$\begin{tikzcd}
0 \arrow[r] & A^0 \arrow[r] \arrow[d, "f"] & B^0 \arrow[r] \arrow[d, "g"] & C^0 \arrow[r] \arrow[d, "h"] & 0 \\
0 \arrow[r] & A^1 \arrow[r] & B^1 \arrow[r] & C^1 \arrow[r] & 0
\end{tikzcd}$$

Read each column as a complex concentrated in degrees 0 and 1, so that $A^\bullet = (A^0 \xrightarrow{f} A^1)$ and likewise for $B^\bullet$ and $C^\bullet$. Exactness of the two rows says precisely that $0 \to A^\bullet \to B^\bullet \to C^\bullet \to 0$ is a short exact sequence of complexes, and for a two-term complex $H^0 = \ker$ and $H^1 = \mathrm{coker}$. Since H^n vanishes outside degrees 0 and 1, the long exact sequence of theorem 56.1.15 has only six nonzero terms:

$$0 \to \ker f \to \ker g \to \ker h \xrightarrow{\partial} \mathrm{coker} f \to \mathrm{coker} g \to \mathrm{coker} h \to 0$$

The connecting morphism ∂ is the "snake" that crosses from the kernel row to the cokernel row.

2. *A computation.* Apply the six-term sequence to multiplication by a fixed integer $n \geq 1$ on the short exact sequence $0 \to \mathbb{Z} \to \mathbb{Q} \to \mathbb{Q}/\mathbb{Z} \to 0$. Multiplication by n is injective on $\mathbb{Z}$ and bijective on $\mathbb{Q}$, and $\mathbb{Q}/\mathbb{Z}$ is divisible, so

$$\ker f = 0, \quad \ker g = 0, \quad \ker h = \tfrac{1}{n}\mathbb{Z}/\mathbb{Z} \cong \mathbb{Z}/n\mathbb{Z}$$

$$\mathrm{coker} f = \mathbb{Z}/n\mathbb{Z}, \quad \mathrm{coker} g = 0, \quad \mathrm{coker} h = 0$$

The six-term sequence collapses to $0 \to \mathbb{Z}/n\mathbb{Z} \xrightarrow{\partial} \mathbb{Z}/n\mathbb{Z} \to 0$, forcing ∂ to be an isomorphism. The explicit description confirms it: an element of $\ker h$ is the class of some $q \in \mathbb{Q}$ with $nq \in \mathbb{Z}$, and ∂ sends it to the class of nq in $\mathbb{Z}/n\mathbb{Z}$; the generator $1/n$ goes to the generator 1.

3. *Where the machine is used later.* Every long exact sequence in this book is an instance of theorem 56.1.15. The long exact sequence of derived functors (theorem 56.3.10) applies it to a short exact sequence of resolutions, the exact triangle of a mapping cone (proposition 56.1.19) applies it to the cone sequence, and the exact couple that generates a spectral sequence (theorem 58.2.2) is nothing but all the long exact sequences of a filtration assembled at once. The topological applications, the Mayer-Vietoris sequence and the long exact sequence of a pair, are developed where they are used, in *Algebraic Topology* [38].

The most-used consequence of the snake lemma is a criterion for recognizing an isomorphism in the middle of a diagram from isomorphisms on either side. It is stated here because it is needed whenever two exact sequences are compared, and in particular in the comparison theorem for spectral sequences (theorem 58.2.9).

Lemma 56.1.17: Five Lemma

Consider a commutative diagram in an abelian category with exact rows

$$\begin{tikzcd} A_1 \arrow[r] \arrow[d, "f_1"] & A_2 \arrow[r] \arrow[d, "f_2"] & A_3 \arrow[r] \arrow[d, "f_3"] & A_4 \arrow[r] \arrow[d, "f_4"] & A_5 \arrow[d, "f_5"] \\ B_1 \arrow[r] & B_2 \arrow[r] & B_3 \arrow[r] & B_4 \arrow[r] & B_5 \end{tikzcd}$$

If f_2 and f_4 are isomorphisms, f_1 is an epimorphism, and f_5 is a monomorphism, then f_3 is an isomorphism.
More precisely, f_3 is a monomorphism as soon as f_2 and f_4 are monomorphisms and f_1 is an epimorphism, and f_3 is an epimorphism as soon as f_2 and f_4 are epimorphisms and f_5 is a monomorphism.

***Proof*:**
By theorem 55.1.15 the diagram may be chased with elements. Label the horizontal maps $\alpha_i\colon A_i \to A_{i+1}$ and $\beta_i\colon B_i \to B_{i+1}$.

Step 1: f_3 is a monomorphism. Assume f_2, f_4 monomorphisms and f_1 an epimorphism, and let $a \in A_3$ with $f_3(a) = 0$. Then $f_4(\alpha_3(a)) = \beta_3(f_3(a)) = 0$, and f_4 is a monomorphism, so $\alpha_3(a) = 0$. By exactness of the top row at A_3 there is $b \in A_2$ with $\alpha_2(b) = a$. Now $\beta_2(f_2(b)) = f_3(\alpha_2(b)) = f_3(a) = 0$, so by exactness of the bottom row at B_2 there is $c \in B_1$ with $\beta_1(c) = f_2(b)$. Since f_1 is an epimorphism, $c = f_1(e)$ for some $e \in A_1$. Then

$$f_2(\alpha_1(e)) = \beta_1(f_1(e)) = \beta_1(c) = f_2(b)$$

and f_2 is a monomorphism, so $\alpha_1(e) = b$. Therefore $a = \alpha_2(b) = \alpha_2(\alpha_1(e)) = 0$, the last equality by exactness of the top row at A_2.

Step 2: f_3 is an epimorphism. Assume f_2, f_4 epimorphisms and f_5 a monomorphism, and let $b \in B_3$. Since f_4 is an epimorphism, $\beta_3(b) = f_4(a)$ for some $a \in A_4$. Then

$$f_5(\alpha_4(a)) = \beta_4(f_4(a)) = \beta_4(\beta_3(b)) = 0$$

by exactness of the bottom row at B_4, and f_5 is a monomorphism, so $\alpha_4(a) = 0$. By exactness of the top row at A_4 there is $c \in A_3$ with $\alpha_3(c) = a$. The element $b - f_3(c)$ satisfies

$$\beta_3(b - f_3(c)) = \beta_3(b) - f_4(\alpha_3(c)) = f_4(a) - f_4(a) = 0$$

so by exactness of the bottom row at B_3 there is $e \in B_2$ with $\beta_2(e) = b - f_3(c)$. Since f_2 is an epimorphism, $e = f_2(g)$ for some $g \in A_2$, and then

$$f_3\big(\alpha_2(g) + c\big) = \beta_2(f_2(g)) + f_3(c) = \big(b - f_3(c)\big) + f_3(c) = b$$

so b lies in the image of f_3.

Under the hypotheses of the first statement both steps apply, so f_3 is both a monomorphism and an epimorphism, hence an isomorphism by lemma 55.1.8, completing the proof.

There is another way of looking at chain complexes which shall be important in elucidating triangle categories in section 56.5.2.

Mapping Cones

Using a particular total complex, we can detect when a quasi-isomorphism is an isomorphism. This result requires the snake lemma to prove, hence the need to put this section after the snake lemma.

Definition 56.1.18: Mapping Cone

Let $\alpha^\bullet : L^\bullet \to M^\bullet$ be a morphism of complexes. Then the *mapping cone* is the complex denoted by $MC(\alpha^\bullet)$ defined by:

$$MC(\alpha)^i := L[1]^i \oplus M^i = L^{i+1} \oplus M^i$$

where the morphism $d^i_{MC(\alpha)} : MC(\alpha)^i \to MC(\alpha)^{i+1}$ are given by:

$$d^i_{MC(\alpha)}(l, m) := (-d_L^{i+1}(l), \alpha^{i+1}(l) + d^i_M(m))$$

The term mapping cone comes from the topological notion of a mapping cone of a function. Visually, the mapping cone can be seen as the following commutative diagram:

$$\begin{tikzcd}
\cdots \arrow[r] \arrow[ddr] & L^{i+1} \arrow[r, "-d_L^{i+1}"] \arrow[ddr, "\alpha^{i+1}"] & L^{i+2} \arrow[r] \arrow[ddr] & \cdots \\
& \oplus & \oplus & \\
\cdots \arrow[r] & M^i \arrow[r, "d_M^i"'] & M^{i+1} \arrow[r] & \cdots
\end{tikzcd}$$

Given $MC(\alpha)^\bullet$, we may define two natural chain maps $C^\bullet \to MC(\alpha)^\bullet$ and $MC(\alpha)^\bullet \to L[1]^\bullet$ induced by the natural exact morphisms $M^i \to L^{i+1} \oplus M^i \to L^{i+1}$ which implies that:

$$0 \to C^\bullet \to MC(\alpha)^\bullet \to L[1]^\bullet \to 0$$

is exact.

Proposition 56.1.19: Mapping Cone And Exact Triangles

There is an exact triangle

$$\begin{tikzcd} & H^\bullet(C^\bullet) \arrow[dr] & \\ H^\bullet(L[1]^\bullet) \arrow[ur, "+1\ \delta"] & & H^\bullet(MC(\alpha)^\bullet) \arrow[ll] \end{tikzcd}$$

where δ is the morphism induced by cohomology

***Proof*:**
The short exact sequence of complexes displayed above,

$$0 \to C^\bullet \to MC(\alpha)^\bullet \to L[1]^\bullet \to 0$$

is exact, so theorem 56.1.15 produces a long exact sequence in cohomology

$$\cdots \to H^n(C^\bullet) \to H^n(MC(\alpha)^\bullet) \to H^n(L[1]^\bullet) \xrightarrow{\delta} H^{n+1}(C^\bullet) \to \cdots$$

Exactness at each of the three kinds of term is precisely exactness of the displayed triangle at each of its three corners, the degree shift $H^n(L[1]^\bullet) = H^{n+1}(L^\bullet)$ being what the label $+1$ records.

The connecting morphism is the one induced by α, with no intervening sign; the projection $MC(\alpha)^\bullet \to L[1]^\bullet$ is a chain map precisely because the shift carries the differential $-d_L$, which is what cancels against the sign in the cone. To see this, unwind definition 56.1.18 on representatives: a class in $H^n(L[1]^\bullet)$ is represented by some $l \in L^{n+1}$ with $d_L l = 0$, and its preimage in $MC(\alpha)^n = L^{n+1} \oplus C^n$ may be taken to be $(l, 0)$. Applying the differential of the cone,

$$d_{MC(\alpha)}(l, 0) = \big(-d_L l,\ \alpha^{n+1}(l)\big) = \big(0,\ \alpha^{n+1}(l)\big)$$

which is the image of $\alpha^{n+1}(l) \in C^{n+1}$ under the inclusion. Hence $\delta[l] = [\alpha^{n+1}(l)]$, that is $\delta = H^{n+1}(\alpha)$, completing the proof.

56.1.20 Remark Not all categories have this triangle property, categories which will have this will be called *triangulated categories*

Proposition 56.1.21: Quasi-isomorphism And Isomorphism

Let $\alpha^\bullet : C^\bullet \to N^\bullet$. Then $H^\bullet(\alpha^\bullet)$ is an isomorphism if and only if $MC(\alpha)^\bullet$ is an exact complex.

***Proof*:**
By proposition 56.1.19, applied with $\alpha\colon C^\bullet \to N^\bullet$, the cone sits in a long exact sequence

$$\cdots \to H^n\big(MC(\alpha)^\bullet\big) \to H^n\big(C[1]^\bullet\big) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet) \to H^{n+1}\big(MC(\alpha)^\bullet\big) \to \cdots$$

the connecting morphism having been identified there as the map induced by α, and $H^n(C[1]^\bullet) = H^{n+1}(C^\bullet)$.

Suppose $MC(\alpha)^\bullet$ is exact, so that $H^\bullet(MC(\alpha)^\bullet) = 0$ by lemma 56.1.14. Deleting the vanishing terms leaves

$$0 \to H^{n+1}(C^\bullet) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet) \to 0$$

exact for every n, so each $H^{n+1}(\alpha)$ is an isomorphism.

Conversely suppose every $H^n(\alpha)$ is an isomorphism. Fix n and read the sequence around $H^n(MC(\alpha)^\bullet)$:

$$H^{n-1}(C[1]^\bullet) \xrightarrow{H^n(\alpha)} H^n(N^\bullet) \to H^n\big(MC(\alpha)^\bullet\big) \to H^n(C[1]^\bullet) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet)$$

The left-hand map is surjective and the right-hand map is injective, both being isomorphisms. Exactness at $H^n(N^\bullet)$ then makes the morphism $H^n(N^\bullet) \to H^n(MC(\alpha)^\bullet)$ zero, and exactness at $H^n(C[1]^\bullet)$ makes the morphism $H^n(MC(\alpha)^\bullet) \to H^n(C[1]^\bullet)$ zero. Exactness at $H^n(MC(\alpha)^\bullet)$ therefore gives

$$H^n\big(MC(\alpha)^\bullet\big) = \ker\big(\text{zero morphism}\big) = \operatorname{im}\big(\text{zero morphism}\big) = 0$$

As n was arbitrary the cone is acyclic, hence exact by lemma 56.1.14, completing the proof.

56.1.3 Chain Homotopies and Homotopic Categories

The notion of homotopies originated in topology as a weaker alternative to continuous functions[3]. The topological notion of homotopy settled on the level of continuous functions, where $f, g : X \to Y$ are homotopic (denoted $f \simeq g$) if there exists a continuous function $F : X \times [0,1] \to Y$ where $F(\cdot, t) = f_t$ is continuous, $f_0 = f$ and $f_1 = g$. If we represent X, Y as one dimensional lines, then we may visualize a homotopy as:

[3] every homeomorphic is a homotopy equivalence, however not every homotopy equivalence is a homeomorphism, hence homotopy can be seen as weaker than continuity

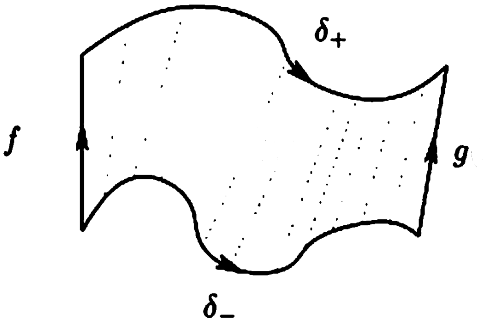


Figure 56.1: homotopy

In the development of homotopy theory, it was found that the (co)homology and homotopy of topological spaces (or their representations as chain complexes) is homology-invariant, hence homotopies are examples of quasi-isomorphisms. The proofs of these results turn out to be independent of the underlying topological structures and is purely algebraic, and hence the notion of homotopy has found a generalization as a purely algebraic notion between two (co)chain complexes.

Due to its origin in topology, the intuitions behind the following definitions will proceed more naturally with a more geometric build-up. Since homotopy may be interpreted purely algebraically, this geometrica build-up will be followed by a more algebraic interpretation. First, the reader may take for granted that given a topological space X, we may induce a chain $C_\bullet$, which is a topological object[4]. Given two continuous maps $f, g : X \to Y$, we may push forward the chain like so:

update image

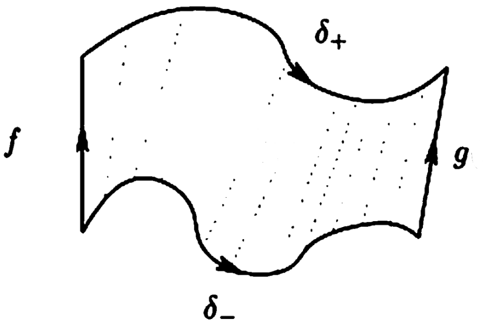

Figure 56.2: homotopy on chain

The space $h(C_\bullet)$ is a topological space, hence we may ask for it's border, $\partial h(C_\bullet)$. By inspecting the image, we see that:

$$\partial h(C_\bullet) = g(C_\bullet) - \delta_+ - f(C_\bullet) + \delta_- = g(C_\bullet) - f(C_\bullet) - h(\partial C_\bullet)$$

re-ordering, we get:

$$g(C_\bullet) - f(C_\bullet) = \partial h(C_\bullet) + h(\partial C_\bullet)$$

[4]The construction of singular chains is in *Algebraic Topology* [38]; [32] is the standard outside reference.

Abstracting notation, we get:

$$g - f = \partial h + h\partial \tag{56.3}$$

Now, recall that in a chain complex, the image of the function ∂ is called the boundary, and that by definition of homology the boundary becomes trivial. In a topological setting, this vocabulary reflects the concrete of the boundary map ∂: it maps a chain to it's boundary. What this means for us is that when taking homology on both sides, we get:

$$H^k(g|_{C_\bullet} - f|_{C_\bullet}) = \overline{0}$$

meaning the two maps are equivalent up to homology! In other words, this "geometric intuition" shows that a homotopy is an example of a quasi-isomorphism. Even better, homotopies shall form an equivalence relation, hence they are an example of a quasi-isomorphism that shall capture some (co)homological information (and in the case where all quasi-isomorphisms are homotopies, they could fully capture the (co)homological information!)

Though this is the origins of chain homotopies being (co)homology-invariant, since they may be interpreted in pure algebraic terms, it is worthwhile taking a moment to have an algebraic build-up as well. Algebraically, homotopies can be seen as forming equivalence classes of (co)chain complexes up to *obstruction from being split-exact*. Recall that a split exact sequence is a short exact sequence that is also split at each map, that is there exists a section morphism $s^n : C^n \to C^{n-1}$ such that $d^{n-1} \circ s^n \circ d^{n-1} = d$, or if we drop the indices and collect all the section maps:

$$d = dsd$$

In other words, it is possible to "inverse" the map d via the map s in such a way that it "cancels" the effect of d (for we may re-apply the map d after sd and get the same result). The simplest source of split-exact (co)chains are exact (co)chains of vector-spaces, for any vector-space maps split[5]. Given a cochain, we may write:

$$C^n = Z^n \oplus B' \qquad (B^n)' \cong C^n/Z^n = d(C^n) = B^{n+1}$$
$$Z^n = B^n \oplus (H^n)' \qquad (H^n)' = Z^n/B^n = H^n(C)$$

Hence, $C^n \cong Z^n \oplus B^{n+1}$. This allows for the definition of the section map via the composition:

$$C^n \hookrightarrow Z^n \hookrightarrow B^n \cong d(C^n) \cong B^{n+1} \subseteq C^{n+1}$$

We may thus define the maps $d \circ s$ and $s \circ d$ where $d \circ s(C^n) = B^n$ and $s \circ d(C^n)(B^n)' \cong B^{n+1}$. Adding these maps together, we get a map $ds + sd : C^n \to C^n$ whose kernel is the homology:

$$\ker(ds + sd)_n = H^n(C^\bullet)$$

The kernel (and cokernel) of the chain map $ds + sd$ is naturally $H^\bullet(C^\bullet)$. Working over more general R-modules (and more generally in an arbitrary abelian category), we loose the natural section maps, for example $0 \to \mathbb{Z} \twoheadrightarrow \mathbb{Z}/2\mathbb{Z} \to 0$ does note have a section map for each map. Instead, we may define arbitrary maps $s^n : C^n \to D^{n-1}$ where we may put them in the following (*not* necessarily commutative) diagram:

$$\begin{tikzcd}
\cdots \arrow[r] & C^{n-1} \arrow[r, "d"] \arrow[dl] & C^n \arrow[r, "d"] \arrow[dl, "s^n"] & C^{n+1} \arrow[r] \arrow[dl, "s^{n+1}"] & \cdots \arrow[dl] \\
\cdots \arrow[r] & D^{n-1} \arrow[r, "d"] & D^n \arrow[r, "d"] & D^{n+1} \arrow[r] & \cdots
\end{tikzcd}$$

[5] More generally, any maps of projective modules split

Given any such collection of morphisms, we may define $f^n = s^{n+1} \circ d^n + d^{n-1} \circ s^n$ (or, if dropping indices and abbreviate, $f = sd + ds$). Notice that even though the maps $s^\bullet$ do not commute, $f^\bullet$ *will* create a commutative diagram, in particular it is a chain map. To see this, notice that (after dropping indices):

$$df = d(ds + sd) = dsd = (ds + sd)d = fd$$

showing it is indeed a chain map:

$$\begin{tikzcd}
\cdots \arrow[r] & C^{n-1} \arrow[r, "d"] \arrow[d, "f^{n-1}"] \arrow[dl, dotted] & C^n \arrow[r, "d"] \arrow[d, "f^n"] \arrow[dl, dotted, "s^n"] & C^{n+1} \arrow[r] \arrow[d, "f^{n+1}"] \arrow[dl, dotted, "s^{n+1}"] & \cdots \arrow[dl, dotted] \\
\cdots \arrow[r] & D^{n-1} \arrow[r, "d"] & D^n \arrow[r, "d"] & D^{n+1} \arrow[r] & \cdots
\end{tikzcd}$$

Thus, given any collection of morphisms $s^\bullet$, we may naturally define a chain map using the differentials. Conversely, is every morphism of complexes representable as $ds + sd$. This is not in general the case; maps being representable like so are given a name:

Definition 56.1.22: Null-homotopic Maps

Let $f^\bullet : C^\bullet \to D^\bullet$ be a morphism of complexes. Then f is called *null-homotopic* if there exists a collection $\{s^i\}_{i\in\mathbb{Z}}$ of morphisms $s^i : C^i \to D^{i-1}$ such that

$$f^\bullet = ds + sd$$

The maps $s^\bullet$ are called the *chain contraction* of $f^\bullet$

To show that not all maps are null-homotopic, consider the following lemma:

Lemma 56.1.23: Null-homotopic And Split Exact Complexes

Let $C^\bullet$ be a complex. Then $C^\bullet$ is split exact if and only if the identity map is null-homotopic.

***Proof*:**
Throughout, split exact means exact together with a family $s^n : C^n \to C^{n-1}$ satisfying $dsd = d$, and null-homotopic means $\mathrm{id} = ds + sd$ for some such family.

Step 1: Null-homotopic implies split exact. Suppose $\mathrm{id} = dt + td$. For exactness, let $c \in \ker d^n$; then

$$c = dt(c) + td(c) = dt(c)$$

so $c \in \mathrm{im} d^{n-1}$, and the reverse inclusion $\mathrm{im} d^{n-1} \subseteq \ker d^n$ holds because $d \circ d = 0$. For the splitting, compute

$$dtd = d(td) = d(\mathrm{id} - dt) = d - d^2 t = d$$

so t is a splitting family.

Step 2: Split exact implies null-homotopic. Suppose $C^\bullet$ is exact and $dsd = d$. Set

$$\varphi = ds + sd$$

Then $d\varphi = dsd = d$ and $\varphi d = dsd = d$, both using $d \circ d = 0$; in particular φ commutes with d.

Put $\psi = \mathrm{id} - \varphi$. From the two identities just proved, $d\psi = d - d = 0$ and $\psi d = d - d = 0$. The first says $\mathrm{im}\psi \subseteq \ker d$, and exactness gives $\ker d = \mathrm{im} d$, so $\mathrm{im}\psi \subseteq \mathrm{im} d$; the second says ψ vanishes on $\mathrm{im} d$. Composing, $\psi \circ \psi = 0$.

Therefore $\varphi = \mathrm{id} - \psi$ is invertible, with inverse $\mathrm{id} + \psi$, and φ^{-1} commutes with d because φ does. Set $t = \varphi^{-1} s$. Then

$$dt + td = d\varphi^{-1}s + \varphi^{-1}sd = \varphi^{-1}(ds + sd) = \varphi^{-1}\varphi = \mathrm{id}$$

so the identity is null-homotopic with contraction t, completing the proof.

The name "null-homotopic" comes from how the (co)homology of such maps are trivial:

Proposition 56.1.24: Null-homotopic And Cohomology

Let $f^\bullet : C^\bullet \to D^\bullet$ be null-homotopic. Then $H^\bullet(f)$ is the zero map

***Proof*:**
Since f is null-homotopic, let $f = ds + sd$. Take a n-cycle representative x of an equivalence class of $H^n(C^\bullet)$. Then:

$$f(x) = d(s(x))$$

Hence, $f(x)$ is an n-boundary in D^n, hence $\overline{f(x)} = \overline{0}$ in $H^n(D^\bullet)$, as we sought to show. (this is an elementary result, but a similar proof is given in Aluffi p.612 if needed)

Thus, maps that are null-homotopic induce zero (co)homology maps![6] Thus, we may think of maps that are null-homotopic as being the "zero" maps. This leads us to the following definition:

Definition 56.1.25: Chain-homotopy

Let $f^\bullet, g^\bullet : C^\bullet \to D^\bullet$ be two morphisms of complexes. Then we say that these two maps are *chain homotopic* or just *homotopic* if there exists maps $h^i : C^i \to D^{i-1}$ such that

$$g^i - f^i = d^{i-1}_{D^\bullet} \circ h^i + h^{i+1} \circ d^i_{C^\bullet}$$

or, dropping indices:

$$g^\bullet - f^\bullet = dh + hd$$

If $f^\bullet, g^\bullet$ are homotopic, we write $f^\bullet \sim g^\bullet$

The s notation has been replaced with h notation to emphasize now the "homotopy" aspect of it rather than the "section" property that was evident in the case of vector spaces. If we were working with chains, then we would have

$$g_\bullet - f_\bullet = \partial h + h\partial$$

which, the reader may recognize as equation (56.3). If we were working with chains, then $h_i : C_i \to D_{i+1}$ would shift up a degree, which would be interpreted in the geometrical setting as moving *up* a dimension, in the same way that homotopies are a "dimension more" than the original spaces X, Y.

[6]TBD How much can we say about the converse, if a map induces the zero morphism, then is it null-homotopic?

Furthermore, the reader should verify the "up to homotopy" *is* an equivalence relation, as the reader should verify!

Importantly, two chain-homotopic maps induce the same (co)homology:

Proposition 56.1.26: Chain-Homotopy and Cohomology

Let $f^\bullet, g^\bullet : C^\bullet \to D^\bullet$ be chain homotopic. Then

$$H^\bullet(f^\bullet) = H^\bullet(g^\bullet)$$

***Proof*:**
Since $f^\bullet$ and $g^\bullet$ are chain-homotopic, by proposition 56.1.24 for each element in $H^k(C^\bullet)$ (since it is an additive functor):

$$H^k(f^\bullet)(\overline{x}) - H^k(g^\bullet)(\overline{x}) = 0 \qquad \Rightarrow \qquad H^k(f^\bullet)(\overline{x}) = H^k(g^\bullet)(\overline{x})$$

as we sought to show.

The above result shows promise in using chain-homotopies to hold (co)homological information. The following definition is the important connection idea:

Definition 56.1.27: Homotopy Equivalent Chains

Let $f^\bullet : C^\bullet \to D^\bullet$ be a morphism of complexes. Then $f^\bullet$ is a *homotopy equivalence* if there exists a morphisms of complexes $g^\bullet : D^\bullet \to C^\bullet$ such that

$$f^\bullet \circ g^\bullet \sim 1_{D^\bullet} \qquad \text{and} \qquad g^\bullet \circ f^\bullet \sim 1_{C^\bullet}$$

If $f^\bullet : C^\bullet \to D^\bullet$ is a homotopy equivalence, then $C^\bullet$ and $D^\bullet$ are said to be *homotopy equivalent*

Proposition 56.1.28: Homotopy Equivalence Ans Cohomology

Let $f^\bullet : C^\bullet \to D^\bullet$ be a homotopy equivalence. Then $f^\bullet$ is a quasi-isomorphism, that is $H^\bullet(f^\bullet)$ is an isomorphism

***Proof*:**
Since $f^\bullet$ is a homotopy equivalence, we have $g^\bullet$ that is it's homotopic inverse. Then the maps $f^\bullet \circ g^\bullet$ and $g^\bullet \circ f^\bullet$ induce inverse morphisms of cohomology by proposition 56.1.26, and hence give an isomorphism, as we sought to show.

As demonstrated in example 56.1.13 not all quasi-isomorphisms are invertible even up to homotopy equivalence, hence quasi-isomorphisms are more general. As mentioned earlier, in nice enough categories these two concepts shall coincide.

Now that homotopy equivalences is established, can be asked if given an (additive) functor $\mathscr{F} : \mathbf{A} \to \mathbf{B}$, if there are two homotopic complexes in $\mathrm{Ch}(\mathbf{A})$, will the (co)homology be isomorphic in $\mathbf{B}$? In other words, when trying to define the derived category that was mentioned earlier, can this category be defined at least up to homotopy? The answer is yes! The proof of this result essentially follows from the following lemma:

Lemma 56.1.29: Homotopy Equivalence And Additive Functors

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories, $C(\mathscr{F})$ the induced functor on chains. Then if $f^\bullet \sim g^\bullet$ in $\mathrm{Ch}(\mathbf{A})$, $C(\mathscr{F})(f^\bullet) \sim \mathrm{Ch}(\mathbf{B})(g^\bullet)$ in $\mathrm{Ch}(\mathbf{B})$. Furthermore, if $C^\bullet$ and $D^\bullet$ are homotopy equivalence, $C(\mathscr{F})(C^\bullet)$ and $C(\mathscr{F})(D^\bullet)$ are homotopy equivalent

***Proof*:**
Given the first assertion, the second is an immediate consequence, hence we prove the first. Let $f^\bullet \sim g^\bullet$ so that :

$$f^i - g^i = d_{D^\bullet}^{i-1} \circ h^i + h^{i+1} \circ d_{C^\bullet}^i$$

Since $\mathscr{F}$ is an additive functor:

$$\mathscr{F}(f^i) - \mathscr{F}(g^i) = \mathscr{F}\left(d_{D^\bullet}^{i-1}\right) \circ \mathscr{F}(h^i) + \mathscr{F}\left(h^{i+1}\right) \circ \mathscr{F}\left(d_{C^\bullet}^i\right)$$

hence, the morphisms $\mathscr{F}(h^i)$ gives a homotopy between $\mathscr{F}(f^\bullet)$ and $\mathscr{F}(g^\bullet)$, as we sought to show.

Note this does *not* hold for quasi-isomorphisms (exercise 4.15 in Aluffi), needing the stronger condition of exact functors.

Theorem 56.1.30: Derived Category And Homotopy Equivalence

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories. Then if $C^\bullet$ and $D^\bullet$ are homotopy-equivalent, then:

$$H^\bullet(\mathscr{F}(C^\bullet)) \cong H^\bullet(\mathscr{F}(D^\bullet))$$

that is, their cohomology is isomorphic.

***Proof*:**
By lemma 56.1.29, an additive functor carries homotopy-equivalent complexes to homotopy-equivalent complexes, so $\mathscr{F}(C^\bullet)$ and $\mathscr{F}(D^\bullet)$ are homotopy equivalent in $\mathrm{Ch}(\mathbf{B})$. By proposition 56.1.28 a homotopy equivalence is a quasi-isomorphism, so the induced map on cohomology is an isomorphism, giving $H^\bullet(\mathscr{F}(C^\bullet)) \cong H^\bullet(\mathscr{F}(D^\bullet))$, as we sought to show.

Hence, up to homotopy, the choice of cochain shall give the same cohomology information!

Homotopic Categories

With chain homotopies being a nicer sub-class of quasi-isomorphisms, their exploration is worth further pursuing. They are in fact almost the solution to the universal problem given in equation (56.2). Let us take for granted that a category $D(A)$ exists that satisfies the universal property. What necessary conditions can be deduced about $D(A)$?

Lemma 56.1.31: Derived Category And Additive Functors

Let $\mathbf{D}$ be an additive category, $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to \mathbf{D}$ be an additive functor that takes quasi-isomorphisms to isomorphisms.

1. Let $C^\bullet$ be an exact complex in $\mathrm{Ch}(\mathbf{A})$. Then $\mathscr{F}(C^\bullet) = 0$, that is $\mathscr{F}(C^\bullet)$ is the zero object in $\mathbf{D}$.
2. Let $\alpha^\bullet : C^\bullet \to E^\bullet$ be a morphism of complexes that factors through an exact complex:

$$\begin{tikzcd} C^\bullet \arrow[rr, "\alpha^\bullet"] \arrow[dr] & & E^\bullet \\ & D^\bullet \arrow[ur] & \end{tikzcd}$$

   where $D^\bullet$ is exact. Then $\mathscr{F}(\alpha^\bullet)$ is the zero morphism.

Proof:

1. Since $C^\bullet$ is exact, the zero morphism $0^\bullet : C^\bullet \to C^\bullet$ is a quasi-isomorphism, and so $\mathscr{F}(0^\bullet)$ maps to an isomorphism (i.e. an invertible morphism in $\mathbf{D}$). Thus:
