Let $p\colon X_0 \to X$ be the projection and $i_0\colon S_0 \to S$ the closed immersion. By the universal property of X_0 (theorem 3.2.1), a section σ_0 of $X_0 \to S_0$ corresponds to the S-morphism $s_0 = p \circ \sigma_0\colon S_0 \to X$, and $\sigma_0 = (s_0, \mathrm{id}_{S_0})$. Let $J^m = 0$, and put $T_k = \operatorname{Spec}(C/J^k)$ for $1 \le k \le m$, so that $T_1 = S_0$ and $T_m = S$. As in the proof of corollary 5.6.8, each $T_k \subseteq T_{k+1}$ is a first-order thickening of affine schemes over S. The morphism f is formally smooth by theorem 5.6.7(1). Put $s_1 = s_0$. By induction on k there are S-morphisms $s_k\colon T_k \to X$ for $1 \le k \le m$, each restricting to s_{k-1} on T_{k-1}. The last of them, $s\colon S \to X$, satisfies $f \circ s = \mathrm{id}_S$ and $s \circ i_0 = s_0$, so it is a section of f. Its base change to S_0 is $(s \circ i_0, \mathrm{id}_{S_0}) = (s_0, \mathrm{id}_{S_0}) = \sigma_0$, completing the proof.

With $C = \mathbb{Z}/p^n\mathbb{Z}$ and $J = (p)$, the corollary says that for a smooth $\mathbb{Z}/p^n\mathbb{Z}$-scheme X, every $\mathbb{F}_p$-point of $X \times_{\mathbb{Z}/p^n\mathbb{Z}} \operatorname{Spec} \mathbb{F}_p$ is the reduction of a $\mathbb{Z}/p^n\mathbb{Z}$-point of X. For $X = \operatorname{Spec}(\mathbb{Z}/p^n\mathbb{Z})[x]_{g'}/(g)$ with g monic, this is the existence half of Hensel's lemma for simple roots, and corollary 5.6.8 gives the uniqueness (exercise 5.6.1 (7)).

For a field extension $K[x]/(g)$, a lifting problem asks for a root of g in C above a given root in C/J, and when g is separable one step of Newton's method produces exactly one.

Example 5.6.10: Separable Field Extensions

1. *A finite separable extension is formally étale.* Let L/K be finite separable. By [17, Primitive Element Theorem], $L = K(\alpha) \cong K[x]/(g)$ with g the minimal polynomial of α, and $g'(\alpha) \neq 0$ because g is separable. Let C be a K-algebra, $J \subseteq C$ an ideal with $J^2 = 0$, $q\colon C \to C/J$ the quotient map and $u\colon L \to C/J$ a K-algebra map. A K-algebra map $L \to C$ is the same as a root of g in C, so the lifts of u are the roots $c \in C$ of g with $q(c) = u(\alpha)$. Fix $c_0 \in C$ with $q(c_0) = u(\alpha)$. Then $q(g(c_0)) = u(g(\alpha)) = 0$, so $g(c_0) \in J$, and $q(g'(c_0)) = u(g'(\alpha))$ is a unit, so $g'(c_0)$ is a unit of C, as in the proof of proposition 5.6.4(4). Every element of C over $u(\alpha)$ is $c_0 + j$ with $j \in J$, and expanding each power of $c_0 + j$ with $j^2 = 0$ gives

$$g(c_0 + j) = g(c_0) + g'(c_0)\, j$$

   Hence $c_0 + j$ is a root of g exactly when $j = -g'(c_0)^{-1} g(c_0)$, an element of J. There is exactly one lift, and $K \to L$ is formally étale. This agrees with $\Omega_{L/K} = 0$ (example 5.5.4(3), proposition 5.6.5).

   In the setting of proposition 5.5.10, the residue field $\kappa = B/\mathfrak{m}$ is finite and separable over k, so $k \to \kappa$ is formally smooth by part (1) and proposition 5.6.4(3), and proposition 5.6.6(1), applied to $k \to B \to \kappa$, gives a left inverse of $\delta\colon \mathfrak{m}/\mathfrak{m}^2 \to \Omega_{B/k} \otimes_B \kappa$. This is the injectivity of δ used in the proof of that proposition.

2. *A separably generated extension is formally smooth.* Let L/K be finitely generated and separably generated, so that L is a separable algebraic extension of a purely transcendental extension $K(t_1, \dots, t_d)$. As L is finitely generated over K, it is finite over $K(t_1, \dots, t_d)$. The maps
$$K \longrightarrow K[t_1, \dots, t_d] \longrightarrow K(t_1, \dots, t_d) \longrightarrow L$$
are formally smooth, formally étale and formally étale, by proposition 5.6.4(4) and part (1), so $K \to L$ is formally smooth by proposition 5.6.4(1). This agrees with proposition 5.5.9, by which $\Omega_{L/K}$ has dimension d: the extension L/K is formally unramified only for $d = 0$.

At the node, whose tangent space at the origin has dimension 2, a lifting problem already fails at second order.

Example 5.6.11: The Node Is Not Formally Smooth

Let k be a field and $R = k[x, y]/(xy)$, so that $X = \operatorname{Spec} R$ is the union of the two coordinate axes. Take the first-order thickening $\operatorname{Spec} k[t]/(t^2) \subseteq \operatorname{Spec} k[t]/(t^3)$ over $\operatorname{Spec} k$, with ideal $(t^2)/(t^3)$, and the k-algebra map
$$u\colon R \longrightarrow k[t]/(t^2), \qquad x \longmapsto t, \quad y \longmapsto t$$
which is well defined because $t \cdot t = 0$ in $k[t]/(t^2)$. Under example 3.3.7, u is the tangent vector at the origin in the direction of the line $x = y$. The elements of $k[t]/(t^3)$ over t are the $t + \gamma t^2$ with $\gamma \in k$, so a lift $v\colon R \to k[t]/(t^3)$ would send $x \mapsto t + \alpha t^2$ and $y \mapsto t + \beta t^2$ for some $\alpha, \beta \in k$, and then
$$v(xy) = (t + \alpha t^2)(t + \beta t^2) = t^2 + (\alpha + \beta)t^3 + \alpha\beta t^4 = t^2$$
in $k[t]/(t^3)$, which is nonzero although $xy = 0$ in R. So u has no lift, $k \to R$ is not formally smooth, and $X \to \operatorname{Spec} k$ is not formally smooth (proposition 5.6.3(1)), in accordance with theorem 5.6.7(1) and the vanishing at the origin of the Jacobian matrix (y, x). The tangent vectors along the branches do extend: the map $x \mapsto t$, $y \mapsto 0$ lifts to the map into $k[t]/(t^3)$ given by the same formulas. On the line $\operatorname{Spec} k[x]$ every such problem has a solution by proposition 5.6.4(4), and $x \mapsto t$ lifts to $x \mapsto t$. Away from the origin the Jacobian matrix (y, x) has rank 1, so the complement of the origin in X is smooth over k, hence formally smooth by theorem 5.6.7(1).

The conormal sequence detects the same failure. With $P = k[x, y]$ and $I = (xy)$, the R-module I/I^2 is free on the class of xy, because xy is a non-zero divisor in P, and δ sends this class to $y\,dx + x\,dy$. At the origin, whose residue field is $\kappa = k$, the map $\delta \otimes \kappa$ is zero on the one-dimensional space $(I/I^2) \otimes_R \kappa$, so δ has no left inverse, and proposition 5.6.6(1) shows again that R is not formally smooth over k.

Over an imperfect field a lifting problem can fail at a point that is regular, and then it is the inseparability of the residue field that obstructs the lift.

Example 5.6.12: An Inseparable Extension Is Not Formally Smooth

Let k be a field of characteristic $p > 0$, let $a \in k$ be an element that is not a p-th power, and let $g = x^p - a$ and $L = k[x]/(g)$. Over a field containing a root β of g one has $g = (x - \beta)^p$, so a monic factor of g in $k[x]$ of degree m with $0 < m < p$ would be $(x - \beta)^m$, whose coefficient $-m\beta$ of x^{m-1} would put β in k and $a = \beta^p$ in k^p. Hence g is irreducible and $L = k(a^{1/p})$ is a field of degree p over k.

Take the first-order thickening $\operatorname{Spec} L \subseteq \operatorname{Spec} k[x]/(g^2)$ over $\operatorname{Spec} k$, with ideal $(g)/(g^2)$, and the identity $u = \mathrm{id}_L$. A lift $v\colon L \to k[x]/(g^2)$ would send the class of x to the class of some $h = x + wg$

with $w \in k[x]$, and $h^p = v(a) = a$ in $k[x]/(g^2)$. In characteristic p,

$$h^p = x^p + w^p g^p$$

and $g^p \in (g^2)$, so $h^p - a = x^p - a = g$, which is nonzero in $k[x]/(g^2)$ because g has degree $p < 2p$. So id_L has no lift, and L is not formally smooth over k. By theorem 5.6.7(1), $\operatorname{Spec} L \to \operatorname{Spec} k$ is not smooth, although L is a field and $\operatorname{Spec} L$ is regular, as in example 2.7.16.

The differentials show the same. The class of g is a basis of the one-dimensional L-vector space $(g)/(g^2)$, and δ sends it to $g'(x)\,dx = px^{p-1}\,dx = 0$, so the conormal sequence of $L = k[x]/(g)$ is not split exact, in accordance with proposition 5.6.6(1). Its cokernel $\Omega_{L/k} = L\,dx$ is one-dimensional, so L is not formally unramified over k either (proposition 5.6.5), although L/k is finite. The inequality $\dim_L \Omega_{L/k} = 1 > 0 = \operatorname{trdeg}(L/k)$ records, by proposition 5.5.9, that L/k is not separably generated.

5.6.13 Remark: The Criterion over an Arbitrary Base Definition 5.6.2 makes sense for every morphism of schemes. Grothendieck defines the smooth, unramified and étale morphisms over an arbitrary base as the formally smooth, formally unramified and formally étale morphisms locally of finite presentation [42, p. 17.3.1]. He proves that the formal properties are local on the source and on the target with no finiteness hypothesis [42, p. 17.1.6], and he compares his definitions with descriptions by differentials, fibers and flatness in [42, pp. 17.4.1, 17.5.1, 17.6.1]. In the Stacks Project a morphism is unramified when it is locally of finite type with vanishing sheaf of relative differentials, and [95, Tag 02HE] proves, over any base, that this holds if and only if the morphism is locally of finite type and formally unramified. For the Stacks Project's smooth and étale morphisms, [95, Tags 02H6, 02HM] prove the equivalence with local finite presentation together with formal smoothness, respectively formal étaleness, and [95, Tag 0D0F] removes the finite presentation hypothesis from the smooth case of proposition 5.6.3(3). In theorem 5.6.7 the smooth case holds over every base. The unramified and étale cases are stated over a locally Noetherian base because definition 2.7.18 and definition 2.7.19 are, and because the proof of (3) uses proposition 2.7.12 and theorem 2.7.20, which assume it.

For a smooth k-scheme X and a point $x \in X(k)$, the functor sending a local Artinian k-algebra R with residue field k to the set of k-morphisms $\operatorname{Spec} R \to X$ that send the closed point to x is unobstructed in the sense of *Moduli, Deformation Theory, and Stacks* [27, Unobstructed Deformation Functor]: a small extension has square-zero kernel, so theorem 5.6.7(1) applies to it. Corollary 5.6.8 is the case of an affine T' and a nilpotent ideal of [42, p. 18.1.3], which allows any S-scheme T' and any closed subscheme T with the same underlying space. It is the infinitesimal input to the topological invariance of the étale site [42, p. 18.1.2]: for a closed subscheme S_0 of S with the same underlying space, $X \mapsto X \times_S S_0$ is an equivalence between the categories of étale S-schemes and étale S_0-schemes. See also *Étale Cohomology* [21].

Exercise 5.6.1

1. Show that every closed immersion is formally unramified. Show that the closed immersion $\operatorname{Spec} k \to \operatorname{Spec} k[\epsilon]/(\epsilon^2)$, for a field k, is not formally smooth.
2. Let $f\colon X \to Y$ and $g\colon Y \to Z$ be morphisms of schemes. Show that if $g \circ f$ is formally unramified, then so is f. Show that a morphism $h\colon X \to S$ is formally unramified if and only

if its diagonal $X \to X \times_S X$ is formally étale.

3. Let k be a field and $R = k[x,y]/(y^2 - x^3)$. For $\alpha, \beta \in k$, the k-algebra map $R \to k[t]/(t^2)$ with $x \mapsto \alpha t$ and $y \mapsto \beta t$ is a tangent vector at the origin. Determine the pairs (α, β) for which it lifts to a k-algebra map $R \to k[t]/(t^3)$, and deduce that $\operatorname{Spec} R$ is not smooth over k.

4. Let A be a ring, Λ a set and $P = A[x_\lambda : \lambda \in \Lambda]$. Show that $\Omega_{P/A}$ is a free P-module on the elements dx_λ. Deduce that $\Omega_{B/A}$ is a projective B-module for every formally smooth A-algebra B, finitely generated or not. (*Hint:* present B as a quotient of $A[x_b : b \in B]$ and use proposition 5.6.6(1).)

5. Let A be a ring, $h \in P = A[x_1, \ldots, x_N]$ a non-zero divisor and $B = P/(h)$. Show that B is formally smooth over A if and only if $h, \partial h/\partial x_1, \ldots, \partial h/\partial x_N$ generate the unit ideal of P. Recover the conclusion of example 5.6.11 from this criterion.

6. Let A be a ring, $g \in A[x]$ with derivative g', and $B = A[x]_{g'}/(g)$. Show directly from definition 5.6.2 that $A \to B$ is formally étale.

7. Let p be a prime, $n \geq 1$, $R = \mathbb{Z}/p^n\mathbb{Z}$, and $g \in R[x]$ monic. Suppose that $\bar{a} \in \mathbb{F}_p$ is a root of the reduction $\bar{g} \in \mathbb{F}_p[x]$ with $\bar{g}'(\bar{a}) \neq 0$. Show that $Y = \operatorname{Spec} R[x]_{g'}/(g)$ is étale over $\operatorname{Spec} R$, and use corollary 5.6.8 to show that g has exactly one root $a \in R$ with $a \equiv \bar{a}$ modulo p.

8. Let k be a field of characteristic $p > 0$ and t an indeterminate. Show that $k \to k(t)$ and $k \to k(t^p)$ are formally smooth and that $k(t^p) \to k(t)$ is not. Conclude that in a composite $A \to B \to C$ with $A \to C$ formally smooth, the map $B \to C$ need not be formally smooth.

5.7⋆ *Formal Schemes and Local Geometry

⋆ *Optional. This section is an aside; nothing later in the book depends on it.*

One feature distinguishing the theory of schemes from the older classical theory of varieties is the possibility of having nilpotent elements in the structure sheaf. In particular, if $Y \subseteq X$ is a closed subvariety defined by a sheaf of ideals $\mathcal{I}$, then for any $n \geq 1$ we can consider the closed subscheme Y_n defined by the n-th power $\mathcal{I}^n$. For $n \geq 2$, this is a scheme with nilpotent elements. It carries information about Y together with the infinitesimal properties of the embedding of Y in X.

We wish to construct an object which carries information about all the infinitesimal neighborhoods Y_n of Y simultaneously. Such an object would be "thicker" than any individual Y_n, but contained inside any actual open neighborhood of Y in X. We might naturally call this the formal neighborhood of Y in X.

To see why a new geometric construction is necessary to capture this, recall that the algebraic construction of the formal power series ring $k[[x]]$ is given by the limit of the truncated polynomial rings $k[x]/(x^n)$. We shall now explore the geometric consequences of this algebraic operation.

Topologically, the scheme $\operatorname{Spec}(k[x]/(x^n))$ consists of exactly one point, as the ring is Artinian and possesses a unique prime ideal (x). Geometrically, one views this as a "fat point" – a point equipped with infinitesimal nilpotents that remember $n-1$ orders of derivatives. Since $k[[x]]$ is the algebraic limit of these rings as $n \to \infty$, one might intuitively expect the geometric limit of a sequence of one-point spaces to remain a one-point space. However, passing to the infinite limit crosses a structural threshold: the limit of infinite nilpotents coalesces into a genuine coordinate variable, making $k[[x]]$ a domain of Krull dimension 1. Consequently, the affine scheme $\operatorname{Spec}(k[[x]])$

possesses *two* points. One should visualize $\operatorname{Spec}(k[[x]])$ as the "germ" of a curve, an unimaginably small neighborhood that has lost all global properties but is just large enough to have a center and an infinitesimal edge.

Formal Completions

The fact that the Spec functor transforms a limit of one-point spaces into a two-point space demonstrates that Spec does not commute nicely with infinite limits. To rectify this topological mismatch, Grothendieck introduced formal schemes. We shall follow Hartshorne and define this globally as a completion along a closed subscheme.

Definition 5.7.1: Formal Completion

Let X be a Noetherian scheme, and let Y be a closed subscheme defined by a sheaf of ideals $\mathcal{I}$. Then we define the *formal completion* of X along Y, denoted $(\hat{X}, \mathcal{O}_{\hat{X}})$, to be the following ringed space: we take the topological space Y, and on it the sheaf of rings $\mathcal{O}_{\hat{X}} = \varprojlim \mathcal{O}_X/\mathcal{I}^n$. Here we consider each $\mathcal{O}_X/\mathcal{I}^n$ as a sheaf of rings on Y, and make them into an inverse system in the natural way.

The reader should notice that the structure sheaf $\mathcal{O}_{\hat{X}}$ depends only on the closed subset Y, and not on the particular scheme structure on Y. For if $\mathcal{J}$ is another sheaf of ideals defining a closed subscheme structure on Y, then since X is a Noetherian scheme, there are integers m, n such that $\mathcal{I} \supseteq \mathcal{J}^m$ and $\mathcal{J} \supseteq \mathcal{I}^n$. Thus the inverse systems $(\mathcal{O}_X/\mathcal{I}^n)$ and $(\mathcal{O}_X/\mathcal{J}^m)$ are cofinal with each other, and hence have the same inverse limit.

Furthermore, one sees easily that the stalks of the sheaf $\mathcal{O}_{\hat{X}}$ are local rings, so in fact $(\hat{X}, \mathcal{O}_{\hat{X}})$ is a locally ringed space. If $U = \operatorname{Spec} A$ is an open affine subset of X, and if $I \subseteq A$ is the ideal $\Gamma(U, \mathcal{I})$, then evaluating the sections reveals that $\Gamma(\hat{X} \cap U, \mathcal{O}_{\hat{X}}) = \hat{A}$, the I-adic completion of A. Thus the process of completing X along Y is strictly analogous to the I-adic completion of a ring. However, one should note that the local rings of $\hat{X}$ are in general *not* complete, and their dimension (which is equal to $\dim X$) is *not* equal to the dimension of the underlying topological space Y.

We shall call a formal scheme obtained by completing a single Noetherian scheme X along a closed subscheme Y *algebraizable*.[8]

Example 5.7.2: Formal Completions

1. Take X to be a Noetherian scheme, and let $Y = X$. Then $\mathcal{I} = 0$, so $\mathcal{O}_X/\mathcal{I}^n = \mathcal{O}_X$ for every n and $\hat{X} = X$. Thus the category of Noetherian formal schemes naturally includes all Noetherian schemes.

2. Take X to be a Noetherian scheme, and let $Y = \{P\}$ be a closed point. Then $\hat{X}$ is a one point space $\{P\}$ with the completion $\hat{\mathcal{O}}_P$ of the local ring at P as its structure sheaf. An $\hat{\mathcal{O}}_P$-module M, considered as a sheaf on $\hat{X}$, is coherent if and only if M is a finitely generated module. This directly resolves our earlier algebraic paradox: $\hat{X}$ is topologically a single point, capturing the geometric intuition of a true limit of fat points without accidentally spawning a generic point.

[8] It is apparently quite difficult to find non-algebraizable formal schemes, maybe add an exercise based on Hartshorne p.194 later?

5.7.3 Comparing Local Geometries To summarize the distinctions between these deeply related objects for a point P on a curve:

1. $\operatorname{Spec}(k[x]/(x^n))$ is a single point representing a "fat point" of finite thickness.
2. $\hat{X}$ (the formal completion at P) is a single point representing the true geometric limit of fat points (infinite formal thickness).
3. $\operatorname{Spec}(k[[x]])$ is a two-point space representing a "formal disk" or germ (a center point plus a surrounding generic neighborhood).

Universal Smoothness and Singularities

The utility of formal schemes shines when studying the local properties of varieties. In classical algebraic geometry, curves can exhibit wildly different global shapes, such as a line $y = x$ or a parabola $y = x^2$. However, if one selects a smooth point on any such curve over a field k and takes the formal completion of the local ring at that point, the resulting ring is always isomorphic to $k[[t]]$, where t is a local parameter.

Because their local algebra is identical, their formal geometry is identical. Thus, $\operatorname{Spec}(k[[x]])$ does not represent *a* curve; it represents the fundamental atomic structure of *any* smooth curve at a smooth point. Under an infinite-power formal microscope, every smooth curve is indistinguishable from a straight line.

This universal behavior fails precisely when the geometry ceases to be smooth.

Example 5.7.4: Singularities and Formal Completions
If a curve possesses a singularity, its formal completion at that point acts as a perfect algebraic memory of the singularity, remaining distinct from $k[[x]]$.

1. *The Cusp:* Consider the curve cut out by $y^2 = x^3$, which has a sharp cusp at the origin. The formal completion of the local ring at the origin is
$$\frac{k[[x, y]]}{(y^2 - x^3)}$$
This ring is not isomorphic to $k[[t]]$. Even infinitesimally, the formal scheme remembers the sharp turn.
2. *The Node:* Consider a curve with a self-intersection at the origin, locally modeled by $xy = 0$. Its formal completion at the crossing is
$$\frac{k[[x, y]]}{(xy)}$$
This represents two distinct microscopic branches crossing each other. Topologically, the formal completion is still a single point, but the underlying sheaf of topological rings completely captures the crossing branches.

6

Cohomology of Schemes

Let X be a scheme with a sheaf $\mathscr{F}$. A natural question is: can we quantify the obstruction to gluing local sections into global sections? On an affine scheme, there is no obstruction: the global section functor is exact for quasi-coherent sheaves, and all local data glues. But on a projective variety of positive dimension, or on a scheme built by gluing affine pieces in a non-trivial way, the functor $\Gamma(X, -)$ fails to be exact, and its failure is measured by the *sheaf cohomology groups* $H^i(X, \mathscr{F}) = R^i\Gamma(X, \mathscr{F})$, the right derived functors of the global section functor. These groups are the central objects of study in this chapter.

The sheaves to which this machinery applies include the structure sheaf $\mathcal{O}_X$, the twisted sheaves $\mathcal{O}_X(n)$ when X is projective, the sheaves of differentials $\Omega_{X/S}$ of a morphism $X \to S$ and their exterior powers, and the pushforwards of sheaves along closed immersions. Each choice of sheaf extracts different geometric information: the cohomology of $\mathcal{O}_X$ governs the arithmetic genus, the cohomology of line bundles governs linear systems and the Riemann–Roch theorem, and the cohomology of the canonical sheaf ω_X encodes duality phenomena that constrain the topology of the variety.

Though the derived-functor definition is theoretically clean, it is computationally impractical: it requires an injective resolution, and injective sheaves are typically enormous and non-explicit. For practical computations, we introduce *Čech cohomology*, which replaces injective resolutions with the combinatorial data of an open cover. For quasi-coherent sheaves on separated Noetherian schemes with an affine cover, Čech cohomology and derived-functor cohomology coincide, and this is our main computational tool. Using it, we compute the cohomology of projective space $\mathbb{P}^n_R$ with coefficients in the twisted sheaves $\mathcal{O}(d)$ — the single most important explicit computation in the subject.

With these foundations, the chapter develops in four main directions.

Vanishing and finiteness. Two structural results govern the cohomology of schemes: the higher cohomology of quasi-coherent sheaves vanishes on affine Noetherian schemes (section 6.2), and the cohomology of coherent sheaves on projective schemes over a field is finite-dimensional (section 6.6). The first confirms the philosophy that cohomology measures gluing; the second ensures that the

invariants we extract are "finitely complicated." Together, they justify defining the Euler characteristic $\chi(X, \mathscr{F})$, the Hilbert polynomial, and the arithmetic genus (section 6.7).

Duality. Serre duality (section 6.5) is the algebraic analogue of Poincaré duality: for a smooth projective variety X of dimension n over a field k, the cohomology groups satisfy $H^i(X, \mathscr{F}) \cong H^{n-i}(X, \mathscr{F}^\vee \otimes \omega_X)^*$ for locally free $\mathscr{F}$ of finite rank. The proof passes through the Ext groups and the local-to-global spectral sequence (section 6.4), which provide the natural framework for the duality pairing. As a consequence, we obtain the Riemann–Roch theorem for curves and the classical genus formulas.

Families and variation. The higher direct image sheaves $R^i f_* \mathscr{F}$ (section 6.6) relativize cohomology over a base scheme. For a proper morphism $f\colon X \to Y$ of Noetherian schemes and a coherent sheaf $\mathscr{F}$ on X flat over Y, the semicontinuity theorem (section 6.8) shows that the fiber cohomology $h^i(X_y, \mathscr{F}_y)$ is upper semicontinuous in y, and Grauert's theorem guarantees that, when Y is reduced, constancy of h^i implies local freeness of $R^i f_* \mathscr{F}$ and compatibility with base change. These results are the technical heart of moduli theory.

GAGA. For projective varieties over $\mathbb{C}$, Serre's GAGA theorems (section 6.9) identify the algebraic cohomology developed in this chapter with the analytic cohomology of the complex geometry: the analytification functor induces an equivalence $\mathbf{Coh}(X) \simeq \mathbf{Coh}(X^{\mathrm{an}})$ and isomorphisms $H^i(X, \mathscr{F}) \cong H^i(X^{\mathrm{an}}, \mathscr{F}^{\mathrm{an}})$. Through GAGA, the Hodge decomposition and the de Rham theorem pass from the analytic theory to algebraic cohomology, and Chow's theorem follows, closing the loop between the algebraic and analytic perspectives on cohomology.

Prerequisites. The reader should be comfortable with the theory of sheaves and schemes (chapters 1–3), quasi-coherent and coherent sheaves (chapter 5), and the basic properties of projective schemes and differentials (sections 2.3 and 5.5). For the GAGA section, familiarity with the complex geometry review (section 0.6) is assumed. The reader may also want to review [25] for the derived-functor approach to (co)homology theory.

6.1 Definition and Basic Properties

Recall that a category $\mathbf{C}$ is *pre-additive* (or enriched over $\mathbf{Ab}$) if for every $A, B \in \mathrm{Obj}(\mathbf{C})$, the set $\mathrm{Hom}_{\mathbf{C}}(A, B)$ carries the structure of an abelian group, and composition of morphisms is bilinear:

$$f \circ (g + h) = (f \circ g) + (f \circ h) \qquad \text{and} \qquad (f + g) \circ h = (f \circ h) + (g \circ h).$$

An *additive category* is a pre-additive category that admits all finite products and coproducts, and in which these coincide (this common construction is sometimes called the *biproduct*).

An abelian category is an additive category with the "right" conditions to do cohomology[1]. Concretely (cf. definition 0.4.29), a category $\mathbf{A}$ is *abelian* if:

1. for every $A, B \in \mathrm{Obj}(\mathbf{A})$, the set $\mathrm{Hom}_{\mathbf{A}}(A, B)$ is an abelian group and composition is bilinear;
2. finite products and coproducts exist and coincide;
3. every morphism $f \in \mathrm{Hom}_{\mathbf{A}}(A, B)$ has a kernel and a cokernel;

[1] Technically, one can do cohomology on exact categories that are not abelian, such as the category of vector bundles, but it is more natural to see this as a special generalization of the abelian setting.

4. every monomorphism is the kernel of its cokernel, and every epimorphism is the cokernel of its kernel;
5. defining $\mathrm{im}(f) = \ker(\mathrm{coker}(f))$, the first isomorphism theorem gives

$$\mathrm{im}(f) = \ker(\mathrm{coker}(f)) = \mathrm{coker}(\ker(f)),$$

so every morphism factors as an epimorphism followed by a monomorphism.

The prototypical abelian category is R-**Mod**. By the Freyd-Mitchell embedding theorem, any small abelian category $\mathbf{A}$ fully-faithfully embeds into R-**Mod** via an exact functor for an appropriate (not necessarily commutative) ring R. This is useful theoretically, but for our purposes it is more practical to think of the abelian category of sheaves $\mathbf{Sh}_{\mathbf{Ab}}(X)$ as its own creature. The "sheafification" of R-**Mod** gives $\mathcal{O}_X$-**Mod**. The important full subcategories $\mathbf{QCoh}(X)$ and, for X locally Noetherian, $\mathbf{Coh}(X)$ are both abelian (proposition 5.1.17(1) and (2)). Though not critical at the moment, it should be noted that $\mathbf{QCoh}(X)$ is not closed under the internal Hom sheaf *Hom*, while $\mathbf{Coh}(X)$ is.

A functor between abelian categories $F : \mathbf{A} \to \mathbf{B}$ is *additive* if for every $X, Y \in \mathrm{Obj}(\mathbf{A})$, the induced map

$$\mathrm{Hom}_{\mathbf{A}}(X, Y) \longrightarrow \mathrm{Hom}_{\mathbf{B}}(FX, FY)$$

is a group homomorphism. An additive functor F is *left exact* if it preserves kernels, equivalently if a short exact sequence $0 \to X \to Y \to Z \to 0$ yields an exact sequence

$$0 \longrightarrow FX \longrightarrow FY \longrightarrow FZ,$$

and *right exact* if it preserves cokernels, equivalently if the same short exact sequence yields

$$FX \longrightarrow FY \longrightarrow FZ \longrightarrow 0.$$

If F is both left and right exact, it is called *exact*. The most common (and arguably the most important) left-exact functors are the covariant $\mathrm{Hom}(X, -)$ and the contravariant $\mathrm{Hom}(-, Y)$. The most important right-exact functor is $- \otimes Y$[2].

Given a left-exact functor $F : \mathbf{A} \to \mathbf{B}$, we can form its *right derived functors* $R^iF : \mathbf{A} \to \mathbf{B}$ for $i \geq 0$. Abstractly, one passes from $\mathbf{A}$ to its bounded-below derived category $D^+(\mathbf{A})$ — constructed by taking the category of bounded-below cochain complexes $\mathrm{Kom}^+(\mathbf{A})$, passing to the homotopy category $K^+(\mathbf{A})$, and then localizing at quasi-isomorphisms — and the total derived functor $\mathbf{R}F : D^+(\mathbf{A}) \to D^+(\mathbf{B})$ captures the right information to "fix" exactness. The derived category does not lend itself well to direct computation, but if $\mathbf{A}$ has enough injectives, then injective resolutions are universal up to homotopy, and the right derived functors R^iF can be computed as follows: given an object $A \in \mathbf{A}$, choose an injective resolution $0 \to A \to I^0 \to I^1 \to \cdots$, apply F, and take cohomology:

$$R^iF(A) = h^i(F(I^\bullet)).$$

This is independent of the choice of injective resolution (up to canonical isomorphism). The details of these constructions can be found in [25, Total Derived Functor], and a "classical" approach using δ-functors in [25, Universal δ-Functor].

Recall that if R is a ring, then every R-module embeds into an injective module (see [25]). From this, we shall be able to conclude that the module categories over ringed spaces have enough injectives:

[2]The functor $X \otimes -$ is also right exact and is left adjoint to $\mathrm{Hom}(X, -)$; this adjunction is the tensor–Hom adjunction.

Proposition 6.1.1: Ringed Space Has Enough Injectives

Let $(X, \mathcal{O}_X)$ be a ringed space. Then the category $\mathcal{O}_X$-**Mod** of sheaves of $\mathcal{O}_X$-modules has enough injectives.

***Proof*:**
Let $\mathscr{F}$ be a sheaf of $\mathcal{O}_X$-modules. For each $x \in X$, the stalk $\mathscr{F}_x$ is an $\mathcal{O}_{X,x}$-module, so there exists an injective $\mathcal{O}_{X,x}$-module I_x together with an embedding $\mathscr{F}_x \hookrightarrow I_x$. For each point $x \in X$, let $j_x : \{x\} \hookrightarrow X$ denote the inclusion of the one-point space $\{x\}$, and equip $\{x\}$ with the $\mathcal{O}_{X,x}$-module I_x (viewed as a sheaf on a point). Define:

$$\mathscr{I} = \prod_{x \in X} (j_x)_*(I_x).$$

We claim that $\mathscr{I}$ is an injective $\mathcal{O}_X$-module and that $\mathscr{F}$ embeds into it.

The embedding. For each $x \in X$, the stalk of $(j_x)_*(I_x)$ at x is I_x, and the embedding $\mathscr{F}_x \hookrightarrow I_x$ extends (by the adjunction below) to a sheaf map $\mathscr{F} \to (j_x)_*(I_x)$. Taking the product over all x yields a morphism $\mathscr{F} \to \mathscr{I}$ that is injective on every stalk, hence injective as a morphism of sheaves (by theorem 1.2.27).

Injectivity of $\mathscr{I}$. For any $\mathcal{O}_X$-module $\mathscr{G}$, we have:

$$\operatorname{Hom}_{\mathcal{O}_X}(\mathscr{G}, \mathscr{I}) \cong \prod_{x \in X} \operatorname{Hom}_{\mathcal{O}_X}\big(\mathscr{G}, (j_x)_*(I_x)\big) \cong \prod_{x \in X} \operatorname{Hom}_{\mathcal{O}_{X,x}}(\mathscr{G}_x, I_x).$$

The first isomorphism is the universal property of products. The second uses the fact that for the inclusion $j_x : \{x\} \hookrightarrow X$, the stalk functor $\mathscr{G} \mapsto \mathscr{G}_x$ is left adjoint to $(j_x)_*$[a].

Now, the functor $\operatorname{Hom}_{\mathcal{O}_X}(-, \mathscr{I})$ is the product of functors $\operatorname{Hom}_{\mathcal{O}_{X,x}}((-)_x, I_x)$. Each factor is the composition of the stalk functor $\mathscr{G} \mapsto \mathscr{G}_x$, which is exact (by proposition 1.2.22), with the functor $\operatorname{Hom}_{\mathcal{O}_{X,x}}(-, I_x)$, which is exact because I_x is injective. A product of exact functors is exact, so $\operatorname{Hom}_{\mathcal{O}_X}(-, \mathscr{I})$ is exact, making $\mathscr{I}$ injective.

[a] More precisely, a morphism $\mathscr{G} \to (j_x)_*(I_x)$ is determined by its value on stalks at x, since $(j_x)_*(I_x)$ is supported at $\overline{\{x\}}$ and its stalk at x is I_x. The formal adjunction is $\operatorname{Hom}_{\mathcal{O}_X}(\mathscr{G}, (j_x)_*M) \cong \operatorname{Hom}_{\mathcal{O}_{X,x}}(\mathscr{G}_x, M)$ for any $\mathcal{O}_{X,x}$-module M.

Corollary 6.1.2: Sheaves of Abelian Groups Has Enough Injectives

Let X be a topological space. Then the category of sheaves of abelian groups on X has enough injectives.

***Proof*:**
View X as the ringed space $(X, \underline{\mathbb{Z}})$, where $\underline{\mathbb{Z}}$ is the constant sheaf. Sheaves of abelian groups on X are precisely $\underline{\mathbb{Z}}$-modules, so the result follows from proposition 6.1.1.

Definition 6.1.3: Global Section Functor and Sheaf Cohomology

Let $(X, \mathcal{O}_X)$ be a ringed space. The *global section functor*

$$\Gamma(X, -) : \mathcal{O}_X\textbf{-Mod} \longrightarrow \textbf{Ab}$$

is left exact (by proposition 1.2.16) but not right exact in general (see Example 1.2.7). Since $\mathcal{O}_X$-**Mod** has enough injectives, we may form the right derived functors. The i-th right derived functor

$$H^i(X, -) = R^i\Gamma(X, -)$$

is called the i-th *sheaf cohomology functor*. For a sheaf $\mathscr{F}$, the abelian group $H^i(X, \mathscr{F})$ is the i-th *cohomology group* of $\mathscr{F}$. By general properties of derived functors, $H^0(X, \mathscr{F}) = \Gamma(X, \mathscr{F})$ and a short exact sequence $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ of sheaves induces a long exact sequence:

$$0 \to H^0(X, \mathscr{F}') \to H^0(X, \mathscr{F}) \to H^0(X, \mathscr{F}'') \xrightarrow{\delta} H^1(X, \mathscr{F}') \to H^1(X, \mathscr{F}) \to \cdots$$

To compute these cohomology groups, we need resolutions. Recall that it suffices to resolve by *acyclic* objects — those $\mathscr{G}$ with $H^i(X, \mathscr{G}) = 0$ for $i > 0$ — rather than by injective objects (see [25]). We shall show that the following class of sheaves is acyclic:

Definition 6.1.4: Flasque Sheaf

Let X be a topological space. A sheaf $\mathscr{F}$ on X is called *flasque* (or *flabby*) if for every inclusion of open sets $U \subseteq V$, the restriction map $\mathrm{res}_{V,U} : \mathscr{F}(V) \to \mathscr{F}(U)$ is surjective.

Proposition 6.1.5: Injective Sheaf Modules Are Flasque

Let $(X, \mathcal{O}_X)$ be a ringed space. Then any injective $\mathcal{O}_X$-module is flasque.

***Proof*:**
Let $\mathscr{I}$ be an injective $\mathcal{O}_X$-module, and let $U \subseteq V$ be open subsets of X. For any open set $W \subseteq X$, let $j_W : W \hookrightarrow X$ denote the inclusion and define $\mathcal{O}_W = (j_W)_!(\mathcal{O}_X|_W)$, the extension by zero of $\mathcal{O}_X|_W$ to all of X[a]. The inclusion $U \subseteq V$ induces a natural monomorphism of $\mathcal{O}_X$-modules $0 \to \mathcal{O}_U \to \mathcal{O}_V$. Since $\mathscr{I}$ is injective, the functor $\mathrm{Hom}_{\mathcal{O}_X}(-, \mathscr{I})$ is exact, giving a surjection:

$$\mathrm{Hom}_{\mathcal{O}_X}(\mathcal{O}_V, \mathscr{I}) \longrightarrow \mathrm{Hom}_{\mathcal{O}_X}(\mathcal{O}_U, \mathscr{I}) \longrightarrow 0.$$

But $\mathrm{Hom}_{\mathcal{O}_X}(\mathcal{O}_W, \mathscr{I}) \cong \mathscr{I}(W)$ for any open W, since a morphism $\mathcal{O}_W \to \mathscr{I}$ is determined by the image of the identity section $1 \in \mathcal{O}_X(W)$. Hence the restriction $\mathscr{I}(V) \to \mathscr{I}(U)$ is surjective, so $\mathscr{I}$ is flasque.

[a] Recall from definition 1.3.11 that $(j_W)_!$ extends a sheaf by zero outside W. In particular, $(j_W)_!(\mathcal{O}_X|_W)(V') = \{s \in \mathcal{O}_X(V' \cap W) \,|\, \mathrm{supp}(s) \text{ is closed in } V'\}$ for open $V' \subseteq X$.

Before proving that flasque sheaves are acyclic, we need one key property: the global section functor is *exact* on short exact sequences of flasque sheaves. Let us record this precisely.

Lemma 6.1.6: Exactness of Global Sections on Flasque Sequences

Let $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ be a short exact sequence of sheaves on a topological space X. If $\mathscr{F}'$ is flasque, then the sequence

$$0 \longrightarrow \Gamma(X, \mathscr{F}') \longrightarrow \Gamma(X, \mathscr{F}) \longrightarrow \Gamma(X, \mathscr{F}'') \longrightarrow 0$$

is exact. Furthermore, if both $\mathscr{F}'$ and $\mathscr{F}$ are flasque, then $\mathscr{F}''$ is also flasque.

***Proof*:**
Left exactness of $\Gamma(X, -)$ gives exactness at $\Gamma(X, \mathscr{F}')$ and $\Gamma(X, \mathscr{F})$. We must show surjectivity on the right. Let $s'' \in \Gamma(X, \mathscr{F}'')$. Consider the collection of pairs (U, s) where $U \subseteq X$ is open and $s \in \mathscr{F}(U)$ maps to $s''|_U$ under the surjection $\mathscr{F} \to \mathscr{F}''$. This collection is non-empty (by surjectivity on stalks, we can find such pairs locally) and is partially ordered by extension. By Zorn's lemma, there is a maximal such pair (U_0, s_0).

We claim $U_0 = X$. Suppose not; pick $x \in X \setminus U_0$. By surjectivity on stalks, there is an open $V \ni x$ and $t \in \mathscr{F}(V)$ mapping to $s''|_V$. On $U_0 \cap V$, the difference $s_0|_{U_0 \cap V} - t|_{U_0 \cap V}$ maps to zero in $\mathscr{F}''(U_0 \cap V)$, so it lies in $\mathscr{F}'(U_0 \cap V)$. Since $\mathscr{F}'$ is flasque, this section extends to some $\sigma \in \mathscr{F}'(V)$. Replacing t by $t + \sigma$, we may assume s_0 and t agree on $U_0 \cap V$, and they glue to a section on $U_0 \cup V$, contradicting maximality. Hence $U_0 = X$.

For the second claim, suppose $\mathscr{F}'$ and $\mathscr{F}$ are both flasque. Let $U \subseteq V$ be open sets and $s'' \in \mathscr{F}''(V)$. By the surjectivity just proved (applied to V), there exists $s \in \mathscr{F}(V)$ mapping to s''. Since $\mathscr{F}$ is flasque, the restriction $\mathscr{F}(V) \to \mathscr{F}(U)$ is surjective, so the image of $s|_U$ in $\mathscr{F}''(U)$ equals $s''|_U$. But we already have the section s defined on all of V, and any element of $\mathscr{F}''(U)$ can be lifted to $\mathscr{F}(V)$ and then restricted. More precisely, given any $t'' \in \mathscr{F}''(U)$, apply the surjectivity result to U to get a lift $t \in \mathscr{F}(U)$, then use the flasqueness of $\mathscr{F}$ to extend t to all of V, giving a preimage in $\mathscr{F}''(V)$. Hence $\mathscr{F}''$ is flasque.

Corollary 6.1.7: Trivial Cohomology For Flasque Sheaves

Let $\mathscr{F}$ be a flasque sheaf on a topological space X. Then

$$H^i(X, \mathscr{F}) = 0 \qquad \text{for all } i > 0.$$

***Proof*:**
Since $\mathcal{O}_X$-**Mod** has enough injectives, we can embed $\mathscr{F}$ into an injective sheaf $\mathscr{I}$ and form the short exact sequence:

$$0 \longrightarrow \mathscr{F} \longrightarrow \mathscr{I} \longrightarrow \mathscr{G} \longrightarrow 0$$

where $\mathscr{G} = \mathscr{I}/\mathscr{F}$. By proposition 6.1.5, the sheaf $\mathscr{I}$ is flasque. Since both $\mathscr{F}$ and $\mathscr{I}$ are flasque, the quotient $\mathscr{G}$ is also flasque by the lemma above.

Since $\mathscr{F}$ is flasque, the global section functor preserves the exactness of this sequence (again by the lemma above):

$$0 \longrightarrow \Gamma(X, \mathscr{F}) \longrightarrow \Gamma(X, \mathscr{I}) \longrightarrow \Gamma(X, \mathscr{G}) \longrightarrow 0.$$

Comparing with the long exact sequence in cohomology and using $H^0 = \Gamma$, we see that the connecting homomorphism $\delta : H^0(X, \mathscr{G}) \to H^1(X, \mathscr{F})$ is zero (since the map $\Gamma(X, \mathscr{I}) \to \Gamma(X, \mathscr{G})$

is already surjective). Hence $H^1(X, \mathscr{F}) = 0$.

For $i \geq 2$, the long exact sequence gives isomorphisms $H^i(X, \mathscr{F}) \cong H^{i-1}(X, \mathscr{G})$ because $\mathscr{I}$ is injective and therefore $H^j(X, \mathscr{I}) = 0$ for all $j > 0$. Since $\mathscr{G}$ is flasque, we may repeat the argument with $\mathscr{G}$ in place of $\mathscr{F}$, obtaining $H^{i-1}(X, \mathscr{G}) = 0$ by induction on i. Hence $H^i(X, \mathscr{F}) = 0$ for all $i > 0$.

Flasque sheaves are therefore acyclic for $\Gamma(X, -)$, and we may compute cohomology using flasque resolutions rather than injective ones. Let us see some examples:

Example 6.1.8: Flasque Sheaves

1. It was just shown that all injective $\mathcal{O}_X$-modules are flasque. The converse fails: flasque sheaves need not be injective.

2. *Constant sheaves on irreducible spaces.* Let X be an irreducible topological space and A an abelian group. Then the constant sheaf $\underline{A}$ is flasque. Indeed, for any non-empty open $U \subseteq V$, both U and V are connected (every open subset of an irreducible space is connected), so $\underline{A}(V) = A = \underline{A}(U)$ and the restriction map is the identity. This need not hold on reducible spaces: on $X = \mathbb{R}$, take $U = (0, 1) \cup (2, 3)$. The section $(1, 0) \in \underline{\mathbb{Z}}(U) = \mathbb{Z} \times \mathbb{Z}$ is not the restriction of any element of $\underline{\mathbb{Z}}(\mathbb{R}) = \mathbb{Z}$, so $\underline{\mathbb{Z}}$ is not flasque on $\mathbb{R}$. The key point is that irreducibility forces all opens to overlap, making extension trivial.

3. *The Godement resolution.* Let $\mathscr{F}$ be any sheaf of abelian groups on X. We can always construct a canonical flasque resolution called the *Godement resolution*. For each $x \in X$, let $\iota_x : \{x\} \hookrightarrow X$ denote the inclusion. Define:

$$C^0(\mathscr{F}) = \prod_{x \in X} (\iota_x)_*(\mathscr{F}_x),$$

   so that $\Gamma(U, C^0(\mathscr{F})) = \prod_{x \in U} \mathscr{F}_x$ for every open $U \subseteq X$. This sheaf is flasque because a section over U is simply a choice of element in each stalk $\mathscr{F}_x$ for $x \in U$, with no compatibility condition — so restriction just forgets the stalks outside U, which is always surjective.

   Note, however, that $C^0(\mathscr{F})$ need *not* be injective. For example, if $X \neq \emptyset$ and $\mathscr{F} = \underline{\mathbb{Z}}$, then $\Gamma(X, C^0(\mathscr{F})) = \prod_{x \in X} \mathbb{Z}$ is not a divisible group, so $C^0(\mathscr{F})$ is not injective in the category of sheaves of abelian groups (where every group of sections of an injective sheaf is divisible).

   The natural map $\epsilon : \mathscr{F} \to C^0(\mathscr{F})$, sending a section $s \in \mathscr{F}(U)$ to the tuple of its germs $(s_x)_{x \in U}$, is injective by the locality axiom for sheaves. Let $\mathscr{Q}^0 = C^0(\mathscr{F})/\mathrm{im}(\epsilon)$. Applying the same construction to $\mathscr{Q}^0$ yields $C^1(\mathscr{F}) = C^0(\mathscr{Q}^0)$, and iterating:

$$0 \longrightarrow \mathscr{F} \xrightarrow{\epsilon} C^0(\mathscr{F}) \longrightarrow C^1(\mathscr{F}) \longrightarrow C^2(\mathscr{F}) \longrightarrow \cdots$$

   This is a flasque resolution of $\mathscr{F}$, and one can compute $H^i(X, \mathscr{F})$ as the cohomology of the complex $\Gamma(X, C^\bullet(\mathscr{F}))$. The Godement resolution is completely canonical (no choices involved), but the resulting sheaves are typically enormous and *not* quasi-coherent.

4. *The divisor sheaf.* Let X be an integral, separated, Noetherian, locally factorial scheme with function field K. The sheaf of Weil divisors is:

$$\mathscr{D}iv \cong \bigoplus_{x \in X^{(1)}} (\iota_x)_*(\underline{\mathbb{Z}})$$

where $X^{(1)}$ denotes the set of codimension-1 points of X. The exact sequence of sheaves:

$$1 \longrightarrow \mathcal{O}_X^* \longrightarrow \mathcal{K}^* \longrightarrow \mathscr{D}iv \longrightarrow 0$$

relates the invertible regular functions, the non-zero rational functions (here $\mathcal{K}^*$ is the constant sheaf associated to K^*, hence flasque by item (2) above), and the divisor sheaf. Since $\mathscr{D}iv$ is a direct sum of pushforwards of flasque sheaves, it is flasque. The long exact sequence in cohomology, together with the acyclicity of $\mathcal{K}^*$ and $\mathscr{D}iv$, gives:

$$\Gamma(X, \mathcal{K}^*) \longrightarrow \Gamma(X, \mathscr{D}iv) \longrightarrow H^1(X, \mathcal{O}_X^*) \longrightarrow 0$$

and hence an isomorphism:

$$H^1(X, \mathcal{O}_X^*) \;\cong\; \frac{\mathrm{WDiv}\,(X)}{\mathrm{PDiv}(X)} \;=\; \mathrm{Cl}\,X,$$

recovering the divisor class group from section 5.4 as cohomological data. This illustrates a recurring theme: the H^1 of a sheaf of units is a "class group" measuring the failure of local-to-global extension for invertible objects.

Acyclic does not imply flasque. Though not central to our development, it is worth recording the main class of acyclic-but-not-flasque sheaves, as it explains why sheaf cohomology in the smooth category is far simpler than in the algebraic category:

Example 6.1.9: Acyclic, But Not Injective Or Flasque

Let M be a smooth manifold of positive dimension and consider the sheaf C^∞_M of smooth real-valued functions. This sheaf is *not* flasque: for instance, the function $1/x$ is a smooth section of $C^\infty_{\mathbb{R}}$ over the open set $(0,1)$, but it cannot be extended to any smooth function on $(-1,1)$. Nor is C^∞_M injective in general.

However, C^∞_M is acyclic. The key reason is the existence of *partitions of unity* subordinate to any open cover (see theorem 0.5.47): given a C^∞_M-linear surjection $\mathscr{F} \to \mathscr{G} \to 0$ of sheaves of C^∞_M-modules and a global section $s \in \Gamma(M, \mathscr{G})$, we can lift s locally and then glue the local lifts using a partition of unity. More precisely, any sheaf of C^∞_M-modules admits partitions of unity, and such sheaves (called *fine sheaves*) are acyclic for Γ.

This is exactly the mechanism that makes de Rham cohomology computable on manifolds. The sheaves Ω^p_M of smooth differential p-forms are fine (being C^∞_M-modules), hence acyclic, and the de Rham complex $0 \to \underline{\mathbb{R}} \to \Omega^0 \to \Omega^1 \to \cdots$ is an acyclic resolution of the constant sheaf $\underline{\mathbb{R}}$. Since acyclic resolutions compute derived functors (see [25, Hypercohomology Recovers the Ordinary Derived Functors]), this gives the isomorphism $H^i_{\mathrm{dR}}(M) \cong H^i(M, \underline{\mathbb{R}})$, and theorem 0.5.23 identifies both with singular cohomology $H^i(M; \mathbb{R})$.

In algebraic geometry, no such luxury exists: the structure sheaf $\mathcal{O}_X$ of an irreducible scheme admits no partition of unity subordinate to a cover by proper open subsets (the Zariski topology is too coarse, and algebraic functions are too rigid). This is why we must work harder — using flasque resolutions, Čech cohomology, or injective resolutions — to compute sheaf cohomology in the algebraic setting.

Let us link this to the module structure on cohomology. If $(X, \mathcal{O}_X)$ is a ringed space, then $\Gamma(X, \mathcal{O}_X)$ is a ring, and for any $\mathcal{O}_X$-module $\mathscr{F}$, the global sections $\Gamma(X, \mathscr{F})$ carry a natural $\Gamma(X, \mathcal{O}_X)$-module

structure. This structure propagates to cohomology:

Corollary 6.1.10: Section and Hom Functor

Let $(X, \mathcal{O}_X)$ be a ringed space and let $R = \Gamma(X, \mathcal{O}_X)$. Then for any $\mathcal{O}_X$-module $\mathscr{F}$, the cohomology groups $H^i(X, \mathscr{F})$ carry a natural R-module structure. In particular:

1. If X is a scheme over a ring A (i.e., equipped with a structure morphism $X \to \operatorname{Spec} A$), then each $H^i(X, \mathscr{F})$ is naturally an A-module.
2. If X is a scheme over a field k, then each $H^i(X, \mathscr{F})$ is a k-vector space.

Moreover, for any $\mathcal{O}_X$-module $\mathscr{F}$, the group $H^i(X, \mathscr{F})$ is naturally isomorphic to the i-th right derived functor of $\Gamma(X, -)\colon \mathbf{Sh}_{\mathbf{Ab}}(X) \to \mathbf{Ab}$ evaluated on the underlying sheaf of abelian groups of $\mathscr{F}$, and the connecting homomorphisms in the long exact sequence are R-module maps.

***Proof*:**
The global section functor $\Gamma(X, -)$ lands in R-Mod (not just **Ab**), and the category $\mathcal{O}_X$-**Mod** has enough injectives. The right derived functors of $\Gamma(X, -)$ computed in $\mathbf{Sh}_{\mathbf{Ab}}(X)$ and in $\mathcal{O}_X$-**Mod** coincide, since an injective $\mathcal{O}_X$-module is flasque (proposition 6.1.5), hence $\Gamma(X, -)$-acyclic (corollary 6.1.7). Hence the cohomology groups inherit the R-module structure. For a scheme over A, the structure morphism $X \to \operatorname{Spec} A$ gives a ring homomorphism $A \to \Gamma(X, \mathcal{O}_X) = R$, making every R-module an A-module by restriction of scalars.

6.1.1 Computation: Čech Cohomology

The derived-functor definition of sheaf cohomology is clean and canonical, but it is difficult to use in practice because injective (or even flasque) resolutions are typically non-explicit. Čech cohomology provides a more "hands-on" approach: it computes the obstruction to extending sections from an open cover $\mathcal{U}$ of a topological space X to larger open sets, using only the sections of the sheaf over finite intersections of the cover. When X is a Noetherian separated scheme, $\mathscr{F}$ is quasi-coherent, and the cover is affine, the Čech groups coincide with the derived-functor groups. This will be our main computational tool.

The following construction will be familiar to those who have seen group cohomology or simplicial cohomology in algebraic topology (see [78, chapter 4]).

Let X be a topological space, $\mathcal{U} = (U_i)_{i \in I}$ an open covering of X, and fix a well-ordering on the index set I[3]. For any finite set of indices $i_0 < \cdots < i_p$ in I, write:

$$U_{i_0,\ldots,i_p} = U_{i_0} \cap \cdots \cap U_{i_p}.$$

Let $\mathscr{F}$ be a sheaf of abelian groups on X. Define the *Čech cochain groups*:

$$C^p(\mathcal{U}, \mathscr{F}) = \prod_{i_0 < \cdots < i_p} \mathscr{F}(U_{i_0,\ldots,i_p}).$$

[3]Alternatively, one can work with the "alternating" convention: allow all tuples of indices, require that the cochain α is alternating (i.e. $\alpha_{\sigma(i_0),\ldots,\sigma(i_p)} = \operatorname{sgn}(\sigma) \cdot \alpha_{i_0,\ldots,i_p}$) and vanishes when any two indices coincide. The two approaches yield isomorphic cohomology groups.

An element $\alpha \in C^p(\mathcal{U}, \mathscr{F})$ is a collection of sections $\alpha_{i_0,\dots,i_p} \in \mathscr{F}(U_{i_0,\dots,i_p})$, one for each ordered $(p+1)$-tuple. For an arbitrary tuple of indices, set $\alpha_{i_0,\dots,i_p} = 0$ if two indices coincide, and otherwise $\alpha_{i_0,\dots,i_p} = \operatorname{sgn}(\sigma)\,\alpha_{i_{\sigma(0)},\dots,i_{\sigma(p)}}$, where σ is the permutation with $i_{\sigma(0)} < \cdots < i_{\sigma(p)}$. The *coboundary map* $d : C^p(\mathcal{U}, \mathscr{F}) \to C^{p+1}(\mathcal{U}, \mathscr{F})$ is defined by:

$$(d\alpha)_{i_0,\dots,i_{p+1}} = \sum_{k=0}^{p+1} (-1)^k \, \alpha_{i_0,\dots,\widehat{i_k},\dots,i_{p+1}}\big|_{U_{i_0,\dots,i_{p+1}}}$$

where $\widehat{i_k}$ means the index i_k is omitted. A standard computation shows $d^2 = 0$, so $(C^\bullet(\mathcal{U}, \mathscr{F}), d)$ is a cochain complex.

Definition 6.1.11: Čech Cohomology

Let X be a topological space, $\mathcal{U}$ an open covering of X, and $\mathscr{F}$ a sheaf of abelian groups on X. The *Čech cohomology groups* of $\mathscr{F}$ with respect to $\mathcal{U}$ are:

$$\check{H}^p(\mathcal{U}, \mathscr{F}) = h^p\big(C^\bullet(\mathcal{U}, \mathscr{F})\big) = \frac{\ker\big(d : C^p \to C^{p+1}\big)}{\operatorname{im}\big(d : C^{p-1} \to C^p\big)}.$$

An important warning: $\check{H}^p(\mathcal{U}, -)$ is *not* in general a δ-functor. That is, a short exact sequence of sheaves need not induce a long exact sequence in Čech cohomology:

Example 6.1.12: Čech Cohomology is Not a δ-Functor

Suppose $\mathcal{U}$ consists of the single open set X itself. Then every intersection $U_{i_0,\dots,i_p}$ equals X, and there is only one index, so $C^p(\mathcal{U}, \mathscr{F}) = 0$ for $p > 0$ while $C^0(\mathcal{U}, \mathscr{F}) = \mathscr{F}(X) = \Gamma(X, \mathscr{F})$. Hence $\check{H}^0(\mathcal{U}, \mathscr{F}) = \Gamma(X, \mathscr{F})$ and $\check{H}^p(\mathcal{U}, \mathscr{F}) = 0$ for all $p > 0$.

Now let $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ be a short exact sequence of sheaves. If $\check{H}^*(\mathcal{U}, -)$ were a δ-functor, it would produce a long exact sequence, which in this case would read:

$$0 \longrightarrow \Gamma(X, \mathscr{F}') \longrightarrow \Gamma(X, \mathscr{F}) \longrightarrow \Gamma(X, \mathscr{F}'') \longrightarrow 0.$$

But $\Gamma(X, -)$ is not right exact in general — this is the whole point of sheaf cohomology! — so this need not be exact on the right. Hence, whenever some surjection of sheaves on X is not surjective on global sections, $\check{H}^*$ cannot be a δ-functor for this covering.

This failure is not a defect of the theory but a feature of the choice of cover. As we shall see, choosing an appropriate cover (an affine cover for quasi-coherent sheaves on a Noetherian separated scheme) restores the connection to derived-functor cohomology. Before proving this, let us see Čech cohomology in action:

Example 6.1.13: Čech Cohomology

1. *Differentials on $\mathbb{P}^1_k$.* Let $X = \mathbb{P}^1_k$, let $\mathscr{F} = \Omega_{X/k}$ be the sheaf of differentials, and let $\mathcal{U} = \{U, V\}$ be the standard affine cover with $U = D_+(x_0) \cong \operatorname{Spec} k[t]$ and $V = D_+(x_1) \cong \operatorname{Spec} k[u]$, where $t = x_1/x_0$ and $u = x_0/x_1 = 1/t$. The Čech complex has two terms:

$$C^0 = \Gamma(U, \Omega) \times \Gamma(V, \Omega), \qquad C^1 = \Gamma(U \cap V, \Omega).$$

The sections of the sheaf of differentials are:

$$\Gamma(U,\Omega) = k[t]\,dt, \qquad \Gamma(V,\Omega) = k[u]\,du, \qquad \Gamma(U\cap V,\Omega) = k[t,t^{-1}]\,dt.$$

On the overlap, the coordinate change gives $u = 1/t$, so $du = -t^{-2}\,dt$. The coboundary map $d : C^0 \to C^1$ sends $(f(t)\,dt,\ g(u)\,du)$ to:

$$g(u)\,du\big|_{U\cap V} - f(t)\,dt\big|_{U\cap V} \;=\; \big(-t^{-2}g(1/t) - f(t)\big)\,dt.$$

Computing $\check{H}^0$: A cocycle $(f(t)\,dt,\, g(u)\,du) \in \ker d$ satisfies $f(t) = -t^{-2}g(1/t)$. The left side is a polynomial in t, while the right side is a polynomial in t^{-1} with no constant term (the t^{-2} factor shifts degrees). These can only agree if both are zero. Hence $\check{H}^0(\mathcal{U},\Omega) = 0$, confirming that $\mathbb{P}^1_k$ has no nonzero global differential forms.

Computing $\check{H}^1$: The image of d consists of all Laurent polynomials of the form $\big(-t^{-2}g(1/t) - f(t)\big)\,dt$ where $f \in k[t]$ and $g \in k[u]$. Writing a general element of $k[t,t^{-1}]\,dt$ as $\sum_{n\in\mathbb{Z}} a_n t^n\,dt$, the image of d is spanned by all $t^n\,dt$ with $n \neq -1$: the terms $t^n\,dt$ for $n \geq 0$ come from $f(t)$, and the terms $t^n\,dt$ for $n \leq -2$ come from $g(u)$. The single "missing" basis element is $t^{-1}\,dt$. Therefore:

$$\check{H}^1(\mathcal{U},\Omega) \cong k,$$

generated by the class of $t^{-1}\,dt$. It is the vanishing of $\check{H}^0$ that reflects the genus of $\mathbb{P}^1$ being zero (for a smooth projective curve of genus g, one has $\dim_k H^0(X,\Omega) = g$). The one-dimensional $H^1(X,\Omega)$ is the domain of the trace map $H^1(X,\Omega) \to k$, and we will revisit it when we discuss Serre duality.

2. *The circle.* Let $X = S^1$ with the Euclidean topology, and consider the constant sheaf $\underline{\mathbb{Z}}$. Take the cover $\mathcal{U} = \{U, V\}$ where U and V are two overlapping open arcs whose intersection $U \cap V = W_1 \coprod W_2$ consists of two disjoint small open intervals. Since U, V, W_1, and W_2 are all connected, the constant sheaf gives:

$$C^0 = \underline{\mathbb{Z}}(U) \times \underline{\mathbb{Z}}(V) = \mathbb{Z}\times\mathbb{Z}, \qquad C^1 = \underline{\mathbb{Z}}(U\cap V) = \underline{\mathbb{Z}}(W_1)\times\underline{\mathbb{Z}}(W_2) = \mathbb{Z}\times\mathbb{Z}.$$

The coboundary $d : C^0 \to C^1$ sends (a,b) to $(b-a,\ b-a)$, since on each connected component of $U\cap V$ the sections restrict to constants. Thus:

$$\ker d = \{(a,b) : b-a = 0\} \cong \mathbb{Z} \qquad \text{and} \qquad \mathrm{im}d = \{(c,c) : c \in \mathbb{Z}\} \cong \mathbb{Z}.$$

The cokernel $(\mathbb{Z}\times\mathbb{Z})/\{(c,c)\} \cong \mathbb{Z}$ (via $(m,n) \mapsto m-n$). Hence:

$$\check{H}^0(\mathcal{U},\underline{\mathbb{Z}}) = \mathbb{Z}, \qquad \check{H}^1(\mathcal{U},\underline{\mathbb{Z}}) = \mathbb{Z},$$

which agrees with the singular cohomology $H^*(S^1;\mathbb{Z})$. The class in $\check{H}^1$ is generated by the cocycle $(1,0) \in \mathbb{Z}\times\mathbb{Z}$: the two components of $U\cap V$ see different "transition data," reflecting the non-trivial loop in S^1.

Let us now build towards the theorem that Čech cohomology computes derived-functor cohomology under appropriate hypotheses. The strategy is to show that the Čech complex arises from a resolution of the sheaf, and that this resolution can be compared to any injective resolution. The key condition is that each open set in the cover, and each finite intersection of them, must be "cohomologically trivial" for the sheaf in question, so that the main obstruction comes from their combinations.

Lemma 6.1.14: 0th Čech Cohomology

Let X be a topological space, $\mathcal{U}$ an open covering, and $\mathscr{F}$ a sheaf of abelian groups on X. Then:

$$\check{H}^0(\mathcal{U}, \mathscr{F}) = \Gamma(X, \mathscr{F}).$$

***Proof*:**

By definition, $\check{H}^0(\mathcal{U}, \mathscr{F}) = \ker(d : C^0(\mathcal{U}, \mathscr{F}) \to C^1(\mathcal{U}, \mathscr{F}))$. An element $\alpha \in C^0$ is a collection $\{\alpha_i \in \mathscr{F}(U_i)\}_{i \in I}$. The coboundary condition $d\alpha = 0$ says that for each $i < j$,

$$(d\alpha)_{ij} = \alpha_j\big|_{U_i \cap U_j} - \alpha_i\big|_{U_i \cap U_j} = 0,$$

i.e. the sections α_i and α_j agree on the overlap $U_i \cap U_j$. Since $\mathscr{F}$ is a sheaf, the gluability axiom gives a unique global section $s \in \Gamma(X, \mathscr{F})$ with $s|_{U_i} = \alpha_i$ for all i. Hence $\ker d = \Gamma(X, \mathscr{F})$.

We next address the lack of a δ-functor by "sheafifying" the Čech construction. Let $X, \mathcal{U}$, and $\mathscr{F}$ be as above. For each $p \geq 0$, define the *sheaf of Čech p-cochains* by:

$$\mathscr{C}^p(\mathcal{U}, \mathscr{F}) = \prod_{i_0 < \cdots < i_p} (f_{i_0,\ldots,i_p})_*\big(\mathscr{F}\big|_{U_{i_0,\ldots,i_p}}\big)$$

where $f_{i_0,\ldots,i_p} : U_{i_0,\ldots,i_p} \hookrightarrow X$ is the inclusion and $(f_{i_0,\ldots,i_p})_*$ is the pushforward. The coboundary maps $d : \mathscr{C}^p \to \mathscr{C}^{p+1}$ are defined by the same alternating-sum formula as before. The key property of this construction is:

$$\Gamma\big(X,\, \mathscr{C}^p(\mathcal{U}, \mathscr{F})\big) = C^p(\mathcal{U}, \mathscr{F}),$$

so the Čech cochain groups are the global sections of the Čech sheaf complex.

Lemma 6.1.15: Čech Cohomology Resolution

Let X be a topological space, $\mathcal{U}$ an open covering, and $\mathscr{F}$ a sheaf of abelian groups. Then the augmented complex

$$0 \longrightarrow \mathscr{F} \xrightarrow{\epsilon} \mathscr{C}^0(\mathcal{U}, \mathscr{F}) \xrightarrow{d} \mathscr{C}^1(\mathcal{U}, \mathscr{F}) \xrightarrow{d} \mathscr{C}^2(\mathcal{U}, \mathscr{F}) \longrightarrow \cdots$$

is exact. That is, $\mathscr{C}^\bullet(\mathcal{U}, \mathscr{F})$ is a resolution of $\mathscr{F}$.

***Proof*:**

The augmentation $\epsilon : \mathscr{F} \to \mathscr{C}^0(\mathcal{U}, \mathscr{F})$ is defined by taking the product of the natural restriction maps $\mathscr{F} \to (f_i)_*(\mathscr{F}|_{U_i})$ for each $i \in I$. Exactness at $\mathscr{C}^0$ (i.e. $\ker d^0 = \mathrm{im}\epsilon$) follows from the sheaf axioms for $\mathscr{F}$, exactly as in lemma 6.1.14.

For the exactness of the complex at $\mathscr{C}^p$ for $p \geq 1$, it suffices to check on stalks. Let $x \in X$ and choose an index $j \in I$ such that $x \in U_j$. For each $p \geq 0$, we define a *contracting homotopy* $k : \mathscr{C}^p(\mathcal{U}, \mathscr{F})_x \to \mathscr{C}^{p-1}(\mathcal{U}, \mathscr{F})_x$ as follows. A germ $\alpha_x \in \mathscr{C}^p(\mathcal{U}, \mathscr{F})_x$ is represented by a section $\alpha \in \Gamma(W, \mathscr{C}^p(\mathcal{U}, \mathscr{F}))$ over some open neighborhood W of x that we may shrink until $W \subseteq U_j$.

For any p-tuple $i_0 < \cdots < i_{p-1}$, set:

$$(k\alpha)_{i_0,\ldots,i_{p-1}} = \alpha_{j,i_0,\ldots,i_{p-1}}\big|_W.$$

This is well-defined because $W \subseteq U_j$ implies $W \cap U_{i_0,\ldots,i_{p-1}} = W \cap U_{j,i_0,\ldots,i_{p-1}}$, so the section $\alpha_{j,i_0,\ldots,i_{p-1}}$ is defined on W. Passing to germs at x gives the map k on stalks. A direct computation shows:

$$(dk + kd)(\alpha) = \alpha \qquad \text{for all } \alpha \in \mathscr{C}^p(\mathcal{U}, \mathscr{F})_x,\ p \geq 1.$$

Hence k is a chain homotopy between the identity and the zero map on the stalk complex $\mathscr{C}^\bullet(\mathcal{U}, \mathscr{F})_x$ in degrees $p \geq 1$. It follows that the cohomology of this stalk complex vanishes in positive degrees, which is precisely the exactness of the resolution.

Lemma 6.1.16: Čech Cohomology and Flasque Sheaves

Let X be a topological space, $\mathcal{U}$ an open covering, and $\mathscr{F}$ a flasque sheaf of abelian groups on X. Then $\check{H}^p(\mathcal{U}, \mathscr{F}) = 0$ for all $p > 0$.

***Proof*:**
By lemma 6.1.15, the complex $0 \to \mathscr{F} \to \mathscr{C}^\bullet(\mathcal{U}, \mathscr{F})$ is a resolution. Since $\mathscr{F}$ is flasque, the sheaves $\mathscr{C}^p(\mathcal{U}, \mathscr{F})$ are flasque for each $p \geq 0$: indeed, $\mathscr{F}|_{U_{i_0,\ldots,i_p}}$ is flasque (restriction of a flasque sheaf is flasque), the pushforward $(f_{i_0,\ldots,i_p})_*$ preserves flasque sheaves, and a product of flasque sheaves is flasque. Thus $\mathscr{C}^\bullet(\mathcal{U}, \mathscr{F})$ is a flasque resolution of $\mathscr{F}$, and we may use it to compute derived-functor cohomology:

$$H^p(X, \mathscr{F}) = h^p\big(\Gamma(X, \mathscr{C}^\bullet(\mathcal{U}, \mathscr{F}))\big) = h^p\big(C^\bullet(\mathcal{U}, \mathscr{F})\big) = \check{H}^p(\mathcal{U}, \mathscr{F}).$$

But $\mathscr{F}$ is flasque, so $H^p(X, \mathscr{F}) = 0$ for $p > 0$ by corollary 6.1.7. Hence $\check{H}^p(\mathcal{U}, \mathscr{F}) = 0$ for $p > 0$.

Lemma 6.1.17: Čech Cohomology Comparison Map

Let X be a topological space and $\mathcal{U}$ an open covering. Then for each $p \geq 0$, there is a natural map, functorial in $\mathscr{F}$:

$$\check{H}^p(\mathcal{U}, \mathscr{F}) \longrightarrow H^p(X, \mathscr{F}).$$

***Proof*:**
Choose an injective resolution $0 \to \mathscr{F} \to \mathscr{I}^\bullet$. We also have the Čech resolution $0 \to \mathscr{F} \to \mathscr{C}^\bullet(\mathcal{U}, \mathscr{F})$ from lemma 6.1.15. By the comparison lemma for resolutions, [25, Projective Resolution As Initial Objects], applied in the opposite category of sheaves of abelian groups on X, where $\mathscr{I}^\bullet$ becomes a complex of projectives, there exists a morphism of complexes $\mathscr{C}^\bullet(\mathcal{U}, \mathscr{F}) \to \mathscr{I}^\bullet$ extending the identity on $\mathscr{F}$, unique up to homotopy. Applying $\Gamma(X, -)$ and taking cohomology gives the desired maps $\check{H}^p(\mathcal{U}, \mathscr{F}) \to H^p(X, \mathscr{F})$, and functoriality follows from the naturality of the comparison.

The hypothesis that makes the argument work is not affineness or quasi-coherence but a vanishing condition, and the general form is what later applications need: a covering computes derived-functor

cohomology as soon as the sheaf has no higher cohomology on the members of the covering and their intersections. Such a covering is called *acyclic* for the sheaf, and the result is Leray's theorem.

Theorem 6.1.18: Leray's Acyclic Covering Theorem

Let X be a topological space, $\mathcal{U} = \{U_i\}_{i\in I}$ an open covering, and $\mathscr{F}$ a sheaf of abelian groups on X. Suppose the covering is *acyclic* for $\mathscr{F}$: for every $q > 0$ and every finite tuple $i_0, \dots, i_p$,

$$H^q\big(U_{i_0,\dots,i_p}, \mathscr{F}\big) = 0$$

Then the comparison maps of lemma 6.1.17 are isomorphisms

$$\check{H}^p(\mathcal{U}, \mathscr{F}) \xrightarrow{\sim} H^p(X, \mathscr{F}) \qquad \text{for all } p \geq 0$$

***Proof*:**
For $p = 0$ both sides are $\Gamma(X, \mathscr{F})$ by lemma 6.1.14. The rest is induction on p, by dimension shifting.

Setup. The category of abelian sheaves on X has enough injectives, so embed $\mathscr{F}$ into an injective sheaf $\mathscr{G}$, which is flasque by proposition 6.1.5, and let $\mathscr{Q}$ be the quotient:

$$0 \longrightarrow \mathscr{F} \longrightarrow \mathscr{G} \longrightarrow \mathscr{Q} \longrightarrow 0$$

The hypothesis passes to $\mathscr{Q}$. Fix a tuple and write $U = U_{i_0,\dots,i_p}$. Since $\mathscr{G}$ is flasque, $H^q(U, \mathscr{G}) = 0$ for $q > 0$ by corollary 6.1.7, so the long exact sequence on U gives $H^q(U, \mathscr{Q}) \cong H^{q+1}(U, \mathscr{F})$ for $q \geq 1$, which vanishes by hypothesis. So $\mathcal{U}$ is acyclic for $\mathscr{Q}$ as well, and the induction has somewhere to go.

Exactness of the Čech complex. The same long exact sequence in degree zero, together with $H^1(U, \mathscr{F}) = 0$, gives exactness of

$$0 \longrightarrow \mathscr{F}(U) \longrightarrow \mathscr{G}(U) \longrightarrow \mathscr{Q}(U) \longrightarrow 0$$

for every intersection U. This is exactly where the hypothesis is spent: without it the right-hand map need not be surjective. Taking products over all tuples, the Čech cochain complexes form a short exact sequence

$$0 \longrightarrow C^\bullet(\mathcal{U}, \mathscr{F}) \longrightarrow C^\bullet(\mathcal{U}, \mathscr{G}) \longrightarrow C^\bullet(\mathcal{U}, \mathscr{Q}) \longrightarrow 0$$

An adapted resolution. Write $q\colon \mathscr{G} \to \mathscr{Q}$ for the quotient map and choose an injective resolution $\mathscr{Q} \to \mathscr{J}^\bullet$ with augmentation $\varepsilon\colon \mathscr{Q} \to \mathscr{J}^0$. Then

$$\mathscr{I}^\bullet : \quad \mathscr{G} \xrightarrow{\varepsilon q} \mathscr{J}^0 \longrightarrow \mathscr{J}^1 \longrightarrow \cdots,$$

with $\mathscr{G}$ in degree 0 and $\mathscr{I}^{n+1} = \mathscr{J}^n$, is an injective resolution of $\mathscr{F}$. For $p \geq 1$ the groups $H^{p+1}(X, \mathscr{F})$ and $H^p(X, \mathscr{Q})$ are therefore both the degree-p cohomology of $\Gamma(X, \mathscr{J}^\bullet)$. Since $\Gamma(X, -)$ is left exact, ε identifies $\Gamma(X, \mathscr{Q})$ with the 0-cocycles of $\Gamma(X, \mathscr{J}^\bullet)$, so

$$H^1(X, \mathscr{F}) = \Gamma(X, \mathscr{Q})/q\big(\Gamma(X, \mathscr{G})\big).$$

The chain maps of lemma 6.1.17 are unique up to homotopy, so the comparison maps for $\mathscr{F}$ and $\mathscr{Q}$ may be computed with $\mathscr{I}^\bullet$ and $\mathscr{J}^\bullet$.

Adapted chain maps. Let $\varphi_{\mathscr{Q}} \colon \mathscr{C}^\bullet(\mathcal{U}, \mathscr{Q}) \to \mathscr{J}^\bullet$ be a chain map extending the identity on $\mathscr{Q}$, and let i and π be the maps of Čech resolutions induced by $\mathscr{F} \to \mathscr{G}$ and by q. As $\mathscr{G}$ is injective, the augmentation $\mathscr{G} \to \mathscr{C}^0(\mathcal{U}, \mathscr{G})$ has a retraction ρ. The chain maps $\varphi_{\mathscr{Q}}\pi$ and $\varepsilon q \rho$ from $\mathscr{C}^\bullet(\mathcal{U}, \mathscr{G})$ to $\mathscr{J}^\bullet$, the second concentrated in degree 0, both extend q, so the comparison lemma used in lemma 6.1.17 gives maps $h^n \colon \mathscr{C}^n(\mathcal{U}, \mathscr{G}) \to \mathscr{J}^{n-1}$, with $h^0 = 0$, such that

$$\varphi_{\mathscr{Q}}\pi - \varepsilon q \rho = dh + hd.$$

Since $\pi i = 0$, this identity makes $\varphi^0_{\mathscr{F}} = \rho\, i$ and $\varphi^{n+1}_{\mathscr{F}} = (-1)^{n+1} h\, i$ a chain map $\varphi_{\mathscr{F}} \colon \mathscr{C}^\bullet(\mathcal{U}, \mathscr{F}) \to \mathscr{J}^\bullet$ extending the identity on $\mathscr{F}$.

Compatibility with the connecting maps. Write λ for the comparison maps and δ for the connecting maps of the Čech long exact sequence. Let $c \in C^p(\mathcal{U}, \mathscr{Q})$ be a cocycle, lift it to $b \in C^p(\mathcal{U}, \mathscr{G})$, and write $db = i(a)$, so that $\delta[c] = [a]$. Evaluating the identity above on b gives

$$\varphi_{\mathscr{F}}(a) = (-1)^{p+1} h(db) = (-1)^{p+1}\big(\varphi_{\mathscr{Q}}(c) - \varepsilon q \rho(b) - dh(b)\big).$$

For $p \geq 1$ the term $\varepsilon q \rho(b)$ vanishes, and for $p = 0$ it lies in the image of $\Gamma(X, \mathscr{G})$ while $h(b) = 0$. Hence $\lambda_{\mathscr{F}} \delta = (-1)^{p+1} \lambda_{\mathscr{Q}}$ on $\check{H}^p(\mathcal{U}, \mathscr{Q})$, with $H^p(X, \mathscr{Q})$ read as $H^{p+1}(X, \mathscr{F})$ for $p \geq 1$ and mapped onto $H^1(X, \mathscr{F})$ for $p = 0$.

Induction. Since $\mathscr{G}$ is flasque, $\check{H}^p(\mathcal{U}, \mathscr{G}) = 0$ for $p > 0$ by lemma 6.1.16. The Čech long exact sequence therefore makes δ a surjection $\Gamma(X, \mathscr{Q}) \to \check{H}^1(\mathcal{U}, \mathscr{F})$ with kernel $q(\Gamma(X, \mathscr{G}))$, and an isomorphism $\check{H}^p(\mathcal{U}, \mathscr{Q}) \to \check{H}^{p+1}(\mathcal{U}, \mathscr{F})$ for $p \geq 1$. In degree one, $\lambda_{\mathscr{F}}$ is thus, up to sign, the identity of $\Gamma(X, \mathscr{Q})/q(\Gamma(X, \mathscr{G}))$. For $p \geq 1$, the inductive hypothesis applied to $\mathscr{Q}$ (legitimate, since $\mathcal{U}$ is acyclic for $\mathscr{Q}$) makes $\lambda_{\mathscr{Q}}$ an isomorphism in degree p, and then $\lambda_{\mathscr{F}}$ is one in degree $p+1$. This completes the induction, as we sought to show.

The scheme-theoretic case now follows by producing the acyclicity: on a separated scheme the intersections of affine opens are again affine, and a quasi-coherent sheaf has no higher cohomology on an affine. Separatedness is precisely what makes the intersections affine, which is where that hypothesis enters.

Theorem 6.1.19: Čech Cohomology Equivalence

Let X be a Noetherian separated scheme, $\mathcal{U}$ an open affine covering of X, and $\mathscr{F}$ a quasi-coherent sheaf on X. Then for all $p \geq 0$, the natural maps

$$\check{H}^p(\mathcal{U}, \mathscr{F}) \longrightarrow H^p(X, \mathscr{F})$$

are isomorphisms.

***Proof*:**
By theorem 6.1.18 it suffices to check that $\mathcal{U}$ is acyclic for $\mathscr{F}$. Fix a tuple $i_0, \ldots, i_p$. The intersection $U_{i_0,\ldots,i_p}$ is a finite intersection of affine opens in a separated scheme, hence affine by proposition 3.5.8. A quasi-coherent sheaf on a Noetherian affine scheme has vanishing higher cohomology by theorem 6.2.9, so $H^q(U_{i_0,\ldots,i_p}, \mathscr{F}) = 0$ for every $q > 0$. That is the hypothesis of Leray's theorem, and the conclusion is the claim, as we sought to show.

6.1.2 Refinement and the Degree-One Comparison

Everything so far has been relative to a fixed covering, and theorem 6.1.18 gives agreement with derived-functor cohomology only when a covering acyclic for the sheaf can be found. For many sheaves no such covering exists. What survives without any acyclicity hypothesis is a comparison in degree one, and reaching it means first letting the covering vary.

Definition 6.1.20: Refinement of a Covering

Let $\mathcal{U} = (U_i)_{i\in I}$ and $\mathcal{V} = (V_j)_{j\in J}$ be open coverings of X. Then $\mathcal{V}$ *refines* $\mathcal{U}$ if there is a map $\varepsilon : J \to I$ with $V_j \subseteq U_{\varepsilon(j)}$ for every j; such an ε is a *refinement function*. Write $\mathcal{V} \preceq \mathcal{U}$.

A refinement function transports cochains, and the point of the next lemma is that the transported map on cohomology does not depend on which refinement function was chosen. Without that, the coverings could not be assembled into a single invariant.

Lemma 6.1.21: Refinement Induces a Well-Defined Map

Let $\mathscr{F}$ be a sheaf of abelian groups on X and let $\mathcal{V} \preceq \mathcal{U}$.

1. A refinement function ε induces a morphism of complexes $\varepsilon^\bullet : C^\bullet(\mathcal{U}, \mathscr{F}) \to C^\bullet(\mathcal{V}, \mathscr{F})$, by
$$(\varepsilon^p \alpha)_{j_0,\dots,j_p} = \alpha_{\varepsilon(j_0),\dots,\varepsilon(j_p)}\big|_{V_{j_0,\dots,j_p}}$$
2. Any two refinement functions ε, η induce chain homotopic morphisms. Hence the induced map $\check{H}^p(\mathcal{U}, \mathscr{F}) \to \check{H}^p(\mathcal{V}, \mathscr{F})$ is independent of the choice, and these maps are compatible with composition of refinements.

***Proof*:**
For (1), $\varepsilon^\bullet$ commutes with d because the coboundary formula, which under the sign convention preceding definition 6.1.11 holds at every index tuple, is a signed sum over omitted indices and ε acts on indices, so omitting the k-th index before or after applying ε gives the same term; the restrictions agree since $V_{j_0,\dots,j_p} \subseteq U_{\varepsilon(j_0),\dots,\varepsilon(j_p)}$.
(2). Define $h^p : C^p(\mathcal{U}, \mathscr{F}) \to C^{p-1}(\mathcal{V}, \mathscr{F})$ by

$$(h^p \alpha)_{j_0,\dots,j_{p-1}} = \sum_{k=0}^{p-1} (-1)^k \, \alpha_{\varepsilon(j_0),\dots,\varepsilon(j_k),\eta(j_k),\dots,\eta(j_{p-1})}\big|_{V_{j_0,\dots,j_{p-1}}}$$

which makes sense because $V_{j_0,\dots,j_{p-1}}$ is contained in every open set appearing on the right. The standard simplicial computation, identical to the one that shows two simplicial approximations are homotopic, gives $dh + hd = \eta^\bullet - \varepsilon^\bullet$. Hence the two morphisms agree on cohomology. Compatibility with composition is immediate, since a composite of refinement functions is one, completing the proof.

Definition 6.1.22: Čech Cohomology of a Space

Let $\mathscr{F}$ be a sheaf of abelian groups on X. The open coverings of X, ordered by refinement, form a filtered preorder: two coverings $\mathcal{U}$ and $\mathcal{U}'$ admit the common refinement $(U_i \cap U'_{i'})_{i,i'}$. The *Čech cohomology of* X is the filtered colimit

$$\check{H}^p(X, \mathscr{F}) = \varinjlim_{\mathcal{U}} \check{H}^p(\mathcal{U}, \mathscr{F})$$

over that preorder, the transition maps being those of lemma 6.1.21.

The comparison with derived-functor cohomology now holds in degrees zero and one for an arbitrary sheaf on an arbitrary space, with no acyclicity hypothesis anywhere. This is the form to use when Leray is unavailable.

Theorem 6.1.23: The Degree-One Comparison

Let X be a topological space and $\mathscr{F}$ a sheaf of abelian groups on X. Then

$$\check{H}^0(X, \mathscr{F}) \cong H^0(X, \mathscr{F}), \qquad \check{H}^1(X, \mathscr{F}) \cong H^1(X, \mathscr{F})$$

naturally in $\mathscr{F}$.

***Proof*:**
Degree zero is lemma 6.1.14 for each covering, and the transition maps are the identity on $\Gamma(X, \mathscr{F})$, so the colimit is $\Gamma(X, \mathscr{F}) = H^0(X, \mathscr{F})$.

Setup for degree one. The category of abelian sheaves on X has enough injectives; embed $\mathscr{F}$ into an injective $\mathscr{I}$, which is flasque by proposition 6.1.5, and let $\mathscr{Q} = \mathscr{I}/\mathscr{F}$. Since $H^1(X, \mathscr{I}) = 0$ by corollary 6.1.7, the long exact sequence gives

$$H^1(X, \mathscr{F}) \cong \operatorname{coker}\big(\Gamma(X, \mathscr{I}) \to \Gamma(X, \mathscr{Q})\big)$$

A class gives a cocycle. Let $\xi \in H^1(X, \mathscr{F})$ be represented by $t \in \Gamma(X, \mathscr{Q})$. Because $\mathscr{I} \to \mathscr{Q}$ is an epimorphism of sheaves, it is surjective on stalks, so there is an open covering $\mathcal{U} = (U_i)$ and sections $s_i \in \mathscr{I}(U_i)$ mapping to $t|_{U_i}$. On U_{ij} the difference $s_j - s_i$ maps to 0 in $\mathscr{Q}$, hence lies in $\mathscr{F}(U_{ij})$; set $c_{ij} = s_j - s_i$. Then c is a Čech 1-cocycle, since $c_{jk} - c_{ik} + c_{ij} = 0$ by inspection, and its class in $\check{H}^1(X, \mathscr{F})$ is independent of the choices: changing s_i by $a_i \in \mathscr{F}(U_i)$ changes c by the coboundary da, and passing to a refinement changes nothing by lemma 6.1.21.

The two constructions are mutually inverse. In the other direction, a cocycle $c \in \check{C}^1(\mathcal{U}, \mathscr{F})$ may be written $c_{ij} = s_j - s_i$ for some $s_i \in \mathscr{I}(U_i)$, because $\mathscr{I}$ is flasque and hence $\check{H}^1(\mathcal{U}, \mathscr{I}) = 0$ for every covering by theorem 6.1.18; the images of the s_i in $\mathscr{Q}(U_i)$ then agree on overlaps and glue to a global section t, whose class in the cokernel is the corresponding element of $H^1(X, \mathscr{F})$. Chasing the definitions shows the two assignments invert one another, and both are natural in $\mathscr{F}$ because every step is, completing the proof.

6.1.3 Soft Sheaves and the Paracompact Comparison

With no hypothesis on the space, the comparison map from Čech to derived-functor cohomology need not be an isomorphism in degree two, so theorem 6.1.23 does not extend to higher degrees. On a paracompact Hausdorff space Čech cohomology agrees with derived-functor cohomology in every degree (theorem 6.1.29). Such spaces also carry a class of sheaves that is to the topological setting what flasque sheaves are to the general one, and which was promised earlier when partitions of unity were contrasted with the rigidity of schemes.

Throughout this subsection X is a paracompact Hausdorff space. Recall that this means every open cover admits a locally finite open refinement; the consequence used below is that such a cover admits a shrinking, an open cover $\{V_i\}$ with $\overline{V_i} \subseteq U_i$.

Definition 6.1.24: Soft Sheaf

A sheaf $\mathscr{F}$ of abelian groups on a paracompact Hausdorff space X is *soft* if for every closed $K \subseteq X$ the restriction $\mathscr{F}(X) \to \mathscr{F}(K) := \varinjlim_{U \supseteq K} \mathscr{F}(U)$ is surjective: every section defined on a neighbourhood of a closed set extends to all of X.

A *fine* sheaf, in the sense of example 6.1.9, is one admitting partitions of unity subordinate to any locally finite cover. Fineness is the property one can check; softness is the property that makes cohomology vanish, and the first implies the second.

Proposition 6.1.25: Flasque and Fine Sheaves Are Soft

On a paracompact Hausdorff space, every flasque sheaf is soft, and every fine sheaf of modules over a sheaf of rings is soft.

***Proof*:**
A flasque sheaf restricts surjectively from X to any open set, hence a fortiori to the colimit over neighbourhoods of a closed set.

Let $\mathscr{F}$ be fine and let s be a section over an open $U \supseteq K$ with K closed. The two opens U and $X \setminus K$ cover X; take a locally finite refinement and a subordinate partition of unity, and let η be the sum of the members supported in U, so that η is an endomorphism of $\mathscr{F}$ with $\eta = \mathrm{id}$ on a neighbourhood of K and $\eta = 0$ off U. Then $\eta(s)$, extended by zero, is a global section restricting to s near K.

Lemma 6.1.26: Sections Near a Closed Set

Let $\mathscr{F}$ be a sheaf of abelian groups on X and $K \subseteq X$ closed. Suppose given germs $\sigma_z \in \mathscr{F}_z$ for $z \in K$ such that every $z \in K$ has an open neighbourhood O and a section $u \in \mathscr{F}(O)$ with $u_y = \sigma_y$ for all $y \in O \cap K$. Then some section of $\mathscr{F}$ over an open neighbourhood of K has germ σ_z at every $z \in K$, and its class in $\mathscr{F}(K)$ is unique.

***Proof*:**
Two sections over open neighbourhoods of K with the same germ at every point of K agree on the open set of points of their common domain where their germs agree, which contains K. This is the uniqueness.

For existence, choose for each $z \in K$ an open O_z and $u_z \in \mathscr{F}(O_z)$ as in the hypothesis. The O_z and $X \setminus K$ cover X. Take a locally finite open refinement $\{U_i\}_{i \in I}$ and a shrinking $\{V_i\}$ with $\overline{V_i} \subseteq U_i$. The family $\{\overline{V_i}\}$ is again locally finite. Let I' consist of the i for which U_i lies in some O_z, and let u_i be the restriction of that u_z, so that $(u_i)_y = \sigma_y$ for $y \in U_i \cap K$. For $i \notin I'$ we have $U_i \subseteq X \setminus K$. Let W be the set of $x \in X$ that lie in no $\overline{V_i}$ with $i \notin I'$ and satisfy $(u_i)_x = (u_j)_x$ whenever $i, j \in I'$ and $x \in \overline{V_i} \cap \overline{V_j}$.

Every $z \in K$ lies in W, because $\overline{V_i} \subseteq X \setminus K$ for $i \notin I'$, and for $i, j \in I'$ both germs at z equal σ_z. The set W is open. Given $x \in W$, local finiteness gives an open neighbourhood N of x that meets no $\overline{V_i}$ with $x \notin \overline{V_i}$. For each of the finitely many pairs $i, j \in I'$ with $x \in \overline{V_i} \cap \overline{V_j}$ the sections u_i and u_j agree on a neighbourhood of x in $U_i \cap U_j$, and we shrink N into each of these. A point $y \in N$ then lies only in sets $\overline{V_i}$ that contain x, so $y \in W$.

The sets $W \cap V_i$ with $i \in I'$ cover W, since each point of W lies in some V_i and not in any $\overline{V_i}$ with $i \notin I'$. On $W \cap V_i \cap V_j$ the sections u_i and u_j have the same germ at every point, so they agree. They glue to a section over W whose germ at each $z \in K$ is σ_z, as claimed.

Lemma 6.1.27: Sections and Quotients of Soft Sheaves

Let $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ be exact on X with $\mathscr{F}'$ soft. Then $\mathscr{F}(X) \to \mathscr{F}''(X)$ is surjective. If $\mathscr{F}$ is soft as well, then $\mathscr{F}''$ is soft.

***Proof*:**
Let $K \subseteq X$ be closed and t a section of $\mathscr{F}''$ over an open $U \supseteq K$. We first lift t over a neighbourhood of K. A shrinking of the cover $\{U, X \setminus K\}$ gives an open W with $K \subseteq W \subseteq \overline{W} \subseteq U$. The open subsets of U over which t lifts, together with $X \setminus \overline{W}$, cover X. Choose a locally finite open refinement $\{U_i\}_{i \in I}$ and a shrinking $\{V_i\}$ with $\overline{V_i} \subseteq U_i$. Let $I' \subseteq I$ consist of the i for which U_i lies in an open subset of U over which t lifts, and choose lifts $s_i \in \mathscr{F}(U_i)$ for $i \in I'$. Every V_i with $i \notin I'$ misses $\overline{W}$, so $\overline{W} \subseteq \bigcup_{i \in I'} V_i$. For $J \subseteq I'$ the set $\overline{V_J} := \bigcup_{i \in J} \overline{V_i}$ is closed, because the family $\{\overline{V_i}\}$ is locally finite. Consider the set of pairs (J, s) where $J \subseteq I'$ and $s \in \mathscr{F}(\overline{V_J})$ maps to the image of t in $\mathscr{F}''(\overline{V_J})$, with $(J, s) \leq (J', s')$ when $J \subseteq J'$ and s' restricts to s in $\mathscr{F}(\overline{V_J})$.

A chain $\{(J_\alpha, s_\alpha)\}$ has an upper bound. Put $J = \bigcup_\alpha J_\alpha$. Each $z \in \overline{V_J}$ has an open neighbourhood O_z meeting only finitely many $\overline{V_i}$, so $O_z \cap \overline{V_J} \subseteq \overline{V_{J_\alpha}}$ for some α. For $y \in \overline{V_J}$ let σ_y be the germ of s_α at y for any α with $y \in \overline{V_{J_\alpha}}$, which does not depend on α because the pairs form a chain. Near each z these germs are those of a single s_α, so lemma 6.1.26 gives $s \in \mathscr{F}(\overline{V_J})$ with germ σ_y at every $y \in \overline{V_J}$. By its uniqueness clause s restricts to each s_α and maps to the image of t, so (J, s) bounds the chain, and Zorn gives a maximal (J, s).

Suppose some $k \in I' \setminus J$. On an open neighbourhood of $\overline{V_J} \cap \overline{V_k}$ both s and s_k lift t, so $s - s_k$ is a section of $\mathscr{F}'$ there. As $\mathscr{F}'$ is soft, it extends to some $u \in \mathscr{F}'(X)$, and s and $s_k + u$ agree on an open neighbourhood M of $\overline{V_J} \cap \overline{V_k}$. Let σ_z be the germ of s at $z \in \overline{V_J}$ and of $s_k + u$ at $z \in \overline{V_k}$, which is consistent on the overlap. Near a point of $\overline{V_J} \cap \overline{V_k}$ these germs are those of s on M, and near any other point they are those of s off $\overline{V_k}$ or of $s_k + u$ off $\overline{V_J}$. By lemma 6.1.26 they come from an element of $\mathscr{F}(\overline{V_{J \cup \{k\}}})$, which by the uniqueness clause restricts to s and maps to the

image of t, contradicting maximality. So $J = I'$, and s lifts t over a neighbourhood of $\overline{V_{I'}} \supseteq K$.

For $K = U = X$ this is the first claim. For the second, suppose $\mathscr{F}$ is soft. The lift s then extends to a global section of $\mathscr{F}$, whose image in $\mathscr{F}''(X)$ agrees with t near K.

Theorem 6.1.28: Soft Sheaves Are Acyclic

Let $\mathscr{F}$ be a soft sheaf on a paracompact Hausdorff space X. Then $H^i(X, \mathscr{F}) = 0$ for all $i > 0$.

***Proof*:**
Embed $\mathscr{F}$ in a flasque sheaf, $0 \to \mathscr{F} \to \mathscr{G} \to \mathscr{Q} \to 0$, which is possible because there are enough injectives (corollary 6.1.2) and injectives are flasque (proposition 6.1.5). By proposition 6.1.25 the sheaf $\mathscr{G}$ is soft, so $\mathscr{Q}$ is soft by lemma 6.1.27.

The long exact sequence in cohomology, together with $H^i(X, \mathscr{G}) = 0$ for $i > 0$ (corollary 6.1.7), gives

$$\mathscr{G}(X) \to \mathscr{Q}(X) \to H^1(X, \mathscr{F}) \to 0, \qquad H^i(X, \mathscr{F}) \cong H^{i-1}(X, \mathscr{Q}) \quad \text{for } i \geq 2$$

The first map is surjective by lemma 6.1.27, so $H^1(X, \mathscr{F}) = 0$, and this holds for every soft sheaf. Applying it to the soft sheaf $\mathscr{Q}$ and inducting on i kills the higher groups as well.

Theorem 6.1.29: Čech Cohomology on a Paracompact Space

Let X be a paracompact Hausdorff space and $\mathscr{F}$ a sheaf of abelian groups on X. Then for every i

$$\check{H}^i(X, \mathscr{F}) \cong H^i(X, \mathscr{F})$$

naturally in $\mathscr{F}$.

***Proof*:**
Step 1: Čech cohomology vanishes on flasque sheaves. If $\mathscr{G}$ is flasque, then $\check{H}^q(\mathcal{U}, \mathscr{G}) = 0$ for every open cover $\mathcal{U}$ and every $q \geq 1$ by lemma 6.1.16, so passing to the colimit over covers, $\check{H}^q(X, \mathscr{G}) = 0$.

Step 2: presheaves that vanish locally. This is where paracompactness enters. The complexes $C^\bullet(\mathcal{U}, \mathscr{P})$ and the groups $\check{H}^\bullet(X, \mathscr{P})$ are defined for a presheaf $\mathscr{P}$ by the same formulas. Suppose the sheafification of $\mathscr{P}$ is zero, so that every section of $\mathscr{P}$ vanishes locally. We show $\check{H}^q(X, \mathscr{P}) = 0$ for every q. Let $c \in C^q(\mathcal{U}, \mathscr{P})$ be a cocycle. After refining, $\mathcal{U} = \{U_i\}_{i \in I}$ is locally finite. Choose a shrinking $\{W_i\}$ with $\overline{W_i} \subseteq U_i$. The family $\{\overline{W_i}\}$ is again locally finite. For each $x \in X$ choose $\tau(x)$ with $x \in W_{\tau(x)}$ and an open neighbourhood V_x of x such that

(a) $V_x \subseteq W_{\tau(x)}$, and $V_x \subseteq U_i$ for each of the finitely many i with $x \in U_i$;

(b) V_x meets no $\overline{W_i}$ with $x \notin \overline{W_i}$;

(c) $c_{i_0 \cdots i_q}|_{V_x} = 0$ whenever $x \in U_{i_0} \cap \cdots \cap U_{i_q}$.

Condition (b) is possible because the union of the $\overline{W_i}$ not containing x is closed, and (c) consists of finitely many conditions, each satisfiable because sections of $\mathscr{P}$ vanish locally. The

cover $\mathcal{V} = \{V_x\}_{x\in X}$ refines $\mathcal{U}$ via τ. If $V_{x_0} \cap \cdots \cap V_{x_q} \neq \emptyset$, then V_{x_0} meets each $W_{\tau(x_k)}$, so $x_0 \in \overline{W_{\tau(x_k)}} \subseteq U_{\tau(x_k)}$ by (b), and (c) at x_0 gives $(\tau^q c)_{x_0\cdots x_q} = c_{\tau(x_0)\cdots\tau(x_q)}|_{V_{x_0\cdots x_q}} = 0$. So the class of c dies in the colimit.

Step 3: Čech cohomology has a long exact sequence. Let $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ be exact and let $\mathscr{P}$ be the presheaf $U \mapsto \mathscr{F}(U)/\mathscr{F}'(U)$, a subpresheaf of $\mathscr{F}''$. For every cover the sequence $0 \to C^\bullet(\mathcal{U}, \mathscr{F}') \to C^\bullet(\mathcal{U}, \mathscr{F}) \to C^\bullet(\mathcal{U}, \mathscr{P}) \to 0$ is exact, and filtered colimits are exact, so $\check{H}^\bullet(X, -)$ has a long exact sequence for $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{P} \to 0$, and likewise for $0 \to \mathscr{P} \to \mathscr{F}'' \to \mathscr{F}''/\mathscr{P} \to 0$. The presheaf $\mathscr{F}''/\mathscr{P}$ has zero sheafification because $\mathscr{F} \to \mathscr{F}''$ is surjective on stalks, so Step 2 gives $\check{H}^\bullet(X, \mathscr{P}) \cong \check{H}^\bullet(X, \mathscr{F}'')$. Substituting yields a long exact sequence for $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$, natural in the sequence.

Step 4: comparison. Both $\check{H}^\bullet(X, -)$ and $H^\bullet(X, -)$ are now δ-functors on sheaves of abelian groups over X; they agree in degree 0, both being $\Gamma(X, -)$; and both vanish in positive degrees on flasque sheaves, by Step 1 and corollary 6.1.7. Since every sheaf embeds in a flasque one, both are effaceable, hence universal, so the identification in degree 0 extends to an isomorphism of δ-functors (*Homological Algebra* [25, An Effaceable δ-Functor Is Universal, A Universal δ-Functor Is Determined by Its Degree-Zero Part]).

This is the form that applies outside algebraic geometry. A complex manifold is paracompact, its sheaves of smooth forms are fine, and theorem 6.1.28 together with proposition 6.1.25 is what makes a resolution by smooth forms compute sheaf cohomology.

6.2 Vanishing Theorems

The comparison of the previous section rested on the vanishing in positive degrees of the cohomology of quasi-coherent sheaves on affine Noetherian schemes. This section proves that result, and before it a second: cohomology vanishes above the dimension of the space. These are the foundations on which virtually all further cohomological arguments rest.

The first result — the *dimension theorem* — says that if X is a Noetherian topological space of dimension n, then $H^i(X, \mathscr{F}) = 0$ for all $i > n$ and all sheaves of abelian groups $\mathscr{F}$. This is the scheme-theoretic analogue of the general principle that cohomology should not exceed the dimension of the underlying space[4].

The second result — the *affine vanishing theorem* — says that on an affine Noetherian scheme $X = \operatorname{Spec} R$, all quasi-coherent sheaves have trivial higher cohomology: $H^i(X, \mathscr{F}) = 0$ for $i > 0$. This confirms the philosophy that cohomology measures the obstruction to gluing: on an affine scheme, there is no gluing to be done. Conversely, we shall show that this vanishing property *characterizes* affine schemes among Noetherian schemes.

6.2.1 Dimension Theorem for Schemes

We begin with two lemmas about the behaviour of cohomology on Noetherian spaces. The Noetherian hypothesis enters through a single but crucial property: on Noetherian topological spaces, filtered colimits of sheaves commute with the global section functor. This fails in general.

[4]Recall from [78] that the corresponding statement in singular cohomology is that $H^i(M; \mathbb{Z}) = 0$ for $i > \dim M$ when M is a manifold; in de Rham cohomology, it is the vanishing of the de Rham groups above the manifold dimension.

Lemma 6.2.1: Noetherian Space and Flasque Sheaves

Let X be a Noetherian topological space. Then a filtered colimit of flasque sheaves on X is flasque.

***Proof*:**
Let $(\mathscr{F}_\alpha)$ be a filtered (directed) system of flasque sheaves on X, and let $U \subseteq V$ be open subsets. For each α, the restriction map $\mathscr{F}_\alpha(V) \to \mathscr{F}_\alpha(U)$ is surjective. Since the system is filtered, the colimit functor on abelian groups is exact, so:

$$\varinjlim_\alpha \mathscr{F}_\alpha(V) \longrightarrow \varinjlim_\alpha \mathscr{F}_\alpha(U)$$

is surjective. Now, the key point is that on a Noetherian topological space, every open subset is quasi-compact, so filtered colimits of sheaves commute with the section functor:

$$\big(\varinjlim_\alpha \mathscr{F}_\alpha\big)(U) \;\cong\; \varinjlim_\alpha \mathscr{F}_\alpha(U)$$

for every open U. This is *not* true in general: for a presheaf the colimit is computed section-wise, but for a sheaf one may need to sheafify. On a Noetherian space, however, every open cover has a finite subcover, so any section of the sheafification already comes from some $\mathscr{F}_\alpha$, and sheafification is unnecessary. Combining the two displayed equations, the restriction map

$$\big(\varinjlim_\alpha \mathscr{F}_\alpha\big)(V) \longrightarrow \big(\varinjlim_\alpha \mathscr{F}_\alpha\big)(U)$$

is surjective, so $\varinjlim_\alpha \mathscr{F}_\alpha$ is flasque.

Lemma 6.2.2: Colimit and Cohomology Commuting

Let X be a Noetherian topological space and $(\mathscr{F}_\alpha)$ a filtered direct system of sheaves of abelian groups. Then for each $i \geq 0$ there is a natural isomorphism:

$$\varinjlim_\alpha H^i(X, \mathscr{F}_\alpha) \;\cong\; H^i(X, \varinjlim_\alpha \mathscr{F}_\alpha).$$

***Proof*:**
For each $\mathscr{F}_\alpha$, choose a flasque resolution $0 \to \mathscr{F}_\alpha \to \mathscr{I}_\alpha^\bullet$ functorially (for instance, using the Godement resolution from Example 6.1.8(3), which is canonical). The cohomology groups are then:

$$H^i(X, \mathscr{F}_\alpha) = h^i\big(\Gamma(X, \mathscr{I}_\alpha^\bullet)\big).$$

Since filtered colimits are exact in the category of abelian sheaves, taking the colimit of these resolutions yields an exact sequence:

$$0 \longrightarrow \varinjlim_\alpha \mathscr{F}_\alpha \longrightarrow \varinjlim_\alpha \mathscr{I}_\alpha^\bullet.$$

By lemma 6.2.1, since X is Noetherian, each term $\varinjlim_\alpha \mathscr{I}_\alpha^p$ is flasque. Hence $\varinjlim_\alpha \mathscr{I}_\alpha^\bullet$ is a flasque resolution of $\varinjlim_\alpha \mathscr{F}_\alpha$, and we may use it to compute cohomology:

$$H^i(X, \varinjlim_\alpha \mathscr{F}_\alpha) = h^i\big(\Gamma(X, \varinjlim_\alpha \mathscr{I}_\alpha^\bullet)\big).$$

On the other hand, filtered colimits of abelian groups commute with the cohomology functor h^i (since filtered colimits are exact):

$$\varinjlim_\alpha H^i(X, \mathscr{F}_\alpha) = \varinjlim_\alpha h^i\big(\Gamma(X, \mathscr{I}_\alpha^\bullet)\big) \cong h^i\big(\varinjlim_\alpha \Gamma(X, \mathscr{I}_\alpha^\bullet)\big).$$

It remains to show $\varinjlim_\alpha \Gamma(X, \mathscr{I}_\alpha^p) \cong \Gamma(X, \varinjlim_\alpha \mathscr{I}_\alpha^p)$ for each p. This holds because global sections commute with filtered colimits of sheaves on Noetherian spaces (the same property used in the proof of lemma 6.2.1). Combining these identifications completes the proof.

Corollary 6.2.3: Direct Sum and Cohomology Commuting

Let X be a Noetherian topological space and $(\mathscr{F}_\alpha)_{\alpha \in A}$ a family of sheaves of abelian groups. Then for each $i \geq 0$:

$$\bigoplus_{\alpha \in A} H^i(X, \mathscr{F}_\alpha) \;\cong\; H^i\Big(X, \bigoplus_{\alpha \in A} \mathscr{F}_\alpha\Big).$$

***Proof*:**
A direct sum is a filtered colimit of finite partial sums, and cohomology commutes with finite direct sums (since it is an additive functor). Hence the result follows from lemma 6.2.2.

The following result shows that cohomology computations on a closed subset can be performed on the ambient space by pushing forward:

Proposition 6.2.4: Cohomology of Closed Subsets

Let X be a topological space, $Y \subseteq X$ a closed subset, $j : Y \to X$ the inclusion, and $\mathscr{F}$ a sheaf of abelian groups on Y. Then for all $i \geq 0$:

$$H^i(Y, \mathscr{F}) \cong H^i(X, j_*\mathscr{F}).$$

***Proof*:**
Let $0 \to \mathscr{F} \to \mathscr{I}^\bullet$ be a flasque resolution of $\mathscr{F}$ on Y. Each $j_*\mathscr{I}^p$ is flasque, since for $U \subseteq V$ open in X the surjection $\mathscr{I}^p(V \cap Y) \twoheadrightarrow \mathscr{I}^p(U \cap Y)$ is precisely the restriction map for $j_*\mathscr{I}^p$. Because Y is closed, $(j_*\mathscr{G})_x = \mathscr{G}_x$ for $x \in Y$ and $(j_*\mathscr{G})_x = 0$ for $x \notin Y$, for any sheaf $\mathscr{G}$ on Y, so j_* is exact. Hence the sequence $0 \to j_*\mathscr{F} \to j_*\mathscr{I}^\bullet$ is a flasque resolution of $j_*\mathscr{F}$ on X. Now:

$$H^i(X, j_*\mathscr{F}) = h^i\big(\Gamma(X, j_*\mathscr{I}^\bullet)\big) = h^i\big(\Gamma(Y, \mathscr{I}^\bullet)\big) = H^i(Y, \mathscr{F}),$$

where the middle equality uses $\Gamma(X, j_*\mathscr{G}) = \mathscr{G}(j^{-1}(X)) = \mathscr{G}(Y) = \Gamma(Y, \mathscr{G})$ for any sheaf $\mathscr{G}$ on Y.

By virtue of this result, we shall often write $\mathscr{F}$ in place of $j_*\mathscr{F}$ when Y is a closed subset of X, without risk of ambiguity: the cohomology groups are the same. With these tools, we can prove our first main vanishing theorem:

Theorem 6.2.5: Noetherian Space and Dimension

Let X be a Noetherian topological space of dimension n. Then for all sheaves of abelian groups $\mathscr{F}$ on X:

$$H^i(X, \mathscr{F}) = 0 \qquad \text{for all } i > n.$$

***Proof*:**
We shall need the following notation. For a closed subset $Y \subseteq X$ with inclusion $j : Y \hookrightarrow X$, write $\mathscr{F}_Y = j_*(j^{-1}\mathscr{F})$ for the "restriction of $\mathscr{F}$ to Y, pushed back to X." For an open subset $U \subseteq X$ with inclusion $i : U \hookrightarrow X$, write $\mathscr{F}_U = i_!(i^{-1}\mathscr{F})$, the extension by zero of $\mathscr{F}|_U$. If $U = X \setminus Y$, checking on stalks gives a short exact sequence:

$$0 \longrightarrow \mathscr{F}_U \longrightarrow \mathscr{F} \longrightarrow \mathscr{F}_Y \longrightarrow 0.$$

We prove the theorem by a double induction: on the dimension of X and on the number of irreducible components.

Step 1: Reduction to X irreducible. Suppose X is reducible. Let Y be an irreducible component of X and $U = X \setminus Y$. The short exact sequence above gives a long exact sequence:

$$\cdots \to H^i(X, \mathscr{F}_U) \to H^i(X, \mathscr{F}) \to H^i(X, \mathscr{F}_Y) \to \cdots$$

It suffices to show vanishing for $\mathscr{F}_Y$ and $\mathscr{F}_U$ separately. For $\mathscr{F}_Y$: since Y is closed and irreducible with $\dim Y \leq n$, proposition 6.2.4 gives $H^i(X, \mathscr{F}_Y) = H^i(Y, j^{-1}\mathscr{F})$, which vanishes for $i > n$ by the inductive hypothesis applied to the irreducible space Y. For $\mathscr{F}_U$: the support of $\mathscr{F}_U$ is contained in $\overline{U}$, which is a closed subset with strictly fewer irreducible components than X (we have removed the component Y). By proposition 6.2.4 applied to $\overline{U}$ and induction on the number of irreducible components, we get the required vanishing. Hence we may assume X is irreducible.

Step 2: Base case $\dim X = 0$. If X is irreducible of dimension 0, its only open subsets are $\emptyset$ and X itself (a proper closed irreducible subset would give $\dim X \geq 1$). Hence the global section functor $\Gamma(X, -) : \mathbf{Ab}(X) \to \mathbf{Ab}$ is an equivalence of categories (a sheaf on X is determined by a single abelian group). In particular, $\Gamma(X, -)$ is exact, so all its derived functors vanish: $H^i(X, \mathscr{F}) = 0$ for $i > 0$.

Step 3: Reduction to $\underline{\mathbb{Z}}_U$ and its subsheaves. Now let X be irreducible of dimension $n \geq 1$ and $\mathscr{F}$ arbitrary. For a finite set α of sections of $\mathscr{F}$, each over some open subset, let $\mathscr{F}_\alpha \subseteq \mathscr{F}$ be the subsheaf they generate. These subsheaves form a filtered system under inclusion with colimit $\mathscr{F}$, so by lemma 6.2.2 it suffices to prove the vanishing for each $\mathscr{F}_\alpha$. If $\alpha = \alpha' \cup \{s\}$, then $\mathscr{F}_\alpha/\mathscr{F}_{\alpha'}$ is generated by the image of the single section s, and the long exact sequence of

$$0 \longrightarrow \mathscr{F}_{\alpha'} \longrightarrow \mathscr{F}_\alpha \longrightarrow \mathscr{F}_\alpha/\mathscr{F}_{\alpha'} \longrightarrow 0$$

reduces the vanishing for $\mathscr{F}_\alpha$, by induction on the number of elements of α, to the case of a sheaf $\mathscr{G}$ generated by a single section $s \in \mathscr{G}(U)$. Such a sheaf is a quotient of $\underline{\mathbb{Z}}_U$, by the map

sending 1 to s:

$$0 \longrightarrow \mathcal{K} \longrightarrow \underline{\mathbb{Z}}_U \longrightarrow \mathscr{G} \longrightarrow 0,$$

with $\mathcal{K}$ a subsheaf of $\underline{\mathbb{Z}}_U$. The long exact sequence $H^i(X, \underline{\mathbb{Z}}_U) \to H^i(X, \mathscr{G}) \to H^{i+1}(X, \mathcal{K})$ shows that it suffices to prove, for every open $U \subseteq X$ and every $i > n$, that $H^i(X, \mathcal{K}) = 0$ for each subsheaf $\mathcal{K} \subseteq \underline{\mathbb{Z}}_U$ and that $H^i(X, \underline{\mathbb{Z}}_U) = 0$.

Step 4: Subsheaves of $\underline{\mathbb{Z}}_U$. Let $U \subseteq X$ be open and $\mathcal{K} \subseteq \underline{\mathbb{Z}}_U$ a subsheaf. If $\mathcal{K} = 0$, there is nothing to prove. Otherwise, for each $x \in U$, the stalk $\mathcal{K}_x$ is a subgroup of $\mathbb{Z}$, hence either 0 or $d_x\mathbb{Z}$ for some positive integer d_x. Let d be the smallest positive integer occurring among the stalks. There is a non-empty open subset $V \subseteq U$ on which $\mathcal{K}|_V \cong d \cdot \underline{\mathbb{Z}}|_V \cong \underline{\mathbb{Z}}_V$ (as a subsheaf of $\underline{\mathbb{Z}}|_V$). Thus $\mathcal{K}_V \cong \underline{\mathbb{Z}}_V$, and we have:

$$0 \longrightarrow \underline{\mathbb{Z}}_V \longrightarrow \mathcal{K} \longrightarrow \mathcal{K}/\underline{\mathbb{Z}}_V \longrightarrow 0.$$

The quotient $\mathcal{K}/\underline{\mathbb{Z}}_V$ is supported on the closure $\overline{U \setminus V}$, which is a proper closed subset of X. Since X is irreducible, $\dim \overline{U \setminus V} < n$. By proposition 6.2.4 and the inductive hypothesis on dimension, we get $H^i(X, \mathcal{K}/\underline{\mathbb{Z}}_V) = 0$ for $i \geq n$. From the long exact sequence, it suffices to prove vanishing for $\underline{\mathbb{Z}}_V$.

Step 5: Completing the proof for $\underline{\mathbb{Z}}_U$. It remains to show that for any open subset $U \subseteq X$, we have $H^i(X, \underline{\mathbb{Z}}_U) = 0$ for $i > n$. Let $Y = X \setminus U$ and consider the exact sequence:

$$0 \longrightarrow \underline{\mathbb{Z}}_U \longrightarrow \underline{\mathbb{Z}} \longrightarrow \underline{\mathbb{Z}}_Y \longrightarrow 0.$$

Since X is irreducible, the constant sheaf $\underline{\mathbb{Z}}$ on X is flasque (every non-empty open subset of an irreducible space is connected, so the constant sheaf has the same sections on every non-empty open; see Example 6.1.8(2)). Hence $H^i(X, \underline{\mathbb{Z}}) = 0$ for all $i > 0$. Furthermore, Y is a proper closed subset of the irreducible space X, so $\dim Y < n$. By proposition 6.2.4 and the inductive hypothesis on dimension, $H^i(X, \underline{\mathbb{Z}}_Y) = 0$ for $i \geq n$. The long exact sequence now gives $H^i(X, \underline{\mathbb{Z}}_U) = 0$ for $i > n$, completing the proof.

6.2.2 Vanishing Theorem for Affine Schemes

We now turn to the second fundamental vanishing result: on an affine Noetherian scheme $X = \operatorname{Spec} R$, all quasi-coherent sheaves have trivial higher cohomology. The key insight is that if I is an injective R-module, then the associated sheaf $\widetilde{I}$ on $\operatorname{Spec} R$ is flasque. This is not obvious: the sections of $\widetilde{I}$ on a general open set involve a limit over distinguished opens, and there is no a priori reason for restriction maps to be surjective. The proof requires the Noetherian hypothesis in an essential way, via the Artin–Rees lemma and Noetherian induction.

Let R be a Noetherian ring, M an R-module, and $\mathfrak{a} \subseteq R$ an ideal. The $\mathfrak{a}$-*torsion submodule* of M is:

$$\Gamma_{\mathfrak{a}}(M) = \left\{ m \in M \;\middle|\; \mathfrak{a}^k m = 0 \text{ for some } k > 0 \right\}.$$

Lemma 6.2.6: $\mathfrak{a}$-Torsion of an Injective Module is Injective

Let R be a Noetherian ring, $\mathfrak{a} \subseteq R$ an ideal, and I an injective R-module. Then the submodule $J = \Gamma_{\mathfrak{a}}(I)$ is injective.

***Proof*:**
By Baer's criterion, it suffices to show that for any ideal $\mathfrak{b} \subseteq R$ and any homomorphism $\varphi : \mathfrak{b} \to J$, there exists a homomorphism $\psi : R \to J$ extending φ.

Since R is Noetherian, $\mathfrak{b}$ is finitely generated, and every element of J is annihilated by some power of $\mathfrak{a}$. Hence there exists $n > 0$ such that $\mathfrak{a}^n \cdot \varphi(\mathfrak{b}) = 0$, i.e. $\varphi(\mathfrak{a}^n \mathfrak{b}) = 0$. By the Artin–Rees lemma (see [15, Artin-Rees Lemma]) applied to the inclusion $\mathfrak{b} \subseteq R$ and the $\mathfrak{a}$-adic filtration, there exists $n' \geq n$ such that $\mathfrak{a}^n \mathfrak{b} \supseteq \mathfrak{b} \cap \mathfrak{a}^{n'}$. Hence $\varphi(\mathfrak{b} \cap \mathfrak{a}^{n'}) = 0$, and φ factors through $\mathfrak{b}/(\mathfrak{b} \cap \mathfrak{a}^{n'})$.

Consider the commutative diagram:

$$\begin{array}{ccccccc} R & \twoheadrightarrow & R/\mathfrak{a}^{n'} & & & & \\ \uparrow & & \uparrow & \overset{\psi'}{\searrow} & & & \\ \mathfrak{b} & \twoheadrightarrow & \mathfrak{b}/(\mathfrak{b} \cap \mathfrak{a}^{n'}) & \longrightarrow & J & \hookrightarrow & I \end{array}$$

Since I is injective, the composed map $\mathfrak{b}/(\mathfrak{b} \cap \mathfrak{a}^{n'}) \to I$ extends to a map $\psi' : R/\mathfrak{a}^{n'} \to I$. The image of ψ' is annihilated by $\mathfrak{a}^{n'}$, so it is contained in $J = \Gamma_{\mathfrak{a}}(I)$. Composing with the natural projection $R \twoheadrightarrow R/\mathfrak{a}^{n'}$, we obtain the required extension $\psi : R \to J$.

Lemma 6.2.7: Localization of Injective Modules is Surjective

Let R be a Noetherian ring, I an injective R-module, and $f \in R$. Then the natural localization map $I \to I_f$ is surjective.

***Proof*:**
Let $\varphi : I \to I_f$ be the natural map and let $x \in I_f$. By definition of localization, there exist $y \in I$ and $n \geq 0$ such that $x = \varphi(y)/f^n$.

For each $i > 0$, let $\mathfrak{b}_i = \operatorname{Ann}_R(f^i)$. Since R is Noetherian, the ascending chain $\mathfrak{b}_1 \subseteq \mathfrak{b}_2 \subseteq \cdots$ stabilizes: there exists m such that $\mathfrak{b}_{m+j} = \mathfrak{b}_m$ for all $j \geq 0$. Define a homomorphism $\psi : (f^{n+m}) \to I$ by $f^{n+m} \mapsto f^m y$. This is well-defined: if $r f^{n+m} = 0$, then $r \in \mathfrak{b}_{n+m} = \mathfrak{b}_m$, so $r f^m = 0$, hence $r f^m y = 0$.

Since I is injective, Baer's criterion extends ψ to a map $\Psi : R \to I$. Let $z = \Psi(1)$. Then:

$$f^{n+m} z = f^{n+m} \Psi(1) = \Psi(f^{n+m}) = \psi(f^{n+m}) = f^m y,$$

so in I_f we have $\varphi(z) = z/1 = f^m y / f^{n+m} = y/f^n = x$. Hence φ is surjective.

Lemma 6.2.8: Associated Sheaf of Injective Module is Flasque

Let R be a Noetherian ring and I an injective R-module. Then the associated sheaf $\widetilde{I}$ on $X = \operatorname{Spec} R$ is flasque.

***Proof*:**

The space X is Noetherian (lemma 2.4.2). For a closed subset $Y \subseteq X$ let $P(Y)$ say that $\widetilde{I}$ is flasque for every injective R-module I whose support is contained in Y. By corollary 0.3.5 it suffices to prove $P(Y)$ assuming $P(Y')$ for every closed $Y' \subsetneq Y$, and taking $Y = X$ then gives the lemma. So let I be injective with support in Y.

It suffices to show that for any open set $U \subseteq X$, the restriction $\Gamma(X, \widetilde{I}) \to \Gamma(U, \widetilde{I})$ is surjective. If $Y \cap U = \emptyset$, then $\Gamma(U, \widetilde{I}) = 0$ and there is nothing to prove. Otherwise, choose $f \in R$ such that the distinguished open $D(f)$ satisfies $D(f) \subseteq U$ and $D(f) \cap Y \neq \emptyset$. Let $Z = X \setminus D(f)$, and for any open W let $\Gamma_Z(W, \widetilde{I})$ denote the sections of $\widetilde{I}$ over W with support in Z.

Given a section $s \in \Gamma(U, \widetilde{I})$, its restriction to $D(f)$ yields an element $s' \in \Gamma(D(f), \widetilde{I})$. By the identification $\Gamma(D(f), \widetilde{I}) \cong I_f$ (from definition 5.1.6) and the surjectivity of $I \to I_f$ (lemma 6.2.7), there exists $t \in I = \Gamma(X, \widetilde{I})$ (proposition 5.1.14(2)) with $t|_{D(f)} = s'$. Let t' be the restriction of t to U. Then $s - t'$ restricts to zero on $D(f)$, so it has support in Z: $s - t' \in \Gamma_Z(U, \widetilde{I})$.

It remains to show that $\Gamma_Z(X, \widetilde{I}) \to \Gamma_Z(U, \widetilde{I})$ is surjective. Let $J = \Gamma_{\mathfrak{a}}(I)$ where $\mathfrak{a} = (f)$. Then $\Gamma_Z(X, \widetilde{I}) = J$ (the sections of $\widetilde{I}$ over all of X supported on $Z = V(f)$ are precisely the f-torsion elements of I). By lemma 6.2.6, J is an injective R-module. The support of $\widetilde{J}$ is contained in $Y \cap Z$, a closed set strictly contained in Y (since $D(f) \cap Y \neq \emptyset$, we have removed a non-empty open piece of Y). By the hypothesis $P(Y \cap Z)$, $\widetilde{J}$ is flasque. Since $\Gamma(U, \widetilde{J}) = \Gamma_Z(U, \widetilde{I})$, the flasqueness of $\widetilde{J}$ gives the required surjectivity.

Theorem 6.2.9: Affine Noetherian Scheme: Trivial Cohomology

Let $X = \operatorname{Spec} R$ be the spectrum of a Noetherian ring R, and let $\mathscr{F}$ be a quasi-coherent sheaf on X. Then:

$$H^i(X, \mathscr{F}) = 0 \qquad \text{for all } i > 0.$$

***Proof*:**

Since $\mathscr{F}$ is quasi-coherent on the affine scheme $X = \operatorname{Spec} R$, there exists an R-module M with $\mathscr{F} \cong \widetilde{M}$ (by corollary 5.1.12). Choose an injective resolution $0 \to M \to I^\bullet$ in the category of R-modules. The associated-sheaf functor $\widetilde{(-)}$ is exact (by proposition 5.1.14), so:

$$0 \longrightarrow \widetilde{M} \longrightarrow \widetilde{I}^\bullet$$

is an exact sequence of $\mathcal{O}_X$-modules. By lemma 6.2.8, each $\widetilde{I}^p$ is flasque. Hence $\widetilde{I}^\bullet$ is a flasque resolution of $\mathscr{F} = \widetilde{M}$, and we may use it to compute cohomology:

$$H^i(X, \mathscr{F}) = h^i\big(\Gamma(X, \widetilde{I}^\bullet)\big) = h^i(I^\bullet).$$

But $I^\bullet$ is an injective resolution of M, so its cohomology is $h^0(I^\bullet) = M$ and $h^i(I^\bullet) = 0$ for $i > 0$. Hence:

$$H^0(X, \mathscr{F}) = M = \Gamma(X, \mathscr{F}) \qquad \text{and} \qquad H^i(X, \mathscr{F}) = 0 \text{ for } i > 0.$$

As a useful corollary, we can embed any quasi-coherent sheaf on a Noetherian scheme into a quasi-coherent flasque sheaf.

Corollary 6.2.10: Injective Embedding of Sheaves On Noetherian Schemes

Let X be a Noetherian scheme and $\mathscr{F}$ a quasi-coherent sheaf on X. Then $\mathscr{F}$ can be embedded in a quasi-coherent flasque sheaf.

***Proof*:**
Since X is Noetherian, it is quasi-compact, so it has a finite affine open cover $X = \bigcup_{j=1}^{r} U_j$ with $U_j = \operatorname{Spec} R_j$. For each j, let $\mathscr{F}|_{U_j} \cong \widetilde{M_j}$ for the R_j-module $M_j = \Gamma(U_j, \mathscr{F})$. Embed each M_j into an injective R_j-module I_j, and define:

$$\mathscr{G} = \bigoplus_{j=1}^{r} (\iota_j)_*(\widetilde{I_j})$$

where $\iota_j : U_j \hookrightarrow X$ is the inclusion. For each j, the embedding $\mathscr{F}|_{U_j} \hookrightarrow \widetilde{I_j}$ induces $\mathscr{F} \to (\iota_j)_*(\widetilde{I_j})$ (by adjunction of restriction and pushforward). Taking the direct sum gives an injective morphism $\mathscr{F} \hookrightarrow \mathscr{G}$.

Each $\widetilde{I_j}$ is flasque by lemma 6.2.8 and quasi-coherent on U_j. The pushforward $(\iota_j)_*(\widetilde{I_j})$ is flasque (the pushforward of a flasque sheaf along any continuous map is flasque) and quasi-coherent by proposition 5.1.20[a]. A finite direct sum of flasque quasi-coherent sheaves is flasque and quasi-coherent, so $\mathscr{G}$ has the required properties.

[a] This is where the Noetherian hypothesis enters: the pushforward of a quasi-coherent sheaf along an open immersion is quasi-coherent when the target is Noetherian (or more generally, when the morphism is quasi-compact and quasi-separated), but can fail for non-Noetherian schemes.

The vanishing theorem shows that the higher cohomology of quasi-coherent sheaves detects non-affineness. The converse is also true:

Theorem 6.2.11: Characterizing Affine Schemes via Cohomology

Let X be a Noetherian scheme. Then the following are equivalent:

1. X is affine.
2. $H^i(X, \mathscr{F}) = 0$ for all $i > 0$ and all quasi-coherent sheaves $\mathscr{F}$ on X.
3. $H^1(X, \mathscr{I}) = 0$ for all coherent sheaves of ideals $\mathscr{I} \subseteq \mathcal{O}_X$.

***Proof*:**
(1) ⇒ (2): This is theorem 6.2.9.

(2) ⇒ (3): Every coherent sheaf of ideals is quasi-coherent, so this is immediate.

(3) ⇒ (1): We verify the hypotheses of corollary 3.1.15: we shall find elements $f_1, \dots, f_r \in R = \Gamma(X, \mathcal{O}_X)$ such that each X_{f_j} is affine and $(f_1, \dots, f_r) = R$.

Step A: Finding the f_j. Let $\mathfrak{p}$ be a closed point of X and let U be an affine open neighborhood of $\mathfrak{p}$. Let $Y = X \setminus U$. Then Y and $Y \cup \{\mathfrak{p}\}$ are closed subsets, and their ideal sheaves $\mathscr{I}_Y \supseteq \mathscr{I}_{Y \cup \{\mathfrak{p}\}}$

fit in a short exact sequence:

$$0 \longrightarrow \mathscr{I}_{Y\cup\{\mathfrak{p}\}} \longrightarrow \mathscr{I}_Y \longrightarrow \kappa(\mathfrak{p}) \longrightarrow 0,$$

where $\kappa(\mathfrak{p}) = \mathcal{O}_{X,\mathfrak{p}}/\mathfrak{m}_\mathfrak{p}$ is the skyscraper sheaf at $\mathfrak{p}$. The long exact sequence gives:

$$\Gamma(X, \mathscr{I}_Y) \longrightarrow \Gamma(X, \kappa(\mathfrak{p})) \longrightarrow H^1(X, \mathscr{I}_{Y\cup\{\mathfrak{p}\}}) = 0,$$

where the last group vanishes by hypothesis (3). Hence the map $\Gamma(X, \mathscr{I}_Y) \to \kappa(\mathfrak{p})$ is surjective, so there exists $f \in \Gamma(X, \mathscr{I}_Y) \subseteq R$ with $f_\mathfrak{p} \equiv 1 \pmod{\mathfrak{m}_\mathfrak{p}}$.

By construction, f vanishes on Y, so $\mathfrak{p} \in X_f \subseteq U$. Furthermore, $X_f = U_{\bar{f}}$ where $\bar{f}$ is the image of f in $\Gamma(U, \mathcal{O}_U)$, so X_f is a distinguished open of the affine scheme U, hence affine.

Every closed point of X has an affine neighborhood of the form X_f with $f \in R$. The complement of the union of these X_f is closed and contains no closed point of X, so it is empty, since the closure of any point of the quasi-compact X contains a closed point (proposition 2.4.4). By quasi-compactness we can cover X by finitely many such opens: $X = X_{f_1} \cup \cdots \cup X_{f_r}$.

Step B: Showing $(f_1, \ldots, f_r) = R$. The elements $f_1, \ldots, f_r \in R$ define a morphism of sheaves $\alpha : \mathcal{O}_X^r \to \mathcal{O}_X$ by $(a_1, \ldots, a_r) \mapsto \sum_j f_j a_j$. Since the X_{f_j} cover X, the map α is surjective on stalks, hence surjective. Let $\mathscr{F} = \ker \alpha$:

$$0 \longrightarrow \mathscr{F} \longrightarrow \mathcal{O}_X^r \xrightarrow{\alpha} \mathcal{O}_X \longrightarrow 0.$$

We need to show $H^1(X, \mathscr{F}) = 0$, for then $\Gamma(X, \mathcal{O}_X^r) \to \Gamma(X, \mathcal{O}_X)$ is surjective, giving $1 \in \operatorname{im}(\alpha)$, i.e. $\sum a_j f_j = 1$ for some $a_j \in R$, proving $(f_1, \ldots, f_r) = R$.

Filter $\mathscr{F}$ by:

$$0 = \mathscr{F} \cap \mathcal{O}_X^0 \subseteq \mathscr{F} \cap \mathcal{O}_X^1 \subseteq \cdots \subseteq \mathscr{F} \cap \mathcal{O}_X^r = \mathscr{F}$$

where $\mathcal{O}_X^j$ denotes the first j summands of $\mathcal{O}_X^r$. Each successive quotient $(\mathscr{F} \cap \mathcal{O}_X^{j+1})/(\mathscr{F} \cap \mathcal{O}_X^j)$ embeds into $\mathcal{O}_X^{j+1}/\mathcal{O}_X^j \cong \mathcal{O}_X$, so it is a coherent sheaf of ideals. By hypothesis (3), its H^1 vanishes. Climbing up the filtration via the long exact sequence, we deduce $H^1(X, \mathscr{F}) = 0$.

Hence $(f_1, \ldots, f_r) = R$, and by corollary 3.1.15, X is affine.

6.3 Application: Sheaf Cohomology of Projective Spaces

Let us now compute the cohomology of twisted sheaves on projective space — the single most important explicit computation in the cohomology of schemes.

6.3.1 Cohomology of Twisted Sheaves

Let R be a Noetherian ring, $S_\bullet = R[x_0, \ldots, x_n]$ with the standard grading, and $X = \operatorname{Proj} S_\bullet = \mathbb{P}^n_R$. Recall from definition 5.3.4 that the Serre twisting sheaf $\mathcal{O}_X(1)$ is the invertible sheaf whose sections on the basic open $D_+(x_i)$ are the degree-1 elements $(S_{x_i})_1$ of S_{x_i}. For any sheaf $\mathscr{F}$ of $\mathcal{O}_X$-modules, we write:

$$\Gamma_*(\mathscr{F}) = \bigoplus_{d\in\mathbb{Z}} \Gamma(X, \mathscr{F}(d)),$$

which carries a natural structure of graded $S_\bullet$-module (multiplication by x_i corresponds to the natural map $\mathscr{F}(d) \to \mathscr{F}(d+1)$).

Theorem 6.3.1: Twisted Sheaf Cohomology

Let R be a Noetherian ring and let $X = \mathbb{P}^n_R$, with $n \geq 1$. Then:

1. $H^0(X, \mathcal{O}_X(d)) \cong (S_\bullet)_d$ for all $d \geq 0$, and $H^0(X, \mathcal{O}_X(d)) = 0$ for $d < 0$.
2. $H^n(X, \mathcal{O}_X(-n-1)) \cong R$.
3. The natural multiplication map
$$H^0(X, \mathcal{O}_X(d)) \times H^n(X, \mathcal{O}_X(-d-n-1)) \longrightarrow H^n(X, \mathcal{O}_X(-n-1)) \cong R$$
is a perfect pairing of finitely generated free R-modules, for each $d \geq 0$.
4. $H^i(X, \mathcal{O}_X(d)) = 0$ for $0 < i < n$ and all $d \in \mathbb{Z}$.

In summary:
$$H^i\big(\mathbb{P}^n_R,\, \mathcal{O}_{\mathbb{P}^n_R}(d)\big) = \begin{cases} (R[x_0, \dots, x_n])_d & i = 0,\ d \geq 0, \\ \left(\dfrac{1}{x_0 x_1 \cdots x_n} R[x_0^{-1}, \dots, x_n^{-1}]\right)_d & i = n,\ d \leq -(n+1), \\ 0 & \text{otherwise.} \end{cases}$$

6.3.2 Remark: Sheaf vs. Singular Cohomology The reader should note that this result is fundamentally different from the singular cohomology of complex projective space. When $R = \mathbb{C}$ and $d = 0$, the theorem says $H^i(\mathbb{P}^n_{\mathbb{C}}, \mathcal{O}_{\mathbb{P}^n_{\mathbb{C}}}) = 0$ for all $i > 0$, whereas the singular cohomology $H^i_{\text{sing}}(\mathbb{CP}^n; \mathbb{Z})$ is nontrivial: it equals $\mathbb{Z}$ in each even degree $0 \leq i \leq 2n$ and vanishes in odd degrees (see **??**). The discrepancy arises because sheaf cohomology with coefficients in $\mathcal{O}_X$ measures obstructions to extending *holomorphic* (or algebraic) sections, not topological ones. Singular cohomology is instead the sheaf cohomology of the constant sheaf $\underline{\mathbb{Z}}$ on the analytic space X^{an} with its classical topology, and section 6.9 relates it, with $\mathbb{C}$ coefficients, to algebraic de Rham cohomology.

***Proof*:**

We use Čech cohomology with respect to the standard affine cover. Let $\mathscr{F} = \bigoplus_{d \in \mathbb{Z}} \mathcal{O}_X(d)$. By corollary 6.2.3, cohomology commutes with direct sums on Noetherian spaces, so $H^i(X, \mathscr{F}) = \bigoplus_{d \in \mathbb{Z}} H^i(X, \mathcal{O}_X(d))$. Hence it suffices to compute the cohomology of $\mathscr{F}$ as a graded module and then read off each graded piece.

Let $\mathcal{U} = \{U_0, \dots, U_n\}$ where $U_j = D_+(x_j)$ is the standard affine cover of $\operatorname{Proj} S_\bullet$. By theorem 6.1.19, the Čech cohomology $\check{H}^p(\mathcal{U}, \mathscr{F})$ computes the derived-functor cohomology $H^p(X, \mathscr{F})$. The sections of $\mathscr{F}$ on each intersection are:
$$\mathscr{F}(U_{i_0, \dots, i_p}) = S_{x_{i_0} \cdots x_{i_p}}$$

(the localization of $S_\bullet$ at the product $x_{i_0}\cdots x_{i_p}$, retaining only degree-0 elements for each summand $\mathcal{O}_X(d)$, but over all d we obtain the full localization). The Čech complex is therefore:

$$C^\bullet(\mathcal{U},\mathscr{F}): \quad \prod_i S_{x_i} \xrightarrow{d^0} \prod_{i<j} S_{x_ix_j} \xrightarrow{d^1} \cdots \xrightarrow{d^{n-1}} S_{x_0x_1\cdots x_n}.$$

Proof of (1): Computing H^0. By lemma 6.1.14, $H^0(X,\mathscr{F}) = \Gamma(X,\mathscr{F})$. The global sections of $\mathscr{F}$ are the elements lying in all localizations simultaneously: $\Gamma(X,\mathscr{F}) = \bigcap_{i=0}^n S_{x_i} \cap S = S$ by proposition 5.3.10. The graded piece of degree d is $(S_\bullet)_d$, which is a free R-module with basis $\{x_0^{m_0}\cdots x_n^{m_n} \big| m_i \geq 0, \sum m_i = d\}$ when $d \geq 0$, and is zero when $d < 0$ (there are no monomials of negative degree in a polynomial ring). Hence $H^0(X,\mathcal{O}_X(d)) \cong (S_\bullet)_d$ for $d \geq 0$ and $H^0(X,\mathcal{O}_X(d)) = 0$ for $d < 0$.

Proof of (2): Computing H^n. The group $H^n(X,\mathscr{F})$ is the cokernel of the last differential:

$$d^{n-1} : \prod_{j=0}^n S_{x_0\cdots\widehat{x_j}\cdots x_n} \longrightarrow S_{x_0x_1\cdots x_n}.$$

The target $S_{x_0\cdots x_n}$ is a free R-module with basis consisting of all Laurent monomials $\{x_0^{l_0}\cdots x_n^{l_n} \big| l_i \in \mathbb{Z}\}$. The image of d^{n-1} is the R-submodule generated by those Laurent monomials $x_0^{l_0}\cdots x_n^{l_n}$ for which at least one $l_j \geq 0$: indeed, a monomial with $l_j \geq 0$ lies in $S_{x_0\cdots\widehat{x_j}\cdots x_n}$, so it is in the image of the j-th summand. Conversely, every element of each summand has at least one non-negative exponent.

Therefore, $H^n(X,\mathscr{F})$ is the free R-module with basis

$$\{x_0^{l_0}\cdots x_n^{l_n} \big| l_i < 0 \text{ for all } i\},$$

graded by total degree $\sum l_i$. In degree $-(n+1)$, there is exactly one such monomial, namely $x_0^{-1}x_1^{-1}\cdots x_n^{-1}$. Hence:

$$H^n(X,\mathcal{O}_X(-n-1)) \cong R.$$

More generally, for $d \leq -(n+1)$, the group $H^n(X,\mathcal{O}_X(d))$ is a free R-module of rank $\binom{-d-1}{n}$, and $H^n(X,\mathcal{O}_X(d)) = 0$ for $d > -(n+1)$ (since there are no "all-negative" monomials of degree greater than $-(n+1)$).

Proof of (3): The perfect pairing. For $d \geq 0$, the module $H^0(X,\mathcal{O}_X(d))$ is free over R with basis $\{x_0^{m_0}\cdots x_n^{m_n} \big| m_i \geq 0, \sum m_i = d\}$, and $H^n(X,\mathcal{O}_X(-d-n-1))$ is free with basis $\{x_0^{l_0}\cdots x_n^{l_n} \big| l_i < 0, \sum l_i = -d-n-1\}$. The multiplication map

$$H^0(X,\mathcal{O}_X(d)) \times H^n(X,\mathcal{O}_X(-d-n-1)) \longrightarrow H^n(X,\mathcal{O}_X(-n-1)) \cong R$$

sends $(x_0^{m_0}\cdots x_n^{m_n})\cdot(x_0^{l_0}\cdots x_n^{l_n}) = x_0^{m_0+l_0}\cdots x_n^{m_n+l_n}$, and this product is nonzero in H^n if and only if all exponents remain strictly negative, i.e. $m_j + l_j < 0$ for all j. In particular, the element $x_0^{-m_0-1}\cdots x_n^{-m_n-1}$ (which has total degree $-d-n-1$) pairs with $x_0^{m_0}\cdots x_n^{m_n}$ to give $x_0^{-1}\cdots x_n^{-1}$, the generator of $H^n(X,\mathcal{O}_X(-n-1)) \cong R$. Any other basis monomial in $H^n(X,\mathcal{O}_X(-d-n-1))$ pairs with $x_0^{m_0}\cdots x_n^{m_n}$ to produce a monomial with at least one non-negative exponent, hence zero in H^n.

This shows that the monomial bases are dual to each other under the pairing, so the pairing is perfect.

Proof of (4): Vanishing of intermediate cohomology. We proceed by induction on n. For $n = 1$, the range $0 < i < 1$ is empty, so there is nothing to prove.

Let $n > 1$. We first show that every element of $H^i(X, \mathscr{F})$, for $0 < i < n$, is annihilated by some power of x_n. Localizing the Čech complex $C^\bullet(\mathcal{U}, \mathscr{F})$ at x_n yields the Čech complex of $\mathscr{F}|_{U_n}$ on the affine scheme $U_n = D_+(x_n)$ with respect to the open cover $\{U_j \cap U_n \big| 0 \le j \le n\}$. Each set in this cover is a distinguished affine open of U_n, and U_n itself is one of them. Since U_n is affine and $\mathscr{F}|_{U_n}$ is quasi-coherent, $H^i(U_n, \mathscr{F}|_{U_n}) = 0$ for $i > 0$ by theorem 6.2.9. Since localization is exact, it follows that $H^i(X, \mathscr{F})_{x_n} = 0$ for $i > 0$. In other words, every element of $H^i(X, \mathscr{F})$ is annihilated by some power of x_n.

Next, we show that for $0 < i < n$, multiplication by x_n induces a bijection on $H^i(X, \mathscr{F})$, forcing this module to be zero. Consider the exact sequence of graded $S_\bullet$-modules:

$$0 \longrightarrow S_\bullet(-1) \xrightarrow{\cdot x_n} S_\bullet \longrightarrow S_\bullet/(x_n) \longrightarrow 0,$$

which gives the short exact sequence of sheaves on X:

$$0 \longrightarrow \mathcal{O}_X(-1) \xrightarrow{\cdot x_n} \mathcal{O}_X \longrightarrow \mathcal{O}_H \longrightarrow 0,$$

where $H = V_+(x_n) \cong \mathbb{P}^{n-1}_R$ is the hyperplane $x_n = 0$. Twisting by all $d \in \mathbb{Z}$ and taking the direct sum:

$$0 \longrightarrow \mathscr{F}(-1) \xrightarrow{\cdot x_n} \mathscr{F} \longrightarrow \mathscr{F}_H \longrightarrow 0,$$

where $\mathscr{F}_H = \bigoplus_{d \in \mathbb{Z}} \mathcal{O}_H(d)$. The long exact sequence in cohomology gives:

$$\cdots \longrightarrow H^i(X, \mathscr{F}(-1)) \xrightarrow{\cdot x_n} H^i(X, \mathscr{F}) \longrightarrow H^i(X, \mathscr{F}_H) \longrightarrow \cdots$$

As graded $S_\bullet$-modules, $H^i(X, \mathscr{F}(-1))$ is simply $H^i(X, \mathscr{F})$ shifted by one degree, and the map $H^i(X, \mathscr{F}(-1)) \to H^i(X, \mathscr{F})$ induced by $\cdot x_n$ is multiplication by x_n.

Now $H \cong \mathbb{P}^{n-1}_R$, and $H^i(X, \mathscr{F}_H) = H^i(H, \bigoplus_d \mathcal{O}_H(d))$ by proposition 6.2.4. Applying the inductive hypothesis to $\mathbb{P}^{n-1}_R$, we get $H^i(X, \mathscr{F}_H) = 0$ for $0 < i < n - 1$.

For $0 < i < n - 1$: Since $H^i(X, \mathscr{F}_H) = 0$, multiplication by x_n maps $H^i(X, \mathscr{F}(-1))$ onto $H^i(X, \mathscr{F})$. For injectivity, the preceding term $H^{i-1}(X, \mathscr{F}_H)$ vanishes by the inductive hypothesis when $i \ge 2$. When $i = 1$ it is $H^0(X, \mathscr{F}_H)$, and the map $H^0(X, \mathscr{F}) \to H^0(X, \mathscr{F}_H)$ before it is the surjection $S_\bullet \to S_\bullet/(x_n)$ by part (1), so the connecting map $H^0(X, \mathscr{F}_H) \to H^1(X, \mathscr{F}(-1))$ is zero. So multiplication by x_n is bijective. Since every element is also killed by a power of x_n, we conclude $H^i(X, \mathscr{F}) = 0$.

For $i = n-1$ (when $n \ge 2$): We must show multiplication by x_n is still bijective on $H^{n-1}(X, \mathscr{F})$. The relevant portion of the long exact sequence is:

$$H^{n-2}(X, \mathscr{F}_H) \longrightarrow H^{n-1}(X, \mathscr{F}(-1)) \xrightarrow{\cdot x_n} H^{n-1}(X, \mathscr{F}) \longrightarrow H^{n-1}(X, \mathscr{F}_H) \xrightarrow{\partial} H^n(X, \mathscr{F}(-1)).$$

First, we establish injectivity on the left. If $n \ge 3$, then $H^{n-2}(X, \mathscr{F}_H) = 0$ by the inductive hypothesis (since $0 < n-2 < \dim H = n-1$). If $n = 2$, the term on the left is $H^0(X, \mathscr{F}_H)$; in this case, the preceding map in the sequence is $H^0(X, \mathscr{F}) \to H^0(X, \mathscr{F}_H)$, which is the natural surjection $S_\bullet \to S_\bullet/(x_n)$ by part (1). Exactness then forces the map $H^0(X, \mathscr{F}_H) \to H^1(X, \mathscr{F}(-1))$ to be the zero map. In either case, multiplication by x_n is injective on $H^{n-1}(X, \mathscr{F}(-1))$.

Next, we establish surjectivity on the right. The term $H^{n-1}(X, \mathscr{F}_H)$ is the top cohomology of $H \cong \mathbb{P}^{n-1}_R$, which by part (2) is a free R-module generated by all-negative Laurent monomials in

the variables $x_0, \dots, x_{n-1}$. The connecting homomorphism ∂ maps a basis element $x_0^{l_0} \cdots x_{n-1}^{l_{n-1}}$ to the element $x_0^{l_0} \cdots x_{n-1}^{l_{n-1}} x_n^{-1}$ in $H^n(X, \mathscr{F}(-1))$. This map is visibly injective. Because ∂ is injective, exactness forces the preceding map $H^{n-1}(X, \mathscr{F}) \to H^{n-1}(X, \mathscr{F}_H)$ to be the zero map.

Therefore, multiplication by x_n is surjective on $H^{n-1}(X, \mathscr{F})$. Being both injective and surjective, multiplication by x_n is bijective on $H^{n-1}(X, \mathscr{F})$, and the annihilation argument completes the proof.

6.3.2 Cohomology of Twisted Sheaves of Differentials

The cohomology of the line bundles computes that of every twist $\Omega^p_X(m)$ on projective space. The mechanism is the Euler sequence (theorem 5.5.19): its exterior powers express each Ω^p in terms of sums of line bundles, and theorem 6.3.1 finishes each step. The vanishing statement below is the one used in practice, and it is sharp: the exceptions listed are genuinely nonzero.

Theorem 6.3.3: Bott Vanishing

Let k be a field, $X = \mathbb{P}^n_k$ with $n \geq 1$, and $0 \leq p \leq n$. Then

$$H^q\big(X,\ \Omega^p_X(m)\big) = 0$$

for every q and m except in the following three cases:

1. $q = 0$ and $m > p$;
2. $q = n$ and $m < p - n$;
3. $q = p$ and $m = 0$, where the group is one-dimensional over k.

In particular $H^q(X, \Omega^p_X) = 0$ for $q \neq p$ and $H^p(X, \Omega^p_X) \cong k$, and $H^q(X, \Omega^p_X(m)) = 0$ for all $0 < q < n$ whenever $m \neq 0$.

***Proof*:**

Write $N = \binom{n+1}{p}$. Taking p-th exterior powers in the Euler sequence

$$0 \longrightarrow \Omega_X \longrightarrow \mathcal{O}_X(-1)^{\oplus(n+1)} \longrightarrow \mathcal{O}_X \longrightarrow 0$$

of theorem 5.5.19 gives, for each $p \geq 1$, a short exact sequence

$$0 \longrightarrow \Omega^p_X(m) \longrightarrow \mathcal{O}_X(m-p)^{\oplus N} \longrightarrow \Omega^{p-1}_X(m) \longrightarrow 0 \tag{6.1}$$

The exterior power of a short exact sequence of locally free sheaves with locally free quotient is exact in this form: locally the sequence splits, and for a split sequence $0 \to A \to A \oplus B \to B \to 0$ the filtration of $\Lambda^p(A \oplus B)$ by the number of factors from A has $\Lambda^p A$ as its bottom piece and $\Lambda^{p-1} A \otimes B$ as the next; here $B = \mathcal{O}_X$ has rank one, so the filtration has exactly two steps and (6.1) is what remains after twisting by $\mathcal{O}_X(m)$ and using $\Lambda^p(\mathcal{O}_X(-1)^{\oplus(n+1)}) \cong \mathcal{O}_X(-p)^{\oplus N}$. The identification is independent of the local splitting because the two extreme pieces of the filtration are canonical.

Now induct on p. For $p = 0$ the claim is theorem 6.3.1: the cohomology of $\mathcal{O}_X(m)$ vanishes except in degree 0 for $m \geq 0$ and degree n for $m \leq -n-1$, which is cases (1) and (2) with $p = 0$,

and case (3) reads $H^0(X, \mathcal{O}_X) = k$.

Let $p \geq 1$ and assume the statement for $p-1$. The long exact sequence of (6.1) reads

$$\cdots \to H^{q-1}\big(\Omega_X^{p-1}(m)\big) \to H^q\big(\Omega_X^p(m)\big) \to H^q\big(\mathcal{O}_X(m-p)\big)^{\oplus N} \to H^q\big(\Omega_X^{p-1}(m)\big) \to \cdots$$

so $H^q(\Omega_X^p(m))$ is squeezed between $H^{q-1}(\Omega_X^{p-1}(m))$ and $H^q(\mathcal{O}_X(m-p))^{\oplus N}$, and vanishes as soon as both do.

Global sections. For $m \geq 1$ the map $H^0(\mathcal{O}_X(m-p))^{\oplus N} \to H^0(\Omega_X^{p-1}(m))$ of (6.1) is surjective. Composed with the inclusion of $\Omega_X^{p-1}(m)$ into $\mathcal{O}_X(m-p+1)^{\oplus\binom{n+1}{p-1}}$ given by the same sequence for $p-1$, it is the contraction of Λ^p against the Euler map $(x_0, \ldots, x_n)$. With $S = k[x_0, \ldots, x_n]$ and $H^0(\mathcal{O}_X(d)) = S_d$ (theorem 6.3.1(1)), left exactness of H^0 identifies the global sections of the spliced sequences with the degree-m part of the Koszul complex of $x_0, \ldots, x_n$ over S. The variables form a regular sequence, so for $p \geq 2$ the kernel of the Koszul differential on Λ^{p-1}, which is $H^0(\Omega_X^{p-1}(m))$, is the image of Λ^p [17, Exactness of the Koszul Complex]. For $p = 1$ the map is $(f_j) \mapsto \sum_j x_j f_j$ from $S_{m-1}^{\oplus(n+1)}$ to S_m, onto for $m \geq 1$.

Middle degrees. Let $0 < q < n$. Then $H^q(\mathcal{O}_X(m-p)) = 0$ by theorem 6.3.1(4). By induction $H^{q-1}(\Omega_X^{p-1}(m))$ vanishes unless $q = p$ and $m = 0$, or $q = 1$ and $m \geq p$. In the second case the map $H^0(\mathcal{O}_X(m-p))^{\oplus N} \to H^0(\Omega_X^{p-1}(m))$ before it is surjective, as $m \geq p \geq 1$, so $H^0(\Omega_X^{p-1}(m)) \to H^1(\Omega_X^p(m))$ is zero and $H^1(\Omega_X^p(m))$ vanishes all the same. So for $m \neq 0$ all middle-degree groups vanish, and for $m = 0$ the only possibly nonzero one is at $q = p$, where the sequence gives $H^p(\Omega_X^p) \cong H^{p-1}(\Omega_X^{p-1}) \cong k$ by induction, the neighbouring $\mathcal{O}_X(-p)$ terms vanishing since $0 < p < n$ forces H^{p-1} and H^p of $\mathcal{O}_X(-p)$ to be zero. (For $p = n$ the group $H^n(\mathcal{O}_X(-n))$ also vanishes, as $-n > -n-1$.)

Degree zero. $H^0(\Omega_X^p(m))$ injects into $H^0(\mathcal{O}_X(m-p))^{\oplus N}$, which is zero for $m < p$; so H^0 vanishes unless $m \geq p$. At $m = p$ the sequence identifies $H^0(\Omega_X^p(p))$ with the kernel of $k^{\oplus N} \to H^0(\Omega_X^{p-1}(p))$, and that map is injective, as one checks on the standard basis of Λ^p of the coordinate forms. So $H^0(\Omega_X^p(m)) = 0$ for $m \leq p$. For $m > p$ the group is nonzero, which is (1). The identification of the global-sections step, applied to the sequences for p and $p-1$, makes $H^0(\Omega_X^p(m))$ the kernel of the Koszul differential $\Lambda^p \otimes S_{m-p} \to \Lambda^{p-1} \otimes S_{m-p+1}$, and exactness of the Koszul complex makes this kernel the image of $\Lambda^{p+1} \otimes S_{m-p-1}$. With $e_0, \ldots, e_n$ the basis on which the Koszul complex is built, the image of $e_0 \wedge \cdots \wedge e_p \otimes x_0^{m-p-1}$ has component x_0^{m-p} along $e_1 \wedge \cdots \wedge e_p$, so it is nonzero.

Degree n. The group $H^n(\Omega_X^p(m))$ maps to $H^n(\mathcal{O}_X(m-p))^{\oplus N}$ with kernel the image of $H^{n-1}(\Omega_X^{p-1}(m))$, and $H^n(\mathcal{O}_X(m-p)) = 0$ unless $m - p \leq -n-1$, that is unless $m \leq p-n-1$, which is (2). Combined with the induction hypothesis for $H^{n-1}(\Omega_X^{p-1}(m))$, which for $n \geq 2$ vanishes unless $n-1 = p-1$ and $m = 0$, and which for $n = 1$ and $m \geq 1$ maps to zero in $H^1(\Omega_X^1(m))$ by the surjectivity on global sections, this leaves only the stated cases. For $m < p-n$ the group is nonzero. By corollary 6.5.10, with $\omega_X = \Omega_X^n$ and $(\Omega_X^p)^\vee \otimes \Omega_X^n \cong \Omega_X^{n-p}$, it is dual to $H^0(\Omega_X^{n-p}(-m))$, which is nonzero by case (1) for $n-p$, as $-m > n-p$.

The diagonal case $H^p(X, \Omega_X^p) \cong k$ is the algebraic form of a topological fact: it is generated by the p-th power of the hyperplane class, and with the off-diagonal vanishing it is what makes the Hodge diamond of $\mathbb{P}^n$ a single line of 1s down the diagonal. The vanishing in the middle degrees is what allows the cohomology of a hypersurface in $\mathbb{P}^{n+1}$ to be read off a graded ring, which is how Hodge theory computes the Hodge numbers of hypersurfaces.

6.3.3⋆ Separating Points and Jets

⋆ *Optional. This subsection is an aside; nothing later in the book depends on it.*

A linear system prescribes local data at a point through its jets. The jet of a section is its class in the quotient of its stalk by a power of the maximal ideal, which records the value of the section and its derivatives up to a fixed order. The construction of Lefschetz pencils in *Hodge Theory* [24] needs the sections of a large twist to prescribe every 2-jet at every point of a smooth projective variety, and every pair of 1-jets at every pair of points, with a single twist serving all points at once. Explicit monomials on projective space give a threshold depending only on the order of the jets, uniform in the point, and restriction carries the statement to every closed subscheme.

Definition 6.3.4: Jets of Sections

Let X be a scheme over a field k, let $x \in X$ be a closed point with maximal ideal $\mathfrak{m}_x \subseteq \mathcal{O}_{X,x}$, let $\mathcal{L}$ be an invertible sheaf on X, and let $r \geq 0$ be an integer. The *space of r-jets* of $\mathcal{L}$ at x is the quotient

$$J_x^r(\mathcal{L}) := \mathcal{L}_x \,/\, \mathfrak{m}_x^{r+1}\mathcal{L}_x$$

regarded as a module over $\mathcal{O}_{X,x}/\mathfrak{m}_x^{r+1}$. A k-subspace $V \subseteq \Gamma(X,\mathcal{L})$ *realizes every r-jet at x* if the k-linear map $V \to J_x^r(\mathcal{L})$ sending a section to the class of its germ is surjective, and *realizes every pair of r-jets* at distinct closed points $x \neq y$ if the map $V \to J_x^r(\mathcal{L}) \oplus J_y^r(\mathcal{L})$ is surjective.

When X is locally of finite type over an algebraically closed field k, each $J_x^r(\mathcal{L})$ is a finite-dimensional k-vector space. Indeed x lies in an affine open $\operatorname{Spec} B$ with B a finitely generated k-algebra and stays closed there, so its maximal ideal pulls back along a presentation $k[t_1,\dots,t_l] \twoheadrightarrow B$ to a maximal ideal of the polynomial ring, and $\kappa(x) = k$ by theorem 0.1.12(3). The ring $\mathcal{O}_{X,x}$ is Noetherian: B is Noetherian by [15, Finitely Generated Algebras Are Noetherian], and every ideal of a localization is the extension of its contraction, so ascending chains stabilize. Hence each $\mathfrak{m}_x^i/\mathfrak{m}_x^{i+1}$ with $i \leq r$ is a finitely generated module over $\kappa(x) = k$, and a trivialization of $\mathcal{L}$ at x identifies $J_x^r(\mathcal{L})$ with $\mathcal{O}_{X,x}/\mathfrak{m}_x^{r+1}$, an iterated extension of these finitely many quotients. Jets at distinct closed points are independent conditions in the following sense: if $x \neq y$ lie in a common affine open $\operatorname{Spec} B$ with maximal ideals $\mathfrak{p} \neq \mathfrak{q}$, then $\mathfrak{p}^{r+1}$ and $\mathfrak{q}^{r+1}$ are comaximal, since a maximal ideal containing $\mathfrak{p}^{r+1}+\mathfrak{q}^{r+1}$ would contain $\mathfrak{p}$ and $\mathfrak{q}$ by primality and hence equal each of them, so $B/(\mathfrak{p}^{r+1} \cap \mathfrak{q}^{r+1}) \cong B/\mathfrak{p}^{r+1} \times B/\mathfrak{q}^{r+1}$ by [17, Chinese Remainder Theorem].

Lemma 6.3.5: Forms of Degree d Realize Jets on Projective Space

Let k be an algebraically closed field, let $N \geq 1$ and $r \geq 0$ be integers, and write $S = k[x_0,\dots,x_N]$, so that $\Gamma(\mathbb{P}_k^N, \mathcal{O}(d)) \cong S_d$ for $d \geq 0$ (theorem 6.3.1(1)).

1. For every $d \geq r$ and every closed point $x \in \mathbb{P}_k^N$, the space $\Gamma(\mathbb{P}_k^N, \mathcal{O}(d))$ realizes every r-jet of $\mathcal{O}(d)$ at x.
2. For every $d \geq 2r+1$ and all distinct closed points $x \neq y$ of $\mathbb{P}_k^N$, it realizes every pair of r-jets of $\mathcal{O}(d)$ at x and y.

***Proof*:**

Step 1: closed points are k-points. A closed point x lies in a chart $D_+(x_i) \cong \operatorname{Spec} k[t_j : j \neq i]$ with $t_j = x_j/x_i$ (lemma 2.3.2) and is closed there, so theorem 0.1.12(3) gives $\kappa(x) = k$ and identifies x with a point of k^N, that is with homogeneous coordinates $[v_0 : \cdots : v_N]$ for a vector $v \in k^{N+1} \setminus \{0\}$ with $v_i = 1$. Distinct closed points have non-proportional coordinate vectors: proportional vectors normalize to the same tuple in a common chart, hence give the same maximal ideal and the same point.

Step 2: monomials at a k-point. Let x have homogeneous coordinates $[v]$ with $v_i = 1$, and work on $U_i = D_+(x_i) = \operatorname{Spec} k[t_j : j \neq i]$ with $t_j = x_j/x_i$ (lemma 2.3.2), where $\mathcal{O}(d)$ is free with generator x_i^d (proposition 5.3.5) and division by x_i^d carries $F \in S_d$ to its dehomogenization, a polynomial of total degree at most d. The point x is the k-point $a = (a_j)_{j \neq i}$ with $a_j = v_j$, and maximal ideal $\mathfrak{n}_a = (t_j - a_j : j \neq i)$. The quotient $k[t]/\mathfrak{n}_a^{r+1}$ is local, so localizing at $\mathfrak{n}_a$ leaves it unchanged, and x_i^d identifies $J_x^r(\mathcal{O}(d))$ with $k[t]/\mathfrak{n}_a^{r+1}$, whose k-basis is the set of classes of $(t-a)^\beta := \prod_{j \neq i}(t_j - a_j)^{\beta_j}$ with $|\beta| \leq r$. Under these identifications the jet map sends F to the class of its dehomogenization. For $|\beta| \leq r \leq d$ the polynomial $(t-a)^\beta$ is the dehomogenization of $x_i^{d-|\beta|} \prod_{j \neq i}(x_j - a_j x_i)^{\beta_j} \in S_d$, so the jet map is surjective, proving (1).

Step 3: pairs. Let $x = [v]$ and $y = [w]$ be distinct closed points, let $d \geq 2r+1$, and set $d' = d - r - 1 \geq r$. The linear forms vanishing at w form the kernel of the evaluation $S_1 \to k$ at w, and their common zeros in k^{N+1} are exactly the scalar multiples of w. Since v is not one, there is a linear form h with $h(w) = 0$ and $h(v) \neq 0$. On a chart containing y the function h/x_i vanishes at y, so the germ of h lies in $\mathfrak{m}_y \mathcal{O}(1)_y$, and for every $F \in S_{d'}$ the product Fh^{r+1}, formed with the multiplication of proposition 5.3.8(1), has germ in $\mathfrak{m}_y^{r+1}\mathcal{O}(d)_y$ and zero image in $J_y^r(\mathcal{O}(d))$. On a chart containing x the function h/x_i has nonzero value at x, hence is a unit in $\mathcal{O}_{\mathbb{P}^N_k,x}$, so the germ of h generates $\mathcal{O}(1)_x$, multiplication by the germ of h^{r+1} is an isomorphism $\mathcal{O}(d')_x \to \mathcal{O}(d)_x$, and it induces an isomorphism $J_x^r(\mathcal{O}(d')) \to J_x^r(\mathcal{O}(d))$. By (1) applied to $d' \geq r$, the sections Fh^{r+1} with $F \in S_{d'}$ realize every element of $J_x^r(\mathcal{O}(d)) \oplus 0$. A linear form h' with $h'(v) = 0$ and $h'(w) \neq 0$ symmetrically yields sections realizing every element of $0 \oplus J_y^r(\mathcal{O}(d))$, and sums realize every pair.

For a closed subscheme $\iota\colon X \hookrightarrow \mathbb{P}^N_k$ write $\mathcal{O}_X(d) := \iota^*\mathcal{O}(d)$, extending the notation $\mathcal{O}_X(1) = \iota^*\mathcal{O}(1)$ of proposition 5.3.36. Every $\sigma \in \Gamma(\mathbb{P}^N_k, \mathcal{O}(d))$ has a restriction $\sigma|_X := \iota^*(\sigma) \in \Gamma(X, \mathcal{O}_X(d))$, as in theorem 5.3.43(1): on an open V on which $\mathcal{O}(d)$ is free with generator e, the sheaf $\mathcal{O}_X(d)$ is free on $X \cap V$ with generator ι^*e, and $\sigma = fe$ restricts to $\iota^\#(f) \cdot \iota^*e$. In particular a germ σ_x generating $\mathcal{O}(d)_x$ restricts to a generator of $\mathcal{O}_X(d)_x$, and a germ in $\mathfrak{m}^{r+1}_{\mathbb{P}^N,x}\mathcal{O}(d)_x$ restricts into $\mathfrak{m}_x^{r+1}\mathcal{O}_X(d)_x$, the stalk map $\iota^\#$ being a local homomorphism.

Theorem 6.3.6: Large Twists Separate Points and Jets

Let k be an algebraically closed field, let $\iota\colon X \hookrightarrow \mathbb{P}^N_k$ be a closed subscheme with $N \geq 1$, and let $r \geq 0$ be an integer.

1. For every $d \geq r$, the space $\Gamma(X, \mathcal{O}_X(d))$ realizes every r-jet of $\mathcal{O}_X(d)$ at every closed point of X.
2. For every $d \geq 2r+1$, it realizes every pair of r-jets of $\mathcal{O}_X(d)$ at every two distinct closed points of X.
3. There is an integer d_1, depending on X, such that the restriction map $\Gamma(\mathbb{P}^N_k, \mathcal{O}(d)) \to \Gamma(X, \mathcal{O}_X(d))$, $\sigma \mapsto \sigma|_X$, is surjective for every $d \geq d_1$.

***Proof*:**

Step 1: jets restrict surjectively. Let $x \in X$ be a closed point. Then $\{x\}$ is closed in $\mathbb{P}^N_k$, the subset X being closed. The stalk homomorphism $\iota^{\#}\colon \mathcal{O}_{\mathbb{P}^N_k,x} \to \mathcal{O}_{X,x}$ is surjective (definition 3.1.22) and local, so it carries $\mathfrak{m}_{\mathbb{P}^N,x}$ onto $\mathfrak{m}_x$ and induces a surjection $\mathcal{O}_{\mathbb{P}^N_k,x}/\mathfrak{m}^{r+1}_{\mathbb{P}^N,x} \to \mathcal{O}_{X,x}/\mathfrak{m}^{r+1}_x$. A trivialization of $\mathcal{O}(d)$ near x with generator e, together with the induced trivialization of $\mathcal{O}_X(d)$ by ι^*e, identifies the jet spaces with these two quotients and yields a surjection $\pi_x\colon J^r_x(\mathcal{O}(d)) \to J^r_x(\mathcal{O}_X(d))$ carrying the class of σ_x to the class of $(\sigma|_X)_x$ for every global section σ.

Step 2: parts (1) and (2). Let $d \geq r$ and let $x \in X$ be closed. The composite of the jet map $\Gamma(\mathbb{P}^N_k, \mathcal{O}(d)) \to J^r_x(\mathcal{O}(d))$ with π_x is surjective by lemma 6.3.5(1) and Step 1, and by the compatibility of Step 1 it equals the jet map $\Gamma(X, \mathcal{O}_X(d)) \to J^r_x(\mathcal{O}_X(d))$ preceded by restriction. A surjection factoring through $\Gamma(X, \mathcal{O}_X(d))$ forces the second factor to be surjective, which is (1). For (2), let $d \geq 2r+1$ and let $x \neq y$ be closed points of X. They are distinct closed points of $\mathbb{P}^N_k$, so lemma 6.3.5(2) makes $\Gamma(\mathbb{P}^N_k, \mathcal{O}(d)) \to J^r_x(\mathcal{O}(d)) \oplus J^r_y(\mathcal{O}(d))$ surjective, and composing with the surjection $\pi_x \oplus \pi_y$ and factoring as before proves (2).

Step 3: part (3). The ideal sheaf sequence of the closed subscheme X is

$$0 \longrightarrow \mathcal{I}_X \longrightarrow \mathcal{O}_{\mathbb{P}^N_k} \longrightarrow \iota_*\mathcal{O}_X \longrightarrow 0$$

with $\mathcal{I}_X$ quasi-coherent (proposition 5.1.33) and coherent (proposition 5.1.34), the scheme $\mathbb{P}^N_k$ being Noetherian (example 3.4.31(2) and lemma 3.5.27(1)). Tensoring with $\mathcal{O}(d)$ preserves exactness, the stalks of $\mathcal{O}(d)$ being free of rank one, and gives the exact sequence $0 \to \mathcal{I}_X(d) \to \mathcal{O}(d) \to (\iota_*\mathcal{O}_X)(d) \to 0$ in the notation of definition 5.3.7. The sheaf $(\iota_*\mathcal{O}_X)(d)$ is $\iota_*(\mathcal{O}_X(d))$: on an open V trivializing $\mathcal{O}(d)$ with generator e, a section of the source is uniquely $t \otimes e$ with $t \in \mathcal{O}_X(X \cap V)$, the assignment $t \otimes e \mapsto t \cdot \iota^*e$ is an isomorphism onto the sections of the target, and replacing e by ue for a unit u changes both descriptions by the same factor, so the local isomorphisms agree on overlaps and glue. Under this identification the quotient map $\mathcal{O}(d) \to \iota_*(\mathcal{O}_X(d))$ sends fe to $\iota^{\#}(f) \cdot \iota^*e$, so on global sections it is $\sigma \mapsto \sigma|_X$, using $\Gamma(\mathbb{P}^N_k, \iota_*(\mathcal{O}_X(d))) = \Gamma(X, \mathcal{O}_X(d))$. By lemma 6.8.23 applied to the coherent sheaf $\mathcal{I}_X$ over the Noetherian ring k there is d_1 with $H^1(\mathbb{P}^N_k, \mathcal{I}_X(d)) = 0$ for all $d \geq d_1$. The long exact sequence in cohomology ([25, Long Exact Sequence From a Right-Derived Functor]) applied to the twisted ideal sheaf sequence gives exactness of

$$\Gamma(\mathbb{P}^N_k, \mathcal{O}(d)) \longrightarrow \Gamma(X, \mathcal{O}_X(d)) \longrightarrow H^1(\mathbb{P}^N_k, \mathcal{I}_X(d)) = 0$$

for $d \geq d_1$, which is (3).

Corollary 6.3.7: Lefschetz-Type Jet Conditions Hold after Re-embedding

Let k be an algebraically closed field and let $\iota\colon X \hookrightarrow \mathbb{P}^N_k$ be a closed subscheme that is irreducible of dimension $n \geq 1$ and whose local rings are all regular. Let d_1 be as in theorem 6.3.6(3) and let $d \geq \max(d_1, 3)$. List the monomials of degree d in $x_0, \ldots, x_N$ as $M_0, \ldots, M_{N'}$. Then:

1. The restrictions $M_\alpha|_X$ span $\Gamma(X, \mathcal{O}_X(d))$ and generate $\mathcal{O}_X(d)$, and the morphism $\varphi_d\colon X \to \mathbb{P}^{N'}_k$ they determine (theorem 5.3.43) is a closed immersion with $\varphi_d^*\mathcal{O}(1) \cong \mathcal{O}_X(d)$, the embedding by the complete linear system of $\mathcal{O}_X(d)$.
2. Under φ_d the restrictions to X of the linear forms on $\mathbb{P}^{N'}_k$ are exactly the sections in $\Gamma(X, \mathcal{O}_X(d))$, and they realize every 2-jet at every closed point of X and every pair of 1-jets at every two distinct closed points of X.
3. At every closed point $x \in X$, $\dim_k J^1_x(\mathcal{O}_X(d)) = 1 + n$ and $\dim_k J^2_x(\mathcal{O}_X(d)) = 1 + n + \binom{n+1}{2}$.

***Proof*:**

(1). The monomials form a basis of $S_d \cong \Gamma(\mathbb{P}^N_k, \mathcal{O}(d))$ (theorem 6.3.1(1)) and generate $\mathcal{O}(d)$, each point lying in some $D_+(x_i)$ where the monomial x_i^d generates (proposition 5.3.5). Their restrictions generate $\mathcal{O}_X(d)$, generators restricting to generators, and they span $\Gamma(X, \mathcal{O}_X(d))$ because $d \geq d_1$ makes the restriction map surjective (theorem 6.3.6(3)). Theorem 5.3.43(2) therefore gives the morphism φ_d with $\varphi_d^*\mathcal{O}(1) \cong \mathcal{O}_X(d)$ and $\varphi_d^*(y_\alpha) = M_\alpha|_X$, writing $y_0, \ldots, y_{N'}$ for the homogeneous coordinates of $\mathbb{P}^{N'}_k$.

The immersion ι is itself the morphism determined by $\mathcal{O}_X(1)$ and the sections $x_0|_X, \ldots, x_N|_X$, which generate $\mathcal{O}_X(1)$ as restrictions of the generating x_i, by the uniqueness clause of theorem 5.3.43(2), so lemma 5.3.40(1) applied to ι gives $X_{x_i|_X} = \iota^{-1}(D_+(x_i)) = X \cap D_+(x_i) =: X_i$. A germ of $x_i|_X$ generates $\mathcal{O}_X(1)$ exactly when its d-th power generates $\mathcal{O}_X(d)$, a generator raising to a generator and a germ in $\mathfrak{m}_x\mathcal{O}_X(1)_x$ raising into $\mathfrak{m}_x\mathcal{O}_X(d)_x$, so also $X_{x_i^d|_X} = X_i$. Each X_i is affine and the ring homomorphism $k[t_j : j \neq i] \twoheadrightarrow B_i := \mathcal{O}_X(X_i)$, $t_j \mapsto \bar{t}_j$, induced by ι over the chart $D_+(x_i) \cong \operatorname{Spec} k[t_j : j \neq i]$, with $t_j = x_j/x_i$ (lemma 2.3.2), is surjective (proposition 3.1.24(1)), so the classes $\bar{t}_j$ generate B_i as a k-algebra. Writing α_i for the exponent vector of x_i^d, lemma 5.3.40 applied to φ_d gives $\varphi_d^{-1}(D_+(y_{\alpha_i})) = X_{x_i^d|_X} = X_i$, and the restriction $X_i \to D_+(y_{\alpha_i})$ corresponds to the k-algebra map sending each y_α/y_{α_i} to the ratio $(M_\alpha|_X)/(x_i^d|_X)$. For $M_\alpha = x_j x_i^{d-1}$ this ratio is $\bar{t}_j$, since $x_j x_i^{d-1} = (x_j/x_i)\cdot x_i^d$ on $D_+(x_i)$ restricts to $\bar{t}_j \cdot (x_i^d|_X)$ on X_i. The image of the chart ring map therefore contains every $\bar{t}_j$, so the map is surjective and $X_i \to D_+(y_{\alpha_i})$ is a closed immersion (proposition 3.1.24(2)).

Both X and $\mathbb{P}^{N'}_k$ are Noetherian, the first as a closed subscheme of the Noetherian $\mathbb{P}^N_k$ and the second by example 3.4.31(2) and lemma 3.5.27(1). The scheme X is projective, hence proper, over $\operatorname{Spec} k$ (theorem 3.5.32), and $\mathbb{P}^{N'}_k$ is separated over $\operatorname{Spec} k$ (corollary 3.5.5), so φ_d is proper (proposition 3.5.23(5)) and $\varphi_d(X)$ is closed. The union of the opens $D_+(y_{\alpha_0}), \ldots, D_+(y_{\alpha_N})$ contains $\varphi_d(X)$, the X_i covering X, so together with $\mathbb{P}^{N'}_k \setminus \varphi_d(X)$ they cover $\mathbb{P}^{N'}_k$. The preimage of the last member is empty, and the empty scheme maps to it by a closed immersion. By

lemma 5.3.39, φ_d is a closed immersion.

(2). The pullback of the linear form $\sum_\alpha c_\alpha y_\alpha$ along φ_d is $\sum_\alpha c_\alpha M_\alpha|_X$, so by the spanning in (1) the restrictions of the linear forms are exactly the sections in $\Gamma(X, \mathcal{O}_X(d))$. Theorem 6.3.6(1) with $r = 2$ and $d \geq 3 > 2$ realizes every 2-jet at every closed point, and theorem 6.3.6(2) with $r = 1$ and $d \geq 3$ realizes every pair of 1-jets at every two distinct closed points.

(3). Let $x \in X$ be a closed point. As in the discussion after definition 6.3.4, $\kappa(x) = k$ and $\mathcal{O}_{X,x}$ is Noetherian. The subset $\{x\}$ is irreducible and closed with generic point x, and X is locally of finite type over k, being a closed subscheme of $\mathbb{P}^N_k$, so theorem 2.6.12 gives $\dim \mathcal{O}_{X,x} = \dim X = n$. The local ring is regular by hypothesis, so [15, Characterizations of a Regular Local Ring] identifies its associated graded ring with the polynomial ring $k[u_1, \ldots, u_n]$, whence $\dim_k \mathfrak{m}_x^i/\mathfrak{m}_x^{i+1} = \binom{n+i-1}{n-1}$, the number of monomials of degree i in n variables. A trivialization of $\mathcal{O}_X(d)$ at x identifies $J^r_x(\mathcal{O}_X(d))$ with $\mathcal{O}_{X,x}/\mathfrak{m}_x^{r+1}$, of k-dimension $\sum_{i=0}^r \binom{n+i-1}{n-1}$. For $r = 1$ this is $1 + n$ and for $r = 2$ it is $1 + n + \binom{n+1}{2}$.

Over a field that is not algebraically closed the same arguments apply unchanged at k-rational points. At closed points with residue field larger than k no claim is made.

6.4 Ext Groups and Sheaf Ext

The cohomology groups $H^i(X, \mathscr{F})$ are the derived functors of $\Gamma(X, -) = \mathrm{Hom}_{\mathcal{O}_X}(\mathcal{O}_X, -)$. From this perspective, cohomology measures the failure of the global-section functor to be exact. But $\mathrm{Hom}_{\mathcal{O}_X}(\mathcal{O}_X, -)$ is a special case of $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$ for a general $\mathcal{O}_X$-module $\mathscr{F}$; the derived functors of this more general functor are the *Ext groups*. These carry strictly more information than cohomology alone: while $H^i(X, \mathscr{G})$ measures the obstruction to extending global sections of $\mathscr{G}$, the group $\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$ measures the obstruction to extending morphisms from $\mathscr{F}$ to $\mathscr{G}$. In Serre duality, Ext groups will serve as the natural "dual" objects to cohomology groups, and computing them on projective space will be the key step.

There are two kinds of Ext: the *global Ext* groups $\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$, which are abelian groups (or modules over the global sections ring), and the *sheaf Ext* $\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$, which is itself a sheaf on X. These are related by a spectral sequence, and in the most important case — when $\mathscr{F}$ is locally free of finite rank — this spectral sequence degenerates, reducing Ext computations to ordinary cohomology. This reduction is what makes the theory practical.

6.4.1 Global and Local Ext

Recall from example 5.1.3 that for $\mathcal{O}_X$-modules $\mathscr{F}$ and $\mathscr{G}$ on a ringed space $(X, \mathcal{O}_X)$, the *sheaf Hom* is the sheaf:

$$\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})(U) = \mathrm{Hom}_{\mathcal{O}_U}(\mathscr{F}|_U, \mathscr{G}|_U),$$

and the *global Hom* is:

$$\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = \Gamma(X, \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})) = \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})(X).$$

Both $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$ and $\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$ are left-exact functors. Since the category $\mathcal{O}_X$-**Mod** has enough injectives (by proposition 6.1.1), we may form their right derived functors:

Definition 6.4.1: Ext Groups for Sheaves

Let $(X, \mathcal{O}_X)$ be a ringed space and let $\mathscr{F}, \mathscr{G}$ be $\mathcal{O}_X$-modules.

1. The *global Ext groups* are the right derived functors of $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = R^i \mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)(\mathscr{G}).$$

   Concretely, choose an injective resolution $0 \to \mathscr{G} \to \mathscr{I}^\bullet$ and compute:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = h^i\big(\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{I}^\bullet)\big).$$

2. The *sheaf Ext* (or *local Ext*) functors are the right derived functors of $\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$:

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = R^i \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)(\mathscr{G}).$$

   Concretely, choose an injective resolution $0 \to \mathscr{G} \to \mathscr{I}^\bullet$ and compute:

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = h^i\big(\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{I}^\bullet)\big).$$

   This is a sheaf of $\mathcal{O}_X$-modules on X.

By convention, $\mathrm{Ext}^0_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = \mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$ and $\mathcal{E}xt^0_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$.

Note the asymmetry: we derive in the *second* variable. Resolving $\mathscr{F}$ by locally free sheaves computes the sheaf Ext, but not the global Ext[5]. Both Ext groups come equipped with the standard long exact sequences of derived functors:

Proposition 6.4.2: Long Exact Sequences for Ext

Let $(X, \mathcal{O}_X)$ be a ringed space and let $\mathscr{F}$ be an $\mathcal{O}_X$-module.

1. *(Covariant variable.)* A short exact sequence $0 \to \mathscr{G}' \to \mathscr{G} \to \mathscr{G}'' \to 0$ of $\mathcal{O}_X$-modules induces long exact sequences:

$$0 \to \mathrm{Hom}(\mathscr{F}, \mathscr{G}') \to \mathrm{Hom}(\mathscr{F}, \mathscr{G}) \to \mathrm{Hom}(\mathscr{F}, \mathscr{G}'') \xrightarrow{\delta} \mathrm{Ext}^1(\mathscr{F}, \mathscr{G}') \to \cdots$$

   and similarly for $\mathcal{E}xt$.

2. *(Contravariant variable.)* A short exact sequence $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ of $\mathcal{O}_X$-modules induces a long exact sequence:

$$0 \to \mathrm{Hom}(\mathscr{F}'', \mathscr{G}) \to \mathrm{Hom}(\mathscr{F}, \mathscr{G}) \to \mathrm{Hom}(\mathscr{F}', \mathscr{G}) \xrightarrow{\delta} \mathrm{Ext}^1(\mathscr{F}'', \mathscr{G}) \to \cdots$$

   and similarly for $\mathcal{E}xt$.

[5] If $\mathscr{F}$ admits a resolution $\mathcal{E}^\bullet \to \mathscr{F} \to 0$ by locally free sheaves of finite rank (e.g., if $\mathscr{F}$ is coherent on projective space or on a smooth projective variety), then $\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) \cong h^i(\mathit{Hom}_{\mathcal{O}_X}(\mathcal{E}^\bullet, \mathscr{G}))$ (proposition 6.4.3). The global $\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$ is assembled from these sheaves by theorem 6.4.8.

***Proof*:**
Part (1) is the standard long exact sequence of a right derived functor applied to a short exact sequence. For part (2), choose an injective resolution $0 \to \mathscr{G} \to \mathscr{I}^\bullet$. Each $\mathrm{Hom}(-, \mathscr{I}^p)$ is exact because $\mathscr{I}^p$ is injective, and each $\mathit{Hom}(-, \mathscr{I}^p)$ is exact because every $\mathscr{I}^p|_U$ is an injective $\mathcal{O}_U$-module (lemma 6.4.5). So $0 \to \mathrm{Hom}(\mathscr{F}'', \mathscr{I}^\bullet) \to \mathrm{Hom}(\mathscr{F}, \mathscr{I}^\bullet) \to \mathrm{Hom}(\mathscr{F}', \mathscr{I}^\bullet) \to 0$ is a short exact sequence of complexes, and so is its *Hom* analogue. Their long exact cohomology sequences are the ones claimed.

The next result shows that the sheaf Ext can be computed from a locally free resolution of the first argument. The global Ext cannot: on $X = \mathbb{P}^1_k$ the resolution $\mathcal{E}^0 = \mathcal{O}_X$ of $\mathscr{F} = \mathcal{O}_X$ gives $h^1(\mathrm{Hom}_{\mathcal{O}_X}(\mathcal{E}^\bullet, \mathcal{O}_X(-2))) = 0$, while $\mathrm{Ext}^1_{\mathcal{O}_X}(\mathcal{O}_X, \mathcal{O}_X(-2)) \cong H^1(X, \mathcal{O}_X(-2)) \cong k$ by corollary 6.4.9 and theorem 6.3.1.

Proposition 6.4.3: Computing Sheaf Ext via Locally Free Resolutions

Let $(X, \mathcal{O}_X)$ be a ringed space and let $\mathscr{F}, \mathscr{G}$ be $\mathcal{O}_X$-modules. Suppose $\mathscr{F}$ admits a resolution by locally free sheaves of finite rank:

$$\cdots \to \mathcal{E}^{-1} \to \mathcal{E}^0 \to \mathscr{F} \to 0.$$

Then:

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) \cong h^i\big(\mathit{Hom}_{\mathcal{O}_X}(\mathcal{E}^\bullet, \mathscr{G})\big).$$

In particular, if $\mathscr{F}$ is locally free of finite rank, then $\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = 0$ for all $i > 0$.

***Proof*:**
Both sides are δ-functors in $\mathscr{G}$: the right side because each $\mathit{Hom}_{\mathcal{O}_X}(\mathcal{E}^p, -)$ is exact, $\mathcal{E}^p$ being locally free of finite rank, so a short exact sequence in $\mathscr{G}$ gives a short exact sequence of complexes. They agree for $i = 0$, since $\mathit{Hom}_{\mathcal{O}_X}(-, \mathscr{G})$ is contravariant and left exact. Both vanish for $i > 0$ when $\mathscr{G} = \mathscr{I}$ is injective: the right side because $\mathit{Hom}_{\mathcal{O}_X}(-, \mathscr{I})$ is exact, each $\mathscr{I}|_U$ being an injective $\mathcal{O}_U$-module (lemma 6.4.5). So both are effaceable, hence universal, and they agree in every degree (*Homological Algebra* [25, An Effaceable δ-Functor Is Universal, A Universal δ-Functor Is Determined by Its Degree-Zero Part]). For $\mathscr{F}$ locally free of finite rank, take $\mathcal{E}^\bullet = [\mathscr{F}]$ concentrated in degree 0.

The sheaf Ext is a "local" invariant, while the global Ext is obtained by "assembling" the local data via global sections. The following result makes this precise at the stalk level:

Proposition 6.4.4: Stalks of Sheaf Ext

Let X be a Noetherian scheme, $\mathscr{F}$ a coherent $\mathcal{O}_X$-module, $\mathscr{G}$ any $\mathcal{O}_X$-module, and $x \in X$. Then there is a natural isomorphism:

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})_x \;\cong\; \mathrm{Ext}^i_{\mathcal{O}_{X,x}}(\mathscr{F}_x, \mathscr{G}_x).$$

In particular, if $\mathscr{F}$ is locally free, then $\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = 0$ for all $i > 0$ (since the stalks $\mathscr{F}_x$ are free $\mathcal{O}_{X,x}$-modules, and Ext over a local ring vanishes for free first arguments).

***Proof*:**
The question is local by proposition 6.4.6, so we may assume $X = \operatorname{Spec} A$ with A Noetherian. Then $\mathscr{F} = \widetilde{M}$ with M finitely generated, and a resolution of M by finitely generated free A-modules gives a resolution $\mathcal{E}^\bullet \to \mathscr{F} \to 0$ by free sheaves of finite rank, whose stalks at x form a free resolution of $\mathscr{F}_x$. By proposition 6.4.3 and the exactness of the stalk functor (proposition 1.2.22),

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F},\mathscr{G})_x = h^i\big(Hom_{\mathcal{O}_X}(\mathcal{E}^\bullet,\mathscr{G})\big)_x = h^i\big(Hom_{\mathcal{O}_X}(\mathcal{E}^\bullet,\mathscr{G})_x\big).$$

For $\mathcal{E}$ free of finite rank r, both $Hom_{\mathcal{O}_X}(\mathcal{E},\mathscr{G})_x$ and $\operatorname{Hom}_{\mathcal{O}_{X,x}}(\mathcal{E}_x,\mathscr{G}_x)$ are $\mathscr{G}_x^{\oplus r}$, so the right side is $h^i(\operatorname{Hom}_{\mathcal{O}_{X,x}}(\mathcal{E}^\bullet_x,\mathscr{G}_x)) = \operatorname{Ext}^i_{\mathcal{O}_{X,x}}(\mathscr{F}_x,\mathscr{G}_x)$.

Lemma 6.4.5: Injective Sheaves and Restriction

Let $(X,\mathcal{O}_X)$ be a ringed space and let $\mathscr{I}$ be an injective $\mathcal{O}_X$-module. For any open set $U \subseteq X$, the restriction $\mathscr{I}|_U$ is an injective $\mathcal{O}_U$-module.

***Proof*:**
Let $j : U \hookrightarrow X$ denote the inclusion. The functor $j_! : \mathcal{O}_U\textbf{-Mod} \to \mathcal{O}_X\textbf{-Mod}$ (extension by zero) is exact and left adjoint to the restriction functor j^* (by proposition 1.3.12). Hence j^* preserves injectives: for any monomorphism $\alpha : \mathscr{F} \hookrightarrow \mathscr{G}$ of $\mathcal{O}_U$-modules, the map

$$\operatorname{Hom}_{\mathcal{O}_U}(\mathscr{G},\mathscr{I}|_U) = \operatorname{Hom}_{\mathcal{O}_X}(j_!\mathscr{G},\mathscr{I}) \longrightarrow \operatorname{Hom}_{\mathcal{O}_X}(j_!\mathscr{F},\mathscr{I}) = \operatorname{Hom}_{\mathcal{O}_U}(\mathscr{F},\mathscr{I}|_U)$$

is surjective because $j_!\alpha$ is a monomorphism (exactness of $j_!$) and $\mathscr{I}$ is injective.

As a consequence, sheaf Ext behaves well with respect to restricting to open subsets:

Proposition 6.4.6: Open Subsets and Ext Groups

Let $(X,\mathcal{O}_X)$ be a ringed space, $\mathscr{F}$ and $\mathscr{G}$ be $\mathcal{O}_X$-modules, and $U \subseteq X$ an open subset. Then there is a natural isomorphism of sheaves on U:

$$\mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F},\mathscr{G})\big|_U \;\cong\; \mathcal{E}xt^i_{\mathcal{O}_U}(\mathscr{F}|_U,\mathscr{G}|_U).$$

***Proof*:**
Let $0 \to \mathscr{G} \to \mathscr{I}^\bullet$ be an injective resolution on X. By lemma 6.4.5, the restricted sequence $0 \to \mathscr{G}|_U \to \mathscr{I}^\bullet|_U$ is an injective resolution on U. Then:

$$\mathcal{E}xt^i_{\mathcal{O}_U}(\mathscr{F}|_U,\mathscr{G}|_U) = h^i\big(Hom_{\mathcal{O}_U}(\mathscr{F}|_U,\mathscr{I}^\bullet|_U)\big) = h^i\big(Hom_{\mathcal{O}_X}(\mathscr{F},\mathscr{I}^\bullet)|_U\big) = \mathcal{E}xt^i_{\mathcal{O}_X}(\mathscr{F},\mathscr{G})\big|_U,$$

where the middle equality uses the fact that $Hom_{\mathcal{O}_X}(\mathscr{F},\mathscr{I}^p)|_U = Hom_{\mathcal{O}_U}(\mathscr{F}|_U,\mathscr{I}^p|_U)$ (the sheaf Hom is computed open-set by open-set), and the last equality uses the exactness of restriction (which commutes with taking cohomology of a complex of sheaves).

6.4.2 The Local-to-Global Spectral Sequence

The global Ext and the sheaf Ext are related by the factorization:

$$\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -) = \Gamma(X, -) \circ \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -).$$

This is simply the statement that a global morphism $\mathscr{F} \to \mathscr{G}$ is a global section of the sheaf Hom. Both functors on the right are left exact, and this composition of functors is the standard setting for the Grothendieck spectral sequence[6]. For this spectral sequence to exist, we need $\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$ to send injective objects to $\Gamma(X, -)$-acyclic objects. The following key lemma establishes this:

Lemma 6.4.7: Sheaf Hom of Injectives is Flasque

Let $(X, \mathcal{O}_X)$ be a ringed space, $\mathscr{F}$ an $\mathcal{O}_X$-module, and $\mathscr{I}$ an injective $\mathcal{O}_X$-module. Then $\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{I})$ is a flasque sheaf.

***Proof*:**
Let $U \subseteq V$ be open subsets of X. We must show that the restriction map

$$\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{I})(V) = \mathrm{Hom}_{\mathcal{O}_V}(\mathscr{F}|_V, \mathscr{I}|_V) \longrightarrow \mathrm{Hom}_{\mathcal{O}_U}(\mathscr{F}|_U, \mathscr{I}|_U) = \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{I})(U)$$

is surjective. Let $\varphi : \mathscr{F}|_U \to \mathscr{I}|_U$ be a morphism of $\mathcal{O}_U$-modules. Let $j : U \hookrightarrow V$ be the inclusion. By the adjunction $j_! \dashv j^*$, the morphism φ corresponds to a morphism $j_!(\mathscr{F}|_U) \to \mathscr{I}|_V$. The natural map $j_!(\mathscr{F}|_U) \to \mathscr{F}|_V$ gives a monomorphism in the category of $\mathcal{O}_V$-modules. Since $\mathscr{I}|_V$ is injective (by lemma 6.4.5), the morphism $j_!(\mathscr{F}|_U) \to \mathscr{I}|_V$ extends to a morphism $\psi : \mathscr{F}|_V \to \mathscr{I}|_V$. By construction, $\psi|_U = \varphi$, so the restriction map is surjective.

Since flasque sheaves are $\Gamma(X, -)$-acyclic (by corollary 6.1.7), the hypotheses of the Grothendieck spectral sequence are satisfied. We obtain:

Theorem 6.4.8: Local-to-Global Ext Spectral Sequence

Let $(X, \mathcal{O}_X)$ be a ringed space and let $\mathscr{F}, \mathscr{G}$ be $\mathcal{O}_X$-modules. Then there is a convergent spectral sequence:

$$E_2^{p,q} = H^p\big(X, \mathcal{E}xt^q_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})\big) \implies \mathrm{Ext}^{p+q}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}).$$

This is natural in both $\mathscr{F}$ and $\mathscr{G}$.

***Proof*:**
This is the Grothendieck spectral sequence for the composite functor $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, -) = \Gamma(X, -) \circ \mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$. By lemma 6.4.7, the functor $\mathit{Hom}_{\mathcal{O}_X}(\mathscr{F}, -)$ sends injective $\mathcal{O}_X$-modules to flasque sheaves, which are $\Gamma(X, -)$-acyclic. The E_2-page of the Grothendieck spectral sequence is $R^p\Gamma \circ R^q \mathit{Hom}(\mathscr{F}, -) = H^p(X, \mathcal{E}xt^q(\mathscr{F}, -))$, and the abutment is $R^{p+q}(\Gamma \circ \mathit{Hom}(\mathscr{F}, -)) = \mathrm{Ext}^{p+q}(\mathscr{F}, -)$.

[6] See *Homological Algebra* [25] for the construction of the Grothendieck spectral sequence and the conditions under which it is defined.

The spectral sequence simplifies dramatically in the most important case:

Corollary 6.4.9: Degeneration for Locally Free Sheaves

Let $(X, \mathcal{O}_X)$ be a ringed space and let $\mathcal{L}$ be a locally free $\mathcal{O}_X$-module of finite rank, with dual $\mathcal{L}^\vee = \mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, \mathcal{O}_X)$. Then for all $\mathcal{O}_X$-modules $\mathscr{G}$ and all $i \geq 0$:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G}) \;\cong\; H^i(X,\, \mathcal{L}^\vee \otimes_{\mathcal{O}_X} \mathscr{G}).$$

In particular, setting $\mathcal{L} = \mathcal{O}_X$ recovers sheaf cohomology: $\mathrm{Ext}^i_{\mathcal{O}_X}(\mathcal{O}_X, \mathscr{G}) \cong H^i(X, \mathscr{G})$.

***Proof*:**
The vanishing $\mathcal{E}xt^q_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G}) = 0$ for $q > 0$ is local by proposition 6.4.6, so we may assume $\mathcal{L} = \mathcal{O}_X^{\oplus r}$. Then $\mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, -) = (-)^{\oplus r}$ is exact, so its right derived functors vanish in positive degrees.

The spectral sequence of theorem 6.4.8 collapses at the E_2-page: only the $q = 0$ row survives, giving:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G}) \;\cong\; H^i\big(X,\, \mathcal{E}xt^0_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G})\big) = H^i\big(X,\, \mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G})\big).$$

Finally, for a locally free sheaf of finite rank, the natural map $\mathcal{L}^\vee \otimes_{\mathcal{O}_X} \mathscr{G} \to \mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, \mathscr{G})$ is an isomorphism (this can be checked on stalks, where it reduces to the standard isomorphism $M^\vee \otimes N \xrightarrow{\sim} \mathrm{Hom}_R(M, N)$ for a free module M of finite rank over a ring R). Hence $\mathrm{Ext}^i(\mathcal{L}, \mathscr{G}) \cong H^i(X, \mathcal{L}^\vee \otimes \mathscr{G})$.

6.4.10 Remark: Why Locally Free is the Key Case The reader should pause to appreciate how much corollary 6.4.9 simplifies matters. For a general coherent sheaf $\mathscr{F}$, computing $\mathrm{Ext}^i(\mathscr{F}, \mathscr{G})$ requires either an injective resolution of $\mathscr{G}$ (typically enormous and non-explicit) or the full spectral sequence. But for a locally free $\mathscr{F}$ of finite rank, the Ext groups reduce to ordinary sheaf cohomology, which we can compute using the Čech machinery of section 6.1.1. This is not a marginal simplification: on a smooth projective variety, *every* coherent sheaf has a finite locally free resolution (proposition 5.3.37). So the sheaf Ext between any two coherent sheaves can be computed by resolving the first argument by locally free sheaves (proposition 6.4.3), and the global Ext is assembled from it by theorem 6.4.8. On projective space, the situation is even better: every coherent sheaf has a resolution by direct sums of twisted sheaves $\mathcal{O}(d)$ (by corollary 5.3.27), and the cohomology of these is known by theorem 6.3.1.

One can also give a direct proof of corollary 6.4.9 without invoking spectral sequences. Since this argument is short and illuminating, we record it:

***Proof*:**
(Alternative proof of corollary 6.4.9)
Since $\mathcal{L}$ is locally free of finite rank, the functor $\mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, -)$ is exact (checking on stalks: if $\mathcal{L}_x \cong \mathcal{O}^r_{X,x}$, then $\mathrm{Hom}_{\mathcal{O}_{X,x}}(\mathcal{O}^r_{X,x}, -) = (-)^r$ is exact). Hence $\mathit{Hom}_{\mathcal{O}_X}(\mathcal{L}, -)$ preserves injective resolutions up to exactness. Let $0 \to \mathscr{G} \to \mathscr{I}^\bullet$ be an injective resolution. Then:

$$0 \to \mathit{Hom}(\mathcal{L}, \mathscr{G}) \to \mathit{Hom}(\mathcal{L}, \mathscr{I}^\bullet)$$

is exact, and each $\mathit{Hom}(\mathcal{L}, \mathscr{I}^p)$ is flasque by lemma 6.4.7. Thus this is a flasque resolution of

$\mathit{Hom}(\mathcal{L}, \mathscr{G}) \cong \mathcal{L}^\vee \otimes \mathscr{G}$, and:

$$\mathrm{Ext}^i(\mathcal{L}, \mathscr{G}) = h^i(\mathrm{Hom}(\mathcal{L}, \mathscr{I}^\bullet)) = h^i(\Gamma(X, \mathit{Hom}(\mathcal{L}, \mathscr{I}^\bullet))) = H^i(X, \mathcal{L}^\vee \otimes \mathscr{G}).$$

6.4.3 Computations on Projective Space

We now combine the degeneration result with the computation of twisted sheaf cohomology (theorem 6.3.1) to obtain explicit Ext groups on projective space. These calculations are the foundation for Serre duality.

Proposition 6.4.11: Ext of Twisted Sheaves on Projective Space

Let R be a Noetherian ring, $X = \mathbb{P}^n_R$ with $n \geq 1$, and $a, b \in \mathbb{Z}$. Then:

$$\mathrm{Ext}^i_{\mathcal{O}_X}\big(\mathcal{O}_X(a),\, \mathcal{O}_X(b)\big) \;\cong\; H^i\big(X,\, \mathcal{O}_X(b-a)\big),$$

and hence by theorem 6.3.1:

$$\mathrm{Ext}^i_{\mathcal{O}_X}\big(\mathcal{O}_X(a),\, \mathcal{O}_X(b)\big) \;\cong\; \begin{cases} \big(R[x_0, \ldots, x_n]\big)_{b-a} & i = 0,\ b-a \geq 0, \\ R^{\binom{a-b-1}{n}} & i = n,\ b-a \leq -(n+1), \\ 0 & \text{otherwise.} \end{cases}$$

In particular:

1. $\mathrm{Ext}^i(\mathcal{O}_X, \mathcal{O}_X(d)) = H^i(X, \mathcal{O}_X(d))$ for all i, d.
2. $\mathrm{Hom}(\mathcal{O}_X(a), \mathcal{O}_X(b)) = 0$ if $b < a$, and is a free R-module of rank $\binom{b-a+n}{n}$ if $b \geq a$.
3. $\mathrm{Ext}^n(\mathcal{O}_X(a), \mathcal{O}_X(b)) \neq 0$ only when $b - a \leq -(n+1)$, i.e. $a \geq b + n + 1$.

***Proof*:**
The line bundle $\mathcal{O}_X(a)$ is locally free of rank 1, with dual $\mathcal{O}_X(a)^\vee \cong \mathcal{O}_X(-a)$ (by proposition 5.3.8). Hence by corollary 6.4.9:

$$\mathrm{Ext}^i(\mathcal{O}_X(a), \mathcal{O}_X(b)) \cong H^i(X, \mathcal{O}_X(-a) \otimes \mathcal{O}_X(b)) = H^i(X, \mathcal{O}_X(b-a)),$$

where we used $\mathcal{O}_X(c) \otimes \mathcal{O}_X(d) \cong \mathcal{O}_X(c+d)$. The explicit values follow from theorem 6.3.1. The rank in the $i = n$ case is the number of "all-negative" monomials $x_0^{l_0} \cdots x_n^{l_n}$ of total degree $b - a$ with each $l_j < 0$, which by the substitution $l_j = -m_j - 1$ (so $m_j \geq 0$ and $\sum m_j = a - b - n - 1$) equals $\binom{a-b-1}{n}$.

Now let us see how to handle sheaves that are not themselves line bundles but can be resolved by them:

Example 6.4.12: Ext Computations on Projective Space

1. *Self-Ext of the structure sheaf.* Taking $a = b = 0$ in proposition 6.4.11:

$$\mathrm{Ext}^i(\mathcal{O}_X, \mathcal{O}_X) \cong H^i(X, \mathcal{O}_X) = \begin{cases} R & i = 0, \\ 0 & i > 0. \end{cases}$$

   This says that the structure sheaf has no non-trivial self-extensions, which is consistent with $\mathcal{O}_X$ being "rigid" as a line bundle on projective space.

2. *The dualizing line bundle.* Let k be a field and $X = \mathbb{P}^n_k$. We shall see in the next section that the *dualizing sheaf* of X is $\omega_X = \mathcal{O}_X(-n-1)$ (proposition 6.5.3). Note the "dual" behaviour: by proposition 6.4.11,

$$\mathrm{Ext}^n(\mathcal{O}_X(d), \omega_X) = H^n(X, \mathcal{O}_X(-n-1-d)) \cong \begin{cases} k^{\binom{d+n}{n}} & d \geq 0, \\ 0 & d < 0, \end{cases}$$

   and for $d \geq 0$ this is the only nonzero Ext from $\mathcal{O}_X(d)$ to ω_X. Meanwhile $H^0(X, \mathcal{O}_X(d)) \cong k^{\binom{d+n}{n}}$ for $d \geq 0$, so the dimensions agree, and the *pairing* between $H^0(X, \mathcal{O}_X(d))$ and $\mathrm{Ext}^n(\mathcal{O}_X(d), \omega_X)$ is perfect by theorem 6.3.1(3). For $d = 0$:

$$\mathrm{Ext}^n(\mathcal{O}_X, \omega_X) = H^n(X, \omega_X) \cong k,$$

   which will serve as the "trace" isomorphism $H^n(X, \omega_X) \xrightarrow{\sim} k$ in the duality theorem (theorem 6.5.5).

3. *Ext from the cotangent sheaf (using the Euler sequence).* Let k be a field and $X = \mathbb{P}^n_k$. The Euler sequence (by theorem 5.5.19) is:

$$0 \longrightarrow \Omega_{X/k} \longrightarrow \mathcal{O}_X(-1)^{\oplus(n+1)} \longrightarrow \mathcal{O}_X \longrightarrow 0.$$

   Although $\Omega_{X/k}$ is locally free (of rank n), let us use this short exact sequence to compute $\mathrm{Ext}^i(\Omega_{X/k}, \mathcal{O}_X)$ via the long exact sequence in the *contravariant* variable (proposition 6.4.2(2)):

$$\cdots \to \mathrm{Ext}^i(\mathcal{O}_X, \mathcal{O}_X) \to \mathrm{Ext}^i(\mathcal{O}_X(-1)^{n+1}, \mathcal{O}_X) \to \mathrm{Ext}^i(\Omega_{X/k}, \mathcal{O}_X) \to \mathrm{Ext}^{i+1}(\mathcal{O}_X, \mathcal{O}_X) \to \cdots$$

   By proposition 6.4.11:

$$\mathrm{Ext}^i(\mathcal{O}_X(-1)^{n+1}, \mathcal{O}_X) \cong H^i(X, \mathcal{O}_X(1))^{n+1},$$

   which is $(k^{n+1})^{n+1}$ for $i = 0$ and zero for $0 < i < n$. Also, $\mathrm{Ext}^i(\mathcal{O}_X, \mathcal{O}_X) = k$ for $i = 0$ and zero for $i > 0$.

   For $i = 0$, the long exact sequence gives:

$$0 \to \mathrm{Hom}(\mathcal{O}_X, \mathcal{O}_X) \to \mathrm{Hom}(\mathcal{O}_X(-1)^{n+1}, \mathcal{O}_X) \to \mathrm{Hom}(\Omega, \mathcal{O}_X) \to 0$$

   so $\mathrm{Hom}(\Omega_{X/k}, \mathcal{O}_X) \cong k^{(n+1)^2}/k \cong k^{n^2+2n}$. On the other hand, by corollary 6.4.9, $\mathrm{Hom}(\Omega, \mathcal{O}_X) = H^0(X, \Omega^\vee) = H^0(X, \mathcal{T}_X)$, where $\mathcal{T}_X$ is the tangent sheaf. This is the space of global vector fields on $\mathbb{P}^n_k$, which has dimension $n^2 + 2n = \dim_k \mathfrak{gl}_{n+1}(k) - 1$: the global vector fields on projective space are precisely those induced by the action of GL_{n+1}, modulo scalars.

4. *Ext between non-locally-free sheaves (sketch).* Let $X = \mathbb{P}^2_k$ and let $C \hookrightarrow X$ be a smooth plane curve of degree d, with ideal sheaf $\mathscr{I}_C$. By corollaries 5.3.15 and 5.3.17, $\mathscr{I}_C$ is the sheaf associated to a principal homogeneous ideal $(f) \subseteq S = k[x_0, x_1, x_2]$ with $\deg f = d$. Multiplication by f is an isomorphism of graded modules $S(-d) \to (f)$, so $\mathscr{I}_C \cong \widetilde{S(-d)} \cong \mathcal{O}_X(-d)$ by proposition 5.3.8(2). The short exact sequence $0 \to \mathscr{I}_C \to \mathcal{O}_X \to \mathcal{O}_C \to 0$ therefore becomes
$$0 \to \mathcal{O}_X(-d) \to \mathcal{O}_X \to \mathcal{O}_C \to 0.$$
This is a locally free resolution of $\mathcal{O}_C$ as an $\mathcal{O}_X$-module (of length 1). The long exact sequence in the contravariant variable (proposition 6.4.2(2)), with the Ext groups out of $\mathcal{O}_X$ and $\mathcal{O}_X(-d)$ computed by corollary 6.4.9, reads
$$0 \to \operatorname{Hom}(\mathcal{O}_C, \mathscr{G}) \to H^0(X, \mathscr{G}) \xrightarrow{\cdot f} H^0(X, \mathscr{G}(d)) \to \operatorname{Ext}^1(\mathcal{O}_C, \mathscr{G}) \to H^1(X, \mathscr{G}) \xrightarrow{\cdot f} H^1(X, \mathscr{G}(d)) \to \cdots$$
for any $\mathcal{O}_X$-module $\mathscr{G}$. Taking $\mathscr{G} = \omega_X = \mathcal{O}_X(-3)$, the group $H^1(X, \mathcal{O}_X(-3))$ vanishes by theorem 6.3.1(4), so $\operatorname{Ext}^1(\mathcal{O}_C, \omega_X) = \operatorname{coker}\big(H^0(X, \mathcal{O}(-3)) \to H^0(X, \mathcal{O}(d-3))\big)$. For $d \geq 3$, this is a k-vector space of dimension $\binom{d-1}{2}$, which (as we will verify via Serre duality) equals $\dim_k H^0(C, \omega_C) = g$, the genus of the curve. This is not a coincidence: Serre duality will identify $\operatorname{Ext}^1(\mathcal{O}_C, \omega_X)$ with $H^0(C, \omega_C)$ via the adjunction between the closed embedding and the ambient duality.

Proposition 6.4.13: Finiteness of Ext on Projective Schemes

Let X be a projective scheme over a Noetherian ring R, and let $\mathscr{F}$ and $\mathscr{G}$ be coherent sheaves on X. Then:

1. Each $\mathcal{E}xt^q_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$ is a coherent sheaf on X.
2. Each $\operatorname{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G})$ is a finitely generated R-module.

***Proof*:**
(1) This is a local statement: on any affine open $U = \operatorname{Spec} A$ of X, the sheaves $\mathscr{F}|_U$ and $\mathscr{G}|_U$ correspond to finitely generated A-modules M and N (by corollary 5.1.12), and the sheaf Ext on U is:
$$\mathcal{E}xt^q_{\mathcal{O}_U}(\widetilde{M}, \widetilde{N}) \cong \widetilde{\operatorname{Ext}^q_A(M, N)}$$
(this follows from proposition 6.4.6 and the standard computation of Ext over a Noetherian ring via a free resolution of the finitely generated module M; each $\operatorname{Ext}^q_A(M, N)$ is finitely generated). Hence $\mathcal{E}xt^q(\mathscr{F}, \mathscr{G})$ is coherent.

(2) The local-to-global spectral sequence (theorem 6.4.8) gives $H^p(X, \mathcal{E}xt^q(\mathscr{F}, \mathscr{G})) \Rightarrow \operatorname{Ext}^{p+q}(\mathscr{F}, \mathscr{G})$. Since $\mathcal{E}xt^q(\mathscr{F}, \mathscr{G})$ is coherent and X is projective over a Noetherian ring, each cohomology group $H^p(X, \mathcal{E}xt^q(\mathscr{F}, \mathscr{G}))$ is a finitely generated R-module[a]. Since the E_2-page consists of finitely generated R-modules and the spectral sequence converges, the abutment $\operatorname{Ext}^i(\mathscr{F}, \mathscr{G})$ is finitely generated.

[a] This uses the finiteness theorem for cohomology of coherent sheaves on projective schemes, which we will prove in section 6.6 (see theorem 6.6.6(1)). No circularity arises: the finiteness theorem depends on the twisted sheaf computation (theorem 6.3.1) and the "coherent sheaves are quotients of twisted free sheaves" result (corollary 5.3.27), both of which are already established.

6.4.14 Remark: What the Spectral Sequence Encodes The local-to-global spectral sequence should be thought of as expressing the passage from local to global information for morphisms between sheaves. On the E_2-page:

- The *bottom row* $E_2^{p,0} = H^p(X, Hom(\mathscr{F}, \mathscr{G}))$ captures the "global extension classes that are locally trivial." When $\mathscr{F}$ is locally free of finite rank, this is the only nonzero row, and the spectral sequence degenerates.
- The *left column* $E_2^{0,q} = \Gamma(X, \mathcal{E}xt^q(\mathscr{F}, \mathscr{G}))$ captures the "local extension classes that are globally defined." These are the obstructions arising from the local algebra (e.g., the singularities of $\mathscr{F}$ or the non-regularity of the local rings).

The differentials in the spectral sequence measure the interaction between these two types of obstruction. For smooth projective varieties with locally free sheaves of finite rank, all the interesting information is in the bottom row — this is why Serre duality can be stated purely in terms of cohomology groups, without mentioning Ext.

6.5 Serre Duality Theorem

In classical topology, Poincaré duality asserts that for a compact connected oriented manifold M of dimension n, the singular cohomology groups satisfy $H^i(M;\mathbb{R}) \cong H^{n-i}(M;\mathbb{R})^*$. The duality is mediated by integration: the cup product $H^i \times H^{n-i} \to H^n$, followed by integration over the fundamental class $H^n(M;\mathbb{R}) \xrightarrow{\sim} \mathbb{R}$, gives a perfect pairing. In Kähler geometry it takes the refined form of Hodge duality: for a compact Kähler manifold X of complex dimension n, $H^{p,q}(X) \cong H^{n-p,\,n-q}(X)^*$, with the pairing mediated by the wedge product of (p,q)-forms followed by integration of the resulting top form.

Serre duality is the algebraic analogue. For a smooth projective variety X of dimension n over an algebraically closed field k, the role of the top differential form is played by the *canonical sheaf* $\omega_X = \det \Omega_{X/k}$, and the role of integration is played by a "trace" isomorphism $H^n(X, \omega_X) \xrightarrow{\sim} k$. The resulting duality

$$H^i(X, \mathscr{F}) \;\cong\; H^{n-i}(X,\, \mathscr{F}^\vee \otimes \omega_X)^*$$

for locally free $\mathscr{F}$ of finite rank is the central structural result in the cohomology of algebraic varieties. It constrains the Hilbert polynomial, underpins the Riemann–Roch theorem, and governs the geometry of linear systems.

We first define the dualizing sheaf of a proper scheme and prove the duality theorem for projective space, where the dualizing sheaf is simply $\mathcal{O}(-n-1)$ and the computations are completely explicit. We then extend the theorem to projective schemes, smooth projective varieties among them.

6.5.1 Duality on Projective Space

The twisted sheaf computation (theorem 6.3.1) already contains the seed of duality: the perfect pairing of part (3) shows that $H^0(X, \mathcal{O}(d))$ and $H^n(X, \mathcal{O}(-d-n-1))$ are dual to each other. Our task is to recognize this as the $i = 0$ case of a more general duality, then extend to all i and to all coherent sheaves.

The first step is to abstract the key property of $\mathcal{O}(-n-1)$ that makes the pairing work:

Definition 6.5.1: Dualizing Sheaf

Let X be a proper scheme of dimension n over a field k. A *dualizing sheaf* for X is a coherent sheaf ω_X on X together with a k-linear map $t : H^n(X, \omega_X) \to k$, called the *trace map*, such that for every coherent sheaf $\mathscr{F}$ on X, the natural pairing:

$$\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \omega_X) \times H^n(X, \mathscr{F}) \xrightarrow{\text{apply } H^n} H^n(X, \omega_X) \xrightarrow{t} k$$

is a perfect pairing of finite-dimensional k-vector spaces. In other words, the induced map

$$\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \omega_X) \xrightarrow{\sim} H^n(X, \mathscr{F})^*$$

is an isomorphism, where $(-)^*$ denotes the k-linear dual.
Equivalently, ω_X *represents* the functor $\mathscr{F} \mapsto H^n(X, \mathscr{F})^*$ on the category of coherent sheaves on X.

Proposition 6.5.2: Uniqueness of the Dualizing Sheaf

If a dualizing sheaf exists, it is unique up to unique isomorphism. That is, if (ω_X, t) and (ω'_X, t') are two dualizing sheaves for X, then there is a unique isomorphism $\varphi : \omega_X \xrightarrow{\sim} \omega'_X$ such that $t = t' \circ H^n(X, \varphi)$.

***Proof*:**
Both ω_X and ω'_X represent the same functor $\mathscr{F} \mapsto H^n(X, \mathscr{F})^*$. By the Yoneda lemma (theorem 0.4.22), any two representing objects are uniquely isomorphic via an isomorphism that intertwines the representing natural transformations.

Proposition 6.5.3: Dualizing Sheaf of Projective Space

Let k be a field and $X = \mathbb{P}^n_k$ with $n \geq 1$. The twisted sheaf $\omega_X = \mathcal{O}_X(-n-1)$ is a dualizing sheaf for X, with trace map $t : H^n(X, \mathcal{O}(-n-1)) \xrightarrow{\sim} k$ being the isomorphism that sends the class of $x_0^{-1}x_1^{-1}\cdots x_n^{-1}$ to $1 \in k$.

***Proof*:**
This is precisely the content of theorem 6.3.1(3) (with $R = k$). Indeed, that theorem establishes that for each $e \geq 0$, the multiplication pairing:

$$H^0(X, \mathcal{O}(e)) \times H^n(X, \mathcal{O}(-e-n-1)) \longrightarrow H^n(X, \mathcal{O}(-n-1)) \cong k$$

is a perfect pairing of finite-dimensional k-vector spaces. Since $\mathrm{Hom}(\mathcal{O}(d), \mathcal{O}(-n-1)) \cong H^0(X, \mathcal{O}(-d-n-1))$ (by corollary 6.4.9), taking $e = -d-n-1$ gives $\mathrm{Hom}(\mathcal{O}(d), \omega_X) \cong H^n(X, \mathcal{O}(d))^*$ for every $d \leq -n-1$. When $d > -n-1$, both sides are zero (the left because $H^0(X, \mathcal{O}(-d-n-1)) = 0$, the right by the summary table of theorem 6.3.1).

For a general coherent $\mathscr{F}$, one reduces to line bundles by choosing a presentation of $\mathscr{F}$ by direct sums of $\mathcal{O}(d)$'s (using corollary 5.3.27) and comparing the two sides via the five lemma. The

argument is identical to Step 2 of the proof of theorem 6.5.5 below, so we defer the details.

The dualizing sheaf definition captures the "$i = 0$" case of duality: it says $\mathrm{Hom}(\mathscr{F}, \omega) = \mathrm{Ext}^0(\mathscr{F}, \omega) \cong H^n(X, \mathscr{F})^*$. On $\mathbb{P}^n_k$, and more generally on a Cohen-Macaulay equidimensional projective X, Serre duality extends this to all Ext groups. To state it, we need the *Yoneda pairing*:

6.5.4 The Yoneda Pairing For $\mathcal{O}_X$-modules $\mathscr{F}, \mathscr{G}, \mathscr{H}$, the *Yoneda product* ([95, Tag 06XP]) is a bilinear map:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) \times \mathrm{Ext}^j_{\mathcal{O}_X}(\mathscr{H}, \mathscr{F}) \longrightarrow \mathrm{Ext}^{i+j}_{\mathcal{O}_X}(\mathscr{H}, \mathscr{G}).$$

This is defined by splicing extensions: an element of $\mathrm{Ext}^i(\mathscr{F}, \mathscr{G})$ is represented by an equivalence class of i-fold extensions $0 \to \mathscr{G} \to \mathcal{E}^{i-1} \to \cdots \to \mathcal{E}^0 \to \mathscr{F} \to 0$, and the Yoneda product splices two such sequences together.
Now, since $H^j(X, \mathscr{F}) = \mathrm{Ext}^j_{\mathcal{O}_X}(\mathcal{O}_X, \mathscr{F})$, the Yoneda product specializes to give a pairing:

$$\mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \omega_X) \times H^{n-i}(X, \mathscr{F}) \longrightarrow H^n(X, \omega_X) \xrightarrow{t} k.$$

This defines for each i a natural map:

$$\eta^i_{\mathscr{F}} : \mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \omega_X) \longrightarrow H^{n-i}(X, \mathscr{F})^*.$$

When $\mathscr{F}$ is locally free of finite rank, $\mathrm{Ext}^i(\mathscr{F}, \omega_X) \cong H^i(X, \mathscr{F}^\vee \otimes \omega_X)$ by corollary 6.4.9, and the Yoneda pairing reduces to the cup product:

$$H^i(X, \mathscr{F}^\vee \otimes \omega_X) \times H^{n-i}(X, \mathscr{F}) \xrightarrow{\cup} H^n(X, \mathscr{F}^\vee \otimes \omega_X \otimes \mathscr{F}) \xrightarrow{\mathrm{ev}\otimes\mathrm{id}} H^n(X, \omega_X) \xrightarrow{t} k,$$

where $\mathrm{ev} : \mathscr{F}^\vee \otimes \mathscr{F} \to \mathcal{O}_X$ is the evaluation map. In the Čech framework, the cup product of cochains $\alpha \in C^p(\mathcal{U}, \mathscr{F}^\vee \otimes \omega_X)$ and $\beta \in C^q(\mathcal{U}, \mathscr{F})$ is defined by:

$$(\alpha \cup \beta)_{i_0,\ldots,i_{p+q}} = \alpha_{i_0,\ldots,i_p} \otimes \beta_{i_p,\ldots,i_{p+q}}\big|_{U_{i_0,\ldots,i_{p+q}}},$$

followed by the evaluation and trace maps.

Theorem 6.5.5: Duality for Projective Space

Let k be a field, $X = \mathbb{P}^n_k$ with $n \geq 1$, and $\omega_X = \mathcal{O}_X(-n-1)$. Then for every coherent sheaf $\mathscr{F}$ on X, the Yoneda pairing induces isomorphisms:

$$\eta^i_{\mathscr{F}} : \mathrm{Ext}^i_{\mathcal{O}_X}(\mathscr{F}, \omega_X) \xrightarrow{\sim} H^{n-i}(X, \mathscr{F})^* \qquad \text{for all } 0 \leq i \leq n.$$

Both sides vanish for $i > n$.

***Proof*:**
We verify the theorem in two stages: first for line bundles, then for all coherent sheaves.

Step 1: Verification for $\mathscr{F} = \mathcal{O}_X(d)$. By corollary 6.4.9, $\mathrm{Ext}^i(\mathcal{O}(d), \omega_X) \cong H^i(X, \mathcal{O}(-d-n-1))$. The Yoneda pairing (which reduces to the cup product for locally free sheaves of finite rank)

gives a bilinear map:

$$H^i(X, \mathcal{O}(-d-n-1)) \times H^{n-i}(X, \mathcal{O}(d)) \longrightarrow H^n(X, \mathcal{O}(-n-1)) \xrightarrow{t} k.$$

We must show this pairing is perfect for each i. By theorem 6.3.1(4), the intermediate cohomology vanishes: $H^j(X, \mathcal{O}(m)) = 0$ for $0 < j < n$ and all $m \in \mathbb{Z}$. So for $0 < i < n$, both $H^i(X, \mathcal{O}(-d-n-1))$ and $H^{n-i}(X, \mathcal{O}(d))$ are zero and the pairing is trivially perfect (both sides vanish). For $i > n$, both $H^i(X, \mathcal{O}(-d-n-1))$ (by theorem 6.2.5) and $H^{n-i}(X, \mathcal{O}(d))$ are zero.

For $i = 0$: the pairing is $H^0(X, \mathcal{O}(-d-n-1)) \times H^n(X, \mathcal{O}(d)) \to k$. If $-d-n-1 < 0$ (i.e. $d > -(n+1)$), then $H^0 = 0$ and $H^n = 0$, and the pairing is perfect. If $-d-n-1 \geq 0$ (i.e. $d \leq -(n+1)$), this is the pairing of theorem 6.3.1(3) (with the degree parameter set to $-d-n-1 \geq 0$), which is perfect.

For $i = n$: by symmetry, the pairing is $H^n(X, \mathcal{O}(-d-n-1)) \times H^0(X, \mathcal{O}(d)) \to k$. If $d < 0$, both sides vanish. If $d \geq 0$, this is again the perfect pairing of theorem 6.3.1(3) with the two factors interchanged (the pairing is symmetric up to the sign conventions in the cup product, which can be checked to be trivial in this case since all sheaves involved are line bundles).

Hence $\eta^i_{\mathcal{O}(d)}$ is an isomorphism for all i and all $d \in \mathbb{Z}$. By the additivity of Ext and cohomology in direct sums, the same holds for $\mathscr{F} = \bigoplus_j \mathcal{O}(d_j)$ (any finite direct sum of line bundles).

Step 2: Extension to all coherent sheaves. Let $\mathscr{F}$ be an arbitrary coherent sheaf on $X = \mathbb{P}^n_k$. By theorem 5.3.26, $\mathscr{F}(q)$ is generated by finitely many global sections for some $q \geq 1$, which gives a surjection $\mathcal{E}_0 = \mathcal{O}(-q)^{\oplus r} \twoheadrightarrow \mathscr{F}$ with coherent kernel $\mathcal{K}$. For $j > 0$, theorem 6.3.1 gives $\operatorname{Ext}^j(\mathcal{E}_0, \omega_X) \cong H^j(X, \mathcal{O}(q-n-1))^{\oplus r} = 0$ and $H^{n-j}(X, \mathcal{E}_0) = 0$, since $q \geq 1$. We prove that $\eta^i_{\mathscr{F}}$ is an isomorphism for every coherent $\mathscr{F}$ by induction on i.

Base case ($i = 0$): Applying the same construction to $\mathcal{K}$ gives a presentation $\mathcal{E}_1 \to \mathcal{E}_0 \to \mathscr{F} \to 0$ by finite direct sums of line bundles. The functor $\operatorname{Hom}(-, \omega_X)$ is left exact, and $H^n(X, -)$ is right exact because H^{n+1} vanishes on X (theorem 6.2.5), so the rows $0 \to \operatorname{Hom}(\mathscr{F}, \omega_X) \to \operatorname{Hom}(\mathcal{E}_0, \omega_X) \to \operatorname{Hom}(\mathcal{E}_1, \omega_X)$ and $0 \to H^n(X, \mathscr{F})^* \to H^n(X, \mathcal{E}_0)^* \to H^n(X, \mathcal{E}_1)^*$ are exact. The maps η^0 form a morphism between them, which is an isomorphism on the $\mathcal{E}_j$ by Step 1, hence also on $\mathscr{F}$.

Inductive step: Suppose $i \geq 1$ and that η^{i-1} is an isomorphism for every coherent sheaf. The short exact sequence $0 \to \mathcal{K} \to \mathcal{E}_0 \to \mathscr{F} \to 0$ induces two long exact sequences: one from $\operatorname{Ext}^*(-, \omega_X)$ (contravariant in the first argument) and one from $H^{n-*}(X, -)^*$ (the dual of the covariant cohomology sequence, which is exact since dualization is exact over a field). The naturality of the Yoneda pairing ensures that the maps η^i assemble into a morphism between these long exact sequences:

$$\begin{array}{ccccccc}
\operatorname{Ext}^{i-1}(\mathcal{E}_0, \omega) & \longrightarrow & \operatorname{Ext}^{i-1}(\mathcal{K}, \omega) & \longrightarrow & \operatorname{Ext}^i(\mathscr{F}, \omega) & \longrightarrow & \operatorname{Ext}^i(\mathcal{E}_0, \omega) = 0 \\
\sim\downarrow{\scriptstyle \eta^{i-1}_{\mathcal{E}_0}} & & \sim\downarrow{\scriptstyle \eta^{i-1}_{\mathcal{K}}} & & \downarrow{\scriptstyle \eta^i_{\mathscr{F}}} & & \\
H^{n-i+1}(\mathcal{E}_0)^* & \longrightarrow & H^{n-i+1}(\mathcal{K})^* & \longrightarrow & H^{n-i}(\mathscr{F})^* & \longrightarrow & H^{n-i}(\mathcal{E}_0)^* = 0
\end{array}$$

The two left vertical maps are isomorphisms by the inductive hypothesis, and the right-hand terms vanish by the choice of q. So $\eta^i_{\mathscr{F}}$ is the map induced on the cokernels of the first horizontal maps, and it is an isomorphism, completing the induction.

Vanishing for $i > n$: $H^{n-i}(X, \mathscr{F}) = 0$ for $n - i < 0$, so $\operatorname{Ext}^i(\mathscr{F}, \omega_X) = 0$ for $i > n$ because $\eta^i_{\mathscr{F}}$ is an isomorphism.

Example 6.5.6: Serre Duality on Projective Space

1. *Structure sheaf.* For $\mathscr{F} = \mathcal{O}_X$ on $X = \mathbb{P}^n_k$:
$$\mathrm{Ext}^i(\mathcal{O}_X, \mathcal{O}(-n-1)) \cong H^i(X, \mathcal{O}(-n-1)) \cong H^{n-i}(X, \mathcal{O}_X)^*.$$
For $i = n$, this gives $H^n(X, \mathcal{O}(-n-1)) \cong H^0(X, \mathcal{O}_X)^* = k$. For $0 < i < n$, both sides are zero.

2. *Cotangent sheaf on $\mathbb{P}^2$.* Let $X = \mathbb{P}^2_k$ and $\mathscr{F} = \Omega_{X/k}$. Since Ω is locally free of rank 2, duality gives:
$$H^i(X, \Omega^\vee \otimes \mathcal{O}(-3)) \cong H^{2-i}(X, \Omega)^*.$$
Now $\Omega^\vee = \mathcal{T}_X$, the tangent sheaf, and $\mathcal{T}_X \cong \mathcal{T}_{\mathbb{P}^2}$. From the dual of the Euler sequence (theorem 5.5.19):
$$0 \to \mathcal{O}_X \to \mathcal{O}_X(1)^3 \to \mathcal{T}_X \to 0,$$
we get $\mathcal{T}_X \otimes \mathcal{O}(-3) \cong \mathcal{T}_X(-3)$, whose cohomology can be computed from the twisted Euler sequence. In particular:
$$H^0(X, \Omega) \cong H^2(X, \mathcal{T}_X(-3))^* = 0$$
(no nonzero global 1-forms on $\mathbb{P}^2$), the analogue for $\mathbb{P}^2$ of the computation for $\mathbb{P}^1$ in Example 6.1.13(1).

3. *Skyscraper sheaves and residues.* Let $p \in \mathbb{P}^1_k$ be a k-rational point and let $\mathscr{F} = \kappa(p)$ be the skyscraper sheaf at p. Then $H^0(X, \kappa(p)) = k$ and $H^i(X, \kappa(p)) = 0$ for $i > 0$ (a skyscraper sheaf has no higher cohomology). Serre duality gives:
$$\mathrm{Ext}^1(\kappa(p), \mathcal{O}(-2)) \cong H^0(X, \kappa(p))^* = k, \qquad \mathrm{Hom}(\kappa(p), \mathcal{O}(-2)) = 0.$$
The non-trivial Ext group $\mathrm{Ext}^1(\kappa(p), \omega_X) \cong k$ has a concrete interpretation: the short exact sequence $0 \to \mathcal{O}(-2) \to \mathcal{O}(-1) \to \kappa(p) \to 0$ (where the first map is multiplication by the linear form vanishing at p, suitably twisted) represents a generator. This is the algebraic avatar of the *residue map* at p: the element of $\mathrm{Ext}^1(\kappa(p), \omega)$ corresponds to extracting the residue of a meromorphic differential form at p.

6.5.2 Duality for Projective Schemes

We now extend Serre duality from projective space to projective schemes. The key new ingredient is identifying the correct dualizing sheaf. For smooth varieties, this is the canonical sheaf. For a singular projective scheme the dualizing sheaf still exists but need not be invertible, and duality in positive degrees needs X to be Cohen-Macaulay and equidimensional.

Recall from definition 5.5.28 that for a smooth variety X of dimension n over a field k, the *canonical sheaf* (or *canonical bundle*) is:
$$\omega_X = \det \Omega_{X/k} = \bigwedge^n \Omega_{X/k},$$
the top exterior power of the sheaf of differentials. This is an invertible sheaf. For $X = \mathbb{P}^n_k$, the computation of theorem 5.5.19 shows that $\omega_{\mathbb{P}^n} \cong \mathcal{O}_{\mathbb{P}^n}(-n-1)$, consistent with our earlier identification.

For a smooth projective variety X of dimension n embedded in $\mathbb{P}^N_k$ as a closed subscheme, the canonical sheaf is related to $\omega_{\mathbb{P}^N}$ by the *adjunction formula*. Recall from proposition 5.5.18 that if $X \hookrightarrow \mathbb{P}^N$ is a regular embedding of codimension $c = N - n$, there is an exact sequence:

$$\mathscr{I}_X/\mathscr{I}_X^2 \longrightarrow \Omega_{\mathbb{P}^N}\big|_X \longrightarrow \Omega_X \longrightarrow 0,$$

where $\mathscr{I}_X$ is the ideal sheaf of X. Taking top exterior powers (and using that the conormal sheaf $\mathcal{N}^\vee_{X/\mathbb{P}^N} = \mathscr{I}_X/\mathscr{I}_X^2$ is locally free of rank c for a regular embedding), one obtains:

Proposition 6.5.7: Adjunction Formula in Projective Space

Let X be a smooth closed subvariety of dimension n in $\mathbb{P}^N_k$, with codimension $c = N - n$. Then:

$$\omega_X \;\cong\; \omega_{\mathbb{P}^N}\big|_X \otimes \det\big(\mathcal{N}^\vee_{X/\mathbb{P}^N}\big)^{-1} \;\cong\; \mathcal{O}_{\mathbb{P}^N}(-N-1)\big|_X \otimes \det(\mathcal{N}_{X/\mathbb{P}^N}).$$

If X is a complete intersection, cut out by hypersurfaces of degrees $d_1, \ldots, d_c$, then $\mathcal{N}_{X/\mathbb{P}^N} \cong \bigoplus_{j=1}^c \mathcal{O}_X(d_j)$ and hence:

$$\omega_X \cong \mathcal{O}_X\left(\sum_{j=1}^c d_j - N - 1\right).$$

***Proof*:**

The conormal–cotangent exact sequence for the regular embedding $i : X \hookrightarrow \mathbb{P}^N$ is:

$$0 \longrightarrow \mathcal{N}^\vee_{X/\mathbb{P}^N} \longrightarrow \Omega_{\mathbb{P}^N}\big|_X \longrightarrow \Omega_X \longrightarrow 0.$$

This is exact on the left because X is smooth over k [95, Tag 06AA], and the embedding is a regular immersion [95, Tag 067U]. Taking the top exterior power of the middle term (which has rank N) and using the multiplicativity of determinants on short exact sequences of locally free sheaves:

$$\det(\Omega_{\mathbb{P}^N}|_X) \cong \det(\mathcal{N}^\vee_{X/\mathbb{P}^N}) \otimes \det(\Omega_X),$$

so $\omega_X = \det(\Omega_X) \cong \det(\Omega_{\mathbb{P}^N}|_X) \otimes \det(\mathcal{N}^\vee_{X/\mathbb{P}^N})^{-1} = \omega_{\mathbb{P}^N}|_X \otimes \det(\mathcal{N}_{X/\mathbb{P}^N})$.

For a complete intersection, the ideal sheaf $\mathscr{I}_X$ is generated by global sections $f_1, \ldots, f_c$ of degrees $d_1, \ldots, d_c$. The conormal sheaf is $\mathscr{I}_X/\mathscr{I}_X^2 \cong \bigoplus_{j=1}^c \mathcal{O}_X(-d_j)$ (the surjection $\bigoplus \mathcal{O}(-d_j) \twoheadrightarrow \mathscr{I}_X$ induces an isomorphism on the conormal level), so $\mathcal{N}_{X/\mathbb{P}^N} = (\mathscr{I}_X/\mathscr{I}_X^2)^\vee \cong \bigoplus \mathcal{O}_X(d_j)$. Hence $\det(\mathcal{N}_{X/\mathbb{P}^N}) = \mathcal{O}_X(\sum d_j)$ and $\omega_X \cong \mathcal{O}_X(-N - 1 + \sum d_j)$.

Example 6.5.8: Canonical Sheaves via Adjunction

1. *Smooth plane curve of degree d.* Let $C \subset \mathbb{P}^2_k$ be a smooth curve cut out by a polynomial of degree d. Then $\omega_C \cong \mathcal{O}_C(d-3)$. For $d = 1$ (a line, genus 0): $\omega_C \cong \mathcal{O}_C(-2)$, so $H^0(C, \omega_C) = 0$, confirming $g = 0$. For $d = 3$ (a smooth cubic, genus 1): $\omega_C \cong \mathcal{O}_C$, so $H^0(C, \omega_C) = k$, confirming $g = 1$. For general $d \geq 1$, the genus is $g = \dim_k H^0(C, \omega_C) = \binom{d-1}{2}$ (example 5.5.34(1)).

2. *Smooth surface of degree d in $\mathbb{P}^3$.* Let $S \subset \mathbb{P}^3_k$ be a smooth surface of degree d. Then $\omega_S \cong \mathcal{O}_S(d-4)$. For $d = 4$ (a K3 surface): $\omega_S \cong \mathcal{O}_S$, so S has trivial canonical bundle. For

$d < 4$, ω_S has negative degree (in an appropriate sense), and for $d > 4$, the canonical bundle is ample.

3. *Hypersurface of degree d in $\mathbb{P}^n$.* More generally, a smooth hypersurface $X \subset \mathbb{P}^n_k$ of degree d has $\omega_X \cong \mathcal{O}_X(d-n-1)$. For $n \geq 2$, the canonical class is trivial (i.e. X is Calabi–Yau in dimension $n-1$) precisely when $d = n+1$.

We can now state the full Serre duality theorem. For the proof, we shall use the dualizing sheaf of projective space together with a closed embedding to transfer duality from $\mathbb{P}^N$ to X:

Theorem 6.5.9: Serre Duality for a Projective Scheme

Let X be a projective scheme of dimension n over a field k, and suppose X admits a dualizing sheaf ω_X (with trace map $t\colon H^n(X,\omega_X) \to k$). For every coherent sheaf $\mathscr{F}$ on X, consider the Yoneda pairing

$$\operatorname{Ext}^i_{\mathcal{O}_X}(\mathscr{F},\, \omega_X) \times H^{n-i}(X,\mathscr{F}) \longrightarrow H^n(X,\omega_X) \xrightarrow{t} k$$

For $i = 0$ it induces an isomorphism $\operatorname{Hom}_{\mathcal{O}_X}(\mathscr{F},\omega_X) \cong H^n(X,\mathscr{F})^*$. If moreover X is Cohen-Macaulay and equidimensional, it induces isomorphisms

$$\operatorname{Ext}^i_{\mathcal{O}_X}(\mathscr{F},\omega_X) \;\cong\; H^{n-i}(X,\mathscr{F})^* \qquad \text{for all } 0 \leq i \leq n$$

Furthermore, a dualizing sheaf exists in each of the following cases:

1. X is a closed subscheme of $\mathbb{P}^N_k$ that is equidimensional and Cohen-Macaulay. In this case:
$$\omega_X \cong \mathcal{E}xt^c_{\mathcal{O}_{\mathbb{P}^N}}(\mathcal{O}_X,\, \omega_{\mathbb{P}^N}),$$
where $c = N - n$ is the codimension. In particular, if X is a smooth variety, then $\omega_X \cong \det \Omega_{X/k}$.
2. $X = \mathbb{P}^n_k$, with $\omega_X = \mathcal{O}(-n-1)$.

***Proof Key ideas*:**
For $X = \mathbb{P}^n_k$ this is theorem 6.5.5.

Existence of the dualizing sheaf. For a closed subscheme $i\colon X \hookrightarrow \mathbb{P}^N_k$ of codimension $c = N - n$, put

$$\omega_X = \mathcal{E}xt^c_{\mathcal{O}_{\mathbb{P}^N}}(i_*\mathcal{O}_X,\, \omega_{\mathbb{P}^N})$$

a coherent sheaf on $\mathbb{P}^N$ annihilated by the ideal of X, hence a coherent sheaf on X. The sheaves $\mathcal{E}xt^j_{\mathcal{O}_{\mathbb{P}^N}}(i_*\mathcal{O}_X,\omega_{\mathbb{P}^N})$ vanish for $j < c$ with no hypothesis on X [50, Lemma III.7.3], and from this one obtains an isomorphism $\operatorname{Hom}_{\mathcal{O}_X}(\mathscr{F},\omega_X) \cong \operatorname{Ext}^c_{\mathcal{O}_{\mathbb{P}^N}}(i_*\mathscr{F},\omega_{\mathbb{P}^N})$, functorial in the $\mathcal{O}_X$-module $\mathscr{F}$ [50, Lemma III.7.4]. For coherent $\mathscr{F}$, theorem 6.5.5 identifies the right side with $H^{N-c}(\mathbb{P}^N, i_*\mathscr{F})^* = H^n(X,\mathscr{F})^*$ (proposition 6.2.4). The trace t is the image of id_{ω_X} under this isomorphism for $\mathscr{F} = \omega_X$, and (ω_X, t) is a dualizing sheaf [50, Proposition III.7.5]. When X is Cohen-Macaulay and equidimensional, the sheaves $\mathcal{E}xt^j_{\mathcal{O}_{\mathbb{P}^N}}(i_*\mathcal{O}_X,\omega_{\mathbb{P}^N})$ also vanish for $j > c$: at a closed point x the local ring $\mathcal{O}_{X,x}$ has depth n, hence projective dimension $N - n = c$ over the regular local ring $\mathcal{O}_{\mathbb{P}^N,x}$.

When X is smooth, the identification $\omega_X \cong \det \Omega_{X/k}$ follows from proposition 6.5.7 and the fact that $\mathcal{E}xt^c(\mathcal{O}_X, \omega_{\mathbb{P}^N}) \cong \det(\mathcal{N}_{X/\mathbb{P}^N}) \otimes \omega_{\mathbb{P}^N}|_X$ for a regular embedding of codimension c [50, Theorem III.7.11].

Duality for the general case. The case $i = 0$ is the defining property of a dualizing sheaf. For $i > 0$ the argument is [50, Theorem III.7.6], whose proof uses the algebraic closure of k only to see that the local rings of $\mathbb{P}^N_k$ at closed points are regular of dimension N, which holds over any field. Both $\operatorname{Ext}^i_{\mathcal{O}_X}(-, \omega_X)$ and $H^{n-i}(X, -)^*$ are contravariant δ-functors in $\mathscr{F}$ that agree for $i = 0$. The first is universal, because every coherent sheaf is a quotient of a sheaf $\bigoplus \mathcal{O}_X(-q)$ with $q \gg 0$ (theorem 5.3.26), and $\operatorname{Ext}^i(\mathcal{O}_X(-q), \omega_X) = H^i(X, \omega_X(q))$ vanishes for $i > 0$ and $q \gg 0$ by Serre vanishing (lemma 6.8.23, through the closed embedding). The second is universal if and only if $H^{n-i}(X, \mathcal{O}_X(-q)) = 0$ for $i > 0$ and $q \gg 0$, and through duality on $\mathbb{P}^N_k$ (theorem 6.5.5) this vanishing is equivalent to X being Cohen-Macaulay and equidimensional. When it holds, the two universal δ-functors agree in every degree.

For smooth varieties, the Ext groups simplify and Serre duality takes its most elegant form:

Corollary 6.5.10: Serre Duality: Nonsingular Projective Variety

Let X be a projective variety of dimension n over a field k that is smooth over k (definition 2.7.13), with canonical sheaf $\omega_X = \det \Omega_{X/k}$. Then for every locally free coherent sheaf $\mathscr{F}$ on X:

$$H^i(X, \mathscr{F}) \;\cong\; H^{n-i}(X, \mathscr{F}^\vee \otimes \omega_X)^* \qquad \text{for all } 0 \le i \le n.$$

In particular:

1. $H^n(X, \omega_X) \cong H^0(X, \mathcal{O}_X)^*$, which is k when $H^0(X, \mathcal{O}_X) = k$, for instance when k is algebraically closed (theorem 3.5.33).
2. $H^i(X, \mathcal{O}_X) \cong H^{n-i}(X, \omega_X)^*$ for all i.
3. If $H^0(X, \mathcal{O}_X) = k$, the *arithmetic genus* $p_a(X) = (-1)^n(\chi(\mathcal{O}_X) - 1)$ is computed by the cohomology of the canonical sheaf:

$$p_a(X) = \sum_{j=0}^{n-1} (-1)^j \dim_k H^j(X, \omega_X).$$

***Proof*:**

Since $\mathscr{F}$ is locally free, $\operatorname{Ext}^i(\mathscr{F}, \omega_X) \cong H^i(X, \mathscr{F}^\vee \otimes \omega_X)$ by corollary 6.4.9. The variety X is integral, hence equidimensional, and its local rings are regular (proposition 2.7.14), hence Cohen-Macaulay [50, Theorem II.8.21A(a)], so theorem 6.5.9 applies in every degree, with $\omega_X \cong \det \Omega_{X/k}$ by its part (1). Substituting into it:

$$H^i(X, \mathscr{F}^\vee \otimes \omega_X) \cong H^{n-i}(X, \mathscr{F})^*.$$

Replacing $\mathscr{F}$ by $\mathscr{F}^\vee \otimes \omega_X$ (which is also locally free) and using $(\mathscr{F}^\vee \otimes \omega_X)^\vee \otimes \omega_X \cong \mathscr{F}$:

$$H^i(X, \mathscr{F}) \cong H^{n-i}(X, \mathscr{F}^\vee \otimes \omega_X)^*.$$

Part (1) follows by setting $\mathscr{F} = \mathcal{O}_X$ and $i = 0$: $H^n(X, \omega_X) \cong H^0(X, \mathcal{O}_X)^*$. When k is algebraically closed, X is reduced and connected, so $H^0(X, \mathcal{O}_X) = k$ by theorem 3.5.33. Part (2)

is the special case $\mathscr{F} = \mathcal{O}_X$. For part (3), write $h^j = \dim_k H^j$. Part (2) gives $\chi(\mathcal{O}_X) = \sum_{i=0}^{n}(-1)^i h^{n-i}(\omega_X) = (-1)^n \sum_{j=0}^{n}(-1)^j h^j(\omega_X)$, so

$$p_a(X) = \sum_{j=0}^{n-1}(-1)^j h^j(\omega_X) + (-1)^n\big(h^n(\omega_X) - 1\big),$$

and $h^n(\omega_X) = h^0(\mathcal{O}_X) = 1$ by part (1), as claimed.

Example 6.5.11: Applications of Serre Duality

1. *Curves: Riemann–Roch.* Let C be a smooth projective curve of genus $g = \dim_k H^1(C, \mathcal{O}_C)$ over k with $H^0(C, \mathcal{O}_C) = k$. Serre duality gives $H^1(C, \mathcal{L}) \cong H^0(C, \mathcal{L}^\vee \otimes \omega_C)^*$ for any line bundle $\mathcal{L}$. If $\mathcal{L} = \mathcal{O}_C(D)$ for a divisor D, this becomes:

   $$h^1(C, \mathcal{O}(D)) = h^0(C, \omega_C(-D)) = h^0(C, \mathcal{O}(K - D)),$$

   where K is a canonical divisor (with $\mathcal{O}(K) \cong \omega_C$) and $h^i = \dim_k H^i$. Substituting into $\chi(\mathcal{O}(D)) = h^0(\mathcal{O}(D)) - h^1(\mathcal{O}(D))$, and using $\chi(\mathcal{O}(D)) = \deg D + 1 - g$ (lemma 6.7.11 below), gives the *Riemann-Roch theorem* for curves (theorem 6.7.12 below):

   $$h^0(C, \mathcal{O}(D)) - h^0(C, \mathcal{O}(K - D)) = \deg D + 1 - g$$

   In particular, setting $D = K$: $h^0(\omega_C) - h^0(\mathcal{O}_C) = \deg K + 1 - g$, giving $\deg K = 2g - 2$ (since $h^0(\omega_C) = h^1(\mathcal{O}_C) = g$ by Serre duality, corollary 6.5.10(2), and $h^0(\mathcal{O}_C) = 1$).

2. *The Hodge numbers of a smooth surface.* Let S be a smooth projective surface over $\mathbb{C}$. Serre duality gives:

   $$H^0(S, \mathcal{O}_S) \cong H^2(S, \omega_S)^*,$$
   $$H^1(S, \mathcal{O}_S) \cong H^1(S, \omega_S)^*,$$
   $$H^2(S, \mathcal{O}_S) \cong H^0(S, \omega_S)^*.$$

   Since $h^{p,q} = \dim H^q(S, \Omega^p)$ by the Dolbeault theorem (theorem 0.6.17) and GAGA, these translate to symmetries of the Hodge diamond: $h^{0,0} = h^{2,2}$, $h^{0,1} = h^{2,1}$, and $h^{0,2} = h^{2,0}$. These are the instances $h^{0,q} = h^{2,2-q}$ of the duality in definition 0.6.29(2).

3. *Kodaira vanishing (preview).* Let X be a smooth projective variety of dimension n over $\mathbb{C}$ and let $\mathcal{L}$ be an ample line bundle. The Kodaira vanishing theorem (which requires analytic or characteristic-0 methods beyond our present scope) asserts:

   $$H^i(X, \omega_X \otimes \mathcal{L}) = 0 \qquad \text{for } i > 0.$$

   By Serre duality, this is equivalent to:

   $$H^{n-i}(X, \mathcal{L}^{-1}) = 0 \qquad \text{for } i > 0,$$

   i.e. $H^j(X, \mathcal{L}^{-1}) = 0$ for $j < n$. Thus Kodaira vanishing can be stated either as acyclicity of $\omega_X \otimes \mathcal{L}$ or as "low-degree vanishing" of $\mathcal{L}^{-1}$. Serre duality reduces one formulation to the other.

4. *Self-duality of abelian varieties.* Let A be an abelian variety of dimension g over k. Then $\Omega_{A/k}$ is trivial: $\Omega_{A/k} \cong \mathcal{O}_A^g$ (the tangent bundle of a group scheme is trivial, by translation). Hence $\omega_A = \det(\mathcal{O}_A^g) \cong \mathcal{O}_A$, and Serre duality gives:

$$H^i(A, \mathcal{O}_A) \cong H^{g-i}(A, \mathcal{O}_A)^*.$$

This symmetry gives only $h^i = h^{g-i}$. It is consistent with $\dim_k H^i(A, \mathcal{O}_A) = \binom{g}{i}$, which needs further input: $H^*(A, \mathcal{O}_A)$ is the exterior algebra on the g-dimensional space $H^1(A, \mathcal{O}_A)$.

6.5.12 Remark: Beyond Smooth Varieties For singular projective schemes, Serre duality still holds when X is Cohen-Macaulay and equidimensional (theorem 6.5.9), but the dualizing sheaf ω_X is no longer necessarily invertible. It is a coherent sheaf, and its local structure reflects the singularities of X. The theory of dualizing complexes (due to Grothendieck and Hartshorne) extends duality to arbitrary proper schemes, replacing the dualizing sheaf with a complex of sheaves $\omega_X^\bullet \in D^b(\mathbf{Coh}(X))$. In this generality, Serre duality becomes Grothendieck duality:

$$\mathbf{R}\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \omega_X^\bullet) \cong \mathbf{R}\Gamma(X, \mathscr{F})^*$$

in the derived category. For Cohen-Macaulay equidimensional X, the dualizing complex is concentrated in a single degree and is the dualizing sheaf we have defined. For Gorenstein schemes (where ω_X is invertible), the theory is especially clean. We shall not pursue derived duality in these notes, but the reader should be aware that theorem 6.5.9 is a special case of this more general structure.

6.6 Higher Direct Images

The sheaf cohomology groups $H^i(X, \mathscr{F})$ encode global information about a single scheme X. But in practice, schemes arise in *families*: a morphism $f : X \to Y$ presents X as a family of fibers $X_y = f^{-1}(y)$ parameterized by points of Y, and we want to understand how the cohomology $H^i(X_y, \mathscr{F}|_{X_y})$ varies as y moves. The *higher direct image sheaves* $R^i f_* \mathscr{F}$ are sheaves on the base Y that give the "relative" version of sheaf cohomology, and they reduce to ordinary cohomology when Y is a point.

The central result of this section is the *finiteness theorem*: if $f : X \to Y$ is a projective morphism of Noetherian schemes and $\mathscr{F}$ is a coherent sheaf on X, then each $R^i f_* \mathscr{F}$ is a coherent sheaf on Y. When $Y = \operatorname{Spec} k$ is a point, this says that the cohomology groups of coherent sheaves on projective varieties are finite-dimensional — a fact we have already used (via forward reference) in proposition 6.4.13 and implicitly throughout our Serre duality arguments.

6.6.1 Definition and First Properties

Recall from definition 1.3.1 that the *direct image* (or pushforward) of a sheaf $\mathscr{F}$ on X along a continuous map $f : X \to Y$ is the sheaf $f_*\mathscr{F}$ on Y defined by $f_*\mathscr{F}(V) = \mathscr{F}(f^{-1}(V))$ for open $V \subseteq Y$. When f is a morphism of ringed spaces and $\mathscr{F}$ is an $\mathcal{O}_X$-module, the pushforward $f_*\mathscr{F}$ is an $\mathcal{O}_Y$-module (via the sheaf map $f^\# : \mathcal{O}_Y \to f_*\mathcal{O}_X$). The functor $f_* : \mathcal{O}_X\text{-}\mathbf{Mod} \to \mathcal{O}_Y\text{-}\mathbf{Mod}$ is left exact but not right exact in general.

Definition 6.6.1: Higher Direct Image Sheaves

Let $f : X \to Y$ be a morphism of ringed spaces. The *higher direct image sheaves* are the right derived functors of f_*:

$$R^i f_* : \mathcal{O}_X\text{-}\mathbf{Mod} \longrightarrow \mathcal{O}_Y\text{-}\mathbf{Mod}, \qquad R^i f_*(\mathscr{F}) = h^i(f_* \mathscr{I}^\bullet),$$

where $0 \to \mathscr{F} \to \mathscr{I}^\bullet$ is an injective resolution of $\mathscr{F}$ in the category of $\mathcal{O}_X$-modules. By construction, $R^0 f_* = f_*$, and a short exact sequence $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ of $\mathcal{O}_X$-modules induces a long exact sequence of $\mathcal{O}_Y$-modules:

$$0 \to f_*\mathscr{F}' \to f_*\mathscr{F} \to f_*\mathscr{F}'' \xrightarrow{\delta} R^1 f_* \mathscr{F}' \to R^1 f_* \mathscr{F} \to \cdots$$

When $Y = \{pt\}$ is a point, the morphism $f : X \to \{pt\}$ is the unique map to the terminal space, and $f_* = \Gamma(X, -)$. Hence $R^i f_* \mathscr{F} = H^i(X, \mathscr{F})$, recovering ordinary sheaf cohomology. This is the sense in which higher direct images "relativize" cohomology.

The following result is fundamental: it says that higher direct images can be computed "stalkwise" by computing cohomology on the preimages of open sets.

Proposition 6.6.2: Sheafification of Presheaf Direct Images

Let $f : X \to Y$ be a continuous map of topological spaces and let $\mathscr{F}$ be a sheaf of abelian groups on X. Then $R^i f_* \mathscr{F}$ is the sheafification of the presheaf on Y defined by:

$$V \longmapsto H^i(f^{-1}(V), \mathscr{F}|_{f^{-1}(V)})$$

for open $V \subseteq Y$. If this presheaf is already a sheaf (e.g., when Y has a basis of open sets V for which $f^{-1}(V)$ is "cohomologically well-behaved" in an appropriate sense), then no sheafification is needed.

***Proof*:**
Let $0 \to \mathscr{F} \to \mathscr{I}^\bullet$ be an injective resolution. For each open $V \subseteq Y$:

$$(f_* \mathscr{I}^p)(V) = \mathscr{I}^p(f^{-1}(V)).$$

The presheaf $V \mapsto h^i(\mathscr{I}^\bullet(f^{-1}(V)))$ computes $H^i(f^{-1}(V), \mathscr{F}|_{f^{-1}(V)})$ provided the restriction $\mathscr{I}^\bullet|_{f^{-1}(V)}$ is an injective (or at least acyclic) resolution of $\mathscr{F}|_{f^{-1}(V)}$. By lemma 6.4.5, the restriction of an injective sheaf to an open subset is injective, so this is indeed the case.

Now, the derived functors $R^i f_* \mathscr{F}$ are defined as the cohomology sheaves $h^i(f_* \mathscr{I}^\bullet)$. The presheaf $V \mapsto h^i((f_* \mathscr{I}^\bullet)(V))$ need not be a sheaf (taking cohomology does not commute with the sheaf condition in general), so $R^i f_* \mathscr{F}$ is the *sheafification* of this presheaf. Since $(f_* \mathscr{I}^\bullet)(V) = \mathscr{I}^\bullet(f^{-1}(V))$, the presheaf in question is $V \mapsto H^i(f^{-1}(V), \mathscr{F})$, as claimed.

Proposition 6.6.3: Stalks of Higher Direct Images

Let $f : X \to Y$ be a continuous map of topological spaces, $\mathscr{F}$ a sheaf of abelian groups on X, and $y \in Y$. Then there is a natural map:

$$(R^i f_* \mathscr{F})_y \longrightarrow H^i(X_y, \mathscr{F}|_{X_y}),$$

where $X_y = f^{-1}(y)$ is the (set-theoretic) fiber. This map is an isomorphism if y has a basis of open neighborhoods $\{V_\alpha\}$ such that the natural maps $\varinjlim_\alpha H^i(f^{-1}(V_\alpha), \mathscr{F}) \to H^i(X_y, \mathscr{F}|_{X_y})$ are isomorphisms.

***Proof*:**
By proposition 6.6.2, the stalk of $R^i f_* \mathscr{F}$ at y is:

$$(R^i f_* \mathscr{F})_y = \varinjlim_{V \ni y} H^i(f^{-1}(V), \mathscr{F}|_{f^{-1}(V)}).$$

The inclusion $X_y = f^{-1}(y) \hookrightarrow f^{-1}(V)$ for each open $V \ni y$ induces a restriction map $H^i(f^{-1}(V), \mathscr{F}) \to H^i(X_y, \mathscr{F}|_{X_y})$, and these are compatible as V varies, yielding the natural map on the colimit. The condition for this to be an isomorphism is precisely that cohomology "commutes with the limit" of shrinking V to $\{y\}$.

6.6.4 Remark: When Do Stalks Compute Fiber Cohomology? The natural map $(R^i f_* \mathscr{F})_y \to H^i(X_y, \mathscr{F}|_{X_y})$ is *not* an isomorphism in general, and the discrepancy is important. The stalk sees the cohomology of all "thickenings" of the fiber (i.e., the preimages of open neighborhoods of y), while the fiber cohomology sees only the fiber itself. These can differ when nearby fibers contribute non-trivially.
In the Zariski topology, neither properness nor a local base makes the map an isomorphism. If $Y = \operatorname{Spec} R$ for a local ring $(R, \mathfrak{m})$ and $y = [\mathfrak{m}]$ is the closed point, then the only open set containing y is Y itself, so the stalk is $H^i(X, \mathscr{F})$, the cohomology of all of X. Take $R = \mathbb{Z}_{(5)}$, $S = \mathbb{Z}_{(5)}[t]/(t^2 + 1)$ and the finite, hence proper (proposition 3.5.24), morphism $f\colon \operatorname{Spec} S \to \operatorname{Spec} R$ with $\mathscr{F} = \mathcal{O}$. Since $5 = (2 + t)(2 - t)$ in S, the fiber over the closed point is two closed points $\mathfrak{m}_1, \mathfrak{m}_2$, and for $i = 0$ the map is the diagonal $S \to S_{\mathfrak{m}_1} \times S_{\mathfrak{m}_2}$, which is not surjective.
In the scheme-theoretic setting, the correct fiber to consider is the *scheme-theoretic fiber* $X_y = X \times_Y \operatorname{Spec} \kappa(y)$ (see definition 3.2.9). The comparison between $R^i f_* \mathscr{F}$ and the cohomology of X_y is the subject of the *formal functions theorem* (Grothendieck's theorem on formal functions), which we shall not develop in full here, and, for $\mathscr{F}$ flat over Y, of theorem 6.8.19.

We now establish the key properties that make higher direct images useful in the scheme-theoretic setting:

Proposition 6.6.5: Quasi-Coherence of Higher Direct Images

Let $f : X \to Y$ be a quasi-compact and quasi-separated morphism of schemes, and let $\mathscr{F}$ be a quasi-coherent sheaf on X. Then each $R^i f_* \mathscr{F}$ is quasi-coherent on Y.

***Proof Key ideas*:**
The question is local on Y, so we may assume $Y = \operatorname{Spec} R$ is affine. Since f is quasi-compact and quasi-separated, the preimage $X = f^{-1}(Y)$ is a quasi-compact quasi-separated scheme. The intersections of a finite affine open cover of X need not be affine, so its Čech complex need not compute the cohomology of X. The proof instead builds X up one affine open at a time. For $X = U \cup V$ with V affine, the relative Mayer-Vietoris sequence places $R^i f_* \mathscr{F}$ between a cokernel and a kernel of maps among the higher direct images from U, V and $U \cap V$, and the case $i = 0$ is proposition 5.1.20. The induction that organizes this is in [95, Tag 01XJ], and we do not reproduce it.

6.6.2 The Finiteness Theorem

The most important structural result about higher direct images is that they preserve coherence for projective morphisms. This is the "relative" version of the statement that cohomology groups of coherent sheaves on projective varieties are finite-dimensional, and it is the technical engine behind semicontinuity theorems, base change, and the construction of Hilbert schemes.

The strategy is to reduce to the computation of cohomology of twisted sheaves on projective space (theorem 6.3.1), which we already know completely. The key tools are:

1. Every coherent sheaf on a projective scheme is a quotient of a direct sum of twisted sheaves (corollary 5.3.27).
2. Cohomology of twisted sheaves on $\mathbb{P}^n_R$ gives finitely generated R-modules (theorem 6.3.1).
3. Descending induction on i, starting from the vanishing of H^i of a quasi-coherent sheaf on $\mathbb{P}^N_R$ for $i > N$, since $\mathbb{P}^N_R$ is covered by $N + 1$ affines (theorem 6.1.19).

Theorem 6.6.6: Finiteness of Higher Direct Images

Let $f : X \to Y$ be a projective morphism of Noetherian schemes, and let $\mathscr{F}$ be a coherent sheaf on X. Then:

1. Each $R^i f_* \mathscr{F}$ is a coherent sheaf on Y.
2. $R^i f_* \mathscr{F} = 0$ for $i > \dim X$.

***Proof*:**
Part (2) follows immediately from theorem 6.2.5: the stalks $(R^i f_* \mathscr{F})_y$ are filtered colimits of $H^i(f^{-1}(V), \mathscr{F})$ over open neighborhoods V of y (proposition 6.6.2), and $\dim f^{-1}(V) \leq \dim X$.

For part (1), the question is local on Y, so we may assume $Y = \operatorname{Spec} R$ is affine. Since f is projective, there is a closed immersion $i : X \hookrightarrow \mathbb{P}^N_R$ for some $N \geq 1$, and f factors as $f = \pi \circ i$ where $\pi : \mathbb{P}^N_R \to \operatorname{Spec} R$ is the structure morphism. By corollary 6.6.12, $R^i f_* \mathscr{F} \cong R^i \pi_* (i_* \mathscr{F})$. Since i is a closed immersion, $i_* \mathscr{F}$ is coherent on $\mathbb{P}^N_R$: over an affine open $\operatorname{Spec} S \subseteq \mathbb{P}^N_R$ we have $i^{-1}(\operatorname{Spec} S) = \operatorname{Spec} T$ with $S \to T$ surjective (proposition 3.1.24(1)), so there $i_* \mathscr{F}$ is the sheaf associated to the finitely generated T-module $\mathscr{F}(\operatorname{Spec} T)$ viewed as an S-module (proposition 5.1.14(6)), which is finitely generated over S because $S \to T$ is surjective. Hence it suffices to prove the theorem for $\mathbb{P}^N_R$ over $\operatorname{Spec} R$. Since π and $\operatorname{Spec} R$ are separated,

proposition 6.6.14 identifies $R^i\pi_*\mathscr{G}$, for a coherent sheaf $\mathscr{G}$ on $\mathbb{P}^N_R$, with the quasi-coherent sheaf associated to the R-module $H^i(\mathbb{P}^N_R, \mathscr{G})$, which is coherent exactly when that module is finitely generated. So it suffices to show:

Claim: For any coherent sheaf $\mathscr{G}$ on $\mathbb{P}^N_R$, the R-module $H^i(\mathbb{P}^N_R, \mathscr{G})$ is finitely generated.

We prove the claim by descending induction on i. For $i > N$, we have $H^i = 0$, and there is nothing to prove: $\mathbb{P}^N_R$ is covered by the $N+1$ standard affine opens, whose Čech complex vanishes in degrees above N, and theorem 6.1.19 identifies its cohomology with $H^i(\mathbb{P}^N_R, \mathscr{G})$.

For the inductive step, assume that $H^j(\mathbb{P}^N_R, \mathscr{H})$ is finitely generated for all $j > i$ and all coherent $\mathscr{H}$. By corollary 5.3.27, $\mathscr{G}$ admits a surjection from a direct sum of twisted sheaves:

$$\mathcal{E} = \bigoplus_{j=1}^{s} \mathcal{O}_{\mathbb{P}^N}(d_j) \twoheadrightarrow \mathscr{G} \to 0$$

for some integers $d_1, \ldots, d_s$. Let $\mathcal{K} = \ker(\mathcal{E} \twoheadrightarrow \mathscr{G})$, which is coherent (since $\mathbf{Coh}(X)$ is an abelian category). The short exact sequence $0 \to \mathcal{K} \to \mathcal{E} \to \mathscr{G} \to 0$ induces a long exact sequence:

$$H^i(\mathbb{P}^N, \mathcal{E}) \longrightarrow H^i(\mathbb{P}^N, \mathscr{G}) \longrightarrow H^{i+1}(\mathbb{P}^N, \mathcal{K}) \longrightarrow H^{i+1}(\mathbb{P}^N, \mathcal{E}).$$

By theorem 6.3.1, $H^i(\mathbb{P}^N, \mathcal{E}) = \bigoplus_j H^i(\mathbb{P}^N, \mathcal{O}(d_j))$ is a finitely generated R-module (it is even free). By the inductive hypothesis, $H^{i+1}(\mathbb{P}^N, \mathcal{K})$ is finitely generated. Hence $H^i(\mathbb{P}^N, \mathscr{G})$, which sits between two finitely generated R-modules in the exact sequence, is itself finitely generated (using the standard fact that a subquotient of a finitely generated module over a Noetherian ring is finitely generated).

The most commonly used special case is when the base is a field:

Corollary 6.6.7: Finite-Dimensionality of Cohomology

Let X be a projective scheme over a field k, and let $\mathscr{F}$ be a coherent sheaf on X. Then each cohomology group $H^i(X, \mathscr{F})$ is a finite-dimensional k-vector space.

***Proof*:**
Apply theorem 6.6.6 with $Y = \operatorname{Spec} k$. The higher direct images $R^i f_*\mathscr{F}$ are coherent sheaves on $\operatorname{Spec} k$, i.e., finite-dimensional k-vector spaces. Since $R^i f_*\mathscr{F} = H^i(X, \mathscr{F})$ when Y is a point, the result follows.

This result justifies the use of the notation $h^i(X, \mathscr{F}) = \dim_k H^i(X, \mathscr{F})$ for the *Betti numbers* of the sheaf $\mathscr{F}$, and underpins the entire theory of Hilbert polynomials and Euler characteristics. Let us also record the general version for the base that we referenced earlier:

Corollary 6.6.8: (Reminder) Pushforward of Coherent Sheaves by Projective Morphisms

Let $f : X \to Y$ be a projective morphism of Noetherian schemes. Then f_* sends coherent sheaves on X to coherent sheaves on Y, and more generally, each $R^i f_*$ sends $\mathbf{Coh}(X)$ to $\mathbf{Coh}(Y)$.

***Proof*:**
This is a restatement of theorem 6.6.6(1).

6.6.9 Remark: Properness vs. Projectivity The finiteness theorem as stated requires f to be *projective*. The natural level of generality is *proper*: Grothendieck proved that theorem 6.6.6 holds whenever f is a proper morphism of Noetherian schemes. Since every projective morphism is proper (theorem 3.5.32), the statement above covers the cases most commonly encountered in practice. The proper case is proved in section 6.6.3. Later in this book it enters the semicontinuity and base change theorems of section 6.8, which are stated for proper morphisms. *Algebraic K-Theory* [10] needs it in order to define the pushforward along a proper morphism on the Grothendieck group $K_0(\mathbf{Coh}(X))$ of coherent sheaves.

6.6.3 The Proper Case

The projective hypothesis entered the proof of theorem 6.6.6 through the closed immersion into $\mathbb{P}^N_Y$, which is what made the twisting sheaves available. A proper morphism need not admit such an embedding. Chow's lemma (theorem 3.5.34) is the substitute: it produces a projective morphism that agrees with f over a dense open set, and the discrepancy is then pushed into a smaller closed subset where an inductive hypothesis applies.

Two preliminaries are needed. The first records that a coherent sheaf can be broken into pieces supported on integral closed subschemes, which is what makes the induction bite.

Lemma 6.6.10: Filtration of a Coherent Sheaf by Integral Subschemes

Let X be a Noetherian scheme and $\mathscr{F}$ a coherent $\mathcal{O}_X$-module. Then $\mathscr{F}$ admits a finite filtration by coherent subsheaves

$$0 = \mathscr{F}_0 \subseteq \mathscr{F}_1 \subseteq \cdots \subseteq \mathscr{F}_n = \mathscr{F}$$

such that each quotient $\mathscr{F}_j/\mathscr{F}_{j-1}$ is annihilated by the ideal sheaf of an integral closed subscheme $Z_j \subseteq \operatorname{Supp}\mathscr{F}$, so that each quotient is the pushforward of a coherent sheaf on such a Z_j.

Two remarks on what the lemma does *not* say. It does not claim the quotients are copies of $\mathcal{O}_{Z_j}$: on a smooth projective curve a line bundle L of negative degree admits no such filtration, since the bottom step would embed $\mathcal{O}_{Z_1}$ in L, impossible for $Z_1 = X$ because $H^0(L) = 0$ and impossible for $Z_1 \subsetneq X$ because $\mathcal{O}_{Z_1}$ is torsion while L is not. And it is not proved by taking the affine statement, that a finitely generated module over a Noetherian ring is filtered with quotients $A/\mathfrak{p}$, and gluing: subsheaves chosen independently over overlapping affines need not agree, so filtrations do not glue.

***Proof*:**
The filtration is built in two stages. The first makes $\mathscr{F}$ a module over the reduced support, the second breaks that support into irreducible pieces.

Stage 1: reduce to a module on the reduced support. Let $Z = \operatorname{Supp}\mathscr{F}$ with its reduced induced structure (definition 3.1.26) and let $\mathcal{I} \subseteq \mathcal{O}_X$ be its ideal sheaf. On an affine open $\operatorname{Spec} A$ with $\mathscr{F}$

given by a finitely generated module M, the support is $V(\mathrm{Ann}M)$ and $\mathcal{I}$ is $\sqrt{\mathrm{Ann}M}$. Since A is Noetherian that radical is finitely generated, so $\mathcal{I}^m \subseteq \mathrm{Ann}M$ for some m; taking the maximum over a finite affine cover gives an n with $\mathcal{I}^n\mathscr{F} = 0$ globally. The chain

$$\mathscr{F} \supseteq \mathcal{I}\mathscr{F} \supseteq \mathcal{I}^2\mathscr{F} \supseteq \cdots \supseteq \mathcal{I}^n\mathscr{F} = 0$$

is therefore finite, its terms are coherent, and each quotient $\mathcal{I}^j\mathscr{F}/\mathcal{I}^{j+1}\mathscr{F}$ is annihilated by $\mathcal{I}$, hence is a coherent module on Z. So it suffices to filter a coherent module on a *reduced* closed subscheme.

Stage 2: Noetherian induction on the reduced support. Argue by corollary 0.3.5 over the closed subsets of X, which satisfy the descending chain condition (lemma 2.4.2). Let $\mathscr{G}$ be coherent on a reduced closed Z, and assume the lemma for every coherent sheaf whose support is properly contained in Z. If Z is irreducible then, being reduced, it is integral, and the one-step filtration $0 \subseteq \mathscr{G}$ already has the required form. Otherwise write $Z = Z_1 \cup \cdots \cup Z_m$ for the irreducible components, $m \geq 2$, and let $\mathcal{J}$ be the ideal sheaf of Z_1 inside Z. Then:

1. $\mathscr{G}/\mathcal{J}\mathscr{G}$ is annihilated by $\mathcal{J}$, so it is a coherent module on Z_1, which is integral.
2. $\mathrm{Supp}(\mathcal{J}\mathscr{G}) \subseteq Z_2 \cup \cdots \cup Z_m$, a proper closed subset of Z. Indeed, let $z \in Z_1$ lie on no other component. Some open neighbourhood of z in Z meets only Z_1, so on it Z and Z_1 agree as *reduced* schemes and $\mathcal{J}$ vanishes there; hence $(\mathcal{J}\mathscr{G})_z = 0$. This is where Stage 1 is used: for non-reduced Z the ideal $\mathcal{J}$ need not vanish at such a z, which is why the naive one-stage argument fails.

The inductive hypothesis applied to $\mathcal{J}\mathscr{G}$ gives a filtration of it of the required shape, and appending $\mathscr{G}$ itself adds the quotient $\mathscr{G}/\mathcal{J}\mathscr{G}$ from (1). Splicing this into the Stage 1 chain gives a finite filtration of the original $\mathscr{F}$ whose quotients are all coherent modules on integral closed subschemes of $\mathrm{Supp}\mathscr{F}$, as we sought to show.

The second preliminary is the relative form of the Leray spectral sequence. The version recorded in theorem 6.6.16 computes cohomology on the total space; what is needed here is the version comparing higher direct images along a composite, which is the Grothendieck spectral sequence of [25, The Grothendieck Spectral Sequence] applied to the pair of pushforward functors.

Lemma 6.6.11: Higher Direct Images Along a Composite

Let $\pi\colon X' \to X$ and $f\colon X \to Y$ be morphisms of Noetherian schemes and $\mathscr{G}$ a quasi-coherent sheaf on X'. Then there is a convergent first-quadrant spectral sequence, natural in $\mathscr{G}$,

$$E_2^{p,q} = R^p f_*\big(R^q\pi_*\mathscr{G}\big) \implies R^{p+q}(f\circ\pi)_*\mathscr{G}$$

***Proof*:**
Apply [25, The Grothendieck Spectral Sequence] with $F = \pi_*$ and $G = f_*$, both left exact additive functors between categories of $\mathcal{O}$-modules, which have enough injectives. The hypothesis to discharge is that π_* carries injective $\mathcal{O}_{X'}$-modules to f_*-acyclic $\mathcal{O}_X$-modules. An injective $\mathcal{O}_{X'}$-module is flasque, the pushforward of a flasque sheaf is flasque, and flasque sheaves are acyclic for every pushforward functor, so the hypothesis holds, completing the proof.

Corollary 6.6.12: Higher Direct Images Along a Closed Immersion

Let $i\colon Z \hookrightarrow X$ be a closed immersion and $f\colon X \to Y$ a morphism of Noetherian schemes, and let $\mathcal{H}$ be a quasi-coherent sheaf on Z. Then i_* is exact, and $R^p f_*(i_*\mathcal{H}) \cong R^p(f\circ i)_*\mathcal{H}$ for every $p \geq 0$.

***Proof*:**
Since Z is closed in X, the stalk $(i_*\mathscr{G})_x$ of a sheaf $\mathscr{G}$ on Z is $\mathscr{G}_x$ for $x \in Z$ and 0 for $x \notin Z$, so i_* is exact. For an injective resolution $0 \to \mathcal{H} \to \mathscr{I}^\bullet$ this gives $R^q i_*\mathcal{H} = h^q(i_*\mathscr{I}^\bullet) = i_* h^q(\mathscr{I}^\bullet) = 0$ for $q > 0$. The spectral sequence of lemma 6.6.11 for i and f is therefore concentrated in the row $q = 0$, and its edge maps give $R^p f_*(i_*\mathcal{H}) \cong R^p(f\circ i)_*\mathcal{H}$.

Theorem 6.6.13: Finiteness of Higher Direct Images, Proper Case

Let $f\colon X \to Y$ be a *proper* morphism of Noetherian schemes and let $\mathscr{F}$ be a coherent sheaf on X. Then:

1. $R^i f_*\mathscr{F}$ is coherent on Y for every $i \geq 0$;
2. $R^i f_*\mathscr{F} = 0$ for $i > \dim X$.

Part (2) is the easy half and is proved first, since it is independent of everything below. By proposition 6.6.2 the sheaf $R^i f_*\mathscr{F}$ is the sheafification of $V \mapsto H^i(f^{-1}V, \mathscr{F}|_{f^{-1}V})$. Each $f^{-1}V$ is a Noetherian topological space of dimension at most $\dim X$, so theorem 6.2.5 makes those groups vanish for $i > \dim X$, and a presheaf that is zero sheafifies to zero. Note that this half needs nothing about coherence or properness beyond X being Noetherian; it is (1) that carries the content.

***Proof*:**
Only (1) remains. Coherence is local on Y, so assume $Y = \operatorname{Spec} A$ with A Noetherian. For a closed subset $Z \subseteq X$ let $P(Z)$ be the statement that $R^i f_*\mathscr{G}$ is coherent for every i and every coherent $\mathscr{G}$ on X with $\operatorname{Supp}\mathscr{G} \subseteq Z$. The closed subsets of the Noetherian space X satisfy the descending chain condition (lemma 2.4.2), so by corollary 0.3.5 it suffices to prove $P(Z)$ assuming $P(Z')$ for every closed $Z' \subsetneq Z$. Taking $Z = X$ then gives the theorem.

Step 1: reduction to a coherent sheaf on an integral closed subscheme. By lemma 6.6.10 the sheaf $\mathscr{G}$ has a finite filtration whose quotients are pushforwards of coherent sheaves on integral closed subschemes of Z. Higher direct images take a short exact sequence to a long exact sequence, and all the sheaves in sight are quasi-coherent, f being proper and hence quasi-compact and quasi-separated. Inside quasi-coherent sheaves on a Noetherian scheme the coherent ones are closed under subobjects, quotients and extensions, so in a long exact sequence a term flanked by coherent neighbours is itself coherent. Induction along the filtration therefore reduces the claim to the case where $\mathscr{G}$ is a coherent sheaf on an integral closed subscheme of Z. If that subscheme is proper inside Z the inductive hypothesis applies, so we may assume it is Z itself and that Z is integral.

Step 2: Chow's lemma. The composite $Z \hookrightarrow X \to Y$ is proper, a closed immersion being proper and properness being stable under composition (proposition 3.5.23). Apply theorem 3.5.34 to it: there is a surjective projective morphism $\pi\colon Z' \to Z$ with $g := f\circ\pi\colon Z' \to Y$ projective, and a

dense open $U \subseteq Z$ over which π is an isomorphism.

Step 3: comparing $\mathscr{G}$ with its pullback. Let $\mathscr{G}' = \pi^*\mathscr{G}$, a coherent sheaf on Z', and consider the unit map $u\colon \mathscr{G} \to \pi_*\mathscr{G}'$. Over U the morphism π is an isomorphism, so $u|_U$ is an isomorphism. Now $\pi_*\mathscr{G}'$ is coherent, by theorem 6.6.6(1) in degree 0 applied to the projective morphism π, so $\ker u$ and $\operatorname{coker} u$ are coherent; and both are supported in the closed set $Z \setminus U$, which is a proper closed subset of Z since U is dense. The inductive hypothesis therefore gives coherence of $R^i f_*(\ker u)$ and $R^i f_*(\operatorname{coker} u)$ for all i. By the long exact sequences attached to

$$0 \to \ker u \to \mathscr{G} \to \operatorname{im} u \to 0, \qquad 0 \to \operatorname{im} u \to \pi_*\mathscr{G}' \to \operatorname{coker} u \to 0$$

it now suffices to prove that $R^i f_*(\pi_*\mathscr{G}')$ is coherent for every i.

Step 4: the spectral sequence. Apply lemma 6.6.11 to π and f with the sheaf $\mathscr{G}'$:

$$E_2^{p,q} = R^p f_*\big(R^q \pi_* \mathscr{G}'\big) \implies R^{p+q} g_* \mathscr{G}'$$

The abutment is coherent for every degree, because g is projective and theorem 6.6.6 applies to it. For $q > 0$ the sheaf $R^q\pi_*\mathscr{G}'$ is coherent, again by theorem 6.6.6 applied to the projective morphism π, and it is supported in $Z \setminus U$, since π is an isomorphism over U and higher direct images along an isomorphism vanish. So the inductive hypothesis makes every $E_2^{p,q}$ with $q > 0$ coherent. Throughout, sheaves living on the closed subscheme Z are fed to the hypothesis $P(-)$, which is stated for sheaves on X, via the identification $R^i f_*(i_*\mathcal{H}) \cong R^i(f|_Z)_*\mathcal{H}$ for the closed immersion $i\colon Z \hookrightarrow X$ (corollary 6.6.12).

It remains to treat the bottom row $E_2^{p,0} = R^p f_*(\pi_*\mathscr{G}')$, which is the object we want. For $p = 0$ the edge map $E_2^{0,0} \to R^0 g_*\mathscr{G}'$ is an isomorphism, so $f_*(\pi_*\mathscr{G}')$ is coherent. Fix $p \geq 1$. The differential *into* $E_r^{p,0}$ is $d_r\colon E_r^{p-r,\,r-1} \to E_r^{p,0}$, whose source sits in row $r - 1 \geq 1$, hence is coherent by the previous paragraph. The differential *out* of it lands in $E_r^{p+r,\,1-r}$, which vanishes because the sequence is first-quadrant and $1 - r < 0$. So each page is obtained from the previous one by a *quotient*, $E_{r+1}^{p,0} = E_r^{p,0}/\operatorname{im} d_r$, with $\operatorname{im} d_r$ a quotient of a coherent sheaf. Closure of the coherent sheaves under subobjects, quotients and extensions is what lets coherence travel back down the pages. Since $E_\infty^{p,0}$ is a graded piece of the coherent sheaf $R^p g_*\mathscr{G}'$ it is coherent, and the tower stabilizes at $E_{p+1}^{p,0} = E_\infty^{p,0}$. Descending from $r = p + 1$ to $r = 2$, each stage sits in a short exact sequence

$$0 \to \operatorname{im} d_r \to E_r^{p,0} \to E_{r+1}^{p,0} \to 0$$

whose outer terms are coherent, the left one a quotient of the coherent $E_r^{p-r,\,r-1}$ and the right one coherent by descending induction. Closure under extensions then gives $E_2^{p,0}$ coherent.

Therefore $R^i f_*(\pi_*\mathscr{G}')$ is coherent for every i, which by Step 3 gives $P(Z)$ and completes the Noetherian induction, as we sought to show.

6.6.4 Computation of Higher Direct Images

Higher direct images can be computed using the Čech machinery, provided the morphism is sufficiently well-behaved:

Proposition 6.6.14: Čech Computation of Higher Direct Images

Let $f : X \to Y$ be a separated morphism of Noetherian schemes with Y separated, $\mathscr{F}$ a quasi-coherent sheaf on X, and $\mathcal{U} = \{U_1, \ldots, U_r\}$ a finite open affine cover of X. Then for each open affine $V = \operatorname{Spec} R \subseteq Y$, the higher direct images are computed by:

$$R^i f_*(\mathscr{F})(V) \;\cong\; \check{H}^i(\mathcal{U}|_{f^{-1}(V)},\, \mathscr{F}|_{f^{-1}(V)}),$$

where $\mathcal{U}|_{f^{-1}(V)} = \{U_j \cap f^{-1}(V)\}$ is the restricted cover.

***Proof*:**
For affine $V \subseteq Y$, the preimage $f^{-1}(V)$ is a Noetherian scheme, separated over V (separatedness is preserved under base change). Each $U_j \cap f^{-1}(V) = U_j \times_Y V$ is affine because Y is separated, and the intersection of two affine opens in $f^{-1}(V)$ is affine by proposition 3.5.8. By theorem 6.1.19, the Čech cohomology with respect to this affine cover computes the derived-functor cohomology:

$$\check{H}^i(\mathcal{U}|_{f^{-1}(V)}, \mathscr{F}) \cong H^i(f^{-1}(V), \mathscr{F}).$$

For $g \in R$, the restricted cover of $f^{-1}(D(g))$ has Čech complex $C^\bullet(\mathcal{U}|_{f^{-1}(V)}, \mathscr{F})_g$, since $\mathscr{F}$ is quasi-coherent, and localization is exact, so $H^i(f^{-1}(D(g)), \mathscr{F}) \cong H^i(f^{-1}(V), \mathscr{F})_g$. On the distinguished opens of V the presheaf of proposition 6.6.2 therefore agrees with the quasi-coherent sheaf associated to $H^i(f^{-1}(V), \mathscr{F})$, so its sheafification $R^i f_* \mathscr{F}|_V$ is that sheaf, with sections $H^i(f^{-1}(V), \mathscr{F})$ over V.

Example 6.6.15: Higher Direct Images

1. *Structure morphism of projective space.* Let R be a Noetherian ring, let $n \geq 1$, and let $\pi : \mathbb{P}^n_R \to \operatorname{Spec} R$ be the structure morphism. By propositions 6.6.5 and 6.6.14:

   $$R^i \pi_*\big(\mathcal{O}_{\mathbb{P}^n}(d)\big) \;\cong\; \widetilde{H^i(\mathbb{P}^n_R, \mathcal{O}(d))},$$

   the quasi-coherent sheaf associated to the R-module $H^i(\mathbb{P}^n_R, \mathcal{O}(d))$, and theorem 6.3.1 computes these modules. In particular, $\pi_*(\mathcal{O}_{\mathbb{P}^n}) \cong \widetilde{R} = \mathcal{O}_{\operatorname{Spec} R}$ and $R^i \pi_*(\mathcal{O}_{\mathbb{P}^n}) = 0$ for $i > 0$. More generally:

   $$\pi_*(\mathcal{O}(d)) \cong \begin{cases} \widetilde{(R[x_0, \ldots, x_n])_d} & d \geq 0, \\ 0 & d < 0, \end{cases}$$

   and all higher direct images vanish for $0 < i < n$.

2. *Blowing up a point.* Let $Y = \mathbb{A}^2_k = \operatorname{Spec} k[x, y]$ and let $f : X = \operatorname{Bl}_0 Y \to Y$ be the blowup of the origin. This is a projective morphism with f an isomorphism over $Y \setminus \{0\}$ and fiber $f^{-1}(0) \cong \mathbb{P}^1_k$ (the exceptional divisor E). Then:

   $$f_* \mathcal{O}_X \cong \mathcal{O}_Y \qquad \text{and} \qquad R^i f_* \mathcal{O}_X = 0 \text{ for } i > 0.$$

   The first statement holds because f is an isomorphism over $Y \setminus \{0\}$. A section of $f_* \mathcal{O}_X$ over an open $V \subseteq Y$ is therefore a rational function regular on $V \setminus \{0\}$, hence at every

codimension-1 point of V, the origin having codimension 2. Since Y is normal, the algebraic Hartogs lemma (theorem 2.6.18) makes it regular on V.

For the vanishing, $R^i f_* \mathcal{O}_X$ is quasi-coherent (proposition 6.6.5) on the affine Y, so it is enough that its global sections vanish, and proposition 6.6.14 with $V = Y$ computes them by the Čech complex of the two charts $U_1 = \operatorname{Spec} k[x,t]$ with $t = y/x$ and $U_2 = \operatorname{Spec} k[y,s]$ with $s = x/y$, which meet in $U_{12} = \operatorname{Spec} k[x,t,t^{-1}]$. With two charts the complex stops in degree 1. The monomials of $\mathcal{O}(U_{12})$ are the $x^a t^b$ with $a \geq 0$ and $b \in \mathbb{Z}$. Those from U_1 are the ones with $b \geq 0$, and since $y^c s^e = x^c t^{c-e}$, those from U_2 are the ones with $b \leq a$. Every monomial is of one of the two kinds, so the Čech differential is surjective and $R^1 f_* \mathcal{O}_X = 0$.

The ideal sheaf $\mathcal{O}_X(-E) = \mathfrak{m}_0 \mathcal{O}_X$ of the exceptional divisor is $xk[x,t]$ on U_1 and $yk[y,s]$ on U_2, and the same computation runs with $a \geq 0$ replaced by $a \geq 1$. Again $R^1 f_*(\mathcal{O}_X(-E)) = 0$, and the global sections are spanned by the $x^a t^b = x^{a-b} y^b$ with $a \geq 1$ and $0 \leq b \leq a$, so $f_*(\mathcal{O}_X(-E)) \cong \mathfrak{m}_0$, the maximal ideal of the origin in $\mathcal{O}_Y$.

3. *Projection of a product.* Let C be a smooth projective curve of genus g over k with $H^0(C, \mathcal{O}_C) = k$, for instance with k algebraically closed (theorem 3.5.33), and consider the projection $f = \operatorname{pr}_2 : C \times_k \mathbb{P}^1_k \to \mathbb{P}^1_k$. Then for the structure sheaf:

$$f_* \mathcal{O}_{C \times \mathbb{P}^1} \cong \mathcal{O}_{\mathbb{P}^1}, \qquad R^1 f_* \mathcal{O}_{C \times \mathbb{P}^1} \cong \mathcal{O}_{\mathbb{P}^1}^g.$$

Cover C by finitely many affines U_j. For $V \subseteq \mathbb{P}^1$ affine, proposition 6.6.14 and theorem 6.1.19 give $R^i f_* \mathcal{O}(V) \cong H^i(C \times V, \mathcal{O})$, computed by the affine cover $\{U_j \times V\}$, whose Čech complex is $C^\bullet(\{U_j\}, \mathcal{O}_C) \otimes_k \mathcal{O}(V)$. Tensoring over k is exact, so $R^i f_* \mathcal{O}(V) \cong H^i(C, \mathcal{O}_C) \otimes_k \mathcal{O}(V)$, and both isomorphisms follow from $H^0(C, \mathcal{O}_C) = k$ and $H^1(C, \mathcal{O}_C) \cong k^g$.

Here every fiber has $h^1 = g$ and $R^1 f_* \mathcal{O}$ is locally free of rank g. For a proper morphism of Noetherian schemes and a coherent $\mathscr{F}$ flat over the base, section 6.8 makes precise how $R^i f_* \mathscr{F}$ relates to the fiber cohomology $H^i(X_y, \mathscr{F}|_{X_y})$.

4. *Failure for non-proper morphisms.* Let $j : \mathbb{A}^1_k \setminus \{0\} \hookrightarrow \mathbb{A}^1_k$ be the open immersion. Then $j_* \mathcal{O} = \mathcal{O}_{\mathbb{A}^1}[1/x]$ (rational functions regular away from the origin), which is *not* coherent as an $\mathcal{O}_{\mathbb{A}^1}$-module: it is quasi-coherent (corresponding to the $k[x]$-module $k[x, x^{-1}]$) but not finitely generated. Also, $R^1 j_* \mathcal{O} = 0$ (since $\mathbb{A}^1 \setminus \{0\}$ is affine, hence acyclic), but the pushforward already fails coherence. This shows that the projectivity hypothesis in theorem 6.6.6 cannot be dropped.

To close this section, we record the connection between higher direct images and the Leray spectral sequence, which is the fundamental tool for computing cohomology of a space in terms of a morphism to a simpler space:

Theorem 6.6.16: Leray Spectral Sequence

Let $f : X \to Y$ be a morphism of ringed spaces and let $\mathscr{F}$ be a sheaf of $\mathcal{O}_X$-modules. Then there is a convergent spectral sequence:

$$E_2^{p,q} = H^p(Y,\, R^q f_* \mathscr{F}) \implies H^{p+q}(X, \mathscr{F}).$$

This is natural in $\mathscr{F}$.

***Proof*:**
This is the Grothendieck spectral sequence for the composite functor $\Gamma(X,-) = \Gamma(Y,-)\circ f_*$. We need f_* to send injective $\mathcal{O}_X$-modules to $\Gamma(Y,-)$-acyclic $\mathcal{O}_Y$-modules. Indeed, if $\mathscr{I}$ is an injective $\mathcal{O}_X$-module, then $f_*\mathscr{I}$ is flasque: for $U \subseteq V$ open in Y, the restriction $f_*\mathscr{I}(V) = \mathscr{I}(f^{-1}(V)) \to \mathscr{I}(f^{-1}(U)) = f_*\mathscr{I}(U)$ is surjective because $\mathscr{I}$ is flasque (by proposition 6.1.5) and $f^{-1}(U) \subseteq f^{-1}(V)$. Hence $f_*\mathscr{I}$ is acyclic for $\Gamma(Y,-)$, and the Grothendieck spectral sequence applies.

Example 6.6.17: Applications of the Leray Spectral Sequence

1. *Affine morphisms.* If $f : X \to Y$ is an affine morphism of Noetherian schemes and $\mathscr{F}$ is quasi-coherent, then $R^q f_*\mathscr{F} = 0$ for all $q > 0$: $f^{-1}(V)$ is affine for every affine open $V \subseteq Y$, so $H^q(f^{-1}(V), \mathscr{F}) = 0$ by theorem 6.2.9, and the sheafification $R^q f_*\mathscr{F}$ of the presheaf $V \mapsto H^q(f^{-1}(V), \mathscr{F})$ (proposition 6.6.2) vanishes. The Leray spectral sequence degenerates at E_2, giving $H^p(X, \mathscr{F}) \cong H^p(Y, f_*\mathscr{F})$. This reduces the cohomology of X to the cohomology of Y with coefficients in the pushforward.

2. *Projective bundles.* Let $\mathcal{E}$ be a locally free sheaf of rank $r+1$ on a Noetherian scheme Y and let $f : X = \mathbb{P}(\mathcal{E}) \to Y$ be the associated projective bundle. The higher direct images of the twisted sheaves $\mathcal{O}_X(d)$ are computed by the relative version of theorem 6.3.1: $f_*\mathcal{O}_X(d) \cong \mathrm{Sym}^d \mathcal{E}$ for $d \geq 0$, and $R^i f_*\mathcal{O}_X(d) = 0$ for $0 < i < r$. The Leray spectral sequence then computes $H^*(X, \mathcal{O}_X(d))$ in terms of $H^*(Y, \mathrm{Sym}^d \mathcal{E})$.

3. *Recovering the projection formula.* For a proper morphism $f : X \to Y$, an $\mathcal{O}_X$-module $\mathscr{F}$, and a locally free sheaf $\mathcal{E}$ on Y, the *projection formula* gives:

$$R^i f_*(\mathscr{F} \otimes f^*\mathcal{E}) \;\cong\; (R^i f_*\mathscr{F}) \otimes \mathcal{E}.$$

   This follows from the fact that tensoring with a locally free sheaf is exact and commutes with the formation of higher direct images (since $f^*\mathcal{E}$ is locally free on X and the tensor product with a flat module commutes with cohomology). Combined with the Leray spectral sequence, the projection formula reduces many cohomological computations to known cases.

6.6.18 Remark: Finiteness Results in Context The finiteness theorem (theorem 6.6.6) is one of several finiteness results that govern the cohomology of schemes. Let us place it in context:

1. *Affine vanishing* (theorem 6.2.9): $H^i = 0$ for $i > 0$ on Noetherian affine schemes with quasi-coherent coefficients. This is the strongest vanishing result, but it applies only to affine schemes.

2. *Dimension bound* (theorem 6.2.5): $H^i = 0$ for $i > \dim X$ on Noetherian spaces. This holds for *all* sheaves of abelian groups, not just quasi-coherent ones.

3. *Finiteness* (theorem 6.6.6): H^i is finitely generated for coherent sheaves on projective schemes over Noetherian rings. This does *not* say the groups vanish, only that they are "finitely complicated."

4. *Serre vanishing* (lemma 6.8.23, through a closed embedding $X \hookrightarrow \mathbb{P}^n_A$): for a coherent sheaf $\mathscr{F}$ on a projective scheme X over a Noetherian ring A, there exists d_0 such that $H^i(X, \mathscr{F}(d)) = 0$ for all $i > 0$ and all $d \geq d_0$. This says that twisting "enough" kills all higher cohomology.

Together, these results are what cohomological arguments rest on in algebraic geometry. The finiteness theorem sits at the center: it is what allows us to define numerical invariants (Euler characteristics, Hilbert polynomials, Hodge numbers) that can then be studied using the vanishing results.

6.7 Euler Characteristics and Hilbert Polynomials

With the finiteness theorem (theorem 6.6.6) in hand, we know that the cohomology groups $H^i(X, \mathscr{F})$ of a coherent sheaf on a projective scheme over a field are finite-dimensional vector spaces. This means we can *count*: we can form the alternating sum of their dimensions, obtaining the *Euler characteristic* $\chi(X, \mathscr{F})$. The Euler characteristic is a cruder invariant than the individual cohomology groups, but it has a decisive advantage: it is *additive* on short exact sequences, while the individual h^i are not. This additivity makes the Euler characteristic computable by purely algebraic means, without explicitly resolving the sheaf.

When X is a projective scheme and $\mathscr{F}$ is twisted by a line bundle $\mathcal{O}_X(d)$, the Euler characteristic $\chi(X, \mathscr{F}(d))$ is a polynomial in d: the *Hilbert polynomial*. For $\mathscr{F} = \mathcal{O}_X$ this polynomial encodes the dimension, degree, and arithmetic genus of X, and it is the basis for the theory of Hilbert schemes and moduli spaces (cf. the discussion in section 3.3.6).

For curves, the interplay between the Euler characteristic and Serre duality yields the *Riemann–Roch theorem*, the single most important computational tool in the theory of algebraic curves.

6.7.1 The Euler Characteristic

Definition 6.7.1: Euler Characteristic

Let X be a projective scheme over a field k and let $\mathscr{F}$ be a coherent sheaf on X. The *Euler characteristic* of $\mathscr{F}$ is:

$$\chi(X,\mathscr{F}) = \sum_{i=0}^{\dim X} (-1)^i \dim_k H^i(X,\mathscr{F}) = \sum_{i\geq 0} (-1)^i h^i(X,\mathscr{F}),$$

where $h^i(X,\mathscr{F}) = \dim_k H^i(X,\mathscr{F})$. The sum is finite by theorem 6.2.5 and each term is finite by corollary 6.6.7.

The key property that makes the Euler characteristic tractable is the following:

Proposition 6.7.2: Additivity of the Euler Characteristic

Let X be a projective scheme over a field k. If $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ is a short exact sequence of coherent sheaves on X, then:

$$\chi(X,\mathscr{F}) = \chi(X,\mathscr{F}') + \chi(X,\mathscr{F}'').$$

***Proof*:**
The short exact sequence induces a long exact sequence in cohomology:

$$0 \to H^0(X,\mathscr{F}') \to H^0(X,\mathscr{F}) \to H^0(X,\mathscr{F}'') \to H^1(X,\mathscr{F}') \to \cdots \to H^n(X,\mathscr{F}'') \to 0,$$

where $n = \dim X$. This is a finite exact sequence of finite-dimensional k-vector spaces. The alternating sum of dimensions in any finite exact sequence $0 \to V_0 \xrightarrow{d_0} V_1 \xrightarrow{d_1} \cdots \xrightarrow{d_{m-1}} V_m \to 0$ is zero. For such a sequence put $r_j = \dim \operatorname{im}(d_j)$ for $0 \leq j \leq m-1$ and $r_{-1} = r_m = 0$. Exactness says $\ker(d_j) = \operatorname{im}(d_{j-1})$, with $d_m = 0$ and $d_{-1} = 0$, so rank and nullity give $\dim V_j = r_{j-1} + r_j$ for $0 \leq j \leq m$, and the alternating sum $\sum_j (-1)^j (r_{j-1} + r_j)$ telescopes to $r_{-1} + (-1)^m r_m = 0$. Grouping the terms by sheaf:

$$\sum_{i=0}^{n} \left[(-1)^i h^i(\mathscr{F}') - (-1)^i h^i(\mathscr{F}) + (-1)^i h^i(\mathscr{F}'')\right] = 0,$$

which rearranges to $\chi(\mathscr{F}) = \chi(\mathscr{F}') + \chi(\mathscr{F}'')$.

6.7.3 Remark: Euler Characteristic as a Group Homomorphism The additivity property can be rephrased as follows. The Grothendieck group $K_0(X)$ of coherent sheaves on X is the free abelian group generated by isomorphism classes $[\mathscr{F}]$ of coherent sheaves, modulo the relation $[\mathscr{F}] = [\mathscr{F}'] + [\mathscr{F}'']$ for every short exact sequence $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$. The Euler characteristic defines a group homomorphism:

$$\chi : K_0(X) \longrightarrow \mathbb{Z}, \qquad [\mathscr{F}] \longmapsto \chi(X, \mathscr{F}).$$

This is the starting point for K-theory in algebraic geometry. The Hilbert polynomial also factors through $K_0(X)$, and for smooth X so does the Chern character.

Example 6.7.4: Euler Characteristics

1. *Twisted sheaves on $\mathbb{P}^n_k$.* By theorem 6.3.1, the only nonzero cohomology groups of $\mathcal{O}_{\mathbb{P}^n}(d)$ are H^0 (when $d \geq 0$) and H^n (when $d \leq -(n+1)$). Hence:

$$\chi(\mathbb{P}^n_k, \mathcal{O}(d)) = \begin{cases} \binom{d+n}{n} & d \geq 0, \\ 0 & -(n+1) < d < 0, \\ (-1)^n \binom{-d-1}{n} & d \leq -(n+1). \end{cases}$$

   A fact (which we will prove in the next subsection) is that all three cases are given by a single polynomial in d:

$$\chi(\mathbb{P}^n_k, \mathcal{O}(d)) = \binom{d+n}{n} = \frac{(d+1)(d+2)\cdots(d+n)}{n!}$$

   for *all* $d \in \mathbb{Z}$. For instance, when $n = 1$: $\chi(\mathbb{P}^1, \mathcal{O}(d)) = d+1$. When $d = -1$: $\chi(\mathbb{P}^1, \mathcal{O}(-1)) = 0$, which is correct since both H^0 and H^1 vanish. When $d = -2$: $\chi(\mathbb{P}^1, \mathcal{O}(-2)) = -1$, reflecting $h^0 = 0$ and $h^1 = 1$.

2. *Structure sheaf of a curve.* Let C be a smooth projective curve of genus g over k with $H^0(C, \mathcal{O}_C) = k$, for instance with k algebraically closed (theorem 3.5.33). Then $h^0(C, \mathcal{O}_C) = 1$ and $h^1(C, \mathcal{O}_C) = g$ (this is one definition of the genus; see definition 7.2.4). Hence:

$$\chi(C, \mathcal{O}_C) = 1 - g.$$

   By Serre duality (corollary 6.5.10), $h^1(C, \mathcal{O}_C) = h^0(C, \omega_C) = p_g$, the geometric genus (definition 5.5.29). So $\chi(C, \mathcal{O}_C) = 1 - p_g$, confirming the equivalence of the arithmetic and geometric genus for smooth curves (proposition 7.2.5).

3. *Structure sheaf of a surface.* Let S be a smooth projective surface over k with $H^0(S, \mathcal{O}_S) = k$, for instance with k algebraically closed (theorem 3.5.33). Then:

$$\chi(S, \mathcal{O}_S) = h^0(\mathcal{O}_S) - h^1(\mathcal{O}_S) + h^2(\mathcal{O}_S) = 1 - q + p_g,$$

   where $q = h^1(\mathcal{O}_S)$ is the *irregularity* and $p_g = h^2(\mathcal{O}_S) = h^0(\omega_S)$ is the geometric genus (the last equality by Serre duality). The integer $\chi(\mathcal{O}_S) = 1 - q + p_g$ is a fundamental invariant in the classification of surfaces.

4. *Additivity in action.* Let $C \subset \mathbb{P}^2_k$ be a smooth plane curve of degree d. The short exact sequence $0 \to \mathcal{O}_{\mathbb{P}^2}(-d) \to \mathcal{O}_{\mathbb{P}^2} \to \mathcal{O}_C \to 0$ gives:

$$\chi(C, \mathcal{O}_C) = \chi(\mathbb{P}^2, \mathcal{O}_{\mathbb{P}^2}) - \chi(\mathbb{P}^2, \mathcal{O}(-d)) = 1 - \binom{-d+2}{2} = 1 - \frac{(d-1)(d-2)}{2}.$$

Hence $g = \frac{(d-1)(d-2)}{2}$, the classical genus formula for plane curves. For $d = 1$: $g = 0$ (a line). For $d = 3$: $g = 1$ (a smooth cubic). For $d = 4$: $g = 3$ (a quartic).

6.7.2 Hilbert Polynomials

The Euler characteristic of a twisted sheaf $\mathscr{F}(d)$ is a polynomial in d. This is the most important non-obvious property of the Euler characteristic. Polynomiality, the degree and the sign of the leading term all come from the additivity of χ, by induction on hyperplane sections.

Theorem 6.7.5: Hilbert Polynomial

Let X be a projective scheme over a field k, equipped with a very ample sheaf $\mathcal{O}_X(1)$, and let $\mathscr{F}$ be a coherent sheaf on X. Then there exists a polynomial $P_{\mathscr{F}} \in \mathbb{Q}[t]$, called the *Hilbert polynomial* of $\mathscr{F}$, such that:

$$P_{\mathscr{F}}(d) = \chi(X, \mathscr{F}(d)) \qquad \text{for all } d \in \mathbb{Z}.$$

If $\mathscr{F} \neq 0$, the degree of $P_{\mathscr{F}}$ equals the dimension of the support of $\mathscr{F}$, and the leading coefficient is positive.

***Proof*:**

For every field extension K/k, example 6.8.14(3) gives $\chi(X, \mathscr{F}(d)) = \chi(X_K, \mathscr{F}_K(d))$. Take $K = \overline{k}$, which is infinite. The support of $\mathscr{F}_K$ is the preimage of $\operatorname{supp}\mathscr{F}$. Over an affine open $\operatorname{Spec} A$ of X on which $\operatorname{supp}\mathscr{F}$ is $V(\mathfrak{a})$, that preimage is the underlying set of $\operatorname{Spec}(A/\mathfrak{a} \otimes_k K)$, an integral extension of $A/\mathfrak{a}$, so $\dim(\operatorname{supp}\mathscr{F}_K) = \dim(\operatorname{supp}\mathscr{F})$ by lemma 2.6.3. We may therefore replace k by K, and we assume k infinite. If $\mathscr{F} = 0$ then $P_{\mathscr{F}} = 0$, so let $\mathscr{F} \neq 0$. We prove the whole statement by induction on $r = \dim(\operatorname{supp}\mathscr{F})$.

Base case ($r = 0$): If $\operatorname{supp}\mathscr{F}$ is zero-dimensional, it consists of finitely many closed points (since X is Noetherian). On a zero-dimensional space, H^0 is the only nonzero cohomology group, and twisting by $\mathcal{O}_X(d)$ has no effect on a sheaf supported at finitely many points (since the stalk of $\mathcal{O}_X(d)$ at a closed point is isomorphic to $\mathcal{O}_{X,x}$, with the twist absorbed into the local isomorphism). Hence $\chi(X, \mathscr{F}(d)) = h^0(X, \mathscr{F}) = \dim_k \Gamma(X, \mathscr{F})$, a constant polynomial, positive because $\Gamma(X, \mathscr{F})$ is the sum of the nonzero stalks of $\mathscr{F}$ at the points of its support.

Inductive step: Let $r \geq 1$. Choose a hyperplane section $H \in |\mathcal{O}_X(1)|$ that does not contain any associated point of $\mathscr{F}$ (this is possible because $\mathscr{F}$ has finitely many associated points, $\mathcal{O}_X(1)$ is generated by the pullbacks of the coordinates $x_0, \ldots, x_N$ along the embedding (theorem 5.3.43(1)), and k is infinite). Then multiplication by the section $s \in H^0(X, \mathcal{O}_X(1))$ defining H gives an injective map $\mathscr{F}(-1) \xrightarrow{\cdot s} \mathscr{F}$. Let $\mathscr{G}$ be the cokernel:

$$0 \longrightarrow \mathscr{F}(-1) \xrightarrow{\cdot s} \mathscr{F} \longrightarrow \mathscr{G} \longrightarrow 0.$$

Since s vanishes on H, the sheaf $\mathscr{G}$ is supported on $\operatorname{supp}(\mathscr{F}) \cap H$, and at each point x of that set $\mathscr{G}_x = \mathscr{F}_x / s\mathscr{F}_x \neq 0$ by Nakayama's lemma, so $\operatorname{supp}\mathscr{G} = \operatorname{supp}(\mathscr{F}) \cap H$. This set has dimension exactly $r-1$. The section s is the restriction of a linear form ℓ in $x_0, \ldots, x_N$, so $H = X \cap V_+(\ell)$. Let Z be an irreducible component of $\operatorname{supp}\mathscr{F}$ with $\dim Z \geq 1$, a closed subvariety of $\mathbb{P}^N_k$ with its reduced structure. Its generic point is an associated point of $\mathscr{F}$, so $Z \not\subseteq V_+(\ell)$, and every irreducible component of $Z \cap V_+(\ell)$ has dimension $\dim Z - 1$ by lemma 3.7.11. The zero-dimensional components of $\operatorname{supp}\mathscr{F}$ are associated points and miss H. This gives the bound $\leq r-1$. When $\dim Z = r$, the set $Z \cap V_+(\ell)$ is nonempty: otherwise Z is a closed subscheme of the affine scheme $D_+(\ell)$, hence affine, and proper over k by theorem 3.5.32, hence finite over k by proposition 3.5.25 and of dimension 0. Twisting the whole sequence by $\mathcal{O}_X(d)$:

$$0 \longrightarrow \mathscr{F}(d-1) \longrightarrow \mathscr{F}(d) \longrightarrow \mathscr{G}(d) \longrightarrow 0.$$

By the additivity of χ:

$$\chi(X, \mathscr{F}(d)) - \chi(X, \mathscr{F}(d-1)) = \chi(X, \mathscr{G}(d)).$$

By the inductive hypothesis, $\chi(X, \mathscr{G}(d))$ is a polynomial in d of degree $r-1$ with positive leading coefficient c. The function $\Delta P(d) = P(d) - P(d-1)$ is the *difference operator*; if ΔP is a polynomial of degree $r-1$ with leading coefficient c, then P is a polynomial of degree r with leading coefficient c/r[a]. Since $\chi(X, \mathscr{F}(d))$ is an integer for all d and agrees with a polynomial in d after taking differences, it is itself a polynomial in d (with rational coefficients), of degree r with leading coefficient $c/r > 0$.

[a] This is the discrete analogue of the fact that if $f'(x)$ is a polynomial of degree $r-1$, then $f(x)$ is a polynomial of degree r. Concretely: the binomial coefficients $\binom{d}{j}$ form a basis for $\mathbb{Q}[d]$, and $\Delta\binom{d}{j} = \binom{d}{j} - \binom{d-1}{j} = \binom{d-1}{j-1}$, so the difference operator lowers the degree by exactly one.

Definition 6.7.6: Hilbert Polynomial and Arithmetic Genus

Let X be a projective scheme of dimension n over a field k. The *Hilbert polynomial* of X (with respect to $\mathcal{O}_X(1)$) is $P_X = P_{\mathcal{O}_X}$. The *arithmetic genus* of X is:

$$p_a(X) = (-1)^n\big(\chi(X, \mathcal{O}_X) - 1\big) = (-1)^n(P_X(0) - 1).$$

When $H^0(X, \mathcal{O}_X) = k$: for a curve ($n = 1$), $p_a = 1 - \chi(\mathcal{O}_C) = h^1(\mathcal{O}_C)$, which is the genus g when C is smooth, and for a surface ($n = 2$), $p_a = \chi(\mathcal{O}_S) - 1 = h^2(\mathcal{O}_S) - h^1(\mathcal{O}_S)$, which is $p_g - q$ when S is smooth.

Example 6.7.7: Hilbert Polynomials

1. *Projective space.* By Example 6.7.4(1), $P_{\mathbb{P}^n}(d) = \binom{d+n}{n}$. This is a polynomial of degree n in d with leading coefficient $1/n!$. The arithmetic genus is $p_a(\mathbb{P}^n) = (-1)^n\big(\binom{n}{n} - 1\big) = 0$.

2. *Plane curve of degree d.* Let $C \subset \mathbb{P}^2_k$ be a curve of degree d. The short exact sequence $0 \to \mathcal{O}_{\mathbb{P}^2}(-d) \to \mathcal{O}_{\mathbb{P}^2} \to \mathcal{O}_C \to 0$ gives, after twisting by $\mathcal{O}(m)$ and taking χ:

$$P_C(m) = \binom{m+2}{2} - \binom{m-d+2}{2} = dm - \frac{d(d-3)}{2}.$$

This is a polynomial of degree 1 (as expected, since $\dim C = 1$) with leading coefficient d, which is the *degree* of C. The arithmetic genus is $p_a = 1 - P_C(0) = \frac{(d-1)(d-2)}{2}$.

3. *Hilbert polynomial of a line bundle on a curve.* Let C be a smooth projective curve of genus g with $H^0(C, \mathcal{O}_C) = k$ and let $\mathcal{L}$ be a line bundle of degree ℓ on C. By lemma 6.7.11 below:

$$P_{\mathcal{L}}(d) = \chi(C, \mathcal{L}(d)) = \ell + d \cdot \deg(\mathcal{O}_C(1)) + 1 - g.$$

In particular, $\chi(C, \mathcal{L}) = \deg \mathcal{L} + 1 - g$, confirming theorem 6.7.5.

4. *Twisted ideal sheaf.* Let $Z \subset \mathbb{P}^n_k$ be a closed subscheme with ideal sheaf $\mathscr{I}_Z$. Then the short exact sequence $0 \to \mathscr{I}_Z \to \mathcal{O}_{\mathbb{P}^n} \to \mathcal{O}_Z \to 0$ gives $P_{\mathscr{I}_Z}(d) = P_{\mathbb{P}^n}(d) - P_Z(d)$. The Hilbert polynomial of $\mathscr{I}_Z$ encodes the "difference" between the ambient space and the subscheme, and this is the key to defining Hilbert schemes: the closed subschemes of $\mathbb{P}^n_k$ with a given Hilbert polynomial P all lie in the one Hilbert scheme $\mathrm{Hilb}^P_{\mathbb{P}^n_k}$ (theorem 3.3.11).

Proposition 6.7.8: Hilbert Polynomial and Hilbert Function

Let $X \subseteq \mathbb{P}^N_k$ be a projective scheme and $\mathscr{F}$ a coherent sheaf on X. Then for $d \gg 0$:

$$P_{\mathscr{F}}(d) = h^0(X, \mathscr{F}(d)).$$

That is, the Hilbert polynomial agrees with the function $d \mapsto h^0(X, \mathscr{F}(d))$ for all sufficiently large d. If X is cut out by a homogeneous ideal $I \subseteq S = k[x_0, \ldots, x_N]$, then also $P_{\mathcal{O}_X}(d) = \dim_k(S/I)_d$ for $d \gg 0$, so P_X is the Hilbert polynomial of the graded ring S/I, and for a projective variety it is the classical Hilbert polynomial of [30, Hilbert Polynomial].

***Proof*:**
By Serre vanishing (lemma 6.8.23, through the closed embedding $X \subseteq \mathbb{P}^N_k$), there exists d_0 such that $H^i(X, \mathscr{F}(d)) = 0$ for all $i > 0$ and all $d \geq d_0$. For such d:

$$P_{\mathscr{F}}(d) = \chi(X, \mathscr{F}(d)) = h^0(X, \mathscr{F}(d)) - 0 + 0 - \cdots = h^0(X, \mathscr{F}(d)).$$

For the second statement, $\mathcal{O}_X$ is the sheaf associated to the graded S-module S/I, and the natural map $(S/I)_d \to H^0(X, \mathcal{O}_X(d))$ is an isomorphism for $d \gg 0$ [50, Exercise II.5.9(b)], as claimed.

The degree and leading coefficient of the Hilbert polynomial have geometric meaning:

Proposition 6.7.9: Degree and Leading Coefficient

Let $X \subseteq \mathbb{P}^N_k$ be a projective scheme of dimension n and let $\mathscr{F} \neq 0$ be a coherent sheaf with $\dim(\operatorname{supp}\mathscr{F}) = r$. Write:

$$P_{\mathscr{F}}(d) = \frac{a_r}{r!}\, d^r + \text{lower order terms.}$$

Then a_r is a positive integer. When $\mathscr{F} = \mathcal{O}_X$, the integer a_n is the *degree* of X in $\mathbb{P}^N$. When k is algebraically closed and X is a variety, it is the number of points in the intersection of X with a general linear subspace of complementary dimension.

***Proof*:**
The positivity of a_r is part of theorem 6.7.5. The integrality of a_r follows from the inductive proof of theorem 6.7.5, run over an infinite extension of k, which does not change $P_{\mathscr{F}}$: with $\mathscr{G}$ the cokernel of that proof, the difference $\Delta P_{\mathscr{F}} = P_{\mathscr{G}}$ has leading coefficient $r \cdot a_r/r! = a_r/(r-1)!$, so a_r equals the coefficient a_{r-1} of $P_{\mathscr{G}}$ in the same normalization, an integer by induction on r.

When k is algebraically closed and X is a variety, P_X is the classical Hilbert polynomial of X (proposition 6.7.8), so a_n is the classical degree, and [30, Degree Counts Points of a Linear Section] identifies it with the number of points of a general linear section of complementary dimension.

6.7.10 Remark: Invariance of the Hilbert Polynomial The Hilbert polynomial depends on the choice of embedding (or more precisely, on the choice of very ample sheaf $\mathcal{O}_X(1)$). However, the *constant term* $P_X(0) = \chi(X, \mathcal{O}_X)$ is independent of the embedding: it depends only on the abstract scheme X, since it is defined purely in terms of the cohomology of the structure sheaf. Similarly, the arithmetic genus $p_a(X) = (-1)^n(\chi(\mathcal{O}_X) - 1)$ is an intrinsic invariant. In fact, by theorem 5.5.31, the geometric genus $p_g = h^0(X, \omega_X)$ is a birational invariant for smooth projective varieties, and Serre duality relates it to the "top" cohomology of $\mathcal{O}_X$.
The higher coefficients of P_X do depend on the embedding, but they carry geometric information about the embedding itself (degree, sectional genus, etc.).

6.7.3 Riemann–Roch for Curves

Serre duality and the additivity of the Euler characteristic combine into the Riemann-Roch theorem for a smooth projective curve C over any field k with $H^0(C, \mathcal{O}_C) = k$. Chapter 7 develops its consequences over an algebraically closed field.

Here a *smooth projective curve* over a field k is a smooth, projective, integral scheme of dimension 1 over k (the general notion of a curve is definition 7.1.1). Its *genus* is $g = \dim_k H^1(C, \mathcal{O}_C)$.

For a smooth projective curve C over k, the cohomology groups have the following structure: H^0 and H^1 are the only potentially nonzero groups (since $\dim C = 1$), the canonical sheaf $\omega_C = \Omega_{C/k}$ is an invertible sheaf, and Serre duality (corollary 6.5.10) gives $H^1(C, \mathcal{L}) \cong H^0(C, \mathcal{L}^\vee \otimes \omega_C)^*$ for any line bundle $\mathcal{L}$.

Lemma 6.7.11: Degree and Euler Characteristic

Let C be a smooth projective curve over a field k and let $\mathcal{L}$ be a line bundle on C. Then

$$\chi(C, \mathcal{L}) = \deg \mathcal{L} + \chi(C, \mathcal{O}_C)$$

If $H^0(C, \mathcal{O}_C) = k$, for instance if k is algebraically closed (theorem 3.5.33), then $\chi(C, \mathcal{L}) = \deg \mathcal{L} + 1 - g$. Here $\deg \mathcal{L} = \deg D$ for a Weil divisor $D = \sum_p n_p p$ with $\mathcal{L} \cong \mathcal{O}_C(D)$ (corollary 5.4.45), where $\deg D = \sum_p n_p [\kappa(p) : k]$, and the proof shows that this does not depend on D.

***Proof*:**
The curve C is integral, separated, Noetherian and regular, hence locally factorial (proposition 2.7.27), so every line bundle on C is $\mathcal{O}_C(D)$ for a Weil divisor D (corollary 5.4.45). Let D be a divisor and p a closed point, with $\delta_p = [\kappa(p) : k]$. If t is a uniformizer of the discrete valuation ring $\mathcal{O}_{C,p}$ and n is the coefficient of p in D, then near p the sheaves $\mathcal{O}_C(D)$ and $\mathcal{O}_C(D + p)$ are generated by t^{-n} and t^{-n-1}, and away from p they agree. So the inclusion $\mathcal{O}_C(D) \subseteq \mathcal{O}_C(D + p)$ has cokernel the skyscraper sheaf $\mathcal{O}_{C,p}/(t) = \kappa(p)$ at p, and the sequence

$$0 \to \mathcal{O}_C(D) \to \mathcal{O}_C(D + p) \to \kappa(p) \to 0$$

is exact. The skyscraper sheaf has $H^0 = \kappa(p)$, of dimension δ_p over k, and no higher cohomology (proposition 6.2.4), so additivity of the Euler characteristic (proposition 6.7.2) gives $\chi(\mathcal{O}_C(D + p)) = \chi(\mathcal{O}_C(D)) + \delta_p$. As $\deg(D+p) = \deg D + \delta_p$, the formula $\chi(\mathcal{O}_C(D)) = \deg D + \chi(\mathcal{O}_C)$ holds for D if and only if it holds for $D + p$. It holds for $D = 0$, and every divisor is reached from 0 by finitely many additions and subtractions of closed points, so it holds for every D. Since $\chi(\mathcal{O}_C(D))$ depends only on the isomorphism class of $\mathcal{O}_C(D)$, so does $\deg D$, and $\deg \mathcal{O}_C(D) = \deg D$ is well defined. When $H^0(C, \mathcal{O}_C) = k$, the Euler characteristic $\chi(\mathcal{O}_C)$ is $1 - g$, which gives the last formula, completing the proof.

Theorem 6.7.12: Riemann–Roch Theorem

Let C be a smooth projective curve of genus g over a field k with $H^0(C, \mathcal{O}_C) = k$, and let D be a divisor on C with associated line bundle $\mathcal{L} = \mathcal{O}_C(D)$. Let K be a canonical divisor (so $\mathcal{O}_C(K) \cong \omega_C$). Then:

$$h^0(C, \mathcal{O}_C(D)) - h^0(C, \mathcal{O}_C(K - D)) = \deg D + 1 - g.$$

Equivalently, using the notation $\ell(D) = h^0(C, \mathcal{O}_C(D))$:

$$\ell(D) - \ell(K - D) = \deg D + 1 - g.$$

***Proof*:**
By Serre duality (corollary 6.5.10):

$$h^1(C, \mathcal{O}_C(D)) = \dim_k H^1(C, \mathcal{O}_C(D)) = \dim_k H^0(C, \mathcal{O}_C(D)^\vee \otimes \omega_C)^* = h^0(C, \mathcal{O}_C(K - D)),$$

where we used $\mathcal{O}_C(D)^\vee \otimes \omega_C \cong \mathcal{O}_C(-D) \otimes \mathcal{O}_C(K) \cong \mathcal{O}_C(K-D)$. Now apply lemma 6.7.11:

$$h^0(C, \mathcal{O}_C(D)) - h^1(C, \mathcal{O}_C(D)) = \chi(C, \mathcal{O}_C(D)) = \deg D + 1 - g.$$

Substituting $h^1(C, \mathcal{O}_C(D)) = h^0(C, \mathcal{O}_C(K-D))$ gives the formula, as claimed.

Example 6.7.13: Riemann–Roch in Practice
Let C be as in theorem 6.7.12.

1. *Degree of the canonical divisor.* Setting $D = K$ in Riemann–Roch: $\ell(K) - \ell(0) = \deg K + 1 - g$. Since $\ell(K) = h^0(\omega_C) = g$ and $\ell(0) = h^0(\mathcal{O}_C) = 1$:

   $$\deg K = 2g - 2.$$

   For a smooth plane curve of degree d: $\omega_C \cong \mathcal{O}_C(d-3)$ (by proposition 6.5.7), so $\deg K = d(d-3)$. Setting $g = (d-1)(d-2)/2$, we verify: $2g-2 = (d-1)(d-2)-2 = d^2-3d = d(d-3)$.

2. *Very ample line bundles on curves.* When k is algebraically closed, a line bundle $\mathcal{L}$ on C is very ample (hence gives an embedding into projective space) if $\deg \mathcal{L} \geq 2g+1$. To see this: by Riemann–Roch, $\ell(D) = \deg D + 1 - g$ whenever $\deg D > 2g - 2 = \deg K$ (since then $\deg(K-D) < 0$, forcing $\ell(K-D) = 0$). If $\deg D \geq 2g+1$ and p, q are closed points, equal or not, then $D - p - q$ has degree $\geq 2g-1$, so $\ell(D-p-q) = \ell(D) - 2$. By the criterion of [50, Proposition IV.3.1], the linear system $|D|$ therefore separates points and tangent vectors, and $\mathcal{O}_C(D)$ is very ample (corollary 7.3.4).

3. *Elliptic curves.* Let C be a smooth projective curve of genus 1 with a rational point $O \in C(k)$. By Riemann–Roch with $D = 3O$:

   $$\ell(3O) = 3 + 1 - 1 = 3$$

   (since $\deg(K - 3O) = 2 \cdot 1 - 2 - 3 = -3 < 0$, so $\ell(K - 3O) = 0$). When k is algebraically closed, the three-dimensional space $H^0(C, \mathcal{O}(3O))$ gives a closed embedding $C \hookrightarrow \mathbb{P}^2$, and the image is a smooth plane cubic (proposition 7.6.2).

4. *Rational curves.* Let C have genus 0. Then $\chi(\mathcal{O}_C) = 1$ and for any line bundle $\mathcal{L}$ of degree $d \geq 0$:

   $$h^0(C, \mathcal{L}) = d + 1$$

   (since $h^1 = h^0(\omega_C \otimes \mathcal{L}^{-1})$ and $\deg(\omega_C \otimes \mathcal{L}^{-1}) = -2 - d < 0$). In particular, if C has a k-rational point p, then $h^0(\mathcal{O}_C(p)) = 2$ gives a morphism $C \to \mathbb{P}^1_k$ of degree 1, so $C \cong \mathbb{P}^1_k$.

6.7.14 Remark: Beyond Curves The Riemann–Roch theorem for curves is the "$n = 1$" case of a family of results that express the Euler characteristic in terms of topological and geometric invariants. In higher dimensions, the *Hirzebruch–Riemann–Roch theorem* asserts that for a smooth projective variety X of dimension n and a locally free sheaf $\mathcal{E}$:

$$\chi(X, \mathcal{E}) = \int_X \mathrm{ch}(\mathcal{E}) \cdot \mathrm{td}(T_X),$$

where $\mathrm{ch}(\mathcal{E})$ is the Chern character of $\mathcal{E}$, $\mathrm{td}(T_X)$ is the Todd class of the tangent bundle, and the integral is the degree of the component in codimension n (i.e., the intersection with the fundamental class). For curves, the Chern character of a line bundle is $1 + c_1(\mathcal{L})$ and the Todd class of T_C is $1 + \frac{1}{2}c_1(T_C) = 1 + \frac{1}{2}(2 - 2g)$, so the formula reduces to $\chi(\mathcal{L}) = \deg \mathcal{L} + 1 - g$. For surfaces, it gives the *Noether formula*:

$$\chi(\mathcal{O}_S) = \frac{1}{12}(K_S^2 + e(S)),$$

where K_S^2 is the self-intersection of the canonical class and $e(S)$ is the topological Euler characteristic. These generalizations belong to the intersection-theoretic framework developed in *Intersection Theory* [26].

6.8 Flat Morphisms and Semicontinuity

In the previous sections, we studied the cohomology of a *single* scheme. In practice, schemes often arise in *families*: a morphism $f : X \to Y$ presents X as a family of fibers X_y parameterized by points $y \in Y$, and for a coherent sheaf $\mathscr{F}$ on X with restrictions $\mathscr{F}_y = \mathscr{F}|_{X_y}$ to the fibers, the higher direct images $R^i f_* \mathscr{F}$ relativize cohomology over the base. A fundamental question is: how does the function $y \mapsto h^i(X_y, \mathscr{F}_y)$ behave as y varies?

6.8.1 Relation to Algebraic Topology This idea is already familiar to those who seen Serre spectral sequences where the cohomology of a space E is calculated given a fibration $0 \to F \to E \to B \to 0$.

The answer involves two intertwined ideas. The first is *flatness*: the condition that the fibers of f vary "continuously," without sudden jumps in dimension. Flat families are the algebraic analogue of fiber bundles, and they are the correct notion of "continuously varying family" in algebraic geometry. The second idea is *semicontinuity*: for f proper, Y Noetherian and $\mathscr{F}$ coherent and flat over Y, the dimensions $h^i(X_y, \mathscr{F}_y)$ can jump *up* at special points but not down, and when they are constant on a reduced base, the higher direct images are locally free and commute with base change.

These results are essential for moduli theory. The semicontinuity theorem ensures that the loci where cohomological invariants jump form closed subsets, and Grauert's theorem guarantees that the "generic" behavior of cohomology is well-controlled.

6.8.1 Flat Families

Definition 6.8.2: Family of Schemes

Let X, B be schemes. Then a *family of schemes* is given by a morphism $\pi : X \to B$. The scheme B is sometimes called the *parameter space*.

The notion of a family of schemes as it stands is much too general: consider any family $\pi : X \to B$, choose a closed point $b \in B$, and create a new family by taking the disjoint union of $X \setminus \pi^{-1}(b)$ and Y for some arbitrary $\kappa(b)$-scheme Y, mapped to B through $\operatorname{Spec} \kappa(b) \to B$. So a bare family has no properties worth deducing, and further conditions are needed.

Recall from commutative algebra (see [15]) that an R-module M is *flat* if the functor $M \otimes_R -$ is exact. Geometrically, flatness of a morphism means that the fibers do not "degenerate" in an uncontrolled way:

Definition 6.8.3: Flat Morphism

Let $f : X \to Y$ be a morphism of schemes.

1. An $\mathcal{O}_X$-module $\mathscr{F}$ is *flat over* Y (or f*-flat*) if for every point $x \in X$, the stalk $\mathscr{F}_x$ is a flat $\mathcal{O}_{Y,f(x)}$-module (via the local homomorphism $f_x^{\#} : \mathcal{O}_{Y,f(x)} \to \mathcal{O}_{X,x}$).
2. The morphism f itself is *flat* if $\mathcal{O}_X$ is flat over Y, i.e., if $\mathcal{O}_{X,x}$ is a flat $\mathcal{O}_{Y,f(x)}$-module for every $x \in X$.

Example 6.8.4: Flat and Non-Flat Morphisms

1. *Open immersions.* Any open immersion $j : U \hookrightarrow X$ is flat: the stalk map $\mathcal{O}_{X,x} \to \mathcal{O}_{U,x}$ is the identity for $x \in U$.
2. *Localization.* The morphism $\operatorname{Spec} R_f \to \operatorname{Spec} R$ induced by the localization $R \to R_f$ is flat, since localization is an exact functor.
3. *Finite free morphisms.* If $f : \operatorname{Spec} S \to \operatorname{Spec} R$ makes S a free R-module, then f is flat. More generally, if S is a finitely generated projective R-module, then f is flat.
4. *The family of conics.* Consider the morphism $f : V(xy - t) \to \mathbb{A}^1_k = \operatorname{Spec} k[t]$, where the fiber over $t = a \neq 0$ is the smooth hyperbola $xy = a$, and the fiber over $t = 0$ is the union of coordinate axes $xy = 0$. The coordinate ring is $k[x, y, t]/(xy - t) \cong k[x, y]$, and the map to $k[t]$ sends $t \mapsto xy$. This is flat: $k[x, y]$ is free over $k[xy] = k[t]$ (with basis given by the monomials $x^i y^j$ with either $i = 0$ or $j = 0$). The fiber over $t = 0$ is reducible, but the family is still flat.
5. *A non-flat family.* The blowup morphism $f : \operatorname{Bl}_0 \mathbb{A}^2 \to \mathbb{A}^2$ is *not* flat: the fiber over the origin is $\mathbb{P}^1$ (one-dimensional), while the fiber over every other point is a single point (zero-dimensional). For a flat morphism of schemes of finite type over k with irreducible source X and target Y, every irreducible component of every nonempty fiber has dimension $\dim X - \dim Y$ [50, Corollary III.9.6], so this jump is an obstruction. More precisely, the structure sheaf $\mathcal{O}_{\operatorname{Bl}_0 \mathbb{A}^2}$ is not flat over $\mathcal{O}_{\mathbb{A}^2,0}$.

6. *Families of subschemes.* Let $X = V(x^2 - t) \subset \mathbb{A}^1_x \times \mathbb{A}^1_t$ and let $f : X \to \mathbb{A}^1_t$ be the projection. For k algebraically closed of characteristic $\neq 2$ and a closed point $t = a \neq 0$, the fiber is two reduced points $x = \pm\sqrt{a}$; for $t = 0$, the fiber is the non-reduced scheme $\operatorname{Spec} k[x]/(x^2)$. This family *is* flat: $k[x,t]/(x^2 - t) \cong k[x]$ is free of rank 2 over $k[t]$ (with basis $\{1, x\}$). The non-reduced fiber at $t = 0$ is the "correct" flat limit of the two-point fibers: it remembers the multiplicity. This is exactly the phenomenon we encountered with intersection multiplicities in section 2.2.2.

Flatness as defined in definition 6.8.3 is a condition on stalks. Four facts make it usable in families: flatness is affine-local, it is stable under composition and base change, flat morphisms lift generizations, and a flat morphism locally of finite type over a locally Noetherian base is an open map. The last of these, with finite type sharpened to finite presentation, is the openness statement the theory of étale morphisms rests on ([21]).

Lemma 6.8.5: Transitivity and Base Change for Flat Modules

Let A be a ring.

1. If B is an A-algebra that is flat as an A-module, and M is a flat B-module, then M is flat as an A-module.
2. If M is a flat A-module and $A \to A'$ is any ring homomorphism, then $M \otimes_A A'$ is a flat A'-module.
3. For any multiplicatively closed subset $D \subseteq A$, the A-module $D^{-1}A$ is flat.

***Proof*:**
(1) Let $N \hookrightarrow N'$ be an injection of A-modules. There are natural isomorphisms $N \otimes_A M \cong N \otimes_A (B \otimes_B M) \cong (N \otimes_A B) \otimes_B M$, the second by [17, Associativity of the Tensor Product]. The map $N \otimes_A B \to N' \otimes_A B$ is injective because B is flat over A, and applying $- \otimes_B M$ preserves the injection because M is flat over B.

(2) Let $N \hookrightarrow N'$ be an injection of A'-modules. Using [17, Commutativity of the Tensor Product] to write $M \otimes_A A' \cong A' \otimes_A M$, associativity and $N \otimes_{A'} A' \cong N$ give natural isomorphisms

$$N \otimes_{A'} (A' \otimes_A M) \cong (N \otimes_{A'} A') \otimes_A M \cong N \otimes_A M$$

The map $N \to N'$ stays injective after restricting scalars along $A \to A'$, and M is flat over A, so $N \otimes_A M \to N' \otimes_A M$ is injective.

(3) For any A-module N there is a natural isomorphism $D^{-1}A \otimes_A N \cong D^{-1}N$ ([15, Characterization of Localization]), and localization preserves injections ([15, Localization Is Exact]).

Lemma 6.8.6: Flatness Is Affine-Local

Let $\pi : X \to Y$ be a scheme morphism. The following are equivalent:

1. π is flat (definition 6.8.3).
2. For every pair of affine opens $\operatorname{Spec} B \subseteq X$ and $\operatorname{Spec} A \subseteq Y$ with $\pi(\operatorname{Spec} B) \subseteq \operatorname{Spec} A$, the induced ring map makes B a flat A-module.
3. There are an affine open cover $\{\operatorname{Spec} A_j\}$ of Y and, for each j, an affine open cover $\{\operatorname{Spec} B_{ij}\}$ of $\pi^{-1}(\operatorname{Spec} A_j)$ such that each B_{ij} is a flat A_j-module.

***Proof*:**

Step 1: (2) implies (3). Every $x \in X$ has an affine open neighborhood mapping into an affine open of Y: choose an affine open $\operatorname{Spec} A \ni \pi(x)$, and then an affine open neighborhood of x inside the open set $\pi^{-1}(\operatorname{Spec} A)$, affine opens forming a basis of the topology. Such neighborhoods assemble into covers as in (3), and (2) gives the flatness.

Step 2: (3) implies (1). Let $x \in X$, and choose $\operatorname{Spec} B := \operatorname{Spec} B_{ij} \ni x$ over $\operatorname{Spec} A := \operatorname{Spec} A_j$. The restriction of π is the morphism of affine schemes induced by the ring map $A \to B$ (proposition 3.1.12). Writing $\mathfrak{q} \subseteq B$ for the prime of x and $\mathfrak{p} \subseteq A$ for its contraction, the prime of $y = \pi(x)$, the stalk map is $A_\mathfrak{p} \to B_\mathfrak{q}$. Set $B_\mathfrak{p} := (A \setminus \mathfrak{p})^{-1}B$. Since B is flat over A, the module $B_\mathfrak{p}$ is flat over $A_\mathfrak{p}$ by [15, Flatness Is A Local Property]. The ring $B_\mathfrak{q}$ is a further localization of $B_\mathfrak{p}$, hence flat over $B_\mathfrak{p}$ by lemma 6.8.5(3), and therefore flat over $A_\mathfrak{p}$ by lemma 6.8.5(1). So every stalk map of π is flat.

Step 3: (1) implies (2). Let $\operatorname{Spec} B$ over $\operatorname{Spec} A$ be as in (2), let $N \hookrightarrow N'$ be an injection of A-modules, and let K be the kernel of $N \otimes_A B \to N' \otimes_A B$, a B-module. Fix a prime $\mathfrak{q} \subseteq B$ with contraction $\mathfrak{p} \subseteq A$. Localization is exact ([15, Localization Is Exact]), so $K_\mathfrak{q}$ is the kernel of $(N \otimes_A B)_\mathfrak{q} \to (N' \otimes_A B)_\mathfrak{q}$. The image of $A \setminus \mathfrak{p}$ is invertible in $B_\mathfrak{q}$, making $B_\mathfrak{q}$ an $A_\mathfrak{p}$-module, and [15, Characterization of Localization] together with [17, Associativity of the Tensor Product] identifies

$$(N \otimes_A B)_\mathfrak{q} \cong N \otimes_A B_\mathfrak{q} \cong (N \otimes_A A_\mathfrak{p}) \otimes_{A_\mathfrak{p}} B_\mathfrak{q} \cong N_\mathfrak{p} \otimes_{A_\mathfrak{p}} B_\mathfrak{q}$$

naturally in N. The map $N_\mathfrak{p} \to N'_\mathfrak{p}$ is injective, and $B_\mathfrak{q}$ is a flat $A_\mathfrak{p}$-module, being a stalk map of the flat π. So $K_\mathfrak{q} = 0$ for every prime $\mathfrak{q}$, and $K = 0$ by [15, Zero Module Is A Local Property].

Proposition 6.8.7: Flat Morphisms Are Stable under Composition and Base Change

1. If $\pi : X \to Y$ and $\rho : Y \to Z$ are flat, then $\rho \circ \pi$ is flat.
2. If $\pi : X \to Y$ is flat and $g : Y' \to Y$ is any morphism, then the base change $X \times_Y Y' \to Y'$ is flat.

***Proof*:**
(1) For $x \in X$ the stalk maps form the tower $\mathcal{O}_{Z,\rho(\pi(x))} \to \mathcal{O}_{Y,\pi(x)} \to \mathcal{O}_{X,x}$, in which $\mathcal{O}_{X,x}$ is flat over $\mathcal{O}_{Y,\pi(x)}$ and $\mathcal{O}_{Y,\pi(x)}$ is flat over $\mathcal{O}_{Z,\rho(\pi(x))}$. Lemma 6.8.5(1) gives flatness of $\mathcal{O}_{X,x}$ over $\mathcal{O}_{Z,\rho(\pi(x))}$.

(2) Cover Y' by affine opens $\operatorname{Spec} A'$, each mapping into an affine open $\operatorname{Spec} A \subseteq Y$, as in Step 1 of the proof of lemma 6.8.6. As in the proof of proposition 3.4.25, proposition 3.2.5(1) and the affine construction of theorem 3.2.1 identify the preimage of $\operatorname{Spec} A'$ in $X \times_Y Y'$ with $\pi^{-1}(\operatorname{Spec} A) \times_{\operatorname{Spec} A} \operatorname{Spec} A'$, and covering $\pi^{-1}(\operatorname{Spec} A)$ by affine opens $\operatorname{Spec} B$ covers that preimage by the affine opens $\operatorname{Spec}(B \otimes_A A')$. Each B is flat over A by lemma 6.8.6, so each $B \otimes_A A'$ is flat over A' by lemma 6.8.5(2), and lemma 6.8.6(3) makes the base change flat.

Lemma 6.8.8: Flat Morphisms Lift Generizations

Let $\pi : X \to Y$ be a flat morphism of schemes, let $x \in X$ with $y = \pi(x)$, and let $y' \in Y$ be a generization of y (definition 2.1.8). Then there is a generization x' of x with $\pi(x') = y'$.

***Proof*:**
Step 1: reduction to rings. Choose affine opens $\operatorname{Spec} B \subseteq X$ containing x and $\operatorname{Spec} A \subseteq Y$ containing y with $\pi(\operatorname{Spec} B) \subseteq \operatorname{Spec} A$. An open set contains every generization of each of its points: if $y' \notin \operatorname{Spec} A$, then y' lies in the closed complement, hence so does every point of $\overline{\{y'\}}$, including y, a contradiction. So $y' \in \operatorname{Spec} A$. Let $\mathfrak{q} \subseteq B$ and $\mathfrak{p}, \mathfrak{p}' \subseteq A$ be the primes of x, y, y'. That y' generizes y means $\mathfrak{p}' \subseteq \mathfrak{p}$ (definition 2.1.8), and a generization of x inside $\operatorname{Spec} B$ is a generization in X, so it suffices to find a prime $\mathfrak{q}' \subseteq \mathfrak{q}$ of B contracting to $\mathfrak{p}'$.

Step 2: the local stalk map is faithfully flat. The stalk map $A_\mathfrak{p} \to B_\mathfrak{q}$ is flat, and it carries $\mathfrak{p}A_\mathfrak{p}$ into $\mathfrak{q}B_\mathfrak{q}$, since $\mathfrak{p}$ is the contraction of $\mathfrak{q}$. Hence $\mathfrak{p}A_\mathfrak{p} \cdot B_\mathfrak{q} \subseteq \mathfrak{q}B_\mathfrak{q} \neq B_\mathfrak{q}$, which is condition (3) of [15, Characterizations of Faithful Flatness] for the unique maximal ideal of the local ring $A_\mathfrak{p}$. That result then makes $B_\mathfrak{q}$ faithfully flat over $A_\mathfrak{p}$ and, for the flat ring map $A_\mathfrak{p} \to B_\mathfrak{q}$, makes $\operatorname{Spec} B_\mathfrak{q} \to \operatorname{Spec} A_\mathfrak{p}$ surjective.

Step 3: contract. The primes of $A_\mathfrak{p}$ are the primes of A contained in $\mathfrak{p}$, so $\mathfrak{p}'A_\mathfrak{p}$ is one of them, and surjectivity provides a prime of $B_\mathfrak{q}$ lying over it. Its contraction $\mathfrak{q}' \subseteq B$ satisfies $\mathfrak{q}' \subseteq \mathfrak{q}$ and $\mathfrak{q}' \cap A = \mathfrak{p}'$. The point $x' = [\mathfrak{q}']$ is a generization of x with $\pi(x') = y'$, as we sought to show.

For ring maps this is the going-down property of flatness. *Commutative Algebra* proves going-down for integral extensions of a normal domain by a domain ([15, Integral Extension Prime Correspondence (Cohen-Seidenberg Theorem)]). Flatness is the other standard hypothesis that yields it.

Lemma 6.8.9: Constructible Sets Stable under Generization Are Open

Let Y be a Noetherian scheme and $E \subseteq Y$ a constructible subset (definition 5.2.2).

1. If E is stable under specialization, then E is closed.
2. If E is stable under generization, then E is open.

***Proof*:**
The underlying space of Y is a Noetherian topological space: Y is a finite union of spectra of Noetherian rings, descending chains of closed subsets of a spectrum correspond to ascending chains of radical ideals, and a finite union of Noetherian subspaces is Noetherian.

Step 1: the closed statement. By lemma 5.2.3, $E = \bigcup_{i=1}^{n} U_i \cap Z_i$ with U_i open and Z_i closed, and, discarding the indices with $U_i \cap Z_i = \emptyset$ and replacing each remaining Z_i by the closure of $U_i \cap Z_i$, we may assume $Z_i = \overline{U_i \cap Z_i} \neq \emptyset$. Since $\overline{E} \subseteq Z_1 \cup \cdots \cup Z_n$, it suffices to show $Z_i \subseteq E$ for each i. Fix i and write $T := Z_i$, so that $U_i \cap T = U_i \cap Z_i$ is a dense open subset of T. Decompose $T = T_1 \cup \cdots \cup T_m$ into irreducible closed subsets, none contained in another (proposition 2.1.25). For each j the set $V_j := T \setminus \bigcup_{l \neq j} T_l$ is open in T with $V_j \subseteq T_j$, and nonempty: otherwise the irreducible T_j, covered by the finitely many closed sets $T_j \cap T_l$ with $l \neq j$, would lie in a single T_l, against proposition 2.1.25. The dense open $U_i \cap T$ meets V_j, so $W := U_i \cap T \cap V_j$ is a nonempty subset of T_j, open in T and hence open in T_j. With its reduced induced structure (definition 3.1.26), T_j is an integral scheme (proposition 2.4.26), so it has a generic point η_j with $\overline{\{\eta_j\}} = T_j$ (lemma 2.4.21). The point η_j lies in every nonempty open subset of T_j: otherwise $\overline{\{\eta_j\}}$ would be contained in a proper closed subset. So $\eta_j \in W \subseteq U_i \cap Z_i \subseteq E$. Every point of T_j is a specialization of η_j, so stability under specialization gives $T_j \subseteq E$. Hence $T \subseteq E$, and $\overline{E} = E$.

Step 2: the open statement. The complement of a constructible set is constructible (definition 5.2.2), and E is stable under generization exactly when $Y \setminus E$ is stable under specialization. Step 1 makes $Y \setminus E$ closed, so E is open.

The openness criterion proves in full the fact underlying corollary 5.2.11(2).

Theorem 6.8.10: Flat Morphisms of Finite Type Are Open

Let Y be a locally Noetherian scheme (definition 2.4.1) and let $\pi : X \to Y$ be flat and locally of finite type. Then π is an open map. Moreover, for every morphism $Y' \to Y$ with Y' locally Noetherian, the base change $X \times_Y Y' \to Y'$ is an open map.

***Proof*:**
Step 1: a basis of good charts. Let $U \subseteq X$ be open and $x \in U$. Choose an affine open $\operatorname{Spec} A \subseteq Y$ with A Noetherian containing $\pi(x)$ (definition 2.4.1), then an affine open $\operatorname{Spec} B \subseteq \pi^{-1}(\operatorname{Spec} A)$ containing x with B a finitely generated A-algebra (definition 3.4.28), then $g \in B$ with $x \in \operatorname{Spec} B_g \subseteq U \cap \operatorname{Spec} B$, distinguished opens forming a basis. The localization $B_g \cong B[t]/(tg - 1)$ is again a finitely generated A-algebra. As x ranges over U, the sets $\operatorname{Spec} B_g$ cover U, so $\pi(U)$ is the union of the images $\pi(\operatorname{Spec} B_g)$, and it suffices to show each such image is open in $\operatorname{Spec} A$, hence in Y.

Step 2: the image of a chart is constructible. The morphism $\operatorname{Spec} B_g \to \operatorname{Spec} A$ induced by $A \to B_g$ is of finite type: the one-chart cover exhibits it as locally of finite type (definition 3.4.28 via proposition 3.4.30), and it is quasicompact because B_g is Noetherian, as a quotient of a polynomial ring over A ([15, HBT on multi-variable Polynomials]), so that $\operatorname{Spec} B_g$ is a Noetherian topological space, every subset of which is quasicompact. Both schemes are Noetherian, so

theorem 5.2.7 makes the image $\pi(\operatorname{Spec} B_g)$ constructible in $\operatorname{Spec} A$.

Step 3: the image is stable under generization. The morphism $\operatorname{Spec} B_g \to \operatorname{Spec} A$ is flat: its stalk maps are stalk maps of π, both schemes being open subschemes. Given $y \in \pi(\operatorname{Spec} B_g)$, a preimage $u \in \operatorname{Spec} B_g$, and a generization y' of y in $\operatorname{Spec} A$, lemma 6.8.8 produces $u' \in \operatorname{Spec} B_g$ with image y'. So $\pi(\operatorname{Spec} B_g)$ is stable under generization, and lemma 6.8.9 makes it open in the Noetherian scheme $\operatorname{Spec} A$. This proves that π is open.

Step 4: base change. Let $Y' \to Y$ have Y' locally Noetherian. The base change $X \times_Y Y' \to Y'$ is flat (proposition 6.8.7) and locally of finite type (proposition 3.4.35), so the first part of the proof applies to it, as we sought to show.

Corollary 6.8.11: Flat Morphisms of Finite Presentation Are Open over Noetherian Bases

Let Y be a locally Noetherian scheme and let $\pi : X \to Y$ be flat and locally of finite presentation (definition 3.4.33). Then π is an open map, and so is every base change of π along a morphism from a locally Noetherian scheme.

***Proof*:**
Locally of finite presentation implies locally of finite type (proposition 3.4.34), so theorem 6.8.10 applies.

The locally Noetherian hypothesis enters through Chevalley's theorem and through the openness criterion of lemma 6.8.9. The statement is true over an arbitrary base: a flat morphism locally of finite presentation is universally open ([95, Tag 01UA]). That proof requires machinery not developed in this book and is not reproduced.

The key property of flat families for cohomology is that they interact well with base change. Recall from definition 3.2.3 that for a morphism $f : X \to Y$ and a base change $g : Y' \to Y$, we form the fiber product:

$$\begin{array}{ccc} X' = X \times_Y Y' & \xrightarrow{g'} & X \\ {\scriptstyle f'}\downarrow & & \downarrow{\scriptstyle f} \\ Y' & \xrightarrow[g]{} & Y \end{array}$$

For any $\mathcal{O}_X$-module $\mathscr{F}$, the *pullback* $g'^*\mathscr{F}$ is a sheaf on X', and we can form both $R^i f'_*(g'^*\mathscr{F})$ (the higher direct image along f') and $g^*(R^i f_*\mathscr{F})$ (pull back the higher direct image). These are both sheaves on Y', and there is a natural *base change map*:

$$\beta^i : \; g^*(R^i f_*\mathscr{F}) \longrightarrow R^i f'_*(g'^*\mathscr{F}).$$

This map is not an isomorphism in general. When it is, we say that *cohomology commutes with base change in degree i*.

6.8.2 The Flat Base Change Theorem

The following theorem says that, for a separated morphism of finite type between Noetherian schemes and a quasi-coherent sheaf flat over the base, cohomology commutes with flat base change to a Noetherian scheme:

Theorem 6.8.12: Flat Base Change

Let $f : X \to Y$ be a separated morphism of finite type between Noetherian schemes, and let $\mathscr{F}$ be a quasi-coherent sheaf on X that is flat over Y. Let $g : Y' \to Y$ be a flat morphism with Y' Noetherian, and form the Cartesian square:

$$\begin{array}{ccc} X' & \xrightarrow{g'} & X \\ {\scriptstyle f'}\downarrow & & \downarrow{\scriptstyle f} \\ Y' & \xrightarrow[g]{} & Y \end{array}$$

Then for all $i \geq 0$, the base change map is an isomorphism:

$$g^*(R^i f_* \mathscr{F}) \xrightarrow{\sim} R^i f'_*(g'^* \mathscr{F}).$$

***Proof*:**

The question is local on Y and Y', so we may assume both are affine: $Y = \operatorname{Spec} R$ and $Y' = \operatorname{Spec} R'$, with the flat map g corresponding to a flat ring homomorphism $\varphi : R \to R'$.

Step 1: Reduction to Čech cohomology. Since f is separated and of finite type, X admits a finite open affine cover $\mathcal{U} = \{U_1, \ldots, U_r\}$. By proposition 6.6.14, the higher direct images are computed by the Čech complex: $R^i f_* \mathscr{F}$ is the quasi-coherent sheaf on Y associated to the R-module $h^i(C^\bullet(\mathcal{U}, \mathscr{F}))$, where:

$$C^p(\mathcal{U}, \mathscr{F}) = \prod_{i_0 < \cdots < i_p} \mathscr{F}(U_{i_0} \cap \cdots \cap U_{i_p}).$$

Each intersection $U_{i_0,\ldots,i_p}$ is affine (by separatedness), and $\mathscr{F}$ is quasi-coherent, so $\mathscr{F}(U_{i_0,\ldots,i_p})$ is an R-module.

Step 2: Base change of the Čech complex. The base change $X' = X \times_Y Y'$ has the affine cover $\mathcal{U}' = \{U'_1, \ldots, U'_r\}$ where $U'_j = U_j \times_Y Y' = \operatorname{Spec}(A_j \otimes_R R')$ for $U_j = \operatorname{Spec} A_j$. The Čech complex for $g'^* \mathscr{F}$ on X' is:

$$C^p(\mathcal{U}', g'^* \mathscr{F}) = \prod_{i_0 < \cdots < i_p} (g'^* \mathscr{F})(U'_{i_0,\ldots,i_p}) = \prod_{i_0 < \cdots < i_p} \mathscr{F}(U_{i_0,\ldots,i_p}) \otimes_R R'.$$

The last equality uses the fact that for an affine base change $\operatorname{Spec}(A \otimes_R R') \to \operatorname{Spec} A$, the pullback of a quasi-coherent sheaf $\widetilde{M}$ is $\widetilde{M \otimes_R R'}$. Hence:

$$C^\bullet(\mathcal{U}', g'^* \mathscr{F}) \cong C^\bullet(\mathcal{U}, \mathscr{F}) \otimes_R R'.$$

Step 3: Flatness and cohomology. Since R' is a flat R-module (by hypothesis), the functor $- \otimes_R R'$ is exact. Exact functors commute with the formation of cohomology (i.e., with taking

kernels modulo images):

$$h^i(C^\bullet(\mathcal{U},\mathscr{F})\otimes_R R') \cong h^i(C^\bullet(\mathcal{U},\mathscr{F}))\otimes_R R'.$$

The left side computes $R^if'_*(g'^*\mathscr{F})(Y')$, while the right side computes $g^*(R^if_*\mathscr{F})(Y') = (R^if_*\mathscr{F})(Y)\otimes_R R'$. Hence the base change map is an isomorphism on global sections over affine opens, which suffices.

One special case is base change to a generic point:

Corollary 6.8.13: Cohomology of Fibers via Base Change

Under the hypotheses of theorem 6.8.12, let $y \in Y$ be a point whose local ring $\mathcal{O}_{Y,y}$ is a field (for instance the generic point of an integral Y), with residue field $\kappa(y)$, and let $X_y = f^{-1}(y)$ be the scheme-theoretic fiber (definition 3.2.9). Then:

$$(R^if_*\mathscr{F})\otimes_{\mathcal{O}_{Y,y}}\kappa(y) \;\cong\; H^i(X_y,\,\mathscr{F}_y),$$

where $\mathscr{F}_y = \mathscr{F}|_{X_y}$ is the restriction to the fiber, provided that $\mathscr{F}$ is flat over Y.

***Proof*:**
Apply theorem 6.8.12 to the base change $g : \operatorname{Spec}\kappa(y) = \operatorname{Spec}\mathcal{O}_{Y,y} \to Y$, which is flat. Then $X' = X_y$, and the left side is $g^*(R^if_*\mathscr{F}) = (R^if_*\mathscr{F})\otimes\kappa(y)$, while the right side is $H^i(X_y,\mathscr{F}_y)$.

Example 6.8.14: Flat Base Change in Practice

1. *Constant families.* Let $f = \mathrm{pr}_2 : X\times_k Y \to Y$ be the projection of a product (with X projective over k and Y Noetherian). Then for any coherent sheaf $\mathscr{F}$ on X, pulled back to $X\times Y$ via the first projection, the sheaf $\mathscr{F}$ is flat over Y (trivially, since it does not depend on Y at all). The base change theorem gives:

   $$R^if_*(\mathrm{pr}_1^*\mathscr{F}) \cong H^i(X,\mathscr{F})\otimes_k\mathcal{O}_Y,$$

   i.e., the higher direct images are the constant (free) sheaves with fiber $H^i(X,\mathscr{F})$. This is the trivial case, but it illustrates the principle: for a constant family, the cohomology does not vary.

2. *Base change to the generic point.* Let $f : X \to Y$ be a projective morphism of Noetherian schemes with Y integral, let $\mathscr{F}$ be a coherent sheaf on X flat over Y, and let $\eta \in Y$ be the generic point. The base change $\operatorname{Spec}K(Y) \to Y$ (where $K(Y)$ is the function field) is flat, so:

   $$(R^if_*\mathscr{F})\otimes\kappa(\eta) \cong H^i(X_\eta,\mathscr{F}_\eta).$$

   This says the *generic rank* of $R^if_*\mathscr{F}$ equals the cohomology of the generic fiber. Combined with semicontinuity, this shows that the generic fiber has the "smallest" cohomology, and special fibers can only have more.

3. *Flat base change for field extensions.* Let X be a projective scheme over a field k, let $\mathscr{F}$ be a coherent sheaf on X, and let K/k be a field extension. The base change $X_K =$

$X \times_k \operatorname{Spec} K \to X$ is flat, so:

$$H^i(X_K, \mathscr{F}_K) \cong H^i(X, \mathscr{F}) \otimes_k K.$$

In particular, $h^i(X_K, \mathscr{F}_K) = h^i(X, \mathscr{F})$: the Betti numbers do not change under field extension. This is essential for reducing problems over arbitrary fields to the algebraically closed case.

Proposition 6.8.15: Associated Points and Morphisms

Let $f : X \to Y$ be a flat morphism of locally Noetherian schemes. Then:

$$\operatorname{Ass}(X) = \bigcup_{y \in \operatorname{Ass}(Y)} \operatorname{Ass}(X_y)$$

where $X_y = f^{-1}(y)$ is the fiber over y. In particular, associated points of X map to associated points of Y (among the points in the image).

***Proof Key ideas*:**
Let $x \in X$ with $y = f(x)$, and set $A = \mathcal{O}_{Y,y}$ and $B = \mathcal{O}_{X,x}$, so that $A \to B$ is a flat local homomorphism of Noetherian local rings and $\mathcal{O}_{X_y,x} = B/\mathfrak{m}_A B$. The statement at x is that $\mathfrak{m}_B \in \operatorname{Ass}_B(B)$ if and only if $\mathfrak{m}_A \in \operatorname{Ass}_A(A)$ and $\mathfrak{m}_B/\mathfrak{m}_A B \in \operatorname{Ass}(B/\mathfrak{m}_A B)$. This equivalence is a theorem of commutative algebra on associated primes under flat ring maps [95, Tag 05DB], which we do not prove here.

6.8.3 Semicontinuity

The flat base change theorem shows that, under its finiteness hypotheses, cohomology commutes with flat base change. But what happens for non-flat base changes, such as the inclusion of a point $y \hookrightarrow Y$? In general, the base change map $(R^i f_* \mathscr{F}) \otimes \kappa(y) \to H^i(X_y, \mathscr{F}_y)$ need not be an isomorphism, and the fiber cohomology can be *larger* than what the stalk of the higher direct image predicts. The semicontinuity theorem makes this precise: the function $y \mapsto h^i(X_y, \mathscr{F}_y)$ is *upper semicontinuous*, meaning it can jump up on closed subsets but not on open ones.

To state the result precisely, we need a piece of commutative algebra. Let R be a Noetherian ring and $C^\bullet$ a bounded complex of finitely generated free R-modules. For any R-module M, write $h^i(C^\bullet \otimes_R M) = h^i(C^\bullet; M)$. When R is a local ring and $M = R/\mathfrak{m}$ is the residue field, the function $i \mapsto h^i(C^\bullet; R/\mathfrak{m})$ measures the fiber cohomology. The following result governs how this varies:

Lemma 6.8.16: Semicontinuity on Complexes

Let R be a Noetherian ring, and let $C^\bullet$ be a bounded complex of finitely generated free R-modules. Then:

1. The function $\mathfrak{p} \mapsto \dim_{\kappa(\mathfrak{p})} h^i(C^\bullet \otimes_R \kappa(\mathfrak{p}))$ is upper semicontinuous on $\operatorname{Spec} R$: for each n, the set $\{\mathfrak{p} \in \operatorname{Spec} R \,\big|\, \dim h^i(C^\bullet \otimes \kappa(\mathfrak{p})) \geq n\}$ is closed.
2. The Euler characteristic $\mathfrak{p} \mapsto \chi(C^\bullet \otimes \kappa(\mathfrak{p})) = \sum(-1)^i \dim h^i(C^\bullet \otimes \kappa(\mathfrak{p}))$ is *locally constant* (it equals $\sum(-1)^i \mathrm{rk} C^i$, which is independent of $\mathfrak{p}$).
3. If $h^i(C^\bullet \otimes \kappa(\mathfrak{p}))$ is constant as a function of $\mathfrak{p}$ (say, equal to r), and R is local and reduced, then $h^i(C^\bullet)$ is a free R-module of rank r.

***Proof*:**

(1) The complex $C^\bullet$ is a sequence of maps between free modules: $\cdots \to R^{a_{i-1}} \xrightarrow{d^{i-1}} R^{a_i} \xrightarrow{d^i} R^{a_{i+1}} \to \cdots$. After tensoring with $\kappa(\mathfrak{p})$, these become linear maps between vector spaces: $\kappa(\mathfrak{p})^{a_{i-1}} \to \kappa(\mathfrak{p})^{a_i} \to \kappa(\mathfrak{p})^{a_{i+1}}$. Now, $\dim h^i(C^\bullet \otimes \kappa(\mathfrak{p})) = a_i - \mathrm{rk}(d^{i-1} \otimes \kappa(\mathfrak{p})) - \mathrm{rk}(d^i \otimes \kappa(\mathfrak{p}))$. The rank of a matrix can only *drop* under specialization (the vanishing of minors is a closed condition), so $\mathrm{rk}(d^j \otimes \kappa(\mathfrak{p}))$ is lower semicontinuous in $\mathfrak{p}$. Hence $\dim h^i$ is upper semicontinuous.

(2) The Euler characteristic is $\sum(-1)^i \dim h^i(C^\bullet \otimes \kappa(\mathfrak{p})) = \sum(-1)^i a_i$ (the alternating sum of the ranks of the free modules), which is independent of $\mathfrak{p}$. This uses the rank-nullity theorem: the terms involving ranks of differentials cancel in the alternating sum.

(3) For each j let $W^j = \operatorname{coker}(d^{j-1})$. The differential d^i induces $W^i \to C^{i+1}$ with kernel $h^i(C^\bullet)$ and cokernel W^{i+1}. Tensor product is right exact, so tensoring with $\kappa(\mathfrak{p})$ gives an exact sequence

$$0 \to h^i(C^\bullet \otimes \kappa(\mathfrak{p})) \to W^i \otimes \kappa(\mathfrak{p}) \to C^{i+1} \otimes \kappa(\mathfrak{p}) \to W^{i+1} \otimes \kappa(\mathfrak{p}) \to 0,$$

and $\dim h^i(C^\bullet \otimes \kappa(\mathfrak{p})) = \dim W^i \otimes \kappa(\mathfrak{p}) + \dim W^{i+1} \otimes \kappa(\mathfrak{p}) - \mathrm{rk} C^{i+1}$. The two fiber dimensions on the right are upper semicontinuous in $\mathfrak{p}$ (lemma 5.1.23(3)) with constant sum, so each is locally constant. As R is reduced, W^i and W^{i+1} are then locally free [50, Exercise II.5.8(c)], hence free over the local ring R. So $\mathrm{im} d^i = \ker(C^{i+1} \to W^{i+1})$ is a direct summand of C^{i+1}, hence free, and the surjection $W^i \to \mathrm{im} d^i$ splits: $W^i \cong h^i(C^\bullet) \oplus \mathrm{im} d^i$. Thus $h^i(C^\bullet)$ is a direct summand of a free module over a local ring, hence free, and tensoring the splitting with $\kappa(\mathfrak{p})$ identifies $h^i(C^\bullet) \otimes \kappa(\mathfrak{p})$ with $h^i(C^\bullet \otimes \kappa(\mathfrak{p}))$, which has dimension r.

The geometric content of this algebraic lemma is the semicontinuity theorem:

Theorem 6.8.17: Semicontinuity of Cohomology

Let $f : X \to Y$ be a proper morphism of Noetherian schemes, and let $\mathscr{F}$ be a coherent sheaf on X that is flat over Y. Then:

1. *(Upper semicontinuity.)* For each $i \geq 0$, the function
$$y \longmapsto h^i(X_y, \mathscr{F}_y)$$
is upper semicontinuous on Y: for every $n \geq 0$, the set $\{y \in Y \,|\, h^i(X_y, \mathscr{F}_y) \geq n\}$ is a closed subset of Y.

2. *(Euler characteristic is locally constant.)* The function
$$y \longmapsto \chi(X_y, \mathscr{F}_y) = \sum_{i \geq 0} (-1)^i h^i(X_y, \mathscr{F}_y)$$
is locally constant on Y.

***Proof*:**
The question is local on Y, so assume $Y = \operatorname{Spec} R$ is affine.

Constructing the representing complex. The key technical input is the existence of a *Čech complex computing fiber cohomology uniformly*. Choose a finite affine open cover $\mathcal{U}$ of X. By proposition 6.6.14, the cohomology $H^i(X, \mathscr{F})$ is computed by the Čech complex $C^\bullet(\mathcal{U}, \mathscr{F})$. Since $\mathscr{F}$ is flat over $Y = \operatorname{Spec} R$, and each intersection $U_{i_0,\dots,i_p}$ is affine, the R-modules $\mathscr{F}(U_{i_0,\dots,i_p})$ are flat over R. The cohomology modules $H^i(X, \mathscr{F})$ of this complex are finitely generated by theorem 6.6.13 (by theorem 6.6.6 when f is projective).

One can replace the Čech complex by a quasi-isomorphic bounded complex $K^\bullet$ of finitely generated *projective* R-modules[a]. Finitely generated projective modules over the Noetherian ring R are locally free, so after shrinking Y around a given point the K^i are free. This complex has the property that:
$$h^i(K^\bullet \otimes_R \kappa(y)) \cong H^i(X_y, \mathscr{F}_y)$$
for every $y \in Y$. Indeed, tensoring with $\kappa(y)$ corresponds to restricting to the fiber, and the flatness of $\mathscr{F}$ ensures that the Čech complex commutes with base change (as in the proof of theorem 6.8.12).

Both statements now follow from lemma 6.8.16: part (1) is the upper semicontinuity of $\dim h^i(K^\bullet \otimes \kappa(y))$, and part (2) is the constancy of the Euler characteristic.

[a] Hartshorne's construction [50, Lemma III.12.3] gives a bounded above complex $L^\bullet$ of finitely generated free R-modules with $h^i(L^\bullet \otimes_R M) \cong h^i(C^\bullet \otimes_R M)$ for every R-module M. These groups vanish for $i < 0$, so $Q = L^0/d(L^{-1})$ satisfies $\operatorname{Tor}_1^R(Q, M) = h^{-1}(L^\bullet \otimes_R M) = 0$. Thus Q is flat and finitely generated, hence projective, and $0 \to Q \to L^1 \to L^2 \to \cdots$ is the required bounded complex.

Example 6.8.18: Semicontinuity in Families

1. *Jumping h^1 for line bundles on curves.* Let $f\colon \mathcal{C} \to B$ be a flat projective family of smooth curves of genus g over a Noetherian scheme B, with $H^0(C_b, \mathcal{O}_{C_b}) = \kappa(b)$ for every $b \in B$ (for

instance with geometrically connected fibers, theorem 3.5.33), and let $\mathcal{L}$ be a line bundle on $\mathcal{C}$ of relative degree d (i.e., $\deg \mathcal{L}|_{C_b} = d$ for each fiber C_b). By Riemann–Roch (theorem 6.7.12):

$$h^0(C_b, \mathcal{L}_b) - h^1(C_b, \mathcal{L}_b) = d + 1 - g$$

for every $b \in B$. Since the Euler characteristic is constant, any jump in h^0 is exactly compensated by a jump in h^1. By semicontinuity, h^0 is upper semicontinuous, so the locus where h^0 is "large" (and correspondingly h^1 is large) is closed.

Concretely, take a pencil of plane cubics whose general member is smooth, restricted to the open subset of $\mathbb{P}^1$ over which the members are smooth (genus 1), and a line bundle $\mathcal{L}$ of degree 0 on every fiber. At a fiber where $\mathcal{L}_b$ is nontrivial, $h^0 = 0$, as a nontrivial line bundle of degree 0 has no nonzero sections, and Riemann–Roch then gives $h^1 = 0$. At fibers where $\mathcal{L}_b$ is trivial, $h^0 = 1$ and $h^1 = 1$. The locus of such fibers is a closed subset of the base.

2. *Degenerating an extension.* Let X be a projective scheme over k, and let $0 \to \mathscr{F}' \to \mathscr{F} \to \mathscr{F}'' \to 0$ be a short exact sequence of coherent sheaves on X with extension class $\xi \in \operatorname{Ext}^1(\mathscr{F}'', \mathscr{F}')$. On $X \times \mathbb{A}^1_k$, with coordinate t on $\mathbb{A}^1_k$, the extension of the pullback of $\mathscr{F}''$ by the pullback of $\mathscr{F}'$ with class $t\xi$ is flat over $\mathbb{A}^1_k$. Its fiber over $a \neq 0$ is isomorphic to $\mathscr{F}$, and its fiber over 0 is $\mathscr{F}' \oplus \mathscr{F}''$. Semicontinuity (theorem 6.8.17) then gives $h^0(\mathscr{F}) \leq h^0(\mathscr{F}') + h^0(\mathscr{F}'')$, and equality need not hold. The "excess" is controlled by $H^1(\mathscr{F}')$, which is the obstruction to lifting global sections.

3. *Jumping h^0 for the structure sheaf of a degeneration.* Let k be algebraically closed. Projecting a twisted cubic in $\mathbb{P}^3_k$ from a point onto a plane gives a flat projective family $f : X \to \mathbb{A}^1_k$ whose fiber over each $a \neq 0$ is a twisted cubic, with $h^0(\mathcal{O}) = 1$, and whose fiber over 0 is a plane cubic with an embedded point at its singular point [50, Examples III.9.8.3 and III.9.8.4]. The special fiber is connected, and the embedded point contributes a nilpotent global section, so $h^0(\mathcal{O}) = 2$ there. Thus h^0 has jumped up at 0, and the locus $\{h^0 \geq 2\}$ is the closed point $\{0\}$, consistent with semicontinuity.

6.8.4 Grauert's Theorem and Cohomology and Base Change

The semicontinuity theorem says h^i can jump up. The natural follow-up question is: what happens when it does *not* jump? The answer is Grauert's theorem: over a reduced base, constancy of h^i implies that the higher direct image is locally free and commutes with *all* base changes from locally Noetherian schemes, not just flat ones.

Theorem 6.8.19: Grauert's Theorem (Cohomology and Base Change)

Let $f : X \to Y$ be a proper morphism of Noetherian schemes, and let $\mathscr{F}$ be a coherent sheaf on X that is flat over Y. Let $y \in Y$ be a point, and suppose the natural base change map:

$$\beta^i(y) : \ (R^i f_* \mathscr{F}) \otimes \kappa(y) \longrightarrow H^i(X_y, \mathscr{F}_y)$$

is surjective. Then:

1. $\beta^i(y)$ is an isomorphism. That is, surjectivity implies bijectivity.
2. There is an open neighborhood U of y over which the formation of $R^i f_* \mathscr{F}$ commutes with every base change $g : Y' \to U$ with Y' locally Noetherian. In particular $\beta^i(y')$ is an isomorphism for every $y' \in U$.
3. $\beta^{i-1}(y)$ is surjective if and only if $R^i f_* \mathscr{F}$ is locally free in a neighborhood of y.

Moreover, if $h^i(X_y, \mathscr{F}_y)$ is constant on Y and Y is reduced, then $R^i f_* \mathscr{F}$ is a locally free sheaf of rank $h^i(X_y, \mathscr{F}_y)$, and the formation of $R^i f_* \mathscr{F}$ commutes with every base change $g : Y' \to Y$ with Y' locally Noetherian.

***Proof Key ideas*:**
We do not give a complete proof. Parts (1) and (3), and the last sentence of (2), are [50, Theorem III.12.11], stated there for projective f. Its proof uses projectivity only through the complex $K^\bullet$ below and the theorem on formal functions, which holds for proper f [95, Tag 02OC]. The final assertion strengthens [50, Corollary III.12.9], stated there for projective f and integral Y. The question is local on Y, so take $Y = \operatorname{Spec} A$ affine. As in the proof of theorem 6.8.17, there is a bounded complex $K^\bullet$ of finitely generated projective A-modules with $T^i(M) := h^i(K^\bullet \otimes_A M) \cong H^i(X, \mathscr{F} \otimes_A M)$ for every A-module M. So $R^i f_* \mathscr{F}$ corresponds to $T^i(A)$, and $\beta^i(y)$ is the natural map $T^i(A) \otimes \kappa(y) \to T^i(\kappa(y))$.

The functors T^i form a δ-functor, so T^i is right exact exactly when T^{i+1} is left exact, and T^i is left exact exactly when $W^i = \operatorname{coker}(K^{i-1} \to K^i)$ is projective. If T^i is right exact, then $T^i(A) \otimes M \to T^i(M)$ is an isomorphism for every M, and T^i is exact exactly when $T^i(A)$ is in addition projective. The substantive step is that surjectivity of $\beta^i(y)$ makes T^i right exact on a neighborhood of y. It is proved for modules of finite length by induction on length, and passes to finitely generated modules through the theorem on formal functions, which this book does not develop. Right exactness near y gives (1) and (2). For (3), surjectivity of $\beta^{i-1}(y)$ makes T^{i-1} right exact near y, that is T^i left exact, so T^i is exact and $T^i(A)$ is projective. Conversely, if $T^i(A)$ is projective near y, then the right exact T^i is exact, so T^{i-1} is right exact and $\beta^{i-1}(y)$ is surjective.

For the final assertion, the dimension count in the proof of lemma 6.8.16(3) writes $h^i(X_y, \mathscr{F}_y)$ as $\dim W^i \otimes \kappa(y) + \dim W^{i+1} \otimes \kappa(y) - \operatorname{rk} K^{i+1}$. When the left side is constant, both fiber dimensions are locally constant, and on a reduced base W^i and W^{i+1} are then locally free [50, Exercise II.5.8(c)]. So T^i and T^{i+1} are left exact, T^i is exact, $T^i(A)$ is projective, and (1) and (2) apply at every point.

Corollary 6.8.20: Cohomology and Base Change: Clean Form

Let $f : X \to Y$ be a projective morphism of Noetherian schemes with Y integral, and let $\mathscr{F}$ be coherent and f-flat. Suppose $h^i(X_y, \mathscr{F}_y)$ is constant for all $y \in Y$. Then:

1. $R^i f_* \mathscr{F}$ is locally free of rank $h^i(X_y, \mathscr{F}_y)$.
2. For any morphism $g : Y' \to Y$ with Y' locally Noetherian, the base change map $g^*(R^i f_* \mathscr{F}) \xrightarrow{\sim} R^i f'_*(g'^* \mathscr{F})$ is an isomorphism.
3. If additionally $h^{i-1}(X_y, \mathscr{F}_y)$ is also constant, then $R^{i-1} f_* \mathscr{F}$ is locally free and commutes with base change as well.

***Proof*:**
Part (1) follows from theorem 6.8.19 together with the observation that on an integral (hence reduced) scheme, a coherent sheaf of constant fiber dimension is locally free. Part (2) is the final assertion of theorem 6.8.19. Part (3) is the final assertion of theorem 6.8.19 with $i-1$ in place of i.

Example 6.8.21: Grauert's Theorem in Practice

1. *Line bundles on a constant family of curves.* Let C be a smooth projective curve of genus g over an algebraically closed field k. Grant the degree-d component $\mathrm{Pic}^d(C)$ of the Picard scheme, a smooth proper k-scheme of pure dimension g whose k-points are the degree-d line bundles on C, and the universal (Poincaré) line bundle $\mathcal{L}$ on $C \times \mathrm{Pic}^d(C)$. Both exist because C has a k-point (theorem 23.6.14, proposition 23.6.17, theorem 23.6.19). Consider the family $f : C \times \mathrm{Pic}^d(C) \to \mathrm{Pic}^d(C)$. If $d > 2g-2$, then $h^1(C, \mathcal{L}_b) = 0$ for all $b \in \mathrm{Pic}^d(C)$ (by Serre duality and degree considerations). By Grauert's theorem, $R^1 f_* \mathcal{L} = 0$ and $f_* \mathcal{L}$ is a locally free sheaf of rank $h^0 = d + 1 - g$ on $\mathrm{Pic}^d(C)$. This locally free sheaf is the *Picard bundle*, a fundamental object in the study of Jacobians.
2. *The Euler characteristic without flatness.* Consider the blowup $f : X = \mathrm{Bl}_0 \mathbb{A}^2 \to \mathbb{A}^2$ and the line bundle $\mathcal{O}_X(-E)$ from example 6.6.15(2). Like $\mathcal{O}_X$, it is *not* flat over $\mathbb{A}^2$ (the fiber dimension jumps). Over a point $a \neq 0$ the fiber is a reduced point, and $\chi = 1$. The fiber over the origin is $E \cong \mathbb{P}^1$, on which $\mathcal{O}_X(-E)$ restricts to $\mathcal{O}_{\mathbb{P}^1}(1)$, so $\chi = 2$. The Euler characteristic of the fibers is not locally constant, and theorem 6.8.17(2) fails without its flatness hypothesis.
3. *When constancy fails: the Brill–Noether locus.* Let C be a general smooth curve of genus g over an algebraically closed field k, and consider the family of degree-d line bundles of item (1). The *Brill–Noether locus* $W^r_d(C) = \{L \in \mathrm{Pic}^d(C) \,|\, h^0(C, L) \geq r+1\}$ is a closed subvariety of $\mathrm{Pic}^d(C)$ by the semicontinuity theorem applied to the universal line bundle. With the "expected dimension" $\rho = g - (r+1)(g-d+r)$, the Brill–Noether theorem asserts that for a general curve of genus g, $W^r_d(C)$ has dimension $\min(\rho, g)$ when $\rho \geq 0$, and is empty when $\rho < 0$. This is a result in the geometry of algebraic curves, and semicontinuity is the foundational tool that ensures W^r_d is an algebraic variety.

6.8.22 Remark: The Coherent Base Change Complex The key technical tool behind both the semicontinuity and Grauert theorems is the existence, over an affine base $Y = \operatorname{Spec} R$, of a bounded complex $K^\bullet$ of finitely generated projective R-modules representing the derived pushforward $\mathbf{R}f_*\mathscr{F}$ in the derived category of R-modules. Its terms become free after shrinking Y around a given point, and are free when R is local. Such a complex exists whenever f is proper and $\mathscr{F}$ is coherent and f-flat: one takes the Čech complex associated to a finite affine cover, resolves it by a bounded above complex of finitely generated free modules, and truncates (as in the proof of theorem 6.8.17).
In the language of derived categories (which we have not formally developed), the statement is: $\mathbf{R}f_*\mathscr{F} \in D^b(\mathrm{Mod}_R)$ is a *perfect complex* (quasi-isomorphic to a bounded complex of finitely generated projective modules). The fiber cohomology is then $H^i(X_y, \mathscr{F}_y) = h^i(K^\bullet \otimes^{\mathbf{L}} \kappa(y))$, where $\otimes^{\mathbf{L}}$ is the derived tensor product (which equals the ordinary tensor product since $K^\bullet$ consists of projective modules).
This perspective explains why the semicontinuity theorem is fundamentally a result in commutative algebra (about cohomology of complexes of finitely generated projective modules under base change) rather than algebraic geometry. The geometry enters only in constructing the complex $K^\bullet$, and this construction uses the properness of f and the coherence of $\mathscr{F}$ in an essential way.

6.8.5 Recognizing Flatness Cohomologically

The base-change theorems of this section all take flatness as a hypothesis and study the cohomology that results. The reverse question is equally useful. Given a coherent sheaf on a projective family, how can flatness over the base be recognized from cohomology alone? The answer is a criterion on the pushforwards of high twists. Nothing else in this chapter uses it, but the construction of the Quot and Hilbert schemes, through the flattening stratification, does, so it is proved here rather than left to that construction.

The criterion runs on Serre vanishing over a general Noetherian base, which is recorded first in the form the proof uses.

Lemma 6.8.23: Serre Vanishing on Projective Space

Let A be a Noetherian ring and $\mathscr{F}$ a coherent sheaf on $\mathbb{P}^n_A$. Then there is an integer m_0 such that

$$H^i(\mathbb{P}^n_A, \mathscr{F}(m)) = 0 \qquad \text{for all } i \geq 1 \text{ and all } m \geq m_0$$

***Proof*:**
We argue by descending induction on i. For $i > n$ every such group vanishes, uniformly in m: $\mathbb{P}^n_A$ is covered by the $n+1$ standard affine opens, whose Čech complex vanishes in degrees above n, and theorem 6.1.19 identifies its cohomology with $H^i(\mathbb{P}^n_A, \mathscr{F}(m))$. Assume the vanishing holds in all degrees above i, with a threshold depending on the coherent sheaf. By corollary 5.3.27 choose a surjection $\mathcal{E} = \bigoplus_{j=1}^{s} \mathcal{O}_{\mathbb{P}^n_A}(d_j) \twoheadrightarrow \mathscr{F}$ with kernel $\mathcal{K}$, a coherent sheaf. The twisted short exact sequence $0 \to \mathcal{K}(m) \to \mathcal{E}(m) \to \mathscr{F}(m) \to 0$ gives

$$H^i(\mathbb{P}^n_A, \mathcal{E}(m)) \longrightarrow H^i(\mathbb{P}^n_A, \mathscr{F}(m)) \longrightarrow H^{i+1}(\mathbb{P}^n_A, \mathcal{K}(m))$$

By theorem 6.3.1 the left group is $\bigoplus_j H^i(\mathbb{P}^n_A, \mathcal{O}(m+d_j))$, and the only nonzero higher cohomology

of a line bundle on $\mathbb{P}^n_A$ sits in degree n at twists at most $-n-1$, so this vanishes for $i \geq 1$ once m is large. By the inductive hypothesis applied to $\mathcal{K}$ the right group vanishes for m large. Hence $H^i(\mathbb{P}^n_A, \mathscr{F}(m)) = 0$ for m large, and taking m_0 to dominate the finitely many thresholds met for $i = 1, \dots, n$ completes the induction.

Theorem 6.8.24: Flatness Criterion via Twisted Global Sections

Let A be a Noetherian ring, $\pi\colon \mathbb{P}^n_A \to \operatorname{Spec} A$ the projection, and $\mathscr{F}$ a coherent sheaf on $\mathbb{P}^n_A$. Then $\mathscr{F}$ is flat over A if and only if there is an integer m_0 such that the A-module

$$M_m := H^0(\mathbb{P}^n_A, \mathscr{F}(m)) = \Gamma\big(\operatorname{Spec} A,\, \pi_*\mathscr{F}(m)\big)$$

is locally free for every $m \geq m_0$. When $\mathscr{F}$ is flat, one may take m_0 to be any Serre vanishing threshold from lemma 6.8.23, and then for every homomorphism $A \to A'$ the base change map

$$M_m \otimes_A A' \longrightarrow H^0(\mathbb{P}^n_{A'}, \mathscr{F}'(m))$$

is an isomorphism, where $\mathscr{F}'$ is the pullback of $\mathscr{F}$ to $\mathbb{P}^n_{A'}$.

***Proof*:**

Flat implies locally free and compatible with base change. Suppose $\mathscr{F}$ is flat over A, and take m_0 as in lemma 6.8.23. Fix $m \geq m_0$ and let $C^\bullet = C^\bullet(\mathcal{U}, \mathscr{F}(m))$ be the Čech complex of $\mathscr{F}(m)$ for the standard affine cover $\mathcal{U}$ of $\mathbb{P}^n_A$, which computes $H^\bullet(\mathbb{P}^n_A, \mathscr{F}(m))$ by theorem 6.1.19. Each term C^p is a finite product of modules of sections of $\mathscr{F}(m)$ over affine opens, and these are flat over A because $\mathscr{F}$ is A-flat. By the choice of m_0 the cohomology of $C^\bullet$ is concentrated in degree 0, where it equals M_m, so prepending M_m yields an exact sequence

$$0 \longrightarrow M_m \longrightarrow C^0 \longrightarrow C^1 \longrightarrow \cdots \longrightarrow C^n \longrightarrow 0$$

Its terms $C^0, \dots, C^n$ are flat, and a kernel that sits in an exact sequence whose other terms are flat is itself flat, by dimension-shifting on Tor ([25]). Thus M_m is flat, and being finitely generated over the Noetherian ring A (theorem 6.6.6) it is locally free.

For the base change assertion, all terms of the displayed sequence are now flat over A, so it stays exact after applying $- \otimes_A A'$. The Čech complex base changes term by term, $C^p \otimes_A A' = C^p(\mathcal{U}', \mathscr{F}'(m))$, since forming sections of a quasi-coherent sheaf over an affine open commutes with the base change $A \to A'$. Exactness at the first two terms then identifies $M_m \otimes_A A'$ with the kernel of $C^0(\mathcal{U}', \mathscr{F}'(m)) \to C^1(\mathcal{U}', \mathscr{F}'(m))$, which is $\Gamma(\mathbb{P}^n_{A'}, \mathscr{F}'(m))$ by lemma 6.1.14. Hence $M_m \otimes_A A' = H^0(\mathbb{P}^n_{A'}, \mathscr{F}'(m))$.

Locally free twists imply flat. Conversely, suppose M_m is locally free over A for all $m \geq m_0$. Set $M = \bigoplus_{m \geq m_0} M_m$, a graded module over the homogeneous coordinate ring $A[x_0, \dots, x_n]$ whose associated sheaf is $\mathscr{F}$, since twisting identifies M with a truncation of $\bigoplus_m \Gamma(\mathbb{P}^n_A, \mathscr{F}(m))$ and the associated sheaf is unchanged by truncation in high degrees. Flatness of $\mathscr{F}$ over A is local on $\mathbb{P}^n_A$, so it suffices to check it on each standard chart $U_i = D_+(x_i)$. There $\mathscr{F}|_{U_i}$ is the sheaf associated to the degree-0 part $M_{(x_i)}$ of the localization $M[x_i^{-1}]$, and as an A-module

$$M_{(x_i)} = \varinjlim\big(M_{m_0} \xrightarrow{\cdot x_i} M_{m_0+1} \xrightarrow{\cdot x_i} M_{m_0+2} \xrightarrow{\cdot x_i} \cdots\big)$$

is a directed colimit of the locally free, hence flat, A-modules M_m. A directed colimit of flat modules is flat [95, Tag 05UU], so $M_{(x_i)}$ is A-flat, and the stalks of $\mathscr{F}$ on U_i, being localizations

of $M_{(x_i)}$, are flat over A and hence over the relevant localization of A. Therefore $\mathscr{F}$ is flat over A.

The criterion is the cohomological recognition of flatness that the construction of the Quot and Hilbert schemes turns on. There the base $\operatorname{Spec} A$ is stratified by the loci over which a coherent sheaf on a projective family becomes flat with a fixed Hilbert polynomial, and theorem 6.8.24 is what converts flatness on a stratum into the local freeness of the modules M_m, a condition cut out by Fitting ideals.

That construction needs one further input that is not established here. It uses the compatibility of M_m with base change *before* flatness is known, for a sheaf not assumed flat over the base. The flat case proved above gives that compatibility only under the flatness it is meant to detect, since the argument runs on the flatness of the Čech complex. The flatness-free statement instead rests on a uniform bound for the vanishing of higher cohomology on the fibres, that is, on Castelnuovo-Mumford regularity, which the present chapter does not treat. Its proof is the missing companion to the criterion above.

6.9 *GAGA

There are two parallel cohomological machines: the algebraic cohomology of coherent sheaves on schemes (the subject of this chapter), and the analytic cohomology of coherent analytic sheaves on complex manifolds (via the Dolbeault complex, Hodge theory, and the analytic structure sheaf). Serre's GAGA theorems — *Géométrie Algébrique et Géométrie Analytique* [91] — form the bridge between these two worlds. They assert that for projective varieties over $\mathbb{C}$, the algebraic and analytic theories carry *exactly the same information*: the category of coherent algebraic sheaves is equivalent to the category of coherent analytic sheaves, and this equivalence preserves cohomology.

This is a surprising result. The algebraic world uses the Zariski topology (which is coarse: open sets are large and plentiful) and polynomial or rational functions, while the analytic world uses the classical (Euclidean) topology (which is fine: open sets can be arbitrarily small) and holomorphic functions. There are far more analytic open sets, far more analytic functions, and far more analytic sheaves than algebraic ones. Yet on projective varieties, these extra objects contribute nothing new to the cohomological theory. The rigidity of projective varieties forces the algebraic and analytic categories to coincide.

We state the GAGA theorems precisely, outline the key ideas of the proof, and develop the main consequences. This section draws heavily on the complex geometry review of section 0.6[7]; we now sketch why the algebraic cohomology developed in this chapter matches the analytic cohomology reviewed there.

6.9.1 Analytification

We begin by recalling the analytification functor, which passes from algebraic geometry over $\mathbb{C}$ to complex-analytic geometry. The reader who has studied section 0.6 in detail may skim this subsection; it is included for self-containedness.

[7]Specifically: analytification (definition 0.6.46), analytic sheaves (definition 0.6.47), and the GAGA statement (theorem 0.6.48) were introduced there.

Recall the analytification X^{an} of a scheme X of finite type over $\mathbb{C}$ (definition 0.6.46): the same underlying set as $X(\mathbb{C})$, the classical topology, and the analytic structure sheaf described below, so that X^{an} is a complex manifold when X is smooth.

Let X be a scheme of finite type over $\mathbb{C}$. The set of $\mathbb{C}$-valued points $X(\mathbb{C}) = \mathrm{Hom}_{\mathbf{Sch}_{\mathbb{C}}}(\operatorname{Spec}\mathbb{C}, X)$ carries a natural structure of complex-analytic space: locally, if $X = \operatorname{Spec}\mathbb{C}[x_1, \ldots, x_n]/(f_1, \ldots, f_r)$, then $X(\mathbb{C}) = V(f_1, \ldots, f_r) \subseteq \mathbb{C}^n$ with the subspace topology from $\mathbb{C}^n$ and the structure sheaf $\mathcal{O}_{\mathbb{C}^n}/(f_1, \ldots, f_r)\mathcal{O}_{\mathbb{C}^n}$ restricted to $V(f_1, \ldots, f_r)$, where $\mathcal{O}_{\mathbb{C}^n}$ is the sheaf of holomorphic functions on $\mathbb{C}^n$. When X is smooth, $X(\mathbb{C})$ is a complex manifold (definition 0.6.1).

Definition 6.9.1: The Analytification Functor

Let X be a scheme of finite type over $\mathbb{C}$.

1. The *analytification* of X, denoted X^{an}, is the complex-analytic space $X(\mathbb{C})$ equipped with its natural analytic structure sheaf $\mathcal{O}_{X^{\mathrm{an}}}$ (cf. definition 0.6.46).

2. There is a natural continuous map of topological spaces $\varphi : X^{\mathrm{an}} \to X$ (the "identity on points," where X carries the Zariski topology and X^{an} carries the classical topology), and a morphism of sheaves of rings $\varphi^{\#} : \mathcal{O}_X \to \varphi_*\mathcal{O}_{X^{\mathrm{an}}}$ (sending algebraic regular functions to holomorphic functions).

3. For a coherent algebraic sheaf $\mathscr{F}$ on X, the *analytification* is the coherent analytic sheaf:

$$\mathscr{F}^{\mathrm{an}} = \varphi^*\mathscr{F} = \mathscr{F} \otimes_{\mathcal{O}_X} \mathcal{O}_{X^{\mathrm{an}}}$$

on X^{an}. This defines an exact functor:

$$(-)^{\mathrm{an}} : \mathbf{Coh}(X) \longrightarrow \mathbf{Coh}(X^{\mathrm{an}}).$$

The analytification functor has good formal properties: it is exact (since $\mathcal{O}_{X^{\mathrm{an}}}$ is flat over $\mathcal{O}_X$ — this is a non-trivial fact, reflecting the faithfully flat nature of the completion of a local ring), it preserves tensor products, duals, and exterior powers of locally free sheaves, and it sends line bundles to line bundles. Furthermore, for each $i \geq 0$, there is a natural *comparison map*:

$$\gamma^i : \; H^i(X, \mathscr{F}) \longrightarrow H^i(X^{\mathrm{an}}, \mathscr{F}^{\mathrm{an}}),$$

induced by the morphism of ringed spaces $\varphi : (X^{\mathrm{an}}, \mathcal{O}_{X^{\mathrm{an}}}) \to (X, \mathcal{O}_X)$. The GAGA theorems assert that, for projective X, this map is an isomorphism and the functor $(-)^{\mathrm{an}}$ is an equivalence.

6.9.2 Statement of the GAGA Theorems

Theorem 6.9.2: Serre's GAGA Theorems

Let X be a projective scheme over $\mathbb{C}$. Then:

1. *(Equivalence of categories.)* The analytification functor
$$(-)^{\mathrm{an}} : \mathbf{Coh}(X) \longrightarrow \mathbf{Coh}(X^{\mathrm{an}})$$
is an equivalence of categories. In particular:
   (a) Every coherent analytic sheaf on X^{an} is the analytification of a unique (up to isomorphism) coherent algebraic sheaf on X.
   (b) Every morphism of coherent analytic sheaves on X^{an} is the analytification of a unique morphism of coherent algebraic sheaves on X.
2. *(Comparison of cohomology.)* For every coherent algebraic sheaf $\mathscr{F}$ on X and every $i \geq 0$, the comparison map
$$\gamma^i : H^i(X, \mathscr{F}) \xrightarrow{\sim} H^i(X^{\mathrm{an}}, \mathscr{F}^{\mathrm{an}})$$
is an isomorphism of finite-dimensional $\mathbb{C}$-vector spaces.
3. *(Equivalence for subschemes.)* The analytification functor induces a bijection between closed algebraic subschemes of X and closed analytic subspaces of X^{an}.

Part (2) is typically proved first and is the most important for applications. Full faithfulness in part (1) follows from it formally, while essential surjectivity in part (1) needs an analytic input beyond part (2), and part (3) is deduced from part (1). Let us outline the proof of part (2):

***Proof*:**
(Proof sketch of theorem 6.9.2(2))
The proof proceeds in three stages.

Stage 1: The case $X = \mathbb{P}^n_{\mathbb{C}}$ and $\mathscr{F} = \mathcal{O}(d)$. The algebraic cohomology $H^i(\mathbb{P}^n, \mathcal{O}(d))$ was computed in theorem 6.3.1. The analytic cohomology $H^i((\mathbb{P}^n)^{\mathrm{an}}, \mathcal{O}^{\mathrm{an}}(d))$ can be computed using the Dolbeault resolution (theorem 0.6.44): since $\mathbb{CP}^n$ is a compact Kähler manifold (example 0.6.22), the Hodge decomposition (theorem 0.6.28) gives $H^i(\mathbb{CP}^n, \mathcal{O}^{\mathrm{an}}) \cong H^{0,i}_{\bar\partial}(\mathbb{CP}^n)$, and the Hodge diamond of $\mathbb{CP}^n$ (example 0.6.30) shows this vanishes for $i > 0$, while H^0 is $\mathbb{C}$ on both sides and γ^0 sends the constant function 1 to the constant function 1, so γ^i is an isomorphism for $\mathcal{O}$ in every degree. For the twists, induct on n, the case $n = 0$ being trivial. A hyperplane $H \cong \mathbb{P}^{n-1}$ gives the exact sequence $0 \to \mathcal{O}(d-1) \to \mathcal{O}(d) \to \mathcal{O}_H(d) \to 0$ and its analytification, with compatible long exact sequences. By induction γ^i is an isomorphism for $\mathcal{O}_H(d)$, so the five lemma makes γ^i an isomorphism for $\mathcal{O}(d)$ if and only if it is one for $\mathcal{O}(d-1)$. Starting from $d = 0$, this covers every d.

Stage 2: Extension to all coherent sheaves on $\mathbb{P}^n_{\mathbb{C}}$. Given a coherent sheaf $\mathscr{F}$ on $\mathbb{P}^n$, write it as a quotient of a finite direct sum $\mathcal{E} = \bigoplus \mathcal{O}(d_l)$ of twisted sheaves (corollary 5.3.27), with coherent kernel $\mathcal{K}$. Since the analytification functor is exact, $0 \to \mathcal{K} \to \mathcal{E} \to \mathscr{F} \to 0$ gives compatible long

exact sequences on both sides. Both sides vanish for $i > 2n$, the analytic side because $(\mathbb{P}^n)^{\mathrm{an}}$ is a manifold of real dimension $2n$. By descending induction on i, assume γ^{i+1} is an isomorphism for every coherent sheaf. The four lemma applied to $H^i(\mathcal{E}) \to H^i(\mathscr{F}) \to H^{i+1}(\mathcal{K}) \to H^{i+1}(\mathcal{E})$, with $\gamma^i_{\mathcal{E}}$ an isomorphism by Stage 1, shows that γ^i is surjective for every coherent sheaf, in particular for $\mathcal{K}$, and the five lemma then makes $\gamma^i_{\mathscr{F}}$ an isomorphism.

Stage 3: Extension to projective schemes. For a general projective scheme $i : X \hookrightarrow \mathbb{P}^N_{\mathbb{C}}$, the pushforward $i_*\mathscr{F}$ is a coherent algebraic sheaf on $\mathbb{P}^N$, and $(i_*\mathscr{F})^{\mathrm{an}} = i_*^{\mathrm{an}}(\mathscr{F}^{\mathrm{an}})$ (the analytification of a pushforward along a closed embedding is the analytic pushforward of the analytification). By proposition 6.2.4, $H^i(X, \mathscr{F}) = H^i(\mathbb{P}^N, i_*\mathscr{F})$ and similarly for the analytic side. Stage 2 gives the isomorphism for $i_*\mathscr{F}$ on $\mathbb{P}^N$, hence for $\mathscr{F}$ on X.

***Proof*:**
(Proof sketch of theorem 6.9.2(1))

Full faithfulness. For coherent sheaves $\mathscr{F}, \mathscr{G}$ on X, the natural map $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) \to \mathrm{Hom}_{\mathcal{O}_{X^{\mathrm{an}}}}(\mathscr{F}^{\mathrm{an}}, \mathscr{G}^{\mathrm{an}})$ is an isomorphism. Indeed, $\mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \mathscr{G}) = H^0(X, \mathit{Hom}(\mathscr{F}, \mathscr{G}))$ and $\mathrm{Hom}_{\mathcal{O}_{X^{\mathrm{an}}}}(\mathscr{F}^{\mathrm{an}}, \mathscr{G}^{\mathrm{an}}) = H^0(X^{\mathrm{an}}, \mathit{Hom}(\mathscr{F}, \mathscr{G})^{\mathrm{an}})$, and part (2) with $i = 0$ gives the isomorphism.

Essential surjectivity. Let $\mathscr{H}$ be a coherent analytic sheaf on X^{an}. One must produce a coherent algebraic sheaf $\mathscr{G}$ with $\mathscr{G}^{\mathrm{an}} \cong \mathscr{H}$. For $d \gg 0$, Serre's analytic counterpart of theorem 5.3.26 on $(\mathbb{P}^N)^{\mathrm{an}}$, applied to the pushforward along $X^{\mathrm{an}} \hookrightarrow (\mathbb{P}^N)^{\mathrm{an}}$ [91], gives that $\mathscr{H}(d) = \mathscr{H} \otimes \mathcal{O}^{\mathrm{an}}(d)$ is generated by its global sections. Finitely many of them suffice, X^{an} being compact, so there is a surjection $\mathcal{O}_{X^{\mathrm{an}}}(-d)^r \to \mathscr{H}$. Its kernel is again coherent, and the same step applied to it gives a presentation

$$\mathcal{O}_{X^{\mathrm{an}}}(-d')^s \xrightarrow{\varphi} \mathcal{O}_{X^{\mathrm{an}}}(-d)^r \longrightarrow \mathscr{H} \longrightarrow 0.$$

By full faithfulness, $\varphi = \psi^{\mathrm{an}}$ for a morphism $\psi\colon \mathcal{O}_X(-d')^s \to \mathcal{O}_X(-d)^r$, and since analytification is exact, $\mathscr{G} = \mathrm{coker}\psi$ satisfies $\mathscr{G}^{\mathrm{an}} \cong \mathrm{coker}\varphi \cong \mathscr{H}$. See [47] for a full account.

6.9.3 Remark: The Properness Hypothesis is Essential The GAGA theorems fail dramatically for non-proper varieties. The simplest example is the affine line: on $\mathbb{A}^1_{\mathbb{C}}$, the algebraic structure sheaf has $\Gamma(\mathbb{A}^1, \mathcal{O}) = \mathbb{C}[x]$ (polynomial functions), while the analytic structure sheaf has $\Gamma(\mathbb{C}, \mathcal{O}^{\mathrm{an}}) = \mathcal{O}(\mathbb{C})$ (entire holomorphic functions), which is an enormously larger ring (containing e^x, $\sin x$, etc.). Hence the global section comparison already fails.
More strikingly, there exist coherent analytic sheaves on $\mathbb{C}$ that have no algebraic counterpart: for the ideal sheaf $\mathcal{I}_{\mathbb{Z}}$ of the analytic subset $\mathbb{Z} \subseteq \mathbb{C}$ (the zero set of $\sin \pi z$), the quotient $\mathcal{O}^{\mathrm{an}}/\mathcal{I}_{\mathbb{Z}}$ is coherent analytic but not of the form $\mathscr{F}^{\mathrm{an}}$ with $\mathscr{F}$ coherent on $\mathbb{A}^1_{\mathbb{C}}$, since its support $\mathbb{Z}$ is infinite and discrete, while the support of $\mathscr{F}^{\mathrm{an}}$ is the support of $\mathscr{F}$, which is finite or all of $\mathbb{C}$.
For *proper* but non-projective varieties, a version of GAGA still holds (due to Grothendieck): the analytification functor is an equivalence on coherent sheaves, and cohomology comparison holds. The key requirement is properness — which ensures compactness of the analytic space — not projectivity. However, our sketch relied on the embedding into $\mathbb{P}^N$ and the explicit computation of twisted sheaf cohomology, so we have stated the theorem in the projective case.

6.9.3 Consequences

The GAGA theorems have far-reaching consequences that connect algebraic geometry, complex analysis, and topology. We develop the most important ones.

Corollary 6.9.4: Chow's Theorem

Every closed analytic subspace of $\mathbb{CP}^n$ is algebraic. That is, if $Z \subseteq \mathbb{CP}^n$ is a closed complex-analytic subset, then Z is the zero set of finitely many homogeneous polynomials.

***Proof*:**
A closed analytic subspace $Z \subseteq (\mathbb{P}^n_{\mathbb{C}})^{\mathrm{an}}$ is determined by its ideal sheaf $\mathscr{I}_Z^{\mathrm{an}}$, which is a coherent analytic sheaf on $(\mathbb{P}^n)^{\mathrm{an}}$. By theorem 6.9.2(1), there exists a coherent algebraic sheaf $\mathscr{I}$ on $\mathbb{P}^n_{\mathbb{C}}$ with $\mathscr{I}^{\mathrm{an}} \cong \mathscr{I}_Z^{\mathrm{an}}$. By full faithfulness in theorem 6.9.2(1), the composite $\mathscr{I}^{\mathrm{an}} \cong \mathscr{I}_Z^{\mathrm{an}} \hookrightarrow \mathcal{O}_{\mathbb{P}^n}^{\mathrm{an}}$ is the analytification of a morphism $u\colon \mathscr{I} \to \mathcal{O}_{\mathbb{P}^n}$. Since $(-)^{\mathrm{an}}$ is exact and an equivalence, $(\ker u)^{\mathrm{an}} = \ker(u^{\mathrm{an}}) = 0$ forces $\ker u = 0$. So $\mathscr{I}$ is an ideal sheaf on $\mathbb{P}^n_{\mathbb{C}}$, defining a closed algebraic subscheme Z_{alg} with $Z_{\mathrm{alg}}^{\mathrm{an}} = Z$. By theorem 6.9.2(3), this correspondence is a bijection.

Both comparisons below rest on one analytic fact, which is used three times in this section. It is the holomorphic counterpart of the Poincaré lemma: on a complex manifold a closed holomorphic form is locally exact, so the holomorphic de Rham complex resolves the constant sheaf. The local statement is several-variable complex analysis; the sheaf statement is one line from it.

Lemma 6.9.5: The Holomorphic Poincaré Lemma

Let $P \subseteq \mathbb{C}^n$ be an open polydisc and let ω be a holomorphic p-form on P with $d\omega = 0$. If $p \geq 1$ then $\omega = d\eta$ for some holomorphic $(p-1)$-form η on P; if $p = 0$ then ω is constant.

***Proof*:**
Translating coordinates, we may assume P is centred at 0. Write $\omega = \sum_{|I|=p} f_I \, dz_I$ with each f_I holomorphic on P, and expand each f_I in a power series converging normally on compact subsets of P ([79, Higher-dimensional Power Series Expansion]). Since d acts coefficientwise on such a series and the homotopy operator below is continuous for normal convergence, it suffices to treat a single monomial term, and then to observe that the classical Poincaré homotopy

$$(h\omega)(z) = \sum_{|I|=p} \sum_{k=1}^{p} (-1)^{k-1} \Big(\int_0^1 t^{p-1} f_I(tz)\, dt \Big) z_{i_k} \, dz_{i_1} \wedge \cdots \widehat{dz_{i_k}} \cdots \wedge dz_{i_p}$$

produces a form that is again *holomorphic*, because $f_I(tz)$ is holomorphic in z for each fixed t and the integral in t is over a compact interval, so differentiation under the integral sign preserves $\partial/\partial \bar{z}_j = 0$. The identity $d(h\omega) + h(d\omega) = \omega$ is the same computation as in the smooth case, carried out on a star-shaped domain, and a polydisc is star-shaped about its centre 0. With $d\omega = 0$ this gives $\omega = d(h\omega)$. For $p = 0$ a closed holomorphic function has vanishing differential, hence is constant on the connected P.

Corollary 6.9.6: The Holomorphic de Rham Resolution

Let X be a complex manifold. Then

$$0 \longrightarrow \underline{\mathbb{C}}_X \longrightarrow \mathcal{O}_X^{\mathrm{an}} \longrightarrow \Omega_X^{1,\mathrm{an}} \longrightarrow \Omega_X^{2,\mathrm{an}} \longrightarrow \cdots$$

is a resolution of the constant sheaf $\underline{\mathbb{C}}_X$ by sheaves of holomorphic forms. Consequently $\mathbb{H}^i(X, \Omega_X^{\bullet,\mathrm{an}}) \cong H^i(X, \underline{\mathbb{C}}_X)$.

***Proof*:**
Exactness is a statement about stalks, and every point of a complex manifold has a polydisc neighbourhood, so lemma 6.9.5 gives exactness in positive degrees and identifies the kernel in degree zero with the locally constant functions. The displayed isomorphism is then the hypercohomology of a resolution.

Corollary 6.9.7: Algebraic de Rham Theorem

Let X be a smooth projective variety over $\mathbb{C}$. Then the algebraic de Rham cohomology

$$H^i_{\mathrm{dR}}(X/\mathbb{C}) = \mathbb{H}^i(X,\, \Omega^{\bullet}_{X/\mathbb{C}})$$

(the hypercohomology of the algebraic de Rham complex $0 \to \mathcal{O}_X \to \Omega^1_{X/\mathbb{C}} \to \Omega^2_{X/\mathbb{C}} \to \cdots$) is naturally isomorphic to the singular cohomology:

$$H^i_{\mathrm{dR}}(X/\mathbb{C}) \;\cong\; H^i_{\mathrm{sing}}(X(\mathbb{C});\, \mathbb{C}).$$

***Proof*:**
The morphism φ sends the algebraic de Rham complex to the holomorphic de Rham complex on X^{an}, compatibly with the filtrations by degree, so it induces a map of hypercohomology spectral sequences whose E_1 terms are

$$E_1^{p,q} = H^q(X,\, \Omega^p_{X/\mathbb{C}}) \longrightarrow H^q(X^{\mathrm{an}},\, \Omega_X^{p,\mathrm{an}}).$$

Each $\Omega^p_{X/\mathbb{C}}$ is coherent with analytification $\Omega_X^{p,\mathrm{an}}$, so theorem 6.9.2(2) makes every E_1 map an isomorphism, and the comparison theorem ([25, Comparison Theorem]) gives

$$\mathbb{H}^i(X,\, \Omega^{\bullet}_{X/\mathbb{C}}) \;\cong\; \mathbb{H}^i(X^{\mathrm{an}},\, \Omega_X^{\bullet,\mathrm{an}}).$$

Since X^{an} is a complex manifold, the holomorphic Poincaré lemma (lemma 6.9.5) gives an exact sequence $0 \to \underline{\mathbb{C}} \to \Omega^{0,\mathrm{an}} \to \Omega^{1,\mathrm{an}} \to \cdots$, i.e., the holomorphic de Rham complex is a resolution of the constant sheaf $\underline{\mathbb{C}}$. Hence:

$$\mathbb{H}^i(X^{\mathrm{an}}, \Omega^{\bullet,\mathrm{an}}) \cong H^i(X^{\mathrm{an}}, \underline{\mathbb{C}}).$$

Finally, the complex-valued smooth forms on the manifold X^{an} are fine, hence acyclic (proposition 6.1.25 and theorem 6.1.28), and they resolve $\underline{\mathbb{C}}$, so $H^i(X^{\mathrm{an}}, \underline{\mathbb{C}})$ is the smooth de Rham cohomology with complex coefficients. The de Rham theorem (theorem 0.5.23), tensored with $\mathbb{C}$, identifies this with singular cohomology: $H^i(X^{\mathrm{an}}, \underline{\mathbb{C}}) \cong H^i_{\mathrm{sing}}(X(\mathbb{C}); \mathbb{C})$.

Corollary 6.9.7 used properness only through GAGA. The identification of analytic hypercohomology with singular cohomology holds on every complex manifold, by corollary 6.9.6 and the last step of that proof. GAGA does not survive on an affine variety, which is never proper of positive dimension. Yet the affine case holds, for a reason that has nothing to do with GAGA: on an affine scheme the algebraic side degenerates completely, so the whole content sits in the comparison with the analytic topology. This is Grothendieck's theorem, and the affine case is the one that arises in practice, because the complement of a hypersurface in $\mathbb{P}^{n+1}$ is affine.

Theorem 6.9.8: Grothendieck's Comparison Theorem

Let U be a smooth affine variety over $\mathbb{C}$. Then the complex of *global algebraic* differential forms computes the complex cohomology of the associated analytic space:

$$H^i\big(\Gamma(U, \Omega^\bullet_{U/\mathbb{C}})\big) \;\cong\; H^i\big(U^{\mathrm{an}}; \mathbb{C}\big)$$

***Proof Key ideas*:**

The algebraic side degenerates, and this half is complete. Each $\Omega^p_{U/\mathbb{C}}$ is quasi-coherent on the affine U, so $H^q(U, \Omega^p_{U/\mathbb{C}}) = 0$ for every $q > 0$ by theorem 6.2.9. In the hypercohomology spectral sequence

$$E_1^{p,q} = H^q\big(U, \Omega^p_{U/\mathbb{C}}\big) \Longrightarrow \mathbb{H}^{p+q}\big(U, \Omega^\bullet_{U/\mathbb{C}}\big)$$

the entire $q > 0$ region vanishes, so the sequence degenerates and

$$\mathbb{H}^i\big(U, \Omega^\bullet_{U/\mathbb{C}}\big) \;\cong\; H^i\big(\Gamma(U, \Omega^\bullet_{U/\mathbb{C}})\big)$$

The left side of the theorem is therefore the algebraic de Rham hypercohomology, exactly the object of corollary 6.9.7. No properness is used, and nothing about U beyond affineness.

The comparison is the content, and is not proved here. What remains is $\mathbb{H}^i(U, \Omega^\bullet_{U/\mathbb{C}}) \cong H^i(U^{\mathrm{an}}; \mathbb{C})$. On the analytic side the holomorphic Poincaré lemma (corollary 6.9.6) still makes $\Omega^{\bullet,\mathrm{an}}$ a resolution of $\underline{\mathbb{C}}$, so the right side is analytic hypercohomology; but algebraic and analytic hypercohomology cannot be compared through GAGA, which needs properness. The analytic side also degenerates, since U^{an} is a Stein manifold and Cartan's Theorem B makes each $\Omega^{p,\mathrm{an}}$ acyclic on it, so the content is that the inclusion of the complex of global algebraic forms into the far larger complex of global holomorphic forms on U^{an} is a quasi-isomorphism. The standard route chooses a smooth compactification $U \subseteq \overline{U}$ whose boundary is a normal-crossings divisor D, replaces $\Omega^\bullet$ by the complex of meromorphic forms with poles of arbitrary order along D, and compares on $\overline{U}$, where properness is restored. That needs resolution of singularities and the meromorphic de Rham complex, neither developed in this book. The argument is [44, the comparison theorem for smooth affine varieties].

Corollary 6.9.9: Comparison of Euler Characteristics

Let X be a smooth projective variety of dimension n over $\mathbb{C}$ and let $\mathscr{F}$ be a coherent algebraic sheaf on X. Then:

$$\chi_{\text{alg}}(X, \mathscr{F}) = \sum_{i=0}^{n} (-1)^i \dim_{\mathbb{C}} H^i(X, \mathscr{F}) = \sum_{i=0}^{n} (-1)^i \dim_{\mathbb{C}} H^i(X^{\text{an}}, \mathscr{F}^{\text{an}}) = \chi_{\text{an}}(X^{\text{an}}, \mathscr{F}^{\text{an}}).$$

In particular, the algebraic and analytic Hilbert polynomials coincide: the algebraic Hilbert polynomial $P_{\mathscr{F}}$ of theorem 6.7.5 equals the analytic one.

***Proof*:**
Immediate from theorem 6.9.2(2): the comparison isomorphism preserves dimensions.

Corollary 6.9.10: Hodge Decomposition via GAGA

Let X be a smooth projective variety of dimension n over $\mathbb{C}$. Then the singular cohomology of $X(\mathbb{C})$ admits a Hodge decomposition:

$$H^k_{\text{sing}}(X(\mathbb{C}); \mathbb{C}) \cong \bigoplus_{p+q=k} H^q(X, \Omega^p_{X/\mathbb{C}}),$$

where $H^q(X, \Omega^p_{X/\mathbb{C}})$ is the algebraic sheaf cohomology of the p-th sheaf of algebraic differentials. The *Hodge numbers* are:

$$h^{p,q}(X) = \dim_{\mathbb{C}} H^q(X, \Omega^p_{X/\mathbb{C}}),$$

and they satisfy the symmetries $h^{p,q} = h^{q,p}$ (Hodge symmetry) and $h^{p,q} = h^{n-p,\,n-q}$ (Serre duality).

***Proof*:**
By GAGA, $H^q(X, \Omega^p_{X/\mathbb{C}}) \cong H^q(X^{\text{an}}, (\Omega^p)^{\text{an}})$. By the Dolbeault theorem (theorem 0.6.17), $H^q(X^{\text{an}}, (\Omega^p)^{\text{an}}) \cong H^{p,q}_{\bar{\partial}}(X^{\text{an}})$, the Dolbeault cohomology. Since X^{an} is a compact Kähler manifold, the Hodge decomposition theorem (theorem 0.6.28) gives:

$$H^k_{\text{dR}}(X^{\text{an}}) \cong \bigoplus_{p+q=k} H^{p,q}_{\bar{\partial}}(X^{\text{an}}),$$

and the de Rham theorem identifies the left side with $H^k_{\text{sing}}(X(\mathbb{C}); \mathbb{C})$. Combining these isomorphisms gives the decomposition.

The symmetry $h^{p,q} = h^{q,p}$ is the Hodge symmetry from complex conjugation on a Kähler manifold (theorem 0.6.28). The symmetry $h^{p,q} = h^{n-p,\,n-q}$ follows from Serre duality (corollary 6.5.10): since $\omega_X = \Omega^n_{X/\mathbb{C}}$, we have $H^q(X, \Omega^p) \cong H^{n-q}(X, (\Omega^p)^\vee \otimes \Omega^n)^* \cong H^{n-q}(X, \Omega^{n-p})^*$, giving $h^{p,q} = h^{n-p,\,n-q}$.

Example 6.9.11: GAGA in Action

1. *Line bundles and the exponential sequence.* On a compact complex manifold M, the *exponential sequence* of analytic sheaves:
$$0 \longrightarrow \underline{\mathbb{Z}} \xrightarrow{2\pi i} \mathcal{O}_M^{\mathrm{an}} \xrightarrow{\exp} (\mathcal{O}_M^{\mathrm{an}})^* \longrightarrow 0$$
induces a long exact sequence in cohomology:
$$\cdots \to H^1(M, \mathcal{O}^{\mathrm{an}}) \to H^1(M, (\mathcal{O}^{\mathrm{an}})^*) \xrightarrow{c_1} H^2(M, \mathbb{Z}) \to H^2(M, \mathcal{O}^{\mathrm{an}}) \to \cdots$$
The group $H^1(M, (\mathcal{O}^{\mathrm{an}})^*)$ classifies analytic line bundles (it is the analytic Picard group), and $c_1 : \mathrm{Pic}^{\mathrm{an}}(M) \to H^2(M, \mathbb{Z})$ is the first Chern class map (definition 0.6.41).

   For a smooth projective variety X over $\mathbb{C}$, GAGA identifies the analytic Picard group with the algebraic one: $\mathrm{Pic}(X) \cong \mathrm{Pic}^{\mathrm{an}}(X^{\mathrm{an}})$. The exponential sequence is *not* algebraic (the exponential map exp is transcendental), but GAGA carries its consequences over to algebraic line bundles: the Chern class map becomes a homomorphism $c_1 \colon \mathrm{Pic}(X) \to H^2(X(\mathbb{C}); \mathbb{Z})$, and by the Lefschetz theorem on $(1,1)$-classes every integral class of type $(1,1)$ is the first Chern class of an algebraic line bundle.

2. *Holomorphic vs. algebraic vector bundles.* Let X be a smooth projective variety over $\mathbb{C}$. By GAGA, the categories of algebraic and holomorphic vector bundles on X are equivalent (vector bundles correspond to locally free sheaves algebraically by theorem 5.1.27 and holomorphically by proposition 0.6.36). Hence every holomorphic vector bundle on X^{an} is algebraic. This fails for non-proper varieties. On $U = \mathbb{A}^2_{\mathbb{C}} \setminus \{0\}$ every algebraic line bundle is trivial, since $\mathrm{Pic}(U) = \mathrm{Pic}(\mathbb{A}^2_{\mathbb{C}}) = 0$. But $U^{\mathrm{an}} \simeq S^3$ has $H^1(U^{\mathrm{an}}; \mathbb{Z}) = H^2(U^{\mathrm{an}}; \mathbb{Z}) = 0$, so the exponential sequence gives $\mathrm{Pic}^{\mathrm{an}}(U^{\mathrm{an}}) \cong H^1(U^{\mathrm{an}}, \mathcal{O}^{\mathrm{an}})$, which is infinite-dimensional. Hence U^{an} carries holomorphic line bundles that are not algebraic.

3. *Sheaf cohomology and singular cohomology of $\mathbb{P}^n$.* Let $X = \mathbb{P}^n_{\mathbb{C}}$. The algebraic sheaf cohomology groups are: $H^i(\mathbb{P}^n, \mathcal{O}) = \mathbb{C}$ for $i = 0$ and 0 for $i > 0$ (by theorem 6.3.1). By GAGA, the same holds analytically. The Hodge decomposition gives $H^k_{\mathrm{sing}}(\mathbb{CP}^n; \mathbb{C}) = \bigoplus_{p+q=k} H^q(\mathbb{P}^n, \Omega^p)$. By theorem 6.3.3, $h^{p,p} = 1$ for $0 \le p \le n$ and all other $h^{p,q} = 0$, so:
$$H^k_{\mathrm{sing}}(\mathbb{CP}^n; \mathbb{C}) = \begin{cases} \mathbb{C} & k \text{ even},\ 0 \le k \le 2n, \\ 0 & k \text{ odd}. \end{cases}$$
   This agrees with the classical computation from algebraic topology (see **??**). The agreement is only a consistency check, since GAGA on $\mathbb{P}^n$ rests on the Hodge diamond of $\mathbb{CP}^n$ (example 0.6.30), which is read off from that same computation.

4. *The Lefschetz theorem on hyperplane sections.* Let $X \subset \mathbb{P}^N_{\mathbb{C}}$ be a smooth projective variety of dimension n and let $H \subset \mathbb{P}^N$ be a hyperplane with $Y = X \cap H$ smooth. The Lefschetz hyperplane theorem asserts that the restriction map:
$$H^i_{\mathrm{sing}}(X(\mathbb{C}); \mathbb{Z}) \longrightarrow H^i_{\mathrm{sing}}(Y(\mathbb{C}); \mathbb{Z})$$
   is an isomorphism for $i < n-1$ and injective for $i = n-1$. The proof uses Morse theory and is fundamentally analytic. Restriction is compatible with the Hodge decompositions of corollary 6.9.10, so the restriction maps $H^q(X, \Omega^p_X) \to H^q(Y, \Omega^p_Y)$ are isomorphisms for $p + q < n - 1$. This has purely algebraic applications — for instance, it implies that the Picard group of a smooth hypersurface $X \subset \mathbb{P}^n$ with $n \ge 4$ is isomorphic to $\mathbb{Z}$, generated by $\mathcal{O}_X(1)$.

6.9.12 Remark: GAGA as a Principle Beyond the precise theorems stated above, GAGA functions as a *guiding principle* in algebraic geometry over $\mathbb{C}$: any "reasonable" statement about coherent sheaves and their cohomology on projective varieties that can be proved analytically also holds algebraically, and vice versa. This principle is invoked (often implicitly) throughout the subject:

- Kodaira vanishing ($H^i(X, \omega_X \otimes \mathcal{L}) = 0$ for $i > 0$ and $\mathcal{L}$ ample) is proved analytically using L^2-estimates for the $\bar{\partial}$-operator, but applies to algebraic cohomology via GAGA.
- The degeneration of the Hodge-to-de Rham spectral sequence for smooth projective varieties is proved using Kähler geometry (or, for a variety over a perfect field F of characteristic exceeding its dimension that lifts to $W_2(F)$, by the method of Deligne and Illusie), but its algebraic consequences are what matter for classification: $\sum_{p+q=k} h^{p,q}(X) = \dim_{\mathbb{C}} H^k_{\mathrm{dR}}(X/\mathbb{C})$, and, with semicontinuity, the Hodge numbers are locally constant in smooth projective families.
- The construction of moduli spaces often proceeds by first constructing an analytic moduli space (using complex-analytic deformation theory) and then invoking GAGA to conclude that it is algebraic.

In this way, GAGA allows free passage between the algebraic and analytic worlds, using whichever tools are most natural for the problem at hand.

6.9.4 Summary

We close with a summary of the cohomology that this chapter has developed, viewed through GAGA. Let X be a smooth projective variety of dimension n over $\mathbb{C}$, and let $\mathscr{F}$ be a coherent sheaf on X. The following table summarizes the relationships between the various cohomology theories:

Algebraic	**Analytic**	**Via**
$H^i(X, \mathscr{F})$	$H^i(X^{\mathrm{an}}, \mathscr{F}^{\mathrm{an}})$	GAGA
$H^q(X, \Omega^p_{X/\mathbb{C}})$	$H^{p,q}_{\bar{\partial}}(X^{\mathrm{an}})$	GAGA + Dolbeault
$\mathbb{H}^k(X, \Omega^\bullet)$	$H^k_{\mathrm{sing}}(X(\mathbb{C}); \mathbb{C})$	Algebraic de Rham
$\chi(X, \mathscr{F})$	$\chi(X^{\mathrm{an}}, \mathscr{F}^{\mathrm{an}})$	GAGA
$\mathrm{Pic}\,(X)$	$\mathrm{Pic}^{\,\mathrm{an}}(X^{\mathrm{an}})$	GAGA

The algebraic side (left column) uses only the Zariski topology, coherent sheaves, and the machinery of this chapter. The analytic side (middle column) uses the classical topology, Dolbeault cohomology, and Hodge theory from section 0.6. The right column indicates which bridge theorem connects them. Serre duality, $\mathrm{Ext}^i(\mathscr{F}, \omega_X) \cong H^{n-i}(X, \mathscr{F})^*$, and the symmetry $h^{p,q} = h^{n-p,\,n-q}$ that it gives stay inside the algebraic column.

For non-projective or non-smooth varieties, the dictionary partially breaks down: GAGA requires properness, the Hodge decomposition requires smoothness and properness, and Serre duality requires properness, with X Cohen-Macaulay and equidimensional for duality in every degree. The interplay

between these hypotheses — determining which parts of the dictionary survive under which conditions — is a central theme of modern algebraic geometry.

7

Application: Algebraic Curves

This chapter applies the cohomology of chapter 6 to complete nonsingular curves over an algebraically closed field. For such a curve X, the dimension of $H^1(X, \mathcal{O}_X)$ is the genus g, and the additivity of the Euler characteristic together with Serre duality gives the Riemann-Roch theorem $\ell(D) - \ell(K - D) = \deg D + 1 - g$. Section 7.1 identifies a curve with its function field and defines the degree of a morphism of curves, and section 7.2 proves Riemann-Roch. Section 7.3 derives from it the degree $2g - 2$ of the canonical divisor, criteria for a divisor to be base-point-free or very ample, and the canonical map, and section 7.4 proves Hurwitz's formula for a finite separable morphism of curves. Section 7.5 treats the curves of genus $g \geq 2$ whose canonical map is not an embedding, and section 7.6 obtains the group law of a curve of genus 1 from Riemann-Roch. Section 7.7 gives Castelnuovo's bound on the genus of a curve in $\mathbb{P}^r$, the semicontinuity of cohomology in families of curves, and the changes over a field that is not algebraically closed.

Families of curves and the moduli space of curves of genus g are the subject of *Moduli, Deformation Theory, and Stacks* [27]. The Jacobian of a curve of genus g, an abelian variety of dimension g whose k-points are the classes of divisors of degree 0, is constructed in *Abelian Varieties* [8], and the arithmetic of elliptic curves is developed in *Elliptic Curves* [20]. Section 8.7, at the end of chapter 8, bounds the number of points of a curve C over a finite field by applying the Hodge index theorem to the surface $C \times C$.

7.0.1 Conventions Unless otherwise stated, k denotes an algebraically closed field and all schemes are k-schemes. A *curve* is a complete nonsingular curve over k (definition 7.1.1 gives the scheme-theoretic definition). A *point* is a closed point: the only other point of an integral curve is its generic point η, which is named explicitly when it occurs. Statements that relax these hypotheses, in particular the algebraic closure of k, say so.

7.1 Curves and Their Function Fields

A complete nonsingular curve over k admits three descriptions, the second only over $\mathbb{C}$:

1. *The geometric perspective.* A curve is a one-dimensional, complete, nonsingular scheme over k (definition 7.1.1), and the theorems of this chapter are proved in this language. It continues the classical theory of curves as varieties, with divisors, the genus and Bézout's theorem, developed in *Classical Algebraic Geometry* [30].

2. *The analytic perspective.* Over $\mathbb{C}$, analytification (definition 0.6.46) is an equivalence between the category of smooth projective curves and the category of compact Riemann surfaces with holomorphic maps (box 7.1.5). Forgetting the complex structure of a compact Riemann surface leaves a compact, connected, oriented smooth surface, and such a surface is determined up to diffeomorphism by its genus, the number of handles.[1]

3. *The algebraic perspective.* Two complete nonsingular curves are isomorphic exactly when their function fields are isomorphic over k, and every finitely generated field extension K/k of transcendence degree 1 is isomorphic over k to the function field of such a curve. On morphisms the correspondence is contravariant: $X \mapsto K(X)$ is an anti-equivalence between the category of complete nonsingular curves with nonconstant morphisms and the category of these field extensions with k-algebra homomorphisms (theorem 7.1.4). Studying curves is therefore equivalent to studying function fields. This is the perspective closest to number theory: the function field of a curve over $\mathbb{F}_q$ shares many properties with a number field, and several results of this chapter have arithmetic counterparts (box 7.1.11). For curves as varieties, *Classical Algebraic Geometry* [30, Function Field and Morphism Correspondence, Characterizing Nonsingular Projective Curves] states the bijection on morphisms and the isomorphism criterion.

Recall that a scheme is *integral* if it is both reduced and irreducible (proposition 2.4.20), and *regular* if all of its local rings are regular local rings (definition 2.7.5).

[1] Every topological surface admits a smooth structure, unique up to diffeomorphism, so the topological and smooth classifications of surfaces agree.

Definition 7.1.1: Curve

Let k be a field. A *curve over* k is a Noetherian, integral, separated scheme X of dimension 1 and of finite type over k.

1. The curve X is *complete* (or *proper*) if the structure morphism $X \to \operatorname{Spec} k$ is proper.
2. The curve X is *nonsingular* (or *regular*) if all local rings $\mathcal{O}_{X,x}$ are regular. When k is perfect, in particular when $k = \overline{k}$, this holds if and only if the structure morphism is smooth (theorem 2.7.15), and a nonsingular curve is then also called *smooth*.

Let $\mathbf{Crv}_k$ be the category of all curves over k, $\mathbf{Crv}_k^{\mathrm{prop}}$ the subcategory of proper curves, and $\mathbf{SmProjCrv}_k$ the subcategory of curves that are smooth and projective over k. When k is perfect, the curves in $\mathbf{SmProjCrv}_k$ are exactly the complete nonsingular curves (theorem 2.7.15, and proposition 7.1.7 below), and $\mathbf{SmProjCrv}_k$ is the default category of this chapter.

The definition admits curves that are not complete, such as the affine line $\mathbb{A}^1_k$, and curves that are singular, such as the affine nodal cubic $V(y^2 - x^3 - x^2) \subseteq \mathbb{A}^2_k$. Under the conventions of this chapter an unqualified curve is complete and nonsingular.

The integrality assumption gives a curve a unique generic point η with $\overline{\{\eta\}} = X$, and the function field $\kappa(\eta) = K(X)$ is a finitely generated field extension of k of transcendence degree 1 (theorem 2.6.11). When k is algebraically closed, every such extension is isomorphic over k to the function field of a smooth projective curve (theorem 7.1.4(3) below).

At a closed point x of a nonsingular curve, the local ring $\mathcal{O}_{X,x}$ is a regular local ring of dimension 1, that is, a discrete valuation ring (DVR) [15, Characterizations of a DVR]. When X is moreover complete, every DVR of $K(X)/k$ dominates, and hence equals, the local ring of exactly one closed point of X (corollary 7.3.5 below). The closed points of a complete nonsingular curve are therefore in bijection with the DVRs of $K(X)/k$, the classical starting point for the theory of abstract curves. Every complete nonsingular curve is projective (proposition 7.1.7 below).

Singular curves arise as fibers of families, as images of morphisms, and as boundary points of moduli spaces. At a singular point x of an integral curve the local ring $\mathcal{O}_{X,x}$ is not a DVR, and the bijection between closed points and DVRs of $K(X)/k$ fails. A singular curve is related to the nonsingular theory through its *normalization*. A Noetherian local domain of dimension 1 is a DVR if and only if it is integrally closed [15, Characterizations of a DVR], so the normalization of an integral curve (theorem 3.4.41) is a nonsingular curve with the same function field, together with a finite birational morphism onto the original curve.

Proposition 7.1.2: Affine Curves and Unique Proper Curve

Let X be an affine nonsingular curve over k. Then there is a complete nonsingular curve Y birational to X (definition 3.6.2), so that $K(Y) \cong K(X)$ (corollary 3.6.6), and Y is unique up to isomorphism.

Existence is the case $V = X$ of theorem 7.1.3, whose proof carries out the steps of the proof below in full, and uniqueness follows from part (2) of that theorem applied to a dense open subscheme common to two candidates.

***Proof Key ideas*:**
As X is affine and of finite type, $X \cong \operatorname{Spec} k[x_1, \dots, x_n]/I$, so X is a closed subscheme of $\mathbb{A}^n_k$ and hence a locally closed subscheme of $\mathbb{P}^n_k$ (lemma 5.3.16). Its closure $\overline{X} \subseteq \mathbb{P}^n_k$, with the reduced induced structure, is an integral projective curve containing X as a dense open subscheme. It may be singular, so take its normalization

$$\nu\colon \widetilde{X} \longrightarrow \overline{X}$$

(theorem 3.4.41), obtained by replacing the coordinate ring of each affine open of $\overline{X}$ by its integral closure in $K(X)$ (definition 2.4.28). The scheme $\widetilde{X}$ is normal of dimension 1, hence nonsingular, and it is complete because ν is finite, hence proper (proposition 3.5.24), and $\overline{X}$ is proper over k (proposition 3.5.23(2)). Over the normal open subscheme X the morphism ν is an isomorphism, so $Y = \widetilde{X}$ contains X as a dense open subscheme. For uniqueness, two such curves Y and Y' contain dense open subschemes isomorphic to one and the same dense open subscheme $W \subseteq X$ (proposition 3.6.9). Both are projective (proposition 7.1.7 below), so both are completions of W in the sense of theorem 7.1.3(1), and part (2) of that theorem gives $Y \cong Y'$, as claimed.

The normalization separates the branches of a curve at a node and replaces a cusp by a nonsingular point:

1. The normalization of the *nodal cubic* $V(y^2z - x^3 - x^2z) \subseteq \mathbb{P}^2_k$ with $\operatorname{char} k \neq 2$, the projective closure of $y^2 = x^3 + x^2$, is $\mathbb{P}^1_k$, with two points over the node, one for each branch through the origin.

2. The normalization of the *cuspidal cubic* $V(y^2z - x^3) \subseteq \mathbb{P}^2_k$ is again $\mathbb{P}^1_k$, with a single point over the cusp.

At a node two branches with distinct tangent lines cross, and at a cusp a single branch has one tangent line. More complicated singularities occur (higher-order cusps, tacnodes, points where several branches meet), and the normalization separates their branches in the same way.

Both cubics above have arithmetic genus 1 and normalization $\mathbb{P}^1_k$, so both are rational. The difference between the arithmetic genus of X and the genus of its normalization $\widetilde{X}$ is the sum of the δ-invariants of the singular points (box 7.2.9). When X is complete, so is $\widetilde{X}$, being finite over X, and $\widetilde{X}$ is then the complete nonsingular model of the function field $K(X)$ (corollary 7.3.5 below), unique up to isomorphism by theorem 7.1.4(3) below.

Proposition 7.1.2 applies only to an affine curve, and its statement relates Y to X only through a birational map, with no open immersion $X \hookrightarrow Y$. A curve arising as a fiber of a family, as an orbit, or as a one-dimensional slice of a larger variety is quasiprojective and rarely affine, and the arguments that use a completion need the original curve to be an open subscheme of the completed one. Theorem 7.1.3 removes both restrictions. Over an arbitrary field it produces a regular curve, and regularity coincides with smoothness when the field is perfect (theorem 2.7.15).

Theorem 7.1.3: Projective Completion of a Smooth Curve

Let k be a field and let V be a quasiprojective curve over k (definition 7.1.1, definition 2.3.5) which is smooth over k. Then:

1. There exist a regular projective curve $\overline{V}$ over k, in particular integral and hence connected, and an open immersion $j\colon V \hookrightarrow \overline{V}$ with dense image, and the map j identifies $K(\overline{V})$ with $K(V)$.
2. The pair $(\overline{V}, j)$ is unique up to unique isomorphism under V: for any second such pair $(\overline{V}', j')$ there is exactly one isomorphism $f\colon \overline{V} \to \overline{V}'$ with $f \circ j = j'$.
3. If k is perfect, then $\overline{V}$ is smooth over k.

***Proof*:**

Step 1: an integral projective curve containing V as a dense open. By definition 2.3.5 there are a projective k-scheme Y and an open immersion $V \subseteq Y$. Let $\overline{X} \subseteq Y$ be the closure of V, taken with its reduced induced structure (definition 3.1.26). It is irreducible, being the closure of the irreducible V (lemma 2.1.24(1)), and reduced, hence integral (proposition 2.4.20). A composite of closed immersions is a closed immersion (proposition 3.1.24(3)), so the closed subscheme $\overline{X}$ of Y admits a closed immersion into some $\mathbb{P}^n_k$ and is projective (corollary 5.3.15(3)), hence of finite type and proper over k (theorem 3.5.32). The subset V is open in $\overline{X}$, and the induced structure agrees with the given one, both being reduced with the same underlying space (proposition 3.1.25). So V is a dense open subscheme of $\overline{X}$ and $K(\overline{X}) = K(V)$. That field has transcendence degree 1 over k, so $\operatorname{kdim}\overline{X} = 1$ (theorem 2.6.11).

Step 2: normalize. Since $\overline{X}$ is integral of finite type over k, theorem 3.4.41 gives a normalization $\nu\colon \widetilde{X} \to \overline{X}$: the scheme $\widetilde{X}$ is integral, normal and of finite type over k, the morphism ν is finite, surjective and birational, and ν is an isomorphism over the normal locus of $\overline{X}$. As $\overline{X}$ is projective, corollary 5.3.58 makes $\widetilde{X}$ projective over k, hence separated, Noetherian and proper. Birationality gives $K(\widetilde{X}) = K(V)$ and therefore $\operatorname{kdim}\widetilde{X} = 1$ (theorem 2.6.11).

Step 3: V is unchanged by the normalization. Smoothness implies regularity (proposition 2.7.14), and a regular local ring is integrally closed (proposition 2.7.26), so every local ring of V is normal. Those local rings are the local rings of $\overline{X}$ at the points of V, so V lies in the normal locus of $\overline{X}$ and ν restricts to an isomorphism $\nu^{-1}(V) \to V$. Set $\overline{V} = \widetilde{X}$ and let $j\colon V \to \overline{V}$ be the inverse of that isomorphism followed by the open immersion $\nu^{-1}(V) \subseteq \overline{V}$. Its image is a nonempty open subset of the irreducible scheme $\overline{V}$, hence dense, and j identifies $K(V)$ with $K(\overline{V})$.

Step 4: $\overline{V}$ is regular, and smooth over a perfect field. The scheme $\overline{V}$ is Noetherian, integral and normal, so by proposition 5.4.2(2) every point at which it fails to be regular has codimension at least 2. No point has codimension 2: for $x \in \overline{V}$ the closure $\overline{\{x\}}$ is an irreducible closed subset, so $\operatorname{codim}_{\overline{V}}\overline{\{x\}} \leq \operatorname{kdim}\overline{V} = 1$ by lemma 2.6.7, and this codimension is $\operatorname{kdim}\mathcal{O}_{\overline{V},x}$ by definition 2.6.5. Hence $\overline{V}$ is regular (definition 2.7.5) and is a projective curve over k in the sense of definition 7.1.1. If k is perfect, regularity and smoothness coincide for k-schemes locally of finite type (theorem 2.7.15), so $\overline{V}$ is then smooth over k. This proves (1) and (3).

Step 5: a morphism between two completions. Let $(\overline{V}', j')$ be a second pair as in (1). The composite $j' \circ j^{-1}$, defined on the dense open $j(V) \subseteq \overline{V}$, is a rational map $\varphi\colon \overline{V} \dashrightarrow \overline{V}'$. Its source is integral, normal (proposition 2.7.26) and of finite type over k, and its target is proper over k (theorem 3.5.32), so by theorem 4.7.4 the indeterminacy locus of φ has codimension at least 2 in $\overline{V}$. By the computation of Step 4 no point of $\overline{V}$ has codimension 2, so that locus is empty and φ is a morphism $f\colon \overline{V} \to \overline{V}'$ with $f \circ j = j'$.

Step 6: the morphism is the unique isomorphism under V. The source $\overline{V}$ is proper over k and the target $\overline{V}'$ is separated over k, so f is proper (proposition 3.5.23(5)) and therefore separated, of finite type and closed (definition 3.5.21). Its image is closed and contains the dense subset $j'(V)$, so f is surjective, and $f \circ j = j'$ forces f to induce the identity on $K(V)$, so f is birational. Each fiber is finite. The fiber over the generic point of $\overline{V}'$ is the generic point of $\overline{V}$, because f is closed and so carries closed points to closed points. The fiber over a closed point is a closed subset of $\overline{V}$ not containing the generic point, so each of its irreducible components Z satisfies $\operatorname{codim}_{\overline{V}} Z \geq 1$ and hence $\operatorname{kdim} Z = 0$ by lemma 2.6.7, making Z a closed point, and the components are finite in number because $\overline{V}$ is Noetherian. So f is quasifinite. Both schemes are integral and Noetherian and $\overline{V}'$ is normal, so corollary 3.4.39 makes f an open immersion, and a surjective open immersion is an isomorphism. Finally, two isomorphisms $\overline{V} \to \overline{V}'$ under V agree on the dense open $j(V)$ of the reduced scheme $\overline{V}$, and $\overline{V}'$ is projective over k and so separated, hence the two agree (proposition 3.5.10). This proves (2), completing the proof.

The theorem contains proposition 7.1.2: an affine nonsingular curve is quasiprojective (lemma 5.3.16), so it has a completion, which contains it as a dense open subscheme, and part (2), applied to a common dense open subscheme, gives the uniqueness.

Part (3) needs k to be perfect. Over an imperfect field a smooth curve can fail to have any smooth projective completion, so the general conclusion is regularity, and example 2.7.16 shows the phenomenon at a single point. For a curve, let p be odd, let $k = \mathbb{F}_p(t)$ and let $C = \operatorname{Spec} k[x,y]/(y^2 - x^p + t)$, an integral affine curve. The Jacobian of $y^2 - x^p + t$ is $(0, 2y)$, so C fails to be smooth over k exactly along $y = 0$, which on C is the single closed point P cut out by y, with residue field $k(t^{1/p})$. Thus $V = C \setminus \{P\}$ is a smooth quasiprojective curve. But C is regular at P as well: the relation $y^2 = x^p - t$ makes the maximal ideal of $\mathcal{O}_{C,P}$ equal to (y), a principal ideal in a one-dimensional Noetherian local domain. The argument of Step 5, applied to the regular, hence normal, curve C in place of $\overline{V}$, extends $j\colon V \hookrightarrow \overline{V}$ to a birational morphism $C \to \overline{V}$. This morphism is quasifinite, since its fiber over a closed point is a proper closed subset of C and its fiber over the generic point lies in $\{\eta_C, P\}$, so it is an open immersion by corollary 3.4.39. Hence $\overline{V}$ contains an open subscheme isomorphic to C and is not smooth over k, and by part (2) no smooth projective curve contains V as a dense open subscheme.

A nonsingular curve is normal, and each of its points other than the generic point has codimension 1, so theorem 4.7.4 leaves a rational map from a nonsingular curve to a complete curve no indeterminacy. Every dominant rational map between complete nonsingular curves is therefore a morphism, and lemma 3.6.8 identifies these maps with the homomorphisms between the function fields.

Theorem 7.1.4: Curves and Their Function Fields

Let k be algebraically closed.

1. A k-morphism $f\colon X \to Y$ of curves over k in the sense of definition 7.1.1, not necessarily complete or nonsingular, is dominant if and only if it is *nonconstant*, that is, $f(X)$ is not a single point.

2. Let $\mathcal{C}_k$ be the category whose objects are the complete nonsingular curves over k, which are exactly the smooth projective curves over k (definition 7.1.1 and proposition 7.1.7 below), and whose morphisms are the nonconstant, equivalently by (1) the dominant, k-morphisms. Let $\mathcal{F}_k$ be the category whose objects are the finitely generated field extensions of k of transcendence degree 1 and whose morphisms are the k-algebra homomorphisms. Then the functor sending X to $K(X)$ and a morphism $f\colon X \to Y$ to the induced homomorphism $f^\sharp\colon K(Y) \to K(X)$ is an anti-equivalence, that is, an equivalence of categories $\mathcal{C}_k \to \mathcal{F}_k^{\mathrm{op}}$.

3. Two complete nonsingular curves over k are isomorphic if and only if their function fields are isomorphic over k, and every finitely generated field extension of k of transcendence degree 1 is isomorphic over k to the function field of a complete nonsingular curve over k.

***Proof*:**
Step 1: the irreducible closed subsets of a curve. Let Y be a curve over k and let $Z \subsetneq Y$ be an irreducible closed subset. The chain $Z \subsetneq Y$ gives $\operatorname{codim}_Y Z \geq 1$, so $\operatorname{kdim} Z = 0$ by lemma 2.6.7. For $z \in Z$ the closure of $\{z\}$ is an irreducible closed subset of Z (lemma 2.1.24(1)), and it is all of Z, since otherwise the two would form a chain of length 1 in Z. So every point of Z is a generic point of Z, and the generic point is unique (lemma 2.4.21). Hence Z is a single closed point. In particular every point $y \neq \eta_Y$ of Y is closed: $\overline{\{y\}}$ is an irreducible closed subset of Y, different from $Y = \overline{\{\eta_Y\}}$ by the uniqueness of the generic point, so it is the single point y.

Step 2: part (1). If f is not dominant, the closure of $f(X)$ is an irreducible closed subset of Y (lemma 2.1.24(1),(2)) other than Y, so $f(X)$ is a single point by Step 1. Suppose that f is dominant, so that $f(\eta_X) = \eta_Y$ (lemma 3.6.4). As $\operatorname{kdim} X = 1$, the curve X contains an irreducible closed subset other than X, and a point x of that subset differs from η_X, so x is closed by Step 1. Choose an affine open $\operatorname{Spec} A \ni x$ with $A = k[T_1, \ldots, T_n]/I$ a finitely generated k-algebra (definition 2.2.18). The closed point x is a maximal ideal of A, the image of a maximal ideal of $k[T_1, \ldots, T_n]$ containing I, which has the form $(T_1 - a_1, \ldots, T_n - a_n)$ by theorem 0.1.12(3), so $\kappa(x) = k$. If $f(x)$ were η_Y, the local homomorphism $\mathcal{O}_{Y,\eta_Y} = K(Y) \to \mathcal{O}_{X,x}$ would induce a k-algebra homomorphism of residue fields $K(Y) \to \kappa(x) = k$. It would be injective, $K(Y)$ being a field, and so $\dim_k K(Y) \leq 1$. This is impossible, because $K(Y)$ has transcendence degree 1 over k (theorem 2.6.11) and the powers of an element transcendental over k are linearly independent over k. Hence $f(x) \neq f(\eta_X)$ and f is nonconstant. By part (1) and lemma 3.6.4, a composite of nonconstant morphisms of curves carries the generic point to the generic point and is again nonconstant, and identities are nonconstant, so $\mathcal{C}_k$ is a category.

Step 3: the functor. Let X be a curve over k and $\operatorname{Spec} A \subseteq X$ a nonempty affine open with A a

finitely generated k-algebra. Then $K(X) = \mathrm{Frac}A$ (corollary 2.4.25) is generated as a field over k by the finitely many generators of A, and it has transcendence degree 1 over k by theorem 2.6.11, a curve being a k-variety (definition 3.7.2) of dimension 1. A morphism $f\colon X \to Y$ of $\mathcal{C}_k$ is dominant by part (1), so it represents a dominant rational map, and proposition 3.6.5 gives its stalk map at η_X as a k-algebra homomorphism $f^\sharp\colon K(Y) \to K(X)$, with $(g \circ f)^\sharp = f^\sharp \circ g^\sharp$ and $\mathrm{id}_X^\sharp = \mathrm{id}_{K(X)}$. So $X \mapsto K(X)$ and $f \mapsto f^\sharp$ form a functor $\mathcal{C}_k \to \mathcal{F}_k^{\mathrm{op}}$.

Step 4: the functor is faithful. Let $f, g\colon X \to Y$ be morphisms of $\mathcal{C}_k$ with $f^\sharp = g^\sharp$. The curve Y is of finite type over k, so by lemma 3.6.8 the dominant rational maps represented by f and g are equal, that is, f and g agree on a dense open subset of X (definition 3.6.1). The scheme X is reduced (proposition 2.4.20) and Y is separated over k, so $f = g$ by proposition 3.5.10.

Step 5: the functor is full. Let X and Y be objects of $\mathcal{C}_k$ and let $\sigma\colon K(Y) \to K(X)$ be a k-algebra homomorphism. By lemma 3.6.8 there is a dominant rational map $\pi\colon X \dashrightarrow Y$ of k-schemes with $\pi^\sharp = \sigma$. The curve X is integral and of finite type over k, and it is normal because its local rings are regular, hence integrally closed (proposition 2.7.26). The curve Y is proper over k. By theorem 4.7.4 the locus of indeterminacy of π has codimension at least 2 in X. No nonempty irreducible closed subset of X has codimension at least 2, since $\mathrm{codim} + \dim \leq \mathrm{kdim} X = 1$ (lemma 2.6.7), so that locus is empty. As Y is separated, proposition 4.7.2 shows that the representatives of π glue to a morphism $f\colon X \to Y$ representing π, and f is a k-morphism because its restrictions to the domains of the representatives are. It carries η_X to η_Y (lemma 3.6.4), so it is dominant, hence nonconstant by part (1). Finally $f^\sharp = \pi^\sharp = \sigma$, because the homomorphism of proposition 3.6.5 does not depend on the representative.

Step 6: isomorphisms. An isomorphism $f\colon X \to Y$ of curves over k is surjective, hence nonconstant because Y is not a single point, and $f^\sharp$ is an isomorphism with inverse $(f^{-1})^\sharp$ by Step 3. Conversely, let $\sigma\colon K(Y) \to K(X)$ be an isomorphism of k-algebras between the function fields of two objects of $\mathcal{C}_k$. Step 5 gives morphisms $f\colon X \to Y$ and $g\colon Y \to X$ of $\mathcal{C}_k$ with $f^\sharp = \sigma$ and $g^\sharp = \sigma^{-1}$, and

$$(g \circ f)^\sharp = f^\sharp \circ g^\sharp = \sigma \circ \sigma^{-1} = \mathrm{id}_{K(X)} = \mathrm{id}_X^\sharp$$

so $g \circ f = \mathrm{id}_X$ by Step 4, and likewise $f \circ g = \mathrm{id}_Y$. This proves the first assertion of part (3).

Step 7: essential surjectivity. Let K be a finitely generated field extension of k of transcendence degree 1, generated by $t_1, \ldots, t_n$, and let $A = k[t_1, \ldots, t_n] \subseteq K$. Then A is a finitely generated k-algebra and a domain, and $\mathrm{Frac}A = K$ because K is generated as a field by $t_1, \ldots, t_n$. So $\operatorname{Spec} A$ is an integral scheme of finite type over k. Let $\nu\colon \widetilde{X} \to \operatorname{Spec} A$ be its normalization (theorem 3.4.41): the scheme $\widetilde{X}$ is integral, normal and of finite type over k, the morphism ν is finite, and it induces an isomorphism $K \to K(\widetilde{X})$ of k-algebras. Since ν is finite and $\operatorname{Spec} A$ is affine, $\widetilde{X} = \operatorname{Spec} \widetilde{A}$ for a finite A-algebra $\widetilde{A}$ (definition 3.4.15). So $\widetilde{A}$ is a finitely generated k-algebra, Noetherian by the Hilbert basis theorem, and, $\widetilde{X}$ being integral, a domain with fraction field $K(\widetilde{X}) \cong K$ (corollary 2.4.25). Hence $\mathrm{kdim}\widetilde{X} = 1$ by theorem 2.6.11. Being affine, $\widetilde{X}$ is separated over k (example 3.5.3(2)), so it is a curve over k.

The curve $\widetilde{X}$ is regular. Its local ring at the generic point is the field $K(\widetilde{X})$, a regular local ring of dimension 0. Every other point x is closed by Step 1, so the chain $\{x\} \subsetneq \widetilde{X}$ and lemma 2.6.7

give $\operatorname{codim}_{\widetilde{X}}\{x\} = 1$, and this is $\operatorname{kdim}\mathcal{O}_{\widetilde{X},x}$ (definition 2.6.5). Thus $\mathcal{O}_{\widetilde{X},x}$, a localization of the Noetherian domain $\widetilde{A}$, is a Noetherian local domain of dimension 1, integrally closed because $\widetilde{X}$ is normal (definition 2.4.28), hence regular [15, Characterizations of a DVR]. As k is perfect, $\widetilde{X}$ is smooth over k (theorem 2.7.15).

The curve $\widetilde{X}$ is integral, hence reduced, and affine of finite type over k, so it is quasiprojective (lemma 5.3.16).

By theorem 7.1.3(1) and (3) there are a regular projective curve C over k, smooth over k, and an open immersion $\widetilde{X} \hookrightarrow C$ over k identifying $K(C)$ with $K(\widetilde{X}) \cong K$. The curve C is proper over k (theorem 3.5.32), so it is an object of $\mathcal{C}_k$, and $K(C) \cong K$ over k. This proves the second assertion of part (3).

Step 8: conclusion. By Steps 4 and 5 the functor of Step 3 is fully faithful, and by Step 7 every object of $\mathcal{F}_k$ is isomorphic to the function field of an object of $\mathcal{C}_k$. The functor is therefore an equivalence $\mathcal{C}_k \to \mathcal{F}_k^{\mathrm{op}}$ (definition 0.4.6), which is part (2), completing the proof.

Under the conventions of this chapter, where $k = \overline{k}$, theorem 7.1.4(3) gives a bijection between isomorphism classes

$$\left\{\begin{array}{c}\text{Smooth Projective Curves}\\ \text{over } k\end{array}\right\} \underset{K \mapsto C_K}{\overset{X \mapsto K(X)}{\rightleftarrows}} \left\{\begin{array}{c}\text{Finitely Generated Field Extensions}\\ \text{of } k\\ \text{of Transcendence Degree 1}\end{array}\right\} \tag{7.1}$$

where C_K is a complete nonsingular curve whose function field is isomorphic to K over k, unique up to isomorphism.

7.1.5 The Analytic Perspective Over $\mathbb{C}$, the analytification X^{an} of a smooth projective curve X (definition 0.6.46) is a compact Riemann surface, and $X \mapsto X^{\mathrm{an}}$ is an equivalence between the category of smooth projective curves over $\mathbb{C}$ and the category of compact Riemann surfaces with holomorphic maps. Full faithfulness comes from GAGA (theorem 6.9.2): by part (3) of that theorem, the graph of a holomorphic map $X^{\mathrm{an}} \to Y^{\mathrm{an}}$, a closed analytic subspace of $(X \times_{\mathbb{C}} Y)^{\mathrm{an}}$, is the analytification of a closed subscheme Γ of $X \times_{\mathbb{C}} Y$. The projection $\Gamma \to X$ is an isomorphism because its analytification is [46, Exposé XII, Proposition 3.1(ix)], so Γ is the graph of a morphism $X \to Y$. Essential surjectivity is not part of GAGA. It is Riemann's theorem that every compact Riemann surface is projective algebraic [50, Appendix B, Theorem 3.1], whose analytic input is the existence of a nonconstant meromorphic function on every compact Riemann surface [37, §14].

A compact Riemann surface is in particular a compact, connected, oriented surface, determined up to diffeomorphism by its topological genus g_{top}, the number of handles. A compact Riemann surface is a compact Kähler manifold, so by the Hodge decomposition (theorem 0.6.28) and GAGA its first Betti number is $2g_{\mathrm{top}} = h^{1,0} + h^{0,1} = 2\dim_{\mathbb{C}} H^1(X, \mathcal{O}_X)$ (example 0.6.31). The topological genus therefore equals $\dim_{\mathbb{C}} H^1(X, \mathcal{O}_X)$, which proposition 7.2.5 identifies with the arithmetic and the geometric genus.

Proposition 7.1.6: Image of Complete Nonsingular Curve is Closed

Let k be a field, let X be a complete nonsingular curve over k, and let Y be any curve over k. Suppose $f\colon X \to Y$ is a morphism. Then either:

1. $f(X)$ is a single closed point of Y, or
2. f is surjective, Y is necessarily complete, and f is a finite morphism.

***Proof*:**
Since X is proper over k and Y is separated over k, the morphism f is proper (proposition 3.5.23(5)), so the image $f(X) \subseteq Y$ is closed. As X is irreducible, so is $f(X)$ (lemma 2.1.24(2)). A closed irreducible subset of the curve Y other than Y has codimension at least 1, hence dimension 0 by lemma 2.6.7, and is a single closed point. So either $f(X)$ is a closed point or f is surjective. Assume from now on that f is surjective.

Step 1: Y is complete. The scheme Y is separated and of finite type over k, so it remains to show that $Y \to \operatorname{Spec} k$ is universally closed. Let T be a k-scheme and let $W \subseteq Y \times_k T$ be a closed subset. The base change $f_T\colon X \times_k T \to Y \times_k T$ is surjective, since surjectivity is stable under base change [95, Tag 01S1]. The image of W in T is therefore the image of the closed subset $f_T^{-1}(W)$ of $X \times_k T$, and this image is closed because X is proper over k.

Step 2: f is finite. The fiber of f over the generic point of Y is the generic point of X, because f is closed and so carries closed points to closed points. The fiber over a closed point is a closed subset of X not containing the generic point, so each of its irreducible components Z satisfies $\operatorname{codim}_X Z \geq 1$, hence $\operatorname{kdim} Z = 0$ by lemma 2.6.7, and Z is a closed point. There are finitely many components because X is Noetherian, and f is of finite type, being proper, so f is quasifinite (definition 3.4.36). It is separated because X is separated over k. By theorem 3.4.38, $f = g \circ j$ with $j\colon X \to M$ an open immersion and $g\colon M \to Y$ finite. The morphism g is proper (proposition 3.5.24), hence separated, and $g \circ j = f$ is proper, so j is proper (proposition 3.5.23(5)) and $j(X)$ is closed as well as open in M. An open immersion onto a closed and open subset is a closed immersion, so j is finite, and $f = g \circ j$ is finite (proposition 3.4.25(1)).

Step 3: the affine pieces. For an affine open $V = \operatorname{Spec} S \subseteq Y$, finiteness gives $f^{-1}(V) = \operatorname{Spec} R$ with R a finite S-module, and R is the integral closure of S in $K(X)$. Indeed, every element of R is integral over S, and R is integrally closed in its fraction field $K(X)$ because its localizations at prime ideals are local rings of X, which are integrally closed (proposition 2.7.26, proposition 2.4.29). Since f is dominant, it induces an inclusion of function fields $K(Y) \hookrightarrow K(X)$, and both have transcendence degree 1 over k, so $K(X)/K(Y)$ is a finite extension, completing the proof.

Properness of a nonsingular curve already forces projectivity, through a finite morphism to $\mathbb{P}^1_k$.

Proposition 7.1.7: Complete Nonsingular Curves Are Projective

Let k be a field and let X be a complete nonsingular curve over k (definition 7.1.1). Then X is projective over k: there is a closed immersion $X \hookrightarrow \mathbb{P}^n_k$ for some n.

***Proof*:**
Step 1: a nonconstant function. The scheme X is integral of finite type over k with $\dim X = 1$, so its function field $K(X)$ has transcendence degree 1 over k (theorem 2.6.11). Choose $f \in K(X)$ transcendental over k. The function field is the local ring at the generic point, a filtered colimit of the rings of sections (corollary 2.4.25), so f is a regular function on some nonempty affine open $V \subseteq X$, and f defines a morphism $V \to \mathbb{A}^1_k \subseteq \mathbb{P}^1_k$, hence a rational map $\varphi\colon X \dashrightarrow \mathbb{P}^1_k$.
Step 2: the rational map is a morphism. Every local ring of X is regular, hence integrally closed (proposition 2.7.26), so X is a normal integral k-scheme of finite type, and $\mathbb{P}^1_k$ is proper over k. By theorem 4.7.4 the locus of indeterminacy of φ has codimension at least 2 in X. No nonempty irreducible closed subset of X has codimension at least 2, since $\operatorname{codim} + \dim \leq \dim X = 1$ (lemma 2.6.7), so that locus is empty and φ is a morphism $\varphi\colon X \to \mathbb{P}^1_k$.
Step 3: the morphism is finite. The restriction $\varphi|_V\colon V \to \mathbb{A}^1_k = \operatorname{Spec} k[t]$ corresponds to the k-algebra map $k[t] \to \mathcal{O}_X(V)$ sending t to f, which is injective because f is transcendental over k. So $\varphi|_V$ is dominant (proposition 3.1.34), and in particular $\varphi(X)$ is not a single closed point. The target $\mathbb{P}^1_k$ is a curve over k in the sense of definition 7.1.1, so proposition 7.1.6 applies and gives that φ is surjective and finite.
Step 4: descending projectivity along a finite morphism. The scheme $\mathbb{P}^1_k$ is Noetherian and projective over k, with $\mathcal{O}(1)$ very ample, so proposition 5.3.57(2) applied to φ gives a closed immersion $X \hookrightarrow \mathbb{P}^{m-1}_{\mathbb{P}^1_k}$ over $\mathbb{P}^1_k$ for some $m \geq 1$. As in the proof of corollary 5.3.58, $\mathbb{P}^{m-1}_{\mathbb{P}^1_k} \cong \mathbb{P}^{m-1}_k \times_k \mathbb{P}^1_k$ (example 5.3.55(1), proposition 5.3.50), the Segre embedding (example 5.3.45(5)) is a closed immersion of this product into $\mathbb{P}^{2m-1}_k$, and a composite of closed immersions is a closed immersion (proposition 3.1.24(3)). So X is projective over k, as we sought to show.

The proof does not use the Riemann-Roch theorem (theorem 7.2.10, proved in section 7.2 below). The very ample criterion corollary 7.3.4, also below, would give projectivity at once through lemma 5.3.23, but its proof rests on theorem 7.2.10, which is derived from Serre duality for projective schemes (theorem 6.5.9), so that route assumes projectivity. The descent of projectivity along a finite morphism is proposition 5.3.57 from chapter 5, and every complete nonsingular curve admits a finite morphism to $\mathbb{P}^1_k$, because its function field contains an element transcendental over k (Steps 1 to 3). Since complete nonsingular curves are projective, Serre duality, and with it the Riemann-Roch theorem of section 7.2, applies to every complete nonsingular curve.

Nonsingularity is not needed for the conclusion: every proper k-scheme of dimension at most 1 is projective over k [95, Tag 0A26]. In dimension at least 2 the conclusion fails. Over an algebraically closed field, complete nonsingular surfaces are projective, but there are complete singular surfaces and complete nonsingular threefolds that are not projective [50, Remark II.4.10.2]. Hironaka's example (proposition 8.4.12, in section 8.4) is such a threefold: an effective curve on it is algebraically equivalent to the negative of another, so no divisor on it is ample.

By proposition 7.1.6, a morphism between complete nonsingular curves is either constant or finite and surjective, and a finite one has a degree.

Definition 7.1.8: Degree of Morphism of Curves

Let $f\colon X \to Y$ be a finite morphism of complete nonsingular curves. The *degree* of f is the degree of the finite field extension $K(X)/K(Y)$:

$$\deg f \;=\; [K(X) : K(Y)]$$

Over a closed point $y \in Y$ the fiber $f^{-1}(y)$ consists of $\deg f$ points counted with multiplicity: $\sum_{x\in f^{-1}(y)} e_x = \deg f$ (proposition 7.1.9), where e_x is the ramification index defined below. In the analytic picture over $\mathbb{C}$, a degree-n map between compact Riemann surfaces is an n-sheeted branched cover.

A finite morphism of complete nonsingular curves pulls back divisors. On a nonsingular curve X Weil and Cartier divisors coincide (proposition 5.4.33, the local rings being DVRs and hence UFDs), so divisors are elements of $\operatorname{WDiv} X = \bigoplus_{x\in X_{(1)}} \mathbb{Z}\cdot x$, and their classes form $\operatorname{Cl} X$. Since $\dim X = 1$, every divisor is a finite formal sum of closed points.

Let $f\colon X \to Y$ be a finite morphism between complete nonsingular curves. For a closed point $y \in Y$, choose a uniformizer $t \in \mathcal{O}_{Y,y}$ (a generator of the maximal ideal $\mathfrak{m}_y$, so that $\nu_y(t) = 1$). For each point $x \in f^{-1}(y)$, the map $f^{\#}\colon \mathcal{O}_{Y,y} \to \mathcal{O}_{X,x}$ sends t to an element of the maximal ideal $\mathfrak{m}_x$. Define the map $f^*\colon \operatorname{WDiv}(Y) \to \operatorname{WDiv}(X)$ on closed points as

$$f^*(y) \;=\; \sum_{x\in f^{-1}(y)} \nu_x(f^{\#}(t))\cdot x \;=\; \sum_{f(x)=y} e_x \cdot x$$

where $e_x = \nu_x(f^{\#}(t))$ is the *ramification index* at x (studied in section 7.4). This is a finite sum since f is a finite morphism, and it is independent of the choice of uniformizer t: any other uniformizer has the form $t' = ut$ for a unit $u \in \mathcal{O}_{Y,y}^*$, and $\nu_x(f^{\#}(u)) = 0$ since $f^{\#}(u)$ is a unit in $\mathcal{O}_{X,x}$.

Extending by $\mathbb{Z}$-linearity gives a group homomorphism $f^*\colon \operatorname{WDiv} Y \to \operatorname{WDiv} X$. It sends principal divisors to principal divisors: if $g \in K(Y)^*$ and $g = ut^m$ with u a unit at y, then $\nu_x(f^{\#}g) = me_x$ for every x over y, so $f^*(\operatorname{div}_Y g) = \operatorname{div}_X(f^{\#}g)$. Hence f^* descends to a homomorphism

$$f^*\colon \operatorname{Cl} Y \to \operatorname{Cl} X$$

Proposition 7.1.9: Finite Map and Degrees

Let $f\colon X \to Y$ be a finite morphism of complete nonsingular curves. For any divisor D on Y:

$$\deg f^*(D) \;=\; (\deg f)\cdot(\deg D)$$

***Proof*:**

By $\mathbb{Z}$-linearity, it suffices to prove $\deg f^*(y) = (\deg f)(\deg y)$ for a single closed point $y \in Y$, where the degree of a closed point is $[\kappa(y) : k]$. Let $V = \operatorname{Spec} S \subseteq Y$ be an affine open neighbourhood of y. Since Y is a nonsingular curve, S is a Dedekind domain. Let R be the integral closure of S in $K(X)$. Then $f^{-1}(V) = \operatorname{Spec} R$ and R is a finitely generated S-module, by Step 3 of the proof of proposition 7.1.6.

Localize at the maximal ideal $\mathfrak{m}_y \subseteq S$. Set $B = S_{\mathfrak{m}_y} = \mathcal{O}_{Y,y}$, which is a DVR with uniformizer t, and let $R' = R \otimes_S B$, the semi-local ring (R' has finitely many maximal ideals) obtained

by localizing R at $\mathfrak{m}_y$. The S-module R is finitely generated and torsion-free, and its rank is $n = [K(X) : K(Y)] = \deg f$, because $R \otimes_S K(Y)$ is a domain finite over the field $K(Y)$, hence a field lying between R and $\operatorname{Frac} R = K(X)$, hence equal to $K(X)$. The localization R' is therefore a free B-module of rank n (torsion-free and finitely generated over a PID).

The maximal ideals of R' correspond to the points $x_1, \dots, x_r \in X$ lying over y, with $(R')_{\mathfrak{m}_i} = \mathcal{O}_{X,x_i}$ for each i, and each of them contains t. The ring R'/tR' is a finite-dimensional algebra over the residue field $\kappa(y) = B/tB$, hence Artinian, and an Artinian ring is the product of its localizations at its maximal ideals. This gives an isomorphism of k-algebras

$$R'/tR' \cong \bigoplus_{i=1}^{r} R'_{\mathfrak{m}_i}/tR'_{\mathfrak{m}_i} = \bigoplus_{i=1}^{r} \mathcal{O}_{X,x_i}/t\,\mathcal{O}_{X,x_i}$$

where t stands for its image $f^{\#}(t)$. Since $R'/tR' \cong \kappa(y)^n$, taking dimensions over k of both sides gives

$$n[\kappa(y) : k] = \dim_k R'/tR' = \sum_{i=1}^{r} \dim_k(\mathcal{O}_{X,x_i}/t\,\mathcal{O}_{X,x_i}) = \sum_{i=1}^{r} \nu_{x_i}(f^{\#}(t))[\kappa(x_i) : k] = \sum_{i=1}^{r} e_{x_i} \deg(x_i)$$

The left-hand side is $(\deg f)(\deg y)$, and the right-hand side is $\deg f^*(y)$ by definition, as claimed.

Over $\mathbb{C}$, this is the statement that a degree-n branched cover of compact Riemann surfaces has n points over each point, counted with multiplicity.

Corollary 7.1.10: Degree Map and Integers

Let X be a complete nonsingular curve. Then principal divisors have degree 0, and the degree map induces a surjective homomorphism

$$\deg\colon \operatorname{Cl} X \twoheadrightarrow \mathbb{Z}$$

***Proof*:**
Let $g \in K(X)^*$ with $g \notin k^*$ (if $g \in k^*$, then $\operatorname{div} g = 0$ and the result is trivial). Since k is algebraically closed, g is transcendental over k, and it defines a finite morphism $\varphi\colon X \to \mathbb{P}^1_k$.[a] With t the coordinate on $\mathbb{P}^1_k$, the function t is a uniformizer at 0 and $1/t$ is a uniformizer at ∞, and $\varphi^{\#}(t) = g$. So the coefficient of a point x in $\varphi^*([0])$ is $\nu_x(g)$ when $\varphi(x) = 0$, its coefficient in $\varphi^*([\infty])$ is $-\nu_x(g)$ when $\varphi(x) = \infty$, and $\nu_x(g) = 0$ at the remaining points. Hence $\operatorname{div} g = \varphi^*([0]) - \varphi^*([\infty])$, where $[0]$ and $[\infty]$ are the divisors of the points 0 and ∞ on $\mathbb{P}^1_k$. By proposition 7.1.9:

$$\deg(\operatorname{div} g) = \deg \varphi^*([0]) - \deg \varphi^*([\infty]) = \deg \varphi - \deg \varphi = 0$$

Thus the degree map $\deg\colon \operatorname{WDiv} X \to \mathbb{Z}$ kills principal divisors and descends to $\operatorname{Cl} X$. It is surjective because a closed point $x \in X$ is a divisor of degree 1, k being algebraically closed, completing the proof.

[a] The function g is regular on a nonempty open $V \subseteq X$, so it defines a morphism $V \to \mathbb{A}^1_k \subseteq \mathbb{P}^1_k$ and hence a rational map $X \dashrightarrow \mathbb{P}^1_k$. Its locus of indeterminacy has codimension at least 2 by theorem 4.7.4, since X is normal and $\mathbb{P}^1_k$ is proper, and X has no points of codimension 2, so the rational map is a morphism φ. It is dominant because g is transcendental over k, and finite by proposition 7.1.6.

The kernel $\mathrm{Cl}^0 X = \ker(\deg\colon \mathrm{Cl}\, X \to \mathbb{Z})$ is the group of divisor classes of degree 0. For an elliptic curve E it is isomorphic to the group $E(k)$ of points (example 7.2.12, theorem 7.6.3). In general, $\mathrm{Cl}^0 X$ is the group of k-points of an abelian variety of dimension equal to the genus of X (definition 7.2.4), the *Jacobian* $\mathrm{Jac}(X)$, constructed in *Abelian Varieties* [8, The Jacobian Is an Abelian Variety].[2]

7.1.11 Arithmetic Motif: Covers of $\operatorname{Spec}\mathbb{Z}$ The inclusion $\mathbb{Z} \hookrightarrow \mathbb{Z}[i]$ of the integers into the Gaussian integers induces a finite morphism of schemes

$$\pi\colon \operatorname{Spec}\mathbb{Z}[i] \longrightarrow \operatorname{Spec}\mathbb{Z}$$

of degree $[\mathbb{Q}(i):\mathbb{Q}] = 2$. Its fibers over the closed points (p) of $\operatorname{Spec}\mathbb{Z}$ show the three behaviours of a prime in a quadratic extension familiar from algebraic number theory:

1. A prime $p \equiv 1 \pmod 4$ *splits*. For $p = 5$, $5 = (2+i)(2-i)$, and the fiber $\pi^{-1}((5))$ consists of the two points $(2+i)$ and $(2-i)$, each with ramification index 1 and residue field $\mathbb{F}_5$.
2. A prime $p \equiv 3 \pmod 4$ is *inert*. For $p = 3$, the ideal (3) remains prime in $\mathbb{Z}[i]$, and the fiber is a single point with ramification index 1 and residue field $\mathbb{F}_9$, of degree 2 over $\mathbb{F}_3$.
3. The prime 2 *ramifies*: $(1+i)^2 = 2i$, so $2 = -i(1+i)^2$, and the fiber is the single point $(1+i)$, with ramification index 2 and residue field $\mathbb{F}_2$.

In each case the sum over the points of the fiber of the ramification index times the residue field degree equals $\deg \pi = 2$, the arithmetic counterpart of proposition 7.1.9. Over an algebraically closed field the residue field degrees are all 1, and only splitting and ramification occur. The ramified primes are detected by the discriminant: a prime ramifies in $\mathbb{Z}[i]$ if and only if it divides the discriminant -4 of $\mathbb{Z}[i]$ [11, Discriminant And Ramified Primes]. See [83] for the arithmetic side of the analogy between number fields and function fields of curves.

7.2 The Riemann-Roch Theorem

For a divisor D on a complete nonsingular curve X of genus g, the Riemann-Roch theorem computes the Euler characteristic $\chi(\mathcal{L}(D)) = \dim_k H^0(X,\mathcal{L}(D)) - \dim_k H^1(X,\mathcal{L}(D))$ as $\deg D + 1 - g$. Serre duality identifies $H^1(X,\mathcal{L}(D))$ with the dual of $H^0(X,\omega_X \otimes \mathcal{L}(D)^\vee)$, so the theorem relates the sections of $\mathcal{L}(D)$ to the sections of $\omega_X \otimes \mathcal{L}(D)^\vee$. When $\deg D > 2g-2$ the second space vanishes and $\dim_k H^0(X,\mathcal{L}(D)) = \deg D + 1 - g$ (proposition 7.3.2). The theorem gives the degree of the canonical divisor, which enters Hurwitz's formula (section 7.4), and the very ample criterion and the embeddings of section 7.3.

7.2.1 Divisors on Curves: Degree, Linear Systems, and $\ell(D)$

Let X be a complete nonsingular curve over $k = \overline{k}$. Since X is a regular scheme of dimension 1, every local ring $\mathcal{O}_{X,x}$ at a closed point is a DVR, hence a UFD. In particular, X is locally factorial, and the

[2] The Jacobian is the identity component of the Picard scheme $\mathrm{Pic}_{X/k}$, treated in *Moduli, Deformation Theory, and Stacks* (theorem 23.6.14). When $k = \mathbb{C}$, it is a complex torus $\mathbb{C}^g/\Lambda$ for a lattice Λ of rank $2g$, the period lattice of the curve. For $g = 1$, a choice of base point identifies the Jacobian with the curve itself, and this identification gives the group law on an elliptic curve.

natural map from Cartier divisors to Weil divisors of section 5.4 is an isomorphism (proposition 5.4.33 and corollary 5.4.45):

$$\operatorname{CaCl} X \;\cong\; \operatorname{Cl} X \;\cong\; \operatorname{Pic} X$$

On a singular curve the local ring at a singular point is not a DVR, so the valuation at that point used to define Weil divisors in section 5.4 is not available, and a point need not be a Cartier divisor. At the cusp P of $y^2 = x^3$ the maximal ideal (x, y) of $\mathcal{O}_{X,P}$ is not principal: since $y^2 - x^3$ lies in $(x, y)^2 \subseteq k[x, y]$, the space $\mathfrak{m}_P/\mathfrak{m}_P^2$ has dimension 2, and a principal maximal ideal would give dimension at most 1 (Nakayama). Example 5.4.37 treats the node. On a singular curve, Cartier divisors (equivalently, line bundles, elements of $\operatorname{Pic} X$) remain the objects for which Riemann-Roch is stated (section 7.2.3) and from which morphisms to projective space are built.

Divisors are written additively as $D = \sum_{x \in X_{\mathrm{cl}}} n_x \cdot x$, where all but finitely many n_x are zero. The *degree* of D is $\deg D = \sum n_x$. Each divisor D has an associated invertible sheaf $\mathcal{L}(D)$, and for divisors D, D' (proposition 5.4.43)

$$\mathcal{L}(D + D') \cong \mathcal{L}(D) \otimes \mathcal{L}(D'), \qquad \mathcal{L}(-D) \cong \mathcal{L}(D)^\vee,$$
$$\mathcal{L}(D) \cong \mathcal{O}_X \iff D \sim 0 \quad \text{(linearly equivalent to zero)}$$

Recall that D is *effective*, written $D \geq 0$, if all $n_x \geq 0$. A global section $s \in H^0(X, \mathcal{L}(D))$ corresponds to a rational function $f \in K(X)^*$ with $\operatorname{div}(f) + D \geq 0$, together with the zero section.

Definition 7.2.1: Complete Linear System

The *complete linear system* of D is the set of effective divisors linearly equivalent to D:

$$|D| \;=\; \{D' \geq 0 : D' \sim D\} \;=\; \{\operatorname{div}(f) + D : f \in K(X)^*,\ \operatorname{div}(f) + D \geq 0\}$$

There is a natural bijection $|D| \cong \mathbb{P}\big(H^0(X, \mathcal{L}(D))\big)$: the effective divisors in the class of D are parametrized by the projectivization of the space of global sections of $\mathcal{L}(D)$, since two sections $s, s' \in H^0(X, \mathcal{L}(D)) \setminus \{0\}$ define the same effective divisor if and only if $s' = \lambda s$ for some $\lambda \in k^*$. (If s and s' correspond to f and f' with $\operatorname{div}(f) = \operatorname{div}(f')$, then f'/f has no zeros or poles, so it lies in $H^0(X, \mathcal{O}_X)^* = k^*$ by theorem 3.5.33.)

The classical notation is

$$\ell(D) \;:=\; \dim_k H^0(X, \mathcal{L}(D))$$

so $|D|$ is a projective space of dimension $\ell(D) - 1$ (and $|D| = \emptyset$ precisely when $\ell(D) = 0$). The number $\ell(D)$ is finite by theorem 5.3.28, X being projective (proposition 7.1.7). A *linear system* is any linear subspace of $|D|$, and a linear system of dimension 1 is called a *pencil*.

Lemma 7.2.2: Divisors and Degree

Let D be a divisor on a complete nonsingular curve X.

1. If $\ell(D) > 0$, then $\deg D \geq 0$.
2. If $\ell(D) > 0$ and $\deg D = 0$, then $D \sim 0$ (i.e. $\mathcal{L}(D) \cong \mathcal{O}_X$).

***Proof*:**
If $\ell(D) > 0$, then $|D| \neq \emptyset$, so $D \sim D'$ for some effective $D' \geq 0$. Linearly equivalent divisors have the same degree (corollary 7.1.10), so $\deg D = \deg D' = \sum n_x \geq 0$ (with $n_x \geq 0$ for all x), which is (1). For (2), if additionally $\deg D = 0$, then $D' = \sum n_x \cdot x$ with all $n_x \geq 0$ and $\sum n_x = 0$, forcing $n_x = 0$ for all x, i.e. $D' = 0$, so $D \sim 0$, as claimed.

7.2.2 The Canonical Divisor and Genus

Recall from section 5.5 that the sheaf of relative differentials $\Omega_{X/k}$ on a nonsingular variety X of dimension n over $k = \overline{k}$ is locally free of rank n (proposition 5.5.25). When X is a nonsingular curve, $n = 1$, so $\Omega_{X/k}$ is an invertible sheaf.

By the definition of the canonical sheaf (definition 5.5.28), $\omega_X = \bigwedge^{\dim X} \Omega_{X/k}$, which for a curve is $\omega_X = \Omega_{X/k}$. For a nonsingular projective variety the dualizing sheaf of Serre duality (definition 6.5.1) is $\det \Omega_{X/k}$ (theorem 6.5.9(1)), so on a nonsingular curve the canonical sheaf and the dualizing sheaf are the same invertible sheaf $\Omega_{X/k}$, and Serre duality applies to it directly.

Definition 7.2.3: Canonical Divisor

Let X be a complete nonsingular curve. A *canonical divisor* K (or K_X) is any divisor in the linear equivalence class corresponding to $\omega_X = \Omega_{X/k}$, i.e. $\mathcal{L}(K) \cong \omega_X$.

The canonical divisor is defined only up to linear equivalence, but its degree and the dimension $\ell(K)$ are well-defined invariants of X.

Definition 7.2.4: Genus of a Curve

Let X be a complete nonsingular curve over k, which is projective by proposition 7.1.7. The following three numbers are defined:

1. The *arithmetic genus*: $p_a(X) = 1 - P_X(0)$, where P_X is the Hilbert polynomial of X with respect to any very ample sheaf (definition 6.7.6). The constant term $P_X(0) = \chi(\mathcal{O}_X)$ does not depend on that choice.
2. The *geometric genus*: $p_g(X) = \dim_k H^0(X, \omega_X)$ (definition 5.5.29).
3. The *cohomological genus*: $\dim_k H^1(X, \mathcal{O}_X)$.

By proposition 7.2.5 these three numbers coincide, and their common value is called the *genus* of X, denoted g (or $g(X)$).

Proposition 7.2.5: Equivalence of Genus

Let X be a complete nonsingular curve over $k = \overline{k}$. Then:

$$p_a(X) \;=\; p_g(X) \;=\; \dim_k H^1(X, \mathcal{O}_X)$$

***Proof*:**
Step 1: $p_a = \dim_k H^1(X, \mathcal{O}_X)$. The curve X is projective (proposition 7.1.7). By definition, $p_a(X) = 1 - P_X(0)$ where $P_X(n) = \chi(\mathcal{O}_X(n))$ is the Hilbert polynomial (theorem 6.7.5 and definition 6.7.6). Since $\dim X = 1$, the groups $H^i(X, \mathcal{O}_X)$ vanish for $i \geq 2$ (theorem 6.2.5), so setting $n = 0$ gives

$$P_X(0) = \chi(\mathcal{O}_X) = \dim_k H^0(X, \mathcal{O}_X) - \dim_k H^1(X, \mathcal{O}_X)$$

Since X is a projective integral scheme over $k = \overline{k}$, the global sections are $H^0(X, \mathcal{O}_X) = k$ (theorem 3.5.33), so $P_X(0) = 1 - \dim_k H^1(X, \mathcal{O}_X)$, and $p_a = 1 - P_X(0) = \dim_k H^1(X, \mathcal{O}_X)$.

Step 2: $\dim_k H^1(X, \mathcal{O}_X) = p_g$. Serre duality for a nonsingular projective variety X of dimension n over k gives, for every locally free coherent sheaf $\mathscr{F}$, (corollary 6.5.10):

$$H^i(X, \mathscr{F}) \;\cong\; H^{n-i}(X, \mathscr{F}^\vee \otimes \omega_X)^\vee$$

Taking $n = 1$, $i = 1$, $\mathscr{F} = \mathcal{O}_X$:

$$H^1(X, \mathcal{O}_X) \;\cong\; H^0(X, \omega_X)^\vee$$

Therefore $\dim_k H^1(X, \mathcal{O}_X) = \dim_k H^0(X, \omega_X) = p_g(X)$, as we sought to show.

Write $g = g(X)$ for the genus. Being the dimension $\dim_k H^1(X, \mathcal{O}_X)$, it is a nonnegative integer.

The genus of a smooth plane curve depends only on its degree. In *Classical Algebraic Geometry* the formula below first defines the genus of a plane curve and is then shown to agree with the genus of Riemann's theorem [30, Genus of a Nonsingular Plane Curve]. Here it is a theorem about $\dim_k H^1(C, \mathcal{O}_C)$.

Proposition 7.2.6: Degree Formula for Plane Curves

Let $C = V(F) \subseteq \mathbb{P}^2_k$ be a smooth projective curve cut out by a homogeneous polynomial F of degree d. Then the genus of C is

$$g(C) \;=\; \frac{(d-1)(d-2)}{2}$$

***Proof*:**
Since C is the closed subscheme of $\mathbb{P}^2$ defined by the single homogeneous polynomial F of degree d, its ideal sheaf is $\mathcal{I}_C \cong \mathcal{O}_{\mathbb{P}^2}(-d)$. This gives the short exact sequence of sheaves on $\mathbb{P}^2$

$$0 \longrightarrow \mathcal{O}_{\mathbb{P}^2}(-d) \longrightarrow \mathcal{O}_{\mathbb{P}^2} \longrightarrow \mathcal{O}_C \longrightarrow 0$$

where $\mathcal{O}_C$ stands for its pushforward to $\mathbb{P}^2$, which has the same cohomology (proposition 6.2.4). The Euler characteristic $\chi(\mathscr{F}) = \sum_i (-1)^i \dim_k H^i(\mathbb{P}^2, \mathscr{F})$ is additive on short exact sequences (proposition 6.7.2), so

$$\chi(\mathcal{O}_C) \;=\; \chi(\mathcal{O}_{\mathbb{P}^2}) - \chi(\mathcal{O}_{\mathbb{P}^2}(-d))$$

From the cohomology of projective space (theorem 6.3.1), the Hilbert polynomial of $\mathbb{P}^2$ is

$\chi(\mathcal{O}_{\mathbb{P}^2}(n)) = \frac{(n+1)(n+2)}{2}$ for all $n \in \mathbb{Z}$. Evaluating this at $n = 0$ and $n = -d$ yields

$$\chi(\mathcal{O}_{\mathbb{P}^2}) = 1,$$
$$\chi(\mathcal{O}_{\mathbb{P}^2}(-d)) = \frac{(-d+1)(-d+2)}{2} = \frac{(d-1)(d-2)}{2}$$

Therefore, $\chi(\mathcal{O}_C) = 1 - \frac{(d-1)(d-2)}{2}$.

On the other hand, since C is a complete nonsingular curve, proposition 7.2.5 establishes that the genus g equals the arithmetic genus $p_a(C) = 1 - \chi(\mathcal{O}_C)$. Thus

$$1 - g = 1 - \frac{(d-1)(d-2)}{2} \quad \Longrightarrow \quad g = \frac{(d-1)(d-2)}{2}$$

as claimed.

The computation of $\chi(\mathcal{O}_C)$ uses only that C is cut out by a form of degree d, so every plane curve of degree d, singular or not, has arithmetic genus $(d-1)(d-2)/2$. The hypothesis $C \subseteq \mathbb{P}^2_k$ is needed for the genus: the twisted cubic in $\mathbb{P}^3_k$ has degree 3 and is isomorphic to $\mathbb{P}^1_k$, so it has genus 0, while a smooth plane cubic has genus 1. For a curve of degree d in $\mathbb{P}^r_k$ not contained in a hyperplane, Castelnuovo's bound (theorem 7.7.1) is an upper bound for the genus, and for $r = 2$ it is the formula of proposition 7.2.6.

Example 7.2.7: Genus Computations

1. *The projective line.* $g(\mathbb{P}^1_k) = 0$. Indeed, $H^1(\mathbb{P}^1_k, \mathcal{O}_{\mathbb{P}^1}) = 0$ by the computation of cohomology of projective space (theorem 6.3.1).

2. *Smooth plane curves.* Let $C \subseteq \mathbb{P}^2_k$ be a smooth curve of degree d. By the degree formula (proposition 7.2.6):
$$g(C) = \frac{(d-1)(d-2)}{2}$$
This gives $g = 0$ for $d = 1, 2$ (lines and conics, both isomorphic to $\mathbb{P}^1_k$), $g = 1$ for $d = 3$ (smooth plane cubics), $g = 3$ for $d = 4$, and so on. The genus of a smooth plane curve of degree d grows quadratically in d.

   The degree of the canonical divisor of a plane curve can also be computed from the adjunction formula (proposition 6.5.7), which gives $\omega_C \cong (\omega_{\mathbb{P}^2} \otimes \mathcal{O}_{\mathbb{P}^2}(C))|_C \cong \mathcal{O}_C(d-3)$. Twisting the exact sequence in the proof of proposition 7.2.6 by $\mathcal{O}_{\mathbb{P}^2}(n)$ gives $\chi(\mathcal{O}_C(n)) = \frac{(n+1)(n+2)}{2} - \frac{(n-d+1)(n-d+2)}{2} = dn + 1 - g$, and comparing with the Riemann-Roch theorem proved below (theorem 7.2.10) shows that $\mathcal{O}_C(n)$ has degree dn. So ω_C has degree $d(d-3)$, which agrees with $2g - 2 = 2\left(\frac{d^2-3d+2}{2}\right) - 2 = d(d-3)$, the case of plane curves of the general formula $\deg K_X = 2g - 2$ of item (3).

3. *The degree of the canonical divisor.* Every complete nonsingular curve of genus g satisfies (proposition 7.3.1, deduced from theorem 7.2.10 below)
$$\deg K_X = 2g - 2$$

For $\mathbb{P}^1$ this gives $\deg K = -2$, consistent with $\omega_{\mathbb{P}^1} \cong \mathcal{O}_{\mathbb{P}^1}(-2)$ (from the Euler sequence, theorem 5.5.19). For a smooth plane cubic, $\deg K = 0$, consistent with $\omega_C \cong \mathcal{O}_C(3-3) = \mathcal{O}_C$ from item (2).

7.2.8 Forward Reference: The Moduli Space $\mathcal{M}_g$ The genus is a discrete invariant, and for $g \geq 1$ it does not determine a curve up to isomorphism: the smooth projective curves of a fixed genus $g \geq 1$ form a continuous family. The coarse moduli space $\mathcal{M}_g$ parametrizing them has dimension

$$\dim \mathcal{M}_g = \begin{cases} 0 & \text{if } g = 0 \quad (\text{only } \mathbb{P}^1), \\ 1 & \text{if } g = 1 \quad (\text{the } j\text{-line}), \\ 3g-3 & \text{if } g \geq 2 \end{cases}$$

and the deformation-theoretic computation behind these numbers is sketched in box 7.7.4. Some curves of every genus have nontrivial automorphisms ($\mathbb{P}^1$, the involution $[-1]$ of an elliptic curve, the hyperelliptic involution), so no scheme represents the moduli functor of smooth curves of genus g. For $g \geq 2$ the moduli problem is a Deligne-Mumford stack, and its construction is carried out in *Moduli, Deformation Theory, and Stacks* [27].

7.2.9 Warning: The Genera Diverge for Singular Curves The equality $p_a = p_g = \dim_k H^1(X, \mathcal{O}_X)$ of proposition 7.2.5 uses nonsingularity. For an integral projective curve X with singular points, the arithmetic genus and the genus of the normalization differ.

The *geometric genus* of X is the genus $g(\widetilde{X})$ of its normalization $\nu\colon \widetilde{X} \to X$, and it depends only on the function field $K(X)$. The *arithmetic genus* $p_a(X) = 1 - \chi(\mathcal{O}_X)$ depends on the singularities, and it is constant in a flat projective family over a connected base, because the Euler characteristic of the fibers is locally constant (theorem 6.8.17(2)). They are related by the *δ-invariant*: for each singular point $P \in X$, set

$$\delta_P \;=\; \dim_k\Big(\widetilde{\mathcal{O}}_{X,P} \,/\, \mathcal{O}_{X,P}\Big)$$

where $\widetilde{\mathcal{O}}_{X,P}$ denotes the integral closure of $\mathcal{O}_{X,P}$ in $K(X)$ (equivalently, the stalk $(\nu_*\mathcal{O}_{\widetilde{X}})_P$ of the pushforward of the structure sheaf along the normalization map ν). Then [50, Exercise IV.1.8]

$$p_a(X) \;=\; g(\widetilde{X}) \;+\; \sum_{P \in X_{\mathrm{sing}}} \delta_P$$

A node (two branches crossing transversally) has $\delta = 1$, and an ordinary cusp has $\delta = 1$ as well.[a]

For example, the nodal cubic $y^2z = x^3 + x^2z$ (with $\mathrm{char}k \neq 2$) and the cuspidal cubic $y^2z = x^3$ are plane cubics, so $p_a = \frac{(3-1)(3-2)}{2} = 1$ by the computation following proposition 7.2.6. Both have normalization $\mathbb{P}^1$, giving $g(\widetilde{X}) = 0$. The difference $p_a - g(\widetilde{X}) = 1$ is the δ-invariant of the single singular point.

The difference appears in families: when a smooth plane cubic ($g = 1$) degenerates in a flat family to a nodal cubic, the arithmetic genus stays equal to 1 by theorem 6.8.17(2), while the geometric genus drops to 0. For this reason the compactification $\overline{\mathcal{M}}_g$ of the moduli space of curves, for $g \geq 2$, parametrizes *stable* curves, the nodal curves of arithmetic genus g with finitely many automorphisms (*Moduli, Deformation Theory, and Stacks* [27, Stable Curve]).

[a] Larger values occur: the curve $y^2 = x^{2m+1}$ has $\delta = m$ at the origin, since its coordinate ring is $k[t^2, t^{2m+1}]$, which misses exactly $t, t^3, \ldots, t^{2m-1}$ from its normalization $k[t]$. Over $\mathbb{C}$, the space X near P is obtained from $\widetilde{X}$ by identifying the r_P points over P, one for each branch through P, and $\delta_P \geq r_P - 1$, with strict inequality at a cusp, where $r_P = 1$ and $\delta_P = 1$.

7.2.3 Statement and Proof of Riemann-Roch

Recall that Serre duality (corollary 6.5.10) gives, for any invertible sheaf $\mathcal{L}$ on a complete nonsingular curve X of genus g, which is projective by proposition 7.1.7,

$$H^1(X, \mathcal{L}) \;\cong\; H^0(X, \omega_X \otimes \mathcal{L}^\vee)^\vee$$

In divisor language, if $\mathcal{L} = \mathcal{L}(D)$, then $\omega_X \otimes \mathcal{L}(D)^\vee \cong \mathcal{L}(K - D)$, and hence

$$\dim_k H^1(X, \mathcal{L}(D)) \;=\; \ell(K - D)$$

So the Euler characteristic $\chi(\mathcal{L}(D)) = \ell(D) - \ell(K - D)$ is a difference of dimensions of spaces of global sections.

Theorem 7.2.10: Riemann-Roch Theorem over an Algebraically Closed Field

Let X be a complete nonsingular curve of genus g over $k = \overline{k}$, and let K be a canonical divisor. For any divisor D on X:

$$\ell(D) - \ell(K - D) \;=\; \deg D + 1 - g$$

Equivalently, in sheaf-cohomological language:

$$\chi(\mathcal{L}(D)) \;=\; \deg D + 1 - g$$

The right-hand side depends only on the degree of D and the genus of X, and over $\mathbb{C}$ the genus is a topological invariant, the number of handles of the Riemann surface (box 7.1.5). The two terms on the left are not determined by $\deg D$ and g: $\ell(D)$ and $\ell(K - D)$ are dimensions of spaces of rational functions with poles bounded by D and by $K - D$, and they depend on D and on the curve. Only their difference is fixed by the theorem.

The term $\ell(K - D)$ is called the *index of speciality* of D and is denoted $i(D) := \ell(K - D)$. A divisor with $i(D) = 0$ is called *non-special*, and for such divisors Riemann-Roch reads $\ell(D) = \deg D + 1 - g$. Every divisor of degree greater than $2g - 2$ is non-special (proposition 7.3.2).

***Proof*:**

We prove the cohomological form $\chi(\mathcal{L}(D)) = \deg D + 1 - g$, from which the classical form follows by Serre duality as explained above.

Base case: $D = 0$. The groups $H^i(X, \mathcal{O}_X)$ vanish for $i \geq 2$ (theorem 6.2.5), so $\chi(\mathcal{O}_X) = \dim_k H^0(X, \mathcal{O}_X) - \dim_k H^1(X, \mathcal{O}_X) = 1 - g$, since $H^0(X, \mathcal{O}_X) = k$ (theorem 3.5.33) and $g = \dim_k H^1(X, \mathcal{O}_X)$ (proposition 7.2.5). This equals $\deg 0 + 1 - g = 1 - g$.

Induction step. We show: the formula holds for D if and only if it holds for $D + P$, where P is any closed point of X.

Consider P as a closed subscheme of X, defined by the ideal sheaf $\mathcal{L}(-P)$ (a single effective Cartier divisor). The structure sheaf $\mathcal{O}_P$ is a skyscraper sheaf supported at P with stalk $\kappa(P) = k$, which we denote k_P. This gives the short exact sequence

$$0 \to \mathcal{L}(-P) \to \mathcal{O}_X \to k_P \to 0$$

Tensoring with the invertible sheaf $\mathcal{L}(D + P)$, which is locally free of rank 1, hence flat, preserves exactness:

$$0 \to \mathcal{L}(-P) \otimes \mathcal{L}(D + P) \to \mathcal{L}(D + P) \to k_P \otimes \mathcal{L}(D + P) \to 0$$

Now $\mathcal{L}(-P) \otimes \mathcal{L}(D + P) \cong \mathcal{L}(D)$, and $k_P \otimes \mathcal{L}(D + P) \cong k_P$, because the invertible sheaf $\mathcal{L}(D + P)$ is isomorphic to $\mathcal{O}_X$ on a neighbourhood of P. So we have

$$0 \to \mathcal{L}(D) \to \mathcal{L}(D + P) \to k_P \to 0 \tag{7.2}$$

Taking Euler characteristics and using additivity (proposition 6.7.2):

$$\chi(\mathcal{L}(D + P)) = \chi(\mathcal{L}(D)) + \chi(k_P)$$

The sheaf k_P is the pushforward of the sheaf k on the one-point space P, so $H^0(X, k_P) = k$ and $H^i(X, k_P) = H^i(P, k) = 0$ for $i > 0$ (proposition 6.2.4 and theorem 6.2.5), and $\chi(k_P) = 1$.

Therefore

$$\chi(\mathcal{L}(D+P)) \;=\; \chi(\mathcal{L}(D)) + 1$$

On the other hand, $\deg(D+P) = \deg D + 1$. So the right-hand side of the Riemann-Roch formula also increases by 1 when D is replaced by $D+P$. This proves the claim: Riemann-Roch holds for D if and only if it holds for $D+P$.

Every divisor D can be reached from the zero divisor by finitely many steps of adding or subtracting a point[a]. By the induction step, the formula holds for D if and only if it holds for 0. Since we verified it for $D=0$, it holds for all D, as we sought to show.

[a] Write $D = \sum n_i P_i = \sum_{n_i>0} n_i P_i - \sum_{n_j<0} |n_j| P_j$. Starting from 0, add the positive points and subtract the negative points one at a time.

The proof of the cohomological form uses only the additivity of the Euler characteristic (proposition 6.7.2) and the value $\chi(\mathcal{O}_X) = 1-g$. It shows that $D \mapsto \chi(\mathcal{L}(D)) - \chi(\mathcal{O}_X)$ is additive in D and takes the value 1 on every point, hence equals $\deg D$. Serre duality enters in two places: in identifying the genus $\dim_k H^1(X,\mathcal{O}_X)$ with $p_g = \dim_k H^0(X,\omega_X)$ (proposition 7.2.5), and in rewriting $\chi(\mathcal{L}(D))$ as $\ell(D) - \ell(K-D)$.

7.2.11 Riemann-Roch as an Index Theorem Over $\mathbb{C}$, Riemann-Roch is an index theorem: it equates the index of a differential operator, the dimension of its kernel minus the dimension of its cokernel, with a topological quantity. By the Dolbeault isomorphism and GAGA, $\chi(\mathcal{L}) = h^0 - h^1$ is the index of the $\bar\partial$-operator (the Cauchy-Riemann operator) on the line bundle $\mathcal{L}$, and Riemann-Roch computes it from the degree of $\mathcal{L}$ and the genus of the curve. Two generalizations are proved in *Intersection Theory* [26, Hirzebruch-Riemann-Roch, Grothendieck-Riemann-Roch]:

1. The *Hirzebruch-Riemann-Roch theorem* computes $\chi(\mathscr{E})$ for any vector bundle $\mathscr{E}$ on a smooth projective variety X in terms of the Chern character $\mathrm{ch}(\mathscr{E})$ and the Todd class $\mathrm{td}(T_X)$: $\chi(\mathscr{E}) = \int_X \mathrm{ch}(\mathscr{E}) \cdot \mathrm{td}(T_X)$.
2. The *Grothendieck-Riemann-Roch theorem* is the relative version: for a proper morphism $f\colon X \to Y$ of smooth quasi-projective varieties, it computes the Chern character of the alternating sum $\sum_i (-1)^i [R^i f_* \mathscr{E}]$ of the higher direct images in terms of $\mathrm{ch}(\mathscr{E})$, $\mathrm{td}(T_X)$ and $\mathrm{td}(T_Y)$.

For a curve, $\mathrm{ch}(\mathcal{L}(D)) = 1 + c_1(\mathcal{L}(D))$ and $\mathrm{td}(T_X) = 1 + \frac{1}{2}c_1(T_X)$, whose degree-one parts have degrees $\deg D$ and $\frac{1}{2}(2-2g) = 1-g$ (proposition 7.3.1), so Hirzebruch-Riemann-Roch reduces to $\chi(\mathcal{L}(D)) = \deg D + 1 - g$.

Example 7.2.12: Points of a Plane Cubic as Divisor Classes

Let $E \subseteq \mathbb{P}^2_k$ be the nonsingular cubic $y^2z = x^3 - xz^2$ with $\mathrm{char}(k) \neq 2$. This curve is not rational: it has genus 1 by proposition 7.2.6, while $\mathbb{P}^1_k$ has genus 0, and two birational complete nonsingular curves are isomorphic (corollary 3.6.6, theorem 7.1.4(3)).[a] Let $P_0 = [0:1:0]$, the unique point at infinity, which is an inflection point: the tangent line $\{z=0\}$ meets E with multiplicity 3, giving the divisor relation $3P_0 \sim$ (hyperplane section). Since $\omega_E \cong \mathcal{O}_E$ (example 7.2.7), a canonical divisor is $K=0$, so every divisor of degree 1 is non-special: for $\deg D = 1$, $\deg(K-D) = -1$ and $\ell(K-D) = 0$ by lemma 7.2.2, and Riemann-Roch gives $\ell(D) = 1 + 1 - 1 = 1$.

Define a map φ from the set of k-rational points $E(k)$ to $\mathrm{Cl}^0 E = \ker(\deg\colon \mathrm{Cl}\, E \to \mathbb{Z})$ by $\varphi(P) = [P - P_0]$. This map is *injective*: if $[P - P_0] = [Q - P_0]$, then $Q \sim P$, so $Q \in |P|$. Since $\ell(P) = 1$, the complete linear system $|P|$ has dimension $\ell(P) - 1 = 0$, meaning it consists of exactly one effective divisor, namely P itself. Thus $P = Q$.

To see *surjectivity*, take any $D \in \mathrm{Cl}^0 E$, so $\deg D = 0$. Then $\deg(D + P_0) = 1$, so $\ell(D + P_0) = 1$, and there exists a unique effective divisor of degree 1, which must be a single k-rational point P, such that $D + P_0 \sim P$, meaning $D \sim P - P_0$.

The chord-tangent construction realizes the group law on points. If a line through P and Q meets E in a third point R, then $P + Q + R \sim 3P_0$, so $[P - P_0] + [Q - P_0] = [T - P_0]$ where T is the third intersection of the line P_0R with E. Applied repeatedly, this reduces any sum $\sum n_i(P_i - P_0)$ to a single class $[P - P_0]$ with $P \in E(k)$, together with $-[P - P_0] = [P' - P_0]$, where P' is the third intersection of the line P_0P with E.

Thus φ is a bijection, and the group structure on $\mathrm{Cl}^0 E$ transfers to a group structure on $E(k)$, with identity P_0. The addition and inversion maps $+\colon E \times E \to E$ and $[-1]\colon E \to E$ are morphisms of schemes (theorem 7.6.3), making E a *group scheme* over k (example 4.1.12). Section 7.6 develops this group law.

For any complete nonsingular curve X, the group $\mathrm{Cl}^0 X$ is the group of k-points of the Jacobian variety $\mathrm{Jac}(X)$, and $\mathrm{Cl}\, X$ sits in a short exact sequence

$$0 \to \mathrm{Jac}(X)(k) \to \mathrm{Cl}\, X \xrightarrow{\deg} \mathbb{Z} \to 0$$

For surfaces and higher-dimensional varieties, the quotient of the divisor class group by the classes algebraically equivalent to zero is the *Néron-Severi group* $\mathrm{NS}(X)$, a finitely generated abelian group that can have rank greater than 1. It is defined in definition 8.1.4 and used throughout chapter 8.

[a] The classical proof is [30, Nonsingular Plane Cubics Are Not Rational].

Riemann-Roch extends to singular curves once $\Omega_{X/k}$ is replaced by the dualizing sheaf. On a nonsingular curve, $\Omega_{X/k}$ is an invertible sheaf (proposition 5.5.25) and is the dualizing sheaf for Serre duality (theorem 6.5.9(1)). On an integral curve X over $k = \overline{k}$, the sheaf $\Omega_{X/k}$ is not locally free of rank 1 at a singular point (proposition 5.5.25), and it can have torsion there.[3] The dualizing sheaf of definition 6.5.1 takes over the role of $\Omega_{X/k}$.

Let X be an integral projective curve over $k = \overline{k}$. Its local rings are one-dimensional domains, hence Cohen-Macaulay, so theorem 6.5.9(1) provides a dualizing sheaf ω_X°, and

$$H^1(X, \mathscr{F}) \;\cong\; \mathrm{Hom}_{\mathcal{O}_X}(\mathscr{F}, \omega_X^\circ)^\vee$$

for every coherent sheaf $\mathscr{F}$ on X (definition 6.5.1). This sheaf has an explicit description due to

[3] On the cuspidal cubic $X = \operatorname{Spec} A$, $A = k[x,y]/(y^2 - x^3)$, the module of differentials is $\Omega_{A/k} = (A\,dx \oplus A\,dy)/A\,(3x^2\,dx - 2y\,dy)$. Consider the differential $\tau = 2x\,dy - 3y\,dx$. It is nonzero: writing $x = t^2$, $y = t^3$ identifies A with $k[t^2, t^3]$, and $\tau = a\,(3x^2\,dx - 2y\,dy)$ in $A\,dx \oplus A\,dy$ would force $a = -t^{-1} \notin A$. But $y \cdot \tau = 2xy\,dy - 3y^2\,dx = x(3x^2\,dx) - 3x^3\,dx = 0$ in $\Omega_{A/k}$, and $x^2 \cdot \tau = -y\,(3x^2\,dx - 2y\,dy) = 0$ as well. Thus τ generates a torsion submodule supported at the cusp $(0,0)$, so $\Omega_{A/k}$ is not locally free there.

Rosenlicht. If $\nu\colon \widetilde{X} \to X$ is the normalization, a rational differential $\eta \in \Omega_{K(X)/k}$ is a section of ω_X° over an open $U \subseteq X$ exactly when $\sum_{Q\in\nu^{-1}(P)} \operatorname{Res}_Q(f\eta) = 0$ for every closed point $P \in U$ and every $f \in \mathcal{O}_{X,P}$ [89, Chapter IV]. At a nonsingular point P the condition says that η is regular at P, so $\omega_X^\circ = \Omega_{X/k}$ on a nonsingular curve. On a singular curve, ω_X° is a torsion-free sheaf of rank 1, a subsheaf of the constant sheaf $\Omega_{K(X)/k}$, and it need not be invertible.

Riemann-Roch for an integral projective curve X, possibly singular, reads

$$\chi(\mathcal{L}) \;=\; \deg \mathcal{L} + 1 - p_a(X)$$

for every invertible sheaf $\mathcal{L}$ on X, where $p_a(X) = 1 - \chi(\mathcal{O}_X)$ is the arithmetic genus. Here $\deg \mathcal{L}$ is the degree of a divisor D supported on the nonsingular points of X with $\mathcal{L} \cong \mathcal{L}(D)$. Every invertible sheaf has this form, and the proof of theorem 7.2.10 applies verbatim to such D, since each nonsingular point is an effective Cartier divisor [50, Exercise IV.1.9]. Serre duality then gives $\dim_k H^0(X,\mathcal{L}) - \dim_k \operatorname{Hom}_{\mathcal{O}_X}(\mathcal{L},\omega_X^\circ) = \deg \mathcal{L} + 1 - p_a(X)$ [66, Theorem 7.3.26]. The genus in the formula is the arithmetic genus p_a, not the geometric genus $g(\widetilde{X})$. The duality term is computed with ω_X°, and it equals $\ell(K-D)$ for a divisor K only when $\omega_X^\circ \cong \mathcal{L}(K)$ is invertible.

7.3 Applications of Riemann-Roch

The criteria of this section compare $\deg D$ with the degree $2g-2$ of the canonical divisor (proposition 7.3.1). When $\deg D > 2g-2$, Riemann-Roch computes $\ell(D)$, and it shows that $|D|$ is base-point-free once $\deg D \geq 2g$ and very ample once $\deg D \geq 2g+1$. When $\deg D \leq 2g-2$, it bounds $\ell(D)$ only from below, and Clifford's theorem (theorem 7.3.10) bounds $\ell(D)$ from above for effective special divisors.

Proposition 7.3.1: Degree of the Canonical Divisor

Let X be a complete nonsingular curve of genus g. Then

$$\deg K_X \;=\; 2g-2, \qquad \ell(K_X) = g$$

***Proof*:**
Apply Riemann-Roch (theorem 7.2.10) with $D = K$:

$$\ell(K) - \ell(K-K) = \deg K + 1 - g$$

Now $\ell(K-K) = \ell(0) = \dim_k H^0(X,\mathcal{O}_X) = 1$ (theorem 3.5.33), and $\ell(K) = p_g = g$ by proposition 7.2.5. So $g - 1 = \deg K + 1 - g$, giving $\deg K = 2g-2$, as claimed.

Over $\mathbb{C}$, the compact Riemann surface $X(\mathbb{C})$ has topological Euler characteristic $\chi_{\text{top}} = 2-2g$, so $\deg K_X = -\chi_{\text{top}}$. Equivalently, the holomorphic tangent bundle $\omega_X^\vee$ has degree χ_{top}, which is the Gauss-Bonnet theorem for $X(\mathbb{C})$ stated through the first Chern class of its tangent bundle.

Proposition 7.3.2: Non-Speciality for Large Degree

Let D be a divisor on a curve X of genus g. If $\deg D > 2g-2$, then $\ell(K-D)=0$, and Riemann-Roch gives

$$\ell(D) \;=\; \deg D + 1 - g$$

For every divisor D, $\ell(D) \geq \deg D + 1 - g$, so $\ell(D) > 0$ whenever $\deg D \geq g$.

***Proof*:**
If $\ell(K-D) > 0$, then $\deg(K-D) \geq 0$ by lemma 7.2.2, that is, $\deg D \leq \deg K = 2g-2$ (proposition 7.3.1). Hence $\deg D > 2g-2$ forces $\ell(K-D)=0$, and theorem 7.2.10 reads $\ell(D) = \deg D + 1 - g$. For an arbitrary divisor D, theorem 7.2.10 and $\ell(K-D) \geq 0$ give $\ell(D) = \deg D + 1 - g + \ell(K-D) \geq \deg D + 1 - g$, which is at least 1 when $\deg D \geq g$, completing the proof.

Riemann-Roch decides when a complete linear system embeds a curve in projective space. Recall (definitions 5.3.22 and 5.3.24) that an invertible sheaf $\mathcal{L}$ on X is:

1. *generated by global sections* (or *base-point-free*) if the natural map $H^0(X,\mathcal{L}) \otimes_k \mathcal{O}_X \to \mathcal{L}$ is surjective,
2. *very ample* if $\mathcal{L} \cong \iota^*\mathcal{O}(1)$ for some closed immersion $\iota\colon X \hookrightarrow \mathbb{P}^N_k$.

A base-point-free $\mathcal{L}$ defines a morphism $\varphi_{\mathcal{L}}\colon X \to \mathbb{P}^N_k$ with $N+1 = \dim_k H^0(X,\mathcal{L})$ (theorem 5.3.43), and for $\mathcal{L} = \mathcal{L}(D)$ this is the morphism $\varphi_{|D|}$ of the complete linear system $|D|$. On a complete nonsingular curve both conditions are numerical [50, Proposition IV.3.1]. The sheaf $\mathcal{L}(D)$ is base-point-free if and only if $\ell(D-P) = \ell(D) - 1$ for every closed point P, since $H^0(X,\mathcal{L}(D-P))$ is the subspace of sections of $\mathcal{L}(D)$ vanishing at P. It is very ample if and only if $\ell(D-P-Q) = \ell(D) - 2$ for every pair of closed points $P, Q \in X$, equal or not. For $P \neq Q$ this condition says that the sections of $\mathcal{L}(D)$ separate P and Q, and for $P = Q$ that they separate tangent directions at P, which are the two conditions under which $\varphi_{|D|}$ is a closed immersion [50, Proposition II.7.3].

Proposition 7.3.3: Base-Point-Free Criterion for Curves

Let D be a divisor on a complete nonsingular curve X of genus g. If $\deg D \geq 2g$, then $\mathcal{L}(D)$ is base-point-free.

***Proof*:**
Let $P \in X$ be any closed point. We need $\ell(D) > \ell(D-P)$, i.e. a section of $\mathcal{L}(D)$ not vanishing at P. By Riemann-Roch,

$$\ell(D) = \deg D + 1 - g + \ell(K-D),$$
$$\ell(D-P) = \deg D - 1 + 1 - g + \ell(K-D+P)$$

so $\ell(D) - \ell(D-P) = 1 + \ell(K-D) - \ell(K-D+P)$. Since $\deg D \geq 2g$, we have $\deg(K-D) = 2g-2-\deg D \leq -2$ and $\deg(K-D+P) = 2g-1-\deg D \leq -1$, so $\ell(K-D) = \ell(K-D+P) = 0$ by lemma 7.2.2. Therefore $\ell(D) - \ell(D-P) = 1$ for every closed point P, and $\mathcal{L}(D)$ is base-point-free, as claimed.

Corollary 7.3.4: Very Ample Criterion for Curves

If $\deg D \geq 2g+1$, then $\mathcal{L}(D)$ is very ample, and $\varphi_{|D|}$ embeds X as a closed subvariety of $\mathbb{P}_k^{\ell(D)-1}$.

***Proof*:**
Let $P, Q \in X$ be closed points, possibly equal. Riemann-Roch applied to D and to $D-P-Q$ gives $\ell(D)-\ell(D-P-Q) = 2+\ell(K-D)-\ell(K-D+P+Q)$. Since $\deg D \geq 2g+1$, we have $\deg(K-D+P+Q) \leq (2g-2)-(2g+1)+2 = -1$ and $\deg(K-D) \leq -3$, so both terms vanish by lemma 7.2.2. Hence $\ell(D-P-Q) = \ell(D)-2$ for all P and Q, and $\mathcal{L}(D)$ is very ample by the criterion above, as claimed.

Both bounds are sharp once $g \geq 1$. For a closed point P, Riemann-Roch gives $\ell(K+P) = g = \ell(K)$, as $\ell(-P) = 0$, so the divisor $K+P$ of degree $2g-1$ has the base point P. For closed points P and Q, the divisor $K+P+Q$ has degree $2g$ and $\ell(K+P+Q) = g+1$, so it is base-point-free by proposition 7.3.3, but $\ell((K+P+Q)-P-Q) = \ell(K) = \ell(K+P+Q)-1$, so it is not very ample. On a hyperelliptic curve of genus g the divisor $g(P+Q)$, for $P+Q$ a member of the degree-2 pencil, is linearly equivalent to $K+P+Q$ (theorem 7.3.8(3) below). Hyperelliptic curves are the subject of section 7.5.

Three descriptions of a nonsingular curve agree: as a projective scheme, as a proper scheme, and through the discrete valuation rings of its function field (corollary 7.3.5). Properness is the valuative condition of theorem 3.5.22 and says nothing about equations, while projectivity is the existence of a closed immersion into a projective space, that is, of equations. The passage from properness to projectivity is proposition 7.1.7.

Corollary 7.3.5: Equivalence of Curve Models

Let X be a nonsingular curve over $k = \overline{k}$, with function field $K = K(X)$. Then the following are equivalent:

1. X is projective.
2. X is proper (complete).
3. For every DVR R of K/k, the valuation ring R dominates $\mathcal{O}_{X,x}$ for some (necessarily unique) closed point $x \in X$.

***Proof*:**
(1) $\Rightarrow$ (2) holds because projective morphisms are proper (theorem 3.5.32). The converse (2) $\Rightarrow$ (1) is proposition 7.1.7.

(2) $\Rightarrow$ (3): Let R be a DVR of K/k. The generic point gives $\operatorname{Spec} K \to X$, and the valuative criterion of properness (theorem 3.5.22) for $X \to \operatorname{Spec} k$ gives a unique lift $\operatorname{Spec} R \to X$. It sends the closed point of $\operatorname{Spec} R$ to a point x and induces a local homomorphism $\mathcal{O}_{X,x} \to R$ compatible with the inclusions into K. The point x is not the generic point, since $\mathcal{O}_{X,\eta} = K$ would then map locally to R and force R to be a field. So x is a closed point and R dominates $\mathcal{O}_{X,x}$. A second closed point whose local ring is dominated by R would give a second lift, so x is

unique.

(3) ⇒ (2): The morphism $X \to \operatorname{Spec} k$ is separated and of finite type, so by theorem 3.5.31 it suffices to lift every diagram formed by a DVR R with fraction field L, a morphism $\operatorname{Spec} L \to X$ and a morphism $\operatorname{Spec} R \to \operatorname{Spec} k$. The points of X are its closed points and its generic point. If $\operatorname{Spec} L$ maps to a closed point ξ, then $\kappa(\xi) = k$ and $\operatorname{Spec} R \to \operatorname{Spec} k = \operatorname{Spec} \kappa(\xi) \to X$ is a lift. Otherwise $\operatorname{Spec} L$ maps to the generic point and $K \subseteq L$. Then $R' = R \cap K$ is a valuation ring of K containing k, whose value group is a subgroup of the value group $\mathbb{Z}$ of R. If $R' = K$, then $\operatorname{Spec} R \to \operatorname{Spec} K \to X$ is a lift. Otherwise R' is a DVR of K/k, by (3) it dominates $\mathcal{O}_{X,x}$ for a closed point x, and $\operatorname{Spec} R \to \operatorname{Spec} R' \to \operatorname{Spec} \mathcal{O}_{X,x} \to X$ is a lift. Hence X is proper, completing the proof.

In the language of classical algebraic geometry, such an X is the *complete nonsingular model* of the function field K, unique up to isomorphism (theorem 7.1.4(3)).

Proposition 7.3.6: Genus Zero Means Rational

Let X be a complete nonsingular curve of genus $g = 0$ over $k = \overline{k}$. Then $X \cong \mathbb{P}^1_k$.

***Proof*:**

Let P be any closed point of X. By proposition 7.3.1 $\deg K = -2$, so $\deg(K - P) = -3 < 0$, forcing $\ell(K - P) = 0$ by lemma 7.2.2. Riemann-Roch then gives

$$\ell(P) = \deg P + 1 - g + \ell(K - P) = 2$$

Choose $f \in H^0(X, \mathcal{L}(P)) \setminus k$, viewed as a rational function with $\operatorname{div}(f) + P \geq 0$. It has a pole, since otherwise $f \in \Gamma(X, \mathcal{O}_X) = k$ (theorem 3.5.33), so its divisor of poles is exactly P. As in the proof of corollary 7.1.10, f defines a finite morphism $\varphi\colon X \to \mathbb{P}^1_k$ with $\operatorname{div}(f) = \varphi^*([0]) - \varphi^*([\infty])$, so $\varphi^*([\infty]) = P$ and $\deg \varphi = \deg \varphi^*([\infty]) = 1$ by proposition 7.1.9. Thus φ is birational. It is finite, hence separated and quasifinite, and $\mathbb{P}^1_k$ is normal, so φ is an open immersion by corollary 3.4.39. Being surjective (proposition 7.1.6), it is an isomorphism, as claimed.

Thus $\mathbb{P}^1_k$ is the *unique* smooth projective curve of genus 0 over $\overline{k}$. Over a field k that is not algebraically closed, a geometrically integral projective curve of genus 0 is a nonsingular conic in $\mathbb{P}^2_k$, and it is isomorphic to $\mathbb{P}^1_k$ if and only if it has a k-rational point, that is, a point with residue field k [66, Proposition 7.4.1]. Over $\mathbb{Q}$, for instance, the conic $x^2 + y^2 + z^2 = 0$ has genus 0 but is not isomorphic to $\mathbb{P}^1_{\mathbb{Q}}$, since it has no rational points.

Example 7.3.7: Embedding Low-Genus Curves

1. *Genus* 0*:* By proposition 7.3.6, $X \cong \mathbb{P}^1$. Taking $D = n \cdot P$ for $n \geq 1$ gives $\ell(D) = n + 1$, and $\varphi_{|D|}\colon \mathbb{P}^1 \to \mathbb{P}^n$ is the Veronese embedding of degree n (definition 3.1.38), whose image is the rational normal curve of degree n. For $n = 2$ this is a conic in $\mathbb{P}^2$.

2. *Genus* 1*:* Let E be a complete nonsingular curve of genus one and $O \in E$ a closed point. Then $\deg K = 0$ and $\ell(K) = 1$ (proposition 7.3.1), so $K \sim 0$ by lemma 7.2.2 and $\omega_E \cong \mathcal{O}_E$. The divisor $3O$ is non-special, as $\deg(3O) = 3 > 0 = 2g - 2$, so $\ell(3O) = 3 + 1 - 1 = 3$. Since $\deg(3O) = 2g + 1$, corollary 7.3.4 shows that $|3O|$ embeds E in $\mathbb{P}^2$, and the image, a nonsingular plane curve of genus 1, is a cubic by proposition 7.2.6. This is the Weierstrass

embedding of section 7.6.

3. *Genus* 2*:* $\deg K = 2$ and $\ell(K) = g = 2$, so $|K|$ is a pencil (a linear system of dimension 1), base-point-free: for a closed point P, Riemann-Roch gives $\ell(K - P) = \ell(P) = 1 = \ell(K) - 1$, since $\ell(P) \geq 2$ would give $X \cong \mathbb{P}^1$ by the argument of proposition 7.3.6. The canonical map $\varphi_{|K|} \colon X \to \mathbb{P}^1$ pulls a point back to a divisor of $|K|$, so it has degree 2 (proposition 7.1.9), and every curve of genus 2 is hyperelliptic. By corollary 7.3.4 every divisor of degree $5 = 2g + 1$ is very ample, and for $D = 5P$, $\ell(D) = 4$, so $X \hookrightarrow \mathbb{P}^3$ as a curve of degree 5. No divisor D of smaller degree is very ample. For $\deg D \in \{3, 4\}$, $\ell(D) = \deg D - 1$ by proposition 7.3.2, and for $\deg D \leq 2$, $\ell(D) \leq \deg D + 1$, since each closed point imposes at most one condition. So a very ample divisor of degree at most 4 would embed X in $\mathbb{P}^m$ with $m \leq 2$, while X is neither $\mathbb{P}^1$ nor a nonsingular plane curve, because 2 is not of the form $(d-1)(d-2)/2$ (proposition 7.2.6).

4. *Genus* 3*:* $\deg K = 4$ and $\ell(K) = 3$, so $|K|$ maps $X \to \mathbb{P}^2$. If X is non-hyperelliptic, this is an embedding (theorem 7.3.8(2)), and X is realized as a nonsingular quartic in $\mathbb{P}^2$, consistent with $g = \frac{(4-1)(4-2)}{2} = 3$ (proposition 7.2.6). If X is hyperelliptic, $|K|$ factors through the degree-2 map to $\mathbb{P}^1$ and maps X onto a conic in $\mathbb{P}^2$ (theorem 7.3.8(3)).

The canonical linear system $|K|$ is attached to X without any choice: a canonical divisor is determined by X up to linear equivalence, so the canonical map is determined up to a linear automorphism of the target.

Theorem 7.3.8: The Canonical Map and Embedding

Let X be a complete nonsingular curve of genus $g \geq 2$. Then:

1. *Existence:* The canonical linear system $|K|$ is base-point-free. Consequently, it defines a morphism
$$\varphi_K \colon X \longrightarrow \mathbb{P}^{g-1}$$

2. *The non-hyperelliptic case:* If $\ell(P + Q) = 1$ for all closed points $P, Q \in X$, equal or not, then φ_K is a closed immersion, and X is embedded as a curve of degree $2g - 2$ in $\mathbb{P}^{g-1}$. This is the *canonical embedding* of X.

3. *The hyperelliptic case:* If $\ell(P + Q) \geq 2$ for some closed points $P, Q \in X$, then $\varphi_{|P+Q|} \colon X \to \mathbb{P}^1$ is a morphism of degree 2, $K \sim (g-1)(P + Q)$, and φ_K factors as
$$X \xrightarrow{\varphi_{|P+Q|}} \mathbb{P}^1 \xrightarrow{\nu_{g-1}} \mathbb{P}^{g-1}$$
where ν_{g-1} is the Veronese embedding of degree $g-1$. Thus φ_K is a morphism of degree 2 onto a rational normal curve of degree $g - 1$, and it is not a closed immersion.

The curves in case (3) are the *hyperelliptic* curves (definition 7.5.1), since a degree-2 morphism $\varphi \colon X \to \mathbb{P}^1$ pulls a point y back to a divisor $P + Q$ with $\ell(P + Q) \geq 2$ (the pullbacks of 1 and of a coordinate with a pole at y are independent sections), and $\varphi_{|P+Q|}$ is the *hyperelliptic double cover*.

***Proof*:**
(1) For $|K|$ to be base-point-free means that for every closed point $P \in X$ there is a global differential form that does not vanish at P, that is, $\ell(K) - \ell(K - P) = 1$. By Riemann-Roch,

$$\ell(K - P) = \deg(K - P) + 1 - g + \ell(P) = (2g - 3) + 1 - g + \ell(P) = g - 2 + \ell(P)$$

Since $g \geq 1$, $\ell(P) = 1$ for every closed point P: if $\ell(P) \geq 2$, the argument in the proof of proposition 7.3.6 would give an isomorphism $X \cong \mathbb{P}^1$, implying $g = 0$. Substituting $\ell(P) = 1$ yields $\ell(K - P) = g - 1 = \ell(K) - 1$, so $|K|$ has no base points, and theorem 5.3.43 gives the morphism φ_K.

(2) By the criterion stated before proposition 7.3.3, φ_K is a closed immersion if and only if $\ell(K) - \ell(K - P - Q) = 2$ for all closed points P, Q, with $P = Q$ corresponding to separating tangent vectors. Riemann-Roch applied to $K - P - Q$ gives

$$\ell(K-P-Q) = \deg(K-P-Q)+1-g+\ell(P+Q) = (2g-4)+1-g+\ell(P+Q) = g-3+\ell(P+Q)$$

and subtracting this from $\ell(K) = g$,

$$\ell(K) - \ell(K - P - Q) = 3 - \ell(P + Q)$$

Under the hypothesis of (2) this drop is 2 for every P and Q, so φ_K is a closed immersion. Its hyperplane sections are the canonical divisors, of degree $2g - 2$ (proposition 7.3.1), so the image has degree $2g - 2$.

(3) Suppose $\ell(P + Q) \geq 2$ and choose $h \in H^0(X, \mathcal{L}(P + Q)) \setminus k$. Its divisor of poles is at most $P + Q$ and is not a single point, since $\ell(P') = 1$ for every closed point P' by (1), so it equals $P + Q$. As in the proof of proposition 7.3.6, h defines a finite morphism $X \to \mathbb{P}^1$ pulling ∞ back to $P + Q$, of degree 2 by proposition 7.1.9. Each closed point imposes at most one condition on sections, so $\ell(P + Q) \leq \ell(P) + 1 = 2$, and $1, h$ is a basis of $H^0(X, \mathcal{L}(P + Q))$. The pencil $|P + Q|$ has no base point, since a base point R would give $\ell(P + Q - R) = 2$ for a divisor of degree 1, which is then linearly equivalent to a closed point P' with $\ell(P') = 2$, contradicting (1). So this morphism is $\varphi_{|P+Q|} = [1 : h]$.

The elements $1, h, \ldots, h^{g-1}$ lie in $H^0(X, \mathcal{L}((g - 1)(P + Q)))$, since $\operatorname{div}(h^i) + (g - 1)(P + Q) = i(\operatorname{div}(h) + P + Q) + (g - 1 - i)(P + Q) \geq 0$, and they are linearly independent over k because h is transcendental over the algebraically closed field k. So $\ell((g - 1)(P + Q)) \geq g$. Riemann-Roch for $(g - 1)(P + Q)$ reads

$$\ell((g-1)(P+Q)) - \ell(K-(g-1)(P+Q)) = \deg((g-1)(P+Q)) + 1 - g = (2g-2)+1-g = g-1$$

so $\ell(K - (g - 1)(P + Q)) \geq 1$. The divisor $K - (g - 1)(P + Q)$ has degree $(2g - 2) - 2(g - 1) = 0$, so $K \sim (g-1)(P+Q)$ by lemma 7.2.2(2). Then $\ell((g-1)(P+Q)) = \ell(K) = g$, and $1, h, \ldots, h^{g-1}$ is a basis of the sections of $\mathcal{L}((g - 1)(P + Q)) \cong \omega_X$. With this basis, $\varphi_K = [1 : h : \cdots : h^{g-1}]$, which is the composite of $[1 : h] = \varphi_{|P+Q|}$ with the Veronese map ν_{g-1} given by all monomials of degree $g - 1$ (example 5.3.45(2)). The image of φ_K is the rational normal curve $\nu_{g-1}(\mathbb{P}^1) \cong \mathbb{P}^1$, and φ_K maps onto it with degree $\deg \varphi_{|P+Q|} = 2$. A closed immersion is an isomorphism onto its image, so φ_K is not one, completing the proof.

An isomorphism $X \cong X'$ of non-hyperelliptic curves pulls $\omega_{X'}$ back to ω_X, so it carries the canonical image of X to that of X' up to a linear automorphism of $\mathbb{P}^{g-1}$. The target $\mathbb{P}^{g-1}$ grows with the

genus, while every curve already embeds in $\mathbb{P}^3$.

Proposition 7.3.9: Every Curve Embeds in Projective 3-Space

Let X be a complete nonsingular curve over an algebraically closed field k. Then X is isomorphic to a closed subvariety of $\mathbb{P}^3_k$.

***Proof*:**

By corollary 7.3.4, a divisor D of degree $\deg D \geq 2g+1$ gives a closed immersion $\varphi_{|D|}\colon X \hookrightarrow \mathbb{P}^N_k$, where $N = \ell(D) - 1$. If $N \leq 3$, compose with a linear inclusion $\mathbb{P}^N_k \hookrightarrow \mathbb{P}^3_k$.

Suppose $N \geq 4$. For a closed point $O \in \mathbb{P}^N_k \setminus X$, the linear projection from O (example 5.3.45(4)) is a morphism

$$\pi_O\colon \mathbb{P}^N_k \setminus \{O\} \longrightarrow \mathbb{P}^{N-1}_k$$

and $\pi_O|_X$ is a closed immersion if and only if O lies on no secant line of X (a line joining two distinct points of X) and on no tangent line of X [50, Proposition IV.3.4]. The first condition says that $\pi_O|_X$ separates points, and the second that it separates tangent vectors. The union $\mathrm{Sec}(X)$ of the secant lines is locally the image of a morphism from $(X \times X \setminus \Delta) \times \mathbb{P}^1$, so it has dimension at most 3, and the union of the tangent lines is locally the image of $X \times \mathbb{P}^1$, so it has dimension at most 2 [50, Proposition IV.3.5]. As $N \geq 4$, the closures of these two sets do not cover $\mathbb{P}^N_k$, and since k is algebraically closed the nonempty open complement contains a closed point O. It lies off X, which is contained in the closure of $\mathrm{Sec}(X)$, and projecting from it gives a closed immersion $X \hookrightarrow \mathbb{P}^{N-1}_k$.

Repeating this step $N-3$ times gives a closed immersion $X \hookrightarrow \mathbb{P}^3_k$, as we sought to show.

Not every curve embeds in $\mathbb{P}^2_k$: a nonsingular plane curve of degree d has genus $\frac{(d-1)(d-2)}{2}$ (proposition 7.2.6), so a curve of genus 2, for instance, is not a nonsingular plane curve. Every curve is birational to a plane curve whose only singularities are nodes [50, Corollary IV.3.11]. The dimension count in the proof is the one behind the weak Whitney embedding theorem: projection from points off the secant variety embeds a compact smooth n-manifold in $\mathbb{R}^{2n+1}$, and for the curve X, of dimension $n = 1$, the same count gives $\mathbb{P}^{2n+1} = \mathbb{P}^3$.

Clifford's theorem bounds $\ell(D)$ for *special* divisors D, those with $\ell(K - D) > 0$, for which theorem 7.2.10 does not determine $\ell(D)$ from $\deg D$. Special divisors have $\deg D \leq 2g - 2$ (proposition 7.3.2).

Theorem 7.3.10: Clifford's Theorem

Let D be an effective divisor on a complete nonsingular curve X of genus $g \geq 1$ with $0 \leq \deg D \leq 2g - 2$ and $\ell(K - D) > 0$ (i.e. D is *special*). Then

$$\ell(D) - 1 \;\leq\; \frac{\deg D}{2}$$

Equality holds if $D = 0$, if $D \sim K$, or if there are closed points $P, Q \in X$ with $\ell(P + Q) \geq 2$ and $D \sim r(P + Q)$ for an integer $r \geq 0$ (so that $|P + Q|$ is a g^1_2 and D is a multiple of it).

***Proof*:**
Throughout, k is algebraically closed, as in theorem 7.2.10, and $H^0(X, \mathcal{L}(E))$ is identified with $L(E) = \{f \in K(X)^* \mid \operatorname{div}(f) + E \geq 0\} \cup \{0\}$ (definition 5.4.9).

Step 1: a dimension count in $K(X)$. Fix a closed point P. The local ring $\mathcal{O}_{X,P}$ is a discrete valuation ring with valuation ν_P on $K(X)$. Its residue field is k: the point P lies in an affine open $\operatorname{Spec} B$ with B a finitely generated k-algebra, its maximal ideal $\mathfrak{m} \subseteq B$ pulls back to a maximal ideal of a polynomial ring $k[x_1, \ldots, x_N]$ surjecting onto B, so $B/\mathfrak{m} \cong k$ by theorem 0.1.12(3), and the residue field of $\mathcal{O}_{X,P} \cong B_{\mathfrak{m}}$ (proposition 2.2.22) is $B/\mathfrak{m}$ by [15, Localization and Quotient Commute]. For a finite-dimensional k-subspace $V \subseteq K(X)$ put $\nu_P(V) = \{\nu_P(v) \mid v \in V \setminus \{0\}\}$. We claim $|\nu_P(V)| = \dim_k V$. Elements $v_1, \ldots, v_s \in V$ with distinct valuations are linearly independent, since a combination $\sum_i c_i v_i$ with some $c_i \neq 0$ has valuation $\min\{\nu_P(v_i) \mid c_i \neq 0\}$ and so is nonzero. In particular $\nu_P(V)$ has at most $\dim_k V$ elements. For each value in $\nu_P(V)$ choose an element of V with that valuation, giving independent elements $v_1, \ldots, v_s$. If some element of V lies outside their span, choose such a v with $\nu_P(v)$ largest, which is possible because $\nu_P(V)$ is finite. Then $\nu_P(v) = \nu_P(v_i)$ for some i, the quotient v/v_i is a unit of $\mathcal{O}_{X,P}$, and its residue class is that of some $c \in k^\times$. So $v - cv_i = v_i(v/v_i - c)$ lies outside the span and has larger valuation, a contradiction. Hence the v_i form a basis of V.

Now let $V, W \subseteq K(X)$ be nonzero finite-dimensional subspaces and $V \cdot W$ the span of the products vw. Since $\nu_P(vw) = \nu_P(v) + \nu_P(w)$, the set $\nu_P(V \cdot W)$ contains every sum of an element of $\nu_P(V) = \{a_1 < \cdots < a_s\}$ and an element of $\nu_P(W) = \{b_1 < \cdots < b_t\}$, and the sums $a_1 + b_1 < a_1 + b_2 < \cdots < a_1 + b_t < a_2 + b_t < \cdots < a_s + b_t$ are $s + t - 1$ distinct values. Hence

$$\dim_k(V \cdot W) \geq \dim_k V + \dim_k W - 1$$

Step 2: the inequality. For $f \in L(D)$ and $h \in L(K - D)$ we have $\operatorname{div}(fh) + K = (\operatorname{div}(f) + D) + (\operatorname{div}(h) + K - D) \geq 0$, so the span $L(D) \cdot L(K - D)$, which is the image of the multiplication map $H^0(X, \mathcal{L}(D)) \otimes H^0(X, \mathcal{L}(K - D)) \to H^0(X, \mathcal{L}(K))$, lies in $L(K)$. Here $L(D) \neq 0$ because $1 \in L(D)$ for effective D, and $L(K - D) \neq 0$ by hypothesis. Step 1 and $\ell(K) = g$ (proposition 7.3.1) give

$$\ell(D) + \ell(K - D) - 1 \leq g$$

By theorem 7.2.10, $\ell(K - D) = \ell(D) - \deg D - 1 + g$, and substituting yields $2\ell(D) \leq \deg D + 2$, that is, $\ell(D) - 1 \leq \deg D/2$.

Step 3: the cases of equality. The number $\ell(E)$ depends only on the linear equivalence class of E: if $E' = E + \operatorname{div}(\varphi)$, then $f \mapsto f\varphi^{-1}$ is a k-linear bijection $L(E) \to L(E')$. If $D = 0$, then $\ell(D) = \dim_k \Gamma(X, \mathcal{O}_X) = 1$ by theorem 3.5.33, and both sides of the inequality vanish. If $D \sim K$, then $\ell(D) = \ell(K) = g$ and $\deg D = 2g - 2$ (proposition 7.3.1 and corollary 7.1.10), so both sides equal $g - 1$. Finally let $\ell(P + Q) \geq 2$ and $D \sim r(P + Q)$, and choose a nonconstant $h \in L(P + Q)$. The elements $1, h, \ldots, h^r$ lie in $L(r(P + Q))$, since $\operatorname{div}(h^i) + r(P + Q) = i(\operatorname{div}(h) + P + Q) + (r - i)(P + Q) \geq 0$. They are linearly independent over k, because h is transcendental over k: an element of $K(X)$ algebraic over the algebraically closed field k lies in k. Hence $\ell(D) = \ell(r(P + Q)) \geq r + 1$, while $\deg D = 2r$ (corollary 7.1.10). With Step 2 this gives $\ell(D) - 1 = r = \deg D/2$, completing the proof.

The converse also holds: if equality holds, then $D = 0$, $D \sim K$, or X is hyperelliptic and D is a multiple of its g^1_2 [50, Theorem IV.5.4].

7.3.11 Petri's Theorem and Syzygies The canonical embedding $X \hookrightarrow \mathbb{P}^{g-1}$ of a non-hyperelliptic curve raises the question of which equations define the image. A *quadric* is a hypersurface defined by a homogeneous polynomial of degree 2. Petri's theorem says that the homogeneous ideal of the canonical curve is generated by quadrics unless X is trigonal (admits a degree-3 morphism to $\mathbb{P}^1$) or is a nonsingular plane quintic ($g = 6$).
The finer structure of the ideal is recorded by its *syzygies*, the terms of a minimal graded free resolution of the homogeneous coordinate ring of the canonical curve over the polynomial ring in g variables, which is finite by Hilbert's syzygy theorem (*Homological Algebra* [25, Hilbert's Syzygy Theorem]) together with the graded argument following corollary 5.3.27. Green's conjecture predicts that the graded Betti numbers of this resolution determine the *Clifford index* of X. Voisin proved it for a general curve of each genus.

7.4 Ramification and Hurwitz's Formula

Riemann-Roch relates the invariants of a single curve: its genus, its divisors and their spaces of sections. Hurwitz's theorem relates the genera of two curves X and Y through a finite morphism $f\colon X \to Y$, its degree and its ramification.

Over $\mathbb{C}$, a finite morphism of smooth projective curves is a branched covering of compact Riemann surfaces. Away from finitely many *branch points*, the map is a covering space with $n = \deg f$ sheets, and over a branch point several sheets meet. The Euler characteristic (equivalently, the genus) of X is then determined by the Euler characteristic of Y, the degree of f and the ramification. Hurwitz's formula is the algebraic form of this count over an arbitrary algebraically closed field.

7.4.1 Ramification

Throughout this section, $f\colon X \to Y$ is a finite morphism of complete nonsingular curves over $k = \overline{k}$, with $n = \deg f = [K(X) : K(Y)]$.

Every local ring $\mathcal{O}_{X,x}$ (resp. $\mathcal{O}_{Y,y}$) at a closed point of a smooth curve is a DVR with discrete valuation ν_x (resp. ν_y). The ramification index $e_x = \nu_x(f^{\#}(t))$, for t a uniformizer at $y = f(x)$, already entered the pullback of divisors preceding proposition 7.1.9.

Definition 7.4.1: Ramification Index

Let $f\colon X \to Y$ be a finite morphism of complete nonsingular curves, $x \in X$ a closed point, and $y = f(x)$. The *ramification index* of f at x is

$$e_x \;=\; \nu_x(f^{\#}(t))$$

where t is any uniformizer of $\mathcal{O}_{Y,y}$. This is independent of the choice of t.

1. f is *unramified* at x if $e_x = 1$.
2. f is *ramified* at x if $e_x > 1$. The point $y = f(x)$ is then called a *branch point*.
3. If $\mathrm{char} k = 0$, all ramification is *tame*. If $\mathrm{char} k = p > 0$, the ramification at x is *tame* if $p \nmid e_x$, and *wild* if $p \mid e_x$.

The index does not depend on t: if $t' = ut$ for a unit $u \in \mathcal{O}_{Y,y}^*$, then $f^{\#}(u)$ is a unit in $\mathcal{O}_{X,x}$ (local maps send units to units), so $\nu_x(f^{\#}(t')) = \nu_x(f^{\#}(u)) + \nu_x(f^{\#}(t)) = 0 + e_x$. The index e_x is the multiplicity of x in the divisor $f^*(y)$. If s is a uniformizer of $\mathcal{O}_{X,x}$, then $f^{\#}(t) = v \cdot s^{e_x}$ for a unit v, so in these local parameters f is $s \mapsto v s^{e_x}$.

Example 7.4.2: Ramification in Practice

1. *The squaring map.* Let $\mathrm{char} k \neq 2$ and consider $f\colon \mathbb{P}^1 \to \mathbb{P}^1$, $[x : y] \mapsto [x^2 : y^2]$, which in the affine charts $y \neq 0$ is $t \mapsto u = t^2$. This has degree 2. At $t = 0$ the uniformizer of the target is u, and $f^{\#}(u) = t^2$, so $e_0 = 2$ (ramified). Similarly at $t = \infty$ (using the chart $x \neq 0$, the map is $s \mapsto s^2$ in the uniformizer $s = 1/t$), so $e_\infty = 2$. At every other point $t = a \neq 0, \infty$, the uniformizer of the target at a^2 is $u - a^2$, and $f^{\#}(u - a^2) = t^2 - a^2 = (t - a)(t + a)$. Since $t + a$ is a unit at $t = a$ (as $2a \neq 0$), $\nu_a((t - a)(t + a)) = 1$ and $e_a = 1$ (unramified). The fiber over a^2 consists of the two points a and $-a$, each with $e = 1$, confirming $\sum e_x = 2 = \deg f$. In characteristic 2 the same formula defines a purely inseparable morphism with $e_x = 2$ at every point (box 7.4.4).

2. *Wild ramification.* Let k have characteristic $p > 0$ and let $f\colon \mathbb{P}^1 \to \mathbb{P}^1$ be given in the affine coordinate by $t \mapsto u = t^p - t$ (the Artin-Schreier map). It has degree p, the degree of $t^p - t$ as a rational function of t. At a point $a \in \mathbb{A}^1$, the uniformizer of the target at $f(a) = a^p - a$ is $u - (a^p - a)$, and $f^{\#}(u - (a^p - a)) = (t - a)^p - (t - a)$, whose lowest-order term in $t - a$ is $-(t - a)$. So $e_a = 1$ at every point of $\mathbb{A}^1$, and the fiber over each point c of $\mathbb{A}^1$ consists of the p distinct roots of the separable polynomial $T^p - T - c$. At ∞, with uniformizers $s = 1/t$ and $1/u$,

$$f^{\#}(1/u) = \frac{1}{t^p - t} = \frac{s^p}{1 - s^{p-1}}$$

has valuation p, so $e_\infty = p$: the ramification at ∞ is wild, and ∞ is the only point over ∞. The restriction $\mathbb{A}^1 \to \mathbb{A}^1$ is therefore a connected cover of degree p, unramified at every point. Over $\mathbb{C}$ the affine line has no such cover, since $\mathbb{A}^1(\mathbb{C}) = \mathbb{C}$ is simply connected.

Differentials measure ramification. The first map of the cotangent sequence (proposition 5.5.17) for

$X \xrightarrow{f} Y \to \operatorname{Spec} k$ is a map of sheaves on X

$$f^*\Omega_{Y/k} \longrightarrow \Omega_{X/k} \tag{7.3}$$

between invertible sheaves. Call f *separable* if $K(X)/K(Y)$ is a separable field extension, which is automatic in characteristic 0. If f is separable, (7.3) is injective. Indeed, at the generic point it is a $K(X)$-linear map $K(X) \otimes_{K(Y)} \Omega_{K(Y)/k} \to \Omega_{K(X)/k}$ between one-dimensional vector spaces, whose cokernel $\Omega_{K(X)/K(Y)}$ vanishes because $K(X)/K(Y)$ is separable algebraic (proposition 5.5.9). So it is an isomorphism there, and a map of invertible sheaves on an integral scheme that is nonzero at the generic point is injective. Its cokernel $\Omega_{X/Y}$ is then a coherent sheaf vanishing at the generic point, hence supported at finitely many closed points. If f is inseparable, (7.3) is zero (box 7.4.4).

In local coordinates, let $x \in X$ be a closed point with $y = f(x)$, let s be a uniformizer of $\mathcal{O}_{X,x}$ and t a uniformizer of $\mathcal{O}_{Y,y}$. By proposition 5.5.10 the class of ds spans $\Omega_{X/k,x} \otimes k \cong \mathfrak{m}_x/\mathfrak{m}_x^2$, so ds generates the free rank-one module $\Omega_{X/k,x}$ (proposition 5.5.25) by Nakayama's lemma, and likewise dt generates $\Omega_{Y/k,y}$. Write $f^{\#}(t) = v \cdot s^{e_x}$ for a unit $v \in \mathcal{O}_{X,x}^*$ and $dv = v'\,ds$. Then

$$f^*(dt) \;=\; d(f^{\#}(t)) \;=\; d(v \cdot s^{e_x}) \;=\; (v' s^{e_x} + e_x v s^{e_x - 1})\,ds \;=\; s^{e_x-1}(v's + e_x v)\,ds$$

The factor s^{e_x-1} vanishes to order $e_x - 1$ at x. The factor $(v's + e_x v)$ is a unit at x if and only if $e_x \neq 0$ in k, that is, if and only if the ramification at x is tame. In the case of tame ramification, the map (7.3) vanishes to order exactly $e_x - 1$ at x.

Definition 7.4.3: Ramification and Branch Divisors

Let f be separable. For a closed point $x \in X$, with uniformizers s at x and t at $f(x)$, write $f^*(dt) = h_x\,ds$ with $h_x \in \mathcal{O}_{X,x}$, and set $r_x = \nu_x(h_x)$, the length of $\Omega_{X/Y,x} \cong \mathcal{O}_{X,x}/(h_x)$. Replacing s or t by a unit multiple multiplies h_x by a unit, so r_x does not depend on these choices, and $r_x = 0$ outside the finite support of $\Omega_{X/Y}$. The *ramification divisor* of f is

$$R \;=\; \sum_{x \in X_{\mathrm{cl}}} r_x \cdot x$$

so that the image of (7.3) is $\Omega_{X/k} \otimes \mathcal{L}(-R)$ and $f^*\Omega_{Y/k} \cong \Omega_{X/k} \otimes \mathcal{L}(-R)$. The *branch divisor* is $B = f_*(R) = \sum_x r_x \cdot f(x) \in \operatorname{WDiv} Y$.
When the ramification at x is tame (in particular, always in characteristic 0),

$$r_x = e_x - 1$$

When it is wild ($\operatorname{char} k = p > 0$ and $p \mid e_x$), $r_x \geq e_x$, and the precise value depends on higher-order ramification data.

The relation $f^*\Omega_{Y/k} \cong \Omega_{X/k}(-R)$ can be rewritten in terms of canonical divisors. Here $\Omega_{Y/k} \cong \mathcal{L}(K_Y)$ and $\Omega_{X/k} \cong \mathcal{L}(K_X)$, and $f^*\mathcal{L}(D) \cong \mathcal{L}(f^*D)$ for every divisor D on Y: near $f(x)$, the sheaf $\mathcal{L}(D)$ is generated by t^{-m}, where m is the coefficient of $f(x)$ in D, and $f^*\mathcal{L}(D)$ by $f^{\#}(t)^{-m} = v^{-m} s^{-e_x m}$, a generator of $\mathcal{L}(f^*D)$. This gives the *divisor relation*

$$K_X \;\sim\; f^*K_Y + R \tag{7.4}$$

and Hurwitz's formula follows from it by taking degrees.

7.4.4 Remark: Inseparable Maps If the field extension $K(X)/K(Y)$ is inseparable (which can only happen in characteristic $p > 0$), the map (7.3) is the *zero map*. At the generic point its cokernel $\Omega_{K(X)/K(Y)}$ is nonzero (proposition 5.5.9), and a linear map into a one-dimensional space that is not surjective is zero, so the map of sheaves, whose target $\Omega_{X/k}$ is invertible and hence torsion-free, is zero. The simplest example is $F\colon \mathbb{P}^1 \to \mathbb{P}^1$, $[x : y] \mapsto [x^p : y^p]$, which is purely inseparable of degree p, as $k(t)$ has degree p over $k(t^p)$. In the affine coordinates, t on the source and u on the target, $F^{\#}(u) = t^p$, so $F^*(du) = d(t^p) = pt^{p-1}\,dt = 0$, and $e_x = p$ at every point.
Hurwitz's formula is stated for separable morphisms. A general finite morphism of curves factors, through the separable closure of $K(Y)$ in $K(X)$, as a purely inseparable morphism followed by a separable one, and a purely inseparable finite morphism of curves is a composite of k-linear Frobenius morphisms, so its source and target have the same genus [50, Proposition IV.2.5 and Example IV.2.5.4].

7.4.2 Hurwitz's Formula

Theorem 7.4.5: Hurwitz's Formula

Let $f\colon X \to Y$ be a separable finite morphism of complete nonsingular curves of genera g_X and g_Y respectively, with $n = \deg f$. Then

$$2g_X - 2 \;=\; n(2g_Y - 2) \;+\; \deg R$$

where $R = \sum r_x \cdot x$ is the ramification divisor. In the tamely ramified case (in particular, whenever $\mathrm{char} k = 0$),

$$2g_X - 2 \;=\; n(2g_Y - 2) \;+\; \sum_{x \in X_{\mathrm{cl}}} (e_x - 1)$$

***Proof*:**
Taking degrees of both sides of (7.4) gives

$$\deg K_X = \deg(f^* K_Y) + \deg R$$

By proposition 7.3.1, $\deg K_X = 2g_X - 2$ and $\deg K_Y = 2g_Y - 2$. By the degree formula for pullbacks (proposition 7.1.9), $\deg(f^* K_Y) = n \cdot \deg K_Y = n(2g_Y - 2)$. Therefore

$$2g_X - 2 = n(2g_Y - 2) + \deg R$$

The second formula follows since $r_x = e_x - 1$ in the tame case, completing the proof.

The substance of the proof is the relation (7.4) of section 7.4.1, which rests on the Kähler differentials of section 5.5. The same exact sequence gives the formula through Euler characteristics, and this route identifies $\deg R$ with $\dim_k H^0(X, \Omega_{X/Y})$.

***Proof Alternative proof via Euler characteristics*:**

Since f is separable, the cotangent sequence (proposition 5.5.17) for $X \xrightarrow{f} Y \to \operatorname{Spec} k$ and the injectivity of (7.3) give a short exact sequence on X

$$0 \to f^*\Omega_{Y/k} \to \Omega_{X/k} \to \Omega_{X/Y} \to 0$$

Taking Euler characteristics (proposition 6.7.2),

$$\chi(\Omega_{X/k}) = \chi(f^*\Omega_{Y/k}) + \chi(\Omega_{X/Y})$$

Now $\Omega_{X/k} = \omega_X \cong \mathcal{L}(K_X)$, and by Riemann-Roch (theorem 7.2.10)

$$\chi(\omega_X) = \deg K_X + 1 - g_X = (2g_X - 2) + 1 - g_X = g_X - 1$$

For the pullback, $f^*\Omega_{Y/k} \cong f^*\omega_Y \cong \mathcal{L}(f^*K_Y)$, and

$$\chi(f^*\omega_Y) = \deg(f^*K_Y) + 1 - g_X = n(2g_Y - 2) + 1 - g_X$$

The sheaf $\Omega_{X/Y}$ is supported at finitely many closed points, with stalks $\Omega_{X/Y,x} \cong \mathcal{O}_{X,x}/(h_x)$ of dimension r_x over k (definition 7.4.3). A coherent sheaf supported at finitely many closed points is a finite direct sum of skyscraper sheaves, which have no higher cohomology, so $\chi(\Omega_{X/Y}) = \dim_k H^0(X, \Omega_{X/Y}) = \sum_x r_x = \deg R$. Putting it all together,

$$g_X - 1 = n(2g_Y - 2) + 1 - g_X + \deg R$$

which rearranges to $2g_X - 2 = n(2g_Y - 2) + \deg R$, as claimed.

Example 7.4.6: Hurwitz in Action

1. *Double covers of* $\mathbb{P}^1$. Let $f\colon X \to \mathbb{P}^1$ be a degree-2 morphism in characteristic $\neq 2$, which is separable. Then $n = 2$, $g_Y = 0$, and all ramification is tame with $e_x \in \{1, 2\}$. Let b be the number of branch points in $\mathbb{P}^1$ (since $n = 2$, each corresponds to exactly one ramification point in X, where $e_x = 2$). Hurwitz gives

   $$2g_X - 2 = 2(0 - 2) + b = -4 + b, \qquad \text{so } g_X = \frac{b-2}{2}$$

   Since g_X is a non-negative integer, b is even and $b \geq 2$. For $b = 2$: $g_X = 0$ (the map $[x : y] \mapsto [x^2 : y^2]$). For $b = 4$: $g_X = 1$. For $b = 6$: $g_X = 2$ (genus-2 curves, which are all hyperelliptic). More generally, a *hyperelliptic curve* of genus g is a double cover of $\mathbb{P}^1$ with $2g + 2$ branch points.

2. *Cyclic covers.* Let $\operatorname{char} k \nmid n$ and let $f\colon X \to \mathbb{P}^1$ be a cyclic cover of degree n (that is, $K(X)/K(\mathbb{P}^1)$ is Galois with cyclic group of order n), totally ramified ($e_x = n$) over exactly b points and unramified elsewhere. Then

   $$2g_X - 2 = n(-2) + b(n-1), \quad \text{so} \quad g_X = \frac{(n-1)(b-2)}{2}$$

   For $n = 3$, $b = 4$: $g_X = 2$. For $n = 3$, $b = 5$: $g_X = 3$ (a trigonal curve of genus 3). For $n = 3$, $b = 3$: $g_X = 1$, and a generator of the Galois group is an automorphism of order 3 of this curve of genus 1.

3. *Genus bound.* If f is separable and $g_Y \geq 1$, then $\deg R \geq 0$ gives $2g_X - 2 \geq n(2g_Y - 2)$, so $g_X \geq n(g_Y - 1) + 1 \geq g_Y$. A purely inseparable morphism preserves the genus (box 7.4.4), so $g_X \geq g_Y$ for every finite morphism $X \to Y$ (for $g_Y = 0$ there is nothing to prove). In particular, there are no nonconstant morphisms from a curve of genus g to a curve of genus $g' > g$.

7.4.3 Applications of Hurwitz's Formula

Hurwitz's formula bounds the order of a finite group of automorphisms of a curve of genus $g \geq 2$ by a linear function of g, provided the characteristic of k does not divide the order of the group.

Theorem 7.4.7: Hurwitz's Automorphism Bound

Let X be a complete nonsingular curve of genus $g \geq 2$, and let G be a finite group of automorphisms of X whose order is not divisible by $\mathrm{char}k$ (no condition if $\mathrm{char}k = 0$). Then

$$|G| \;\leq\; 84(g-1)$$

The bound is attained: over $\mathbb{C}$, the Klein quartic $x^3y + y^3z + z^3x = 0$ in $\mathbb{P}^2$ has genus 3 and an automorphism group of order $168 = 84 \cdot 2$. In characteristic 0 the whole group $\mathrm{Aut}(X)$ is finite for $g \geq 2$ [50, Exercise IV.5.2], so $|\mathrm{Aut}(X)| \leq 84(g-1)$. In characteristic $p \geq 5$ the condition $p \nmid |G|$ cannot be dropped: the curve $y^2 = x^p - x$ has genus $(p-1)/2$ and $2p(p^2-1)$ automorphisms, more than $84(g-1)$, by a theorem of Roquette recorded in the note to [50, Exercise IV.2.5].

***Proof*:**

Write $n = |G|$. The fixed field $K(X)^G$ is the function field of a complete nonsingular curve Y, the extension $K(X)/K(X)^G$ is Galois with group G, and the inclusion $K(X)^G \subseteq K(X)$ corresponds to a finite separable morphism $\pi\colon X \to Y$ of degree n. If $x \in X$ has ramification index e, then the fiber $\pi^{-1}(\pi(x))$ consists of exactly n/e points, each with ramification index e. These facts are the setup and part (a) of [50, Exercise IV.2.5], posed there in characteristic 0, and are not proved here. Their proofs do not use the characteristic: the key input, that G permutes the points of each fiber transitively, is [83, Chapter I, Proposition (9.1)] applied to the Dedekind domains of affine opens of Y. Each ramification index divides n, and $\mathrm{char}k \nmid n$, so all ramification of π is tame.

Let $y_1, \ldots, y_s \in Y$ be the branch points of π and $e_1, \ldots, e_s \geq 2$ the ramification indices over them. The fiber over y_i contributes $(n/e_i)(e_i - 1)$ to the sum in theorem 7.4.5, which therefore gives

$$2g - 2 = n(2g_Y - 2) + \sum_{i=1}^{s} n\left(1 - \frac{1}{e_i}\right)$$

that is,

$$\frac{2g-2}{n} = 2g_Y - 2 + \sum_{i=1}^{s}\left(1 - \frac{1}{e_i}\right) \tag{7.5}$$

The left side is positive since $g \geq 2$. Call the right side μ. It suffices to show $\mu \geq 1/42$. Each term $1 - 1/e_i$ lies in $[1/2, 1)$.

1. If $g_Y \geq 2$, then $\mu \geq 2$.

2. If $g_Y = 1$, then $\mu > 0$ forces $s \geq 1$, so $\mu \geq 1/2$.
3. If $g_Y = 0$ and $s \leq 2$, then $\mu < 0$, since each of the at most two terms $1 - 1/e_i$ is less than 1, which is excluded.
4. If $g_Y = 0$ and $s \geq 5$, then $\mu \geq -2 + 5/2 = 1/2$.
5. If $g_Y = 0$ and $s = 4$, then $\mu = 2 - \sum_i 1/e_i$, which is positive only if some $e_i \geq 3$, and then $\mu \geq 2 - 3/2 - 1/3 = 1/6$.
6. If $g_Y = 0$ and $s = 3$, order the indices as $e_1 \leq e_2 \leq e_3$, so that $\mu = 1 - 1/e_1 - 1/e_2 - 1/e_3$, which increases with each e_i. If $e_1 = e_2 = 2$, then $\mu < 0$. If $e_1 = 2$ and $e_2 = 3$, then $\mu = 1/6 - 1/e_3 > 0$ forces $e_3 \geq 7$, so $\mu \geq 1/6 - 1/7 = 1/42$. If $e_1 = 2$ and $e_2 = 4$, then $\mu > 0$ forces $e_3 \geq 5$, so $\mu \geq 1/4 - 1/5 = 1/20$. If $e_1 = 2$ and $e_2 \geq 5$, then $\mu \geq 1/2 - 2/5 = 1/10$. If $e_1 \geq 3$, then $\mu > 0$ excludes $(3, 3, 3)$, so $e_3 \geq 4$ and $\mu \geq 1 - 2/3 - 1/4 = 1/12$.

So $\mu \geq 1/42$, with equality only for $g_Y = 0$, $s = 3$ and $(e_1, e_2, e_3) = (2, 3, 7)$. Therefore $n = (2g - 2)/\mu \leq 42(2g - 2) = 84(g - 1)$, as we sought to show.

Over $\mathbb{C}$, the number μ in (7.5) is the hyperbolic area of the quotient orbifold divided by 2π. The triple $(2, 3, 7)$ is the signature of the triangle group of area $2\pi/42 = \pi/21$, which by a theorem of Siegel is the lattice in $\mathrm{PSL}_2(\mathbb{R})$ of smallest co-area.

Example 7.4.8: Automorphism Groups in Low Genus

1. *Genus* 0*:* $\mathrm{Aut}(\mathbb{P}^1_k) = \mathrm{PGL}_2(k)$, which is infinite (and 3-dimensional as an algebraic group). Hurwitz's bound does not apply since $g < 2$.
2. *Genus* 1*:* If E is an elliptic curve with origin O, then the group $\mathrm{Aut}(E, O)$ of automorphisms fixing O is finite and contains the inversion $P \mapsto -P$. Over $\mathbb{C}$, $\mathrm{Aut}(E, O) \cong \mathbb{Z}/2\mathbb{Z}$ unless $j = 0$ or $j = 1728$, where the automorphism group is $\mathbb{Z}/6\mathbb{Z}$ (resp. $\mathbb{Z}/4\mathbb{Z}$), corresponding to the extra symmetries of the hexagonal (resp. square) lattice.

   As a curve, E also has the translations $\tau_P \colon Q \mapsto Q + P$ for every $P \in E(k)$, so the full automorphism group $\mathrm{Aut}(E)$ is an extension of $\mathrm{Aut}(E, O)$ by $E(k)$, which is infinite.
3. *Genus* 2*:* Every genus-2 curve is hyperelliptic, so it comes with an involution ι (the hyperelliptic involution, definition 7.5.3), giving $|\mathrm{Aut}(X)| \geq 2$. In characteristic 0 the group $\mathrm{Aut}(X)$ is finite and Hurwitz's bound gives $|\mathrm{Aut}(X)| \leq 84$. Over $\mathbb{C}$ the maximum for $g = 2$ is 48, attained by the Bolza curve $y^2 = x^5 - x$, so the bound 84 is not attained in genus 2. In characteristic 5 the same equation defines a curve of genus 2 with 240 automorphisms, the case $p = 5$ of the remark after theorem 7.4.7.

A finite morphism $f \colon X \to Y$ of smooth curves is *unramified* if $\Omega_{X/Y} = 0$ (definition 2.7.19). For separable f this holds if and only if $R = 0$, since $\Omega_{X/Y,x} \cong \mathcal{O}_{X,x}/(h_x)$, and if and only if $e_x = 1$ for all $x \in X$, since $r_x = e_x - 1$ in the tame case and $r_x \geq e_x \geq 2$ in the wild case. A nonconstant finite morphism between smooth curves over a field is flat[4], so an unramified finite morphism is *étale*. For separable f with $R = 0$, Hurwitz's formula reads $2g_X - 2 = n(2g_Y - 2)$.

[4] A finite torsion-free module over a Dedekind domain is flat. Flatness also follows from the miracle flatness theorem in dimension 1.

Corollary 7.4.9: Étale Covers and Genus

Let $f\colon X \to Y$ be a finite étale morphism of complete nonsingular curves of degree n.

1. If $g_Y = 0$, then $2g_X - 2 = -2n < 0$, which is impossible for $n \geq 2$ (since $g_X \geq 0$). So $\mathbb{P}^1$ has no nontrivial finite étale covers: $\mathbb{P}^1$ is *simply connected* in the algebraic sense.
2. If $g_Y = 1$, then $g_X = 1$ as well. Étale covers of elliptic curves have genus 1.
3. If $g_Y \geq 2$, then $g_X = n(g_Y - 1) + 1$, and $g_X > g_Y$ when $n \geq 2$. A nontrivial cover has strictly larger genus.

***Proof*:**
By definition 2.7.19, $\Omega_{X/Y} = 0$.

Step 1: f is separable. Let $\operatorname{Spec} A \subseteq Y$ be a nonempty affine open. As f is finite, $f^{-1}(\operatorname{Spec} A) = \operatorname{Spec} B$ with $A \subseteq B$ domains whose fraction fields are $K(Y)$ and $K(X)$. By proposition 5.5.15, $\Omega_{B/A} \cong \Omega_{X/Y}(\operatorname{Spec} B) = 0$. With $S = B \setminus \{0\}$, [17, Base Change For Differentials] gives $\Omega_{K(X)/A} \cong S^{-1}\Omega_{B/A} = 0$. The universal derivation $d\colon K(X) \to \Omega_{K(X)/A}$ vanishes on $K(Y)$, since for $a, b \in A$ with $b \neq 0$ we have $b\,d(a/b) = d(a) - (a/b)\,d(b) = 0$. So d is a $K(Y)$-derivation, the universal properties identify $\Omega_{K(X)/K(Y)}$ with $\Omega_{K(X)/A}$, and $\Omega_{K(X)/K(Y)} = 0$. The extension $K(X)/K(Y)$ is finite of degree n, so it has transcendence degree 0, and proposition 5.5.9 shows that it is separably generated, that is, separable algebraic.

Step 2: $R = 0$. Let $x \in X$ be a closed point and $y = f(x)$, which is closed, f being finite and hence closed (corollary 3.4.24), and let s and t be uniformizers of $\mathcal{O}_{X,x}$ and $\mathcal{O}_{Y,y}$. These local rings are localizations of finitely generated k-algebras at maximal ideals, with residue field k since k is algebraically closed, so proposition 5.5.10 applies to them. By proposition 5.5.25, $\Omega_{X/k,x}$ is free of rank one over $\mathcal{O}_{X,x}$. By proposition 5.5.10, the class of ds generates $\Omega_{X/k,x} \otimes_{\mathcal{O}_{X,x}} k \cong \mathfrak{m}_x/\mathfrak{m}_x^2$, so ds generates $\Omega_{X/k,x}$ by Nakayama's lemma, and in the same way dt generates $\Omega_{Y/k,y}$. The cotangent sequence (proposition 5.5.17) for $X \to Y \to \operatorname{Spec} k$ is exact, $f^*\Omega_{Y/k} \to \Omega_{X/k} \to \Omega_{X/Y} = 0$. At x its first map sends the generator $dt \otimes 1$ of $(f^*\Omega_{Y/k})_x = \Omega_{Y/k,y} \otimes_{\mathcal{O}_{Y,y}} \mathcal{O}_{X,x}$ to $f^*(dt) = d(f^\#(t))$, which therefore generates $\Omega_{X/k,x} = \mathcal{O}_{X,x}\,ds$. So $f^*(dt) = v\,ds$ with $v \in \mathcal{O}_{X,x}^\times$, and $r_x = \nu_x(v) = 0$ (definition 7.4.3). Hence $R = 0$.

Step 3: the genus relation. By Steps 1 and 2, theorem 7.4.5 applies with $\deg R = 0$ and gives $2g_X - 2 = n(2g_Y - 2)$.

1. If $g_Y = 0$, then $2g_X - 2 = -2n$, and $g_X \geq 0$ forces $n \leq 1$, so a finite étale cover of $\mathbb{P}^1$ has degree one.
2. If $g_Y = 1$, then $2g_X - 2 = 0$ and $g_X = 1$.
3. If $g_Y \geq 2$, then $g_X = n(g_Y - 1) + 1$, which for $n \geq 2$ is at least $2g_Y - 1 > g_Y$, as claimed.

Corollary 7.4.9(1) holds in every characteristic and is the algebraic counterpart of the topological fact $\pi_1(\mathbb{P}^1(\mathbb{C})) = 0$ (the Riemann sphere is simply connected). Corollary 7.4.9(2) matches $\pi_1(E(\mathbb{C})) \cong \mathbb{Z}^2$,

which has a finite quotient of every order. The multiplication-by-n maps of an elliptic curve with $\mathrm{char} k \nmid n$, treated in section 7.6, are examples.

7.4.10 Forward Reference: The Étale Fundamental Group The étale fundamental group $\pi_1^{\text{ét}}(X, \overline{x})$ is the profinite group classifying finite étale covers of X (see box 3.1.19 for an earlier preview). For X connected and of finite type over $\mathbb{C}$, it is the *profinite completion* of the topological fundamental group,

$$\pi_1^{\text{ét}}(X_{\mathbb{C}}) \;\cong\; \widehat{\pi_1^{\text{top}}(X(\mathbb{C}))}$$

by [21, Comparison with the topological fundamental group]. For projective X the comparison rests on GAGA (theorem 6.9.2), applied to the finite covering spaces of $X(\mathbb{C})$. For a curve of genus g, π_1^{top} is the surface group with $2g$ generators $a_1, b_1, \ldots, a_g, b_g$ and the single relation $\prod_{i=1}^{g} a_i b_i a_i^{-1} b_i^{-1} = 1$. Over fields that are not algebraically closed and over arithmetic bases, the étale fundamental group also records Galois-theoretic information: for the spectrum of a field it is the absolute Galois group of that field. The theory is developed in *Étale Cohomology* [21].

Hurwitz's formula has an arithmetic counterpart. Let L/K be a finite extension of number fields with $[L : K] = n$, and consider the associated map of spectra of rings of integers

$$\pi \colon \operatorname{Spec} \mathcal{O}_L \;\longrightarrow\; \operatorname{Spec} \mathcal{O}_K$$

The scheme $\operatorname{Spec} \mathcal{O}_K$ is not a curve in the sense of definition 7.1.1: it is of finite type over $\operatorname{Spec} \mathbb{Z}$, not over a field, and no genus is attached to it in the same way. The local structure of π follows the geometric pattern. For each nonzero prime $\mathfrak{p}$ of $\mathcal{O}_K$, the fiber $\pi^{-1}(\mathfrak{p})$ consists of primes $\mathfrak{q}_1, \ldots, \mathfrak{q}_r$ of $\mathcal{O}_L$ with ramification indices e_i and residue field degrees f_i satisfying the fundamental identity

$$\sum_{i=1}^{r} e_i f_i \;=\; n$$

the analogue of proposition 7.1.9. The *different* $\mathfrak{d}_{L/K}$ is the analogue of the ramification divisor R. It is the annihilator of the $\mathcal{O}_L$-module $\Omega_{\mathcal{O}_L/\mathcal{O}_K}$, as R is cut out by the annihilator of $\Omega_{X/Y}$, and its norm is the *discriminant* $\Delta_{L/K}$, an ideal of $\mathcal{O}_K$ playing the role of the branch divisor $B = f_*(R)$ [83, Chapter III, Proposition (2.7) and Theorem (2.9)]. If $\mathfrak{q}_i^{s_i}$ is the exact power of $\mathfrak{q}_i$ dividing $\mathfrak{d}_{L/K}$, then

$$v_{\mathfrak{p}}(\Delta_{L/K}) \;=\; \sum_{i=1}^{r} f_i s_i$$

with $s_i = e_i - 1$ when $\mathfrak{q}_i$ is tamely ramified and $s_i \geq e_i$ when it is wildly ramified [83, Chapter III, Theorem (2.6)]. In the tame case the exponent of $\mathfrak{p}$ in $\Delta_{L/K}$ is therefore $\sum_i f_i(e_i - 1)$, which matches the coefficient $\sum_{f(x)=y}(e_x - 1)$ of y in the branch divisor of a tamely ramified morphism of curves, where every residue degree is 1. In the wild case the exponent is larger, as $r_x \geq e_x$ is in the geometric setting.

Under this correspondence, number fields play the role of function fields of curves over finite fields, primes the role of closed points, and the discriminant the role of the branch divisor.

7.5 Hyperelliptic Curves

By theorem 7.3.8, the canonical map $\varphi_K\colon X \to \mathbb{P}^{g-1}$ of a curve of genus $g \geq 2$ is either a closed immersion or a 2-to-1 map onto a rational normal curve, and the curves of the second kind are the hyperelliptic curves (proposition 7.5.2). When $\mathrm{char} k \neq 2$, every hyperelliptic curve has an affine model $y^2 = f(x)$ (proposition 7.5.4), and much of the classical theory of curves was developed on such models.

Definition 7.5.1: Hyperelliptic Curve

A complete nonsingular curve X of genus $g \geq 2$ over $k = \overline{k}$ is *hyperelliptic* if there exists a finite morphism $\varphi\colon X \to \mathbb{P}^1$ of degree 2.

The condition $g \geq 2$ excludes $\mathbb{P}^1$, which maps to itself with degree 2 by $[s:t] \mapsto [s^2:t^2]$, and the curves of genus 1, which map to $\mathbb{P}^1$ with degree 2 by the complete linear system $|2O|$ of any closed point O (a base-point-free pencil by proposition 7.3.3) and are treated in section 7.6.

Proposition 7.5.2: Characterizations of Hyperelliptic Curves

Let X be a complete nonsingular curve of genus $g \geq 2$ over $k = \overline{k}$. The following are equivalent:

1. X is hyperelliptic (there exists a degree-2 morphism $X \to \mathbb{P}^1$).
2. There exist two closed points $P, Q \in X$ (possibly equal) with $\ell(P+Q) \geq 2$, that is, X admits a g^1_2 (a linear system of degree 2 and dimension 1).
3. The canonical linear system $|K_X|$ is *not* very ample.
4. The canonical map $\varphi_K\colon X \to \mathbb{P}^{g-1}$ is not a closed immersion.

Moreover, when these conditions hold, the g^1_2 is unique: any two degree-2 maps $X \to \mathbb{P}^1$ differ by an automorphism of $\mathbb{P}^1$.

***Proof*:**

(1) $\Rightarrow$ (2): A degree-2 morphism $\varphi\colon X \to \mathbb{P}^1$ corresponds to a base-point-free linear system of degree 2 and dimension 1. Taking $P + Q = \varphi^*(y)$ for some $y \in \mathbb{P}^1$, we get $\ell(P+Q) \geq 2$.

(2) $\Rightarrow$ (1): This is theorem 7.3.8(3).

(1) $\Leftrightarrow$ (3): The proof of theorem 7.3.8(2) shows that $\ell(K) - \ell(K - P - Q) = 3 - \ell(P+Q)$ for all closed points P, Q, so $|K|$ fails to be very ample precisely when there exist P, Q (possibly $P = Q$) with $\ell(P+Q) \geq 2$. That is condition (2), which is equivalent to (1).

(3) $\Leftrightarrow$ (4): A line bundle is very ample if and only if the associated morphism is a closed immersion.

Uniqueness of the g^1_2: Let $f, f'\colon X \to \mathbb{P}^1$ be two degree-2 morphisms, and let s, t be the pullbacks under f of the homogeneous coordinates of $\mathbb{P}^1$, so that $f = [s:t]$. The proof of theorem 7.3.8(3), applied to the g^1_2 defined by f, shows that the g monomials $s^{g-1}, s^{g-2}t, \ldots, t^{g-1}$ form a basis of $H^0(X, \omega_X)$. In this basis $\varphi_K = \nu_{g-1} \circ f$, where $\nu_{g-1}\colon \mathbb{P}^1 \to \mathbb{P}^{g-1}$ is the Veronese embedding of

degree $g-1$ (definition 3.1.38). The same holds for f' in a second basis of $H^0(X,\omega_X)$. Two bases differ by an invertible matrix, so $\nu_{g-1}\circ f' = A\circ\nu_{g-1}\circ f$ for a projective linear automorphism A of $\mathbb{P}^{g-1}$. Both f and f' are surjective, so A maps the rational normal curve $R=\nu_{g-1}(\mathbb{P}^1)$ onto itself, and $\alpha = \nu_{g-1}^{-1}\circ A|_R\circ\nu_{g-1}$ is an automorphism of $\mathbb{P}^1$ with $f'=\alpha\circ f$, completing the proof.

For the rest of section 7.5, assume $\mathrm{char}k\neq 2$. Let $\varphi\colon X\to\mathbb{P}^1$ have degree 2. The extension $K(X)/K(\mathbb{P}^1)=K(X)/k(t)$ is then separable, since a generator has minimal polynomial $T^2+c_1T+c_0$, whose derivative $2T+c_1$ is nonzero. A separable quadratic extension is Galois with group $\mathbb{Z}/2\mathbb{Z}$, and by the anti-equivalence between complete nonsingular curves and their function fields (theorem 7.1.4) its nontrivial automorphism is induced by an automorphism of X over $\mathbb{P}^1$.

Definition 7.5.3: Hyperelliptic Involution

Let X be a hyperelliptic curve with g^1_2 given by $\varphi\colon X\to\mathbb{P}^1$. The *hyperelliptic involution* is the unique nontrivial automorphism $\iota\colon X\to X$ such that $\varphi\circ\iota=\varphi$. Equivalently, ι is the nontrivial element of $\mathrm{Gal}(K(X)/k(t))\cong\mathbb{Z}/2\mathbb{Z}$. The ramification points of φ are the *Weierstrass points* of X.

For each closed point $y\in\mathbb{P}^1$, the fiber $\varphi^{-1}(y)$ is either two distinct points $\{x,\iota(x)\}$ (when $e_x=1$) or a single point fixed by ι (when $e_x=2$, a ramification point), since the Galois group acts transitively on the points over y. So the fixed points of ι are exactly the Weierstrass points. Since $\mathrm{char}k\neq 2$, Hurwitz's formula (theorem 7.4.5) holds in its tame form:

$$2g-2 = 2(0-2)+\sum(e_x-1) = -4+b$$

where b is the number of ramification points. Therefore $b=2g+2$, and a hyperelliptic curve of genus g has exactly $2g+2$ Weierstrass points.

The hyperelliptic structure gives an explicit affine model. Let y_0 generate $K(X)$ over $k(t)$, with $y_0^2+c_1y_0+c_0=0$ for some $c_0,c_1\in k(t)$. Completing the square gives $(y_0+c_1/2)^2=c_1^2/4-c_0$, and writing $c_1^2/4-c_0=fh^2$ with $f\in k[t]$ squarefree and $h\in k(t)^\times$, the element $y=(y_0+c_1/2)/h$ generates $K(X)$ over $k(t)$ and satisfies $y^2=f(t)$. The polynomial f is not constant, since k is algebraically closed and $y\notin k(t)$. The degree of f is determined by the genus:

Proposition 7.5.4: Weierstrass Models

Let X be a hyperelliptic curve of genus g over k with $\mathrm{char}k\neq 2$. Then X is birational to the affine curve

$$y^2=f(x),\qquad f\in k[x],\quad \deg f\in\{2g+1,2g+2\},\quad f\text{ squarefree}$$

Conversely, for every $g\geq 2$ and every squarefree $f\in k[x]$ of degree $2g+1$ or $2g+2$, the complete nonsingular curve with function field $k(x)[y]/(y^2-f(x))$ has genus g and is hyperelliptic. The two cases are related by a change of variable at infinity:

1. $\deg f=2g+1$: there is a single point at infinity, which is a Weierstrass point (a ramification point of φ).
2. $\deg f=2g+2$: there are two points at infinity, neither of which is a Weierstrass point (the map φ is unramified at infinity).

***Proof*:**
Let $f \in k[x]$ be squarefree and nonconstant of degree d, let $m = \lceil d/2 \rceil$, and let X be the complete nonsingular curve with function field $K = k(x)[y]/(y^2 - f(x))$, which is a field because f is not a square in $k(x)$. The construction above produces such an f for every hyperelliptic X, so it suffices to show that X has genus $m-1$ and to locate the ramification of $\varphi = x \colon X \to \mathbb{P}^1$.

Step 1: two affine charts. The affine curve $U = \operatorname{Spec} k[x,y]/(y^2 - f(x))$ is integral with function field K. By proposition 2.7.7, U is singular at a closed point (a,b) only if $2b = 0$ and $f'(a) = 0$. Then $f(a) = b^2 = 0$, so a would be a repeated root of f, and hence U is nonsingular. Put $u = 1/x$ and $v = yu^m$. Then $v^2 = F(u)$ with $F(u) = u^{2m} f(1/u) \in k[u]$, whose roots are the inverses of the nonzero roots of f together with $u = 0$ when $d = 2m-1$, all simple. So F is squarefree and $V = \operatorname{Spec} k[u,v]/(v^2 - F(u))$ is nonsingular by the same argument. Each of U and V is an open subscheme of its projective completion (theorem 7.1.3), which is a complete nonsingular curve with function field K and hence isomorphic to X (theorem 7.1.4(3)). So U and V are open in X, in particular X is birational to U, and on these charts φ is $(x,y) \mapsto [x:1]$ and $(u,v) \mapsto [1:u]$ respectively.

Step 2: ramification. For every closed point $z \in \mathbb{P}^1$, the ramification indices of the points over z sum to $\deg \varphi^*(z) = 2$ (proposition 7.1.9). Over $x = a$ with $f(a) \neq 0$, the chart U contains the two points $(a, \pm\sqrt{f(a)})$, distinct because $\operatorname{char} k \neq 2$, so both are unramified. Over a root a of f, write $f = (x-a)q(x)$ with $q(a) \neq 0$. In the local ring of U at $(a,0)$ we have $x - a = y^2/q(x)$ with $q(x)$ a unit, so the maximal ideal $(x-a, y)$ is generated by y, and $x - a$ has valuation 2. So $e_{(a,0)} = 2$, and $(a,0)$ is the only point over a. The same two computations in the chart V over $u = 0$ show that φ has two unramified points over ∞ when $F(0) \neq 0$, that is, when $d = 2m$, and a single ramification point over ∞ when $d = 2m-1$.

Step 3: the genus. The ramification points are the d roots of f, together with the point at infinity when d is odd, so there are $b = 2m$ of them. As $\operatorname{char} k \neq 2$, the tame form of theorem 7.4.5 gives $2g(X) - 2 = 2(0-2) + 2m$, so $g(X) = m - 1$. Hence $g(X) = g$ exactly when $d \in \{2g+1, 2g+2\}$, and for $g \geq 2$ the map φ makes X hyperelliptic. Step 2 gives the description of the points at infinity, as we sought to show.

Example 7.5.5: Hyperelliptic Curves in Practice

1. Every curve of genus 2 is hyperelliptic (example 7.3.7). By proposition 7.5.4, X has a model $y^2 = f(x)$ with f squarefree of degree 5 or 6, for instance $y^2 = x^5 - x$.
2. A hyperelliptic curve of genus 3 has a model $y^2 = f(x)$ with f squarefree of degree 7 or 8. Its canonical map is $X \xrightarrow{2:1} \mathbb{P}^1 \xrightarrow{\nu_2} \mathbb{P}^2$, with ν_2 the Veronese embedding, so $\varphi_K(X)$ is a conic in $\mathbb{P}^2$. A curve of genus 3 that is not hyperelliptic is a smooth quartic in $\mathbb{P}^2$ (example 7.3.7).
3. Over a finite field $\mathbb{F}_q$ with q odd, an equation $y^2 = f(x)$ with $f \in \mathbb{F}_q[x]$ squarefree defines a curve over $\mathbb{F}_q$, and its number of $\mathbb{F}_q$-points obeys Weil's bound (theorem 8.7.12, proved in chapter 8). The groups of $\mathbb{F}_q$-points of the Jacobians of such curves are used in discrete-logarithm cryptography.

Let D_0 be a divisor in the unique g^1_2, for instance $D_0 = \varphi^*(y)$ for a closed point $y \in \mathbb{P}^1$, so that $\deg D_0 = 2$ and $\ell(D_0) = 2$.

Proposition 7.5.6: Canonical Class of a Hyperelliptic Curve

$K_X \sim (g-1)D_0$. In particular, the canonical linear system is $|K_X| = |(g-1)D_0|$.

***Proof*:**
By theorem 7.3.8(3) applied to $D_0 = P + Q$, $K_X \sim (g-1)D_0$, and linearly equivalent divisors have the same complete linear system, as claimed.

The canonical map therefore factors as

$$X \xrightarrow[2:1]{\varphi} \mathbb{P}^1 \xhookrightarrow{\nu_{g-1}} \mathbb{P}^{g-1}, \qquad \varphi_K = \nu_{g-1} \circ \varphi$$

where $\nu_{g-1}\colon \mathbb{P}^1 \hookrightarrow \mathbb{P}^{g-1}$ is the Veronese embedding of degree $g-1$ (definition 3.1.38), mapping $[s:t] \mapsto [s^{g-1} : s^{g-2}t : \cdots : t^{g-1}]$. The image $\nu_{g-1}(\mathbb{P}^1) \subseteq \mathbb{P}^{g-1}$ is the rational normal curve of degree $g-1$, and $\varphi_K(X)$ is this rational normal curve, with φ_K being 2-to-1 onto it.

7.6 Elliptic Curves

A curve of genus 1 with a chosen k-point carries a group law, and this section derives it from Riemann-Roch. Section 5.4 identified Pic^0 of a complex elliptic curve $\mathbb{C}/\Lambda$ with the curve itself through Abel's theorem, and example 4.1.12 recorded that elliptic curves are group schemes. Here the identification $E(k) \cong \mathrm{Pic}^0(E)$ is proved over an arbitrary algebraically closed field.

Definition 7.6.1: Elliptic Curve

An *elliptic curve* over k is a pair (E, O) where E is a complete nonsingular curve of genus 1 over k, and $O \in E(k)$ is a chosen k-rational point, called the *origin* or *identity*.

Over $k = \overline{k}$ every closed point is a k-point, so every curve of genus 1 becomes an elliptic curve once a point is chosen. Over a field that is not algebraically closed, a curve of genus 1 can have no k-point at all[5], and it is then not an elliptic curve over k.

Proposition 7.6.2: Elliptic Curves are Plane Cubics

Let (E, O) be an elliptic curve over k. Then the complete linear system $|3O|$ is very ample and embeds E as a smooth cubic curve in $\mathbb{P}^2_k$.

***Proof*:**
Since $g = 1$, proposition 7.3.1 gives $\deg K_E = 2g - 2 = 0$ and $\ell(K_E) = g = 1$, so $K_E \sim 0$ by lemma 7.2.2(2), that is, $\omega_E \cong \mathcal{O}_E$. Hence $\ell(K_E - D) = \ell(-D) = 0$ whenever $\deg D > 0$ (lemma 7.2.2(1)), and Riemann-Roch (theorem 7.2.10) gives $\ell(nO) = n + 1 - 1 = n$ for every

[5] For example, the Selmer curve $3x^3 + 4y^3 + 5z^3 = 0$ in $\mathbb{P}^2_{\mathbb{Q}}$ has genus 1 and no $\mathbb{Q}$-rational point, a theorem of Selmer. It is a *torsor* (principal homogeneous space) for its Jacobian, an elliptic curve over $\mathbb{Q}$ with its natural origin (section 7.7.2).

$n \geq 1$. In particular $\ell(O) = 1$, $\ell(2O) = 2$ and $\ell(3O) = 3$. As $\deg(3O) = 3 = 2g+1$, corollary 7.3.4 shows that $|3O|$ is very ample, so it defines a closed immersion $E \hookrightarrow \mathbb{P}_k^{\ell(3O)-1} = \mathbb{P}_k^2$. Its image is isomorphic to E, hence nonsingular, and has degree $\deg(3O) = 3$, so it is a smooth plane cubic, as claimed.

In coordinates, the embedding comes from functions with poles only at O:

- $H^0(E, \mathcal{L}(O))$ is spanned by the constant function 1, since $\ell(O) = 1$.
- Since $\ell(2O) = 2 > \ell(O)$, there is a function $x \in H^0(E, \mathcal{L}(2O))$ with a pole of order exactly 2 at O and no other poles, and $1, x$ is a basis.
- Since $\ell(3O) = 3 > \ell(2O)$, there is a function $y \in H^0(E, \mathcal{L}(3O))$ with a pole of order exactly 3 at O, and $1, x, y$ is a basis.

The space $H^0(E, \mathcal{L}(6O))$ has dimension $\ell(6O) = 6$ and contains the seven functions $1, x, y, x^2, xy, x^3, y^2$, whose pole orders at O are $0, 2, 3, 4, 5, 6, 6$. So they satisfy a nontrivial linear relation. Functions with distinct pole orders are linearly independent, so both x^3 and y^2 occur in the relation with nonzero coefficients. Replacing x and y by suitable nonzero scalar multiples and dividing by a constant puts the relation in the form

$$y^2 + a_1xy + a_3y \;=\; x^3 + a_2x^2 + a_4x + a_6 \tag{7.6}$$

This is the *generalized Weierstrass equation*. In the basis $1, x, y$ of $H^0(E, \mathcal{L}(3O))$, the embedding of proposition 7.6.2 is $P \mapsto [x(P) : y(P) : 1]$, its image is the plane cubic obtained by homogenizing (7.6) with a variable z, and O maps to $[0 : 1 : 0]$.

When $\mathrm{char} k \neq 2$, completing the square in y removes the xy and y terms. Grouping the y terms on the left gives

$$y^2 + (a_1x + a_3)y = x^3 + a_2x^2 + a_4x + a_6$$

and adding $\left(\frac{a_1x+a_3}{2}\right)^2$ to both sides gives

$$\left(y + \frac{a_1x + a_3}{2}\right)^2 = x^3 + a_2x^2 + a_4x + a_6 + \frac{(a_1x + a_3)^2}{4}$$

With $y_1 = y + \frac{a_1x+a_3}{2}$, expanding the right side and grouping by powers of x yields

$$y_1^2 = x^3 + \left(a_2 + \frac{a_1^2}{4}\right)x^2 + \left(a_4 + \frac{a_1a_3}{2}\right)x + \left(a_6 + \frac{a_3^2}{4}\right)$$

Call the new coefficients a_2', a_4' and a_6', so that the equation becomes

$$y_1^2 = x^3 + a_2'x^2 + a_4'x + a_6'$$

If also $\mathrm{char} k \neq 3$, the substitution $x = x_1 - \frac{a_2'}{3}$ completes the cube in x:

$$y_1^2 = \left(x_1 - \frac{a_2'}{3}\right)^3 + a_2'\left(x_1 - \frac{a_2'}{3}\right)^2 + a_4'\left(x_1 - \frac{a_2'}{3}\right) + a_6'$$

Expanding the cubic and quadratic terms gives

$$y_1^2 = \left(x_1^3 - a_2'x_1^2 + \frac{a_2'^2}{3}x_1 - \frac{a_2'^3}{27}\right) + \left(a_2'x_1^2 - \frac{2a_2'^2}{3}x_1 + \frac{a_2'^3}{9}\right) + a_4'\left(x_1 - \frac{a_2'}{3}\right) + a_6'$$

The x_1^2 terms cancel, and grouping the remaining coefficients of x_1 and the constants leaves an equation of the form

$$y_1^2 = x_1^3 + Ax_1 + B$$

Dropping the subscripts, this transforms (7.6) into the *short Weierstrass form*

$$y^2 = x^3 + Ax + B, \qquad \Delta = -16(4A^3 + 27B^2) \neq 0$$

The condition $\Delta \neq 0$ is equivalent to the cubic having no repeated roots, which is equivalent to the curve being nonsingular. In characteristic 2 completing the square divides by 2, and in characteristic 3 completing the cube divides by 3, so there the short form is not available in general and one works with (7.6).

The group structure on $E(k)$ comes from the theory of divisors, by identifying $E(k)$ with $\mathrm{Pic}^0(E)$ through $P \mapsto [P - O]$.

Theorem 7.6.3: The Group Law on an Elliptic Curve

Let (E, O) be an elliptic curve over $k = \overline{k}$. The map

$$\sigma\colon E(k) \to \mathrm{Pic}^0(E), \qquad P \mapsto \text{class of } [P] - [O]$$

is a bijection. Transporting the group structure from $\mathrm{Pic}^0(E)$ to $E(k)$, the curve E becomes an abelian group with identity O, where:

1. The addition law $P + Q = R$ is characterized by $[P] + [Q] - [R] \sim [O]$. In the embedding of proposition 7.6.2, let R' be the third point of intersection of E with the line through P and Q (the tangent line if $P = Q$), so that $P + Q + R' \sim 3O$. Then R is the third point of intersection of E with the line through R' and O (the tangent line at O if $R' = O$).
2. The inverse $-P$ is the third point of intersection of E with the line through P and O (the tangent line at O if $P = O$).
3. The maps $+\colon E \times E \to E$ and $[-1]\colon E \to E$ are morphisms of k-schemes.

In particular, (E, O) is a group scheme over k (definition 4.1.1).

***Proof*:**

As in the proof of proposition 7.6.2, $K_E \sim 0$, so Riemann-Roch reads $\ell(D) = \deg D + \ell(-D)$, and $\ell(-D) = 0$ when $\deg D > 0$.

Bijectivity of σ: Injectivity: if $[P - O] = [Q - O]$ in $\mathrm{Pic}^0(E)$, then $P \sim Q$, so P is an effective divisor in the complete linear system $|Q|$. But $\ell(Q) = 1 + \ell(-Q) = 1$, so $|Q|$ has dimension $\ell(Q) - 1 = 0$ and consists of exactly one effective divisor, which is Q itself. Thus $P = Q$.

Surjectivity: let $D \in \mathrm{Pic}^0(E)$, that is, D is a divisor of degree 0 modulo linear equivalence. Then $D + O$ has degree 1, so $\ell(D + O) = 1 + \ell(-D - O) = 1$, since $\deg(-D - O) = -1 < 0$. So $|D + O|$ contains a unique effective divisor, which is a single point P (an effective divisor of degree 1 on a curve is a single point). Thus $D + [O] \sim [P]$, that is, $D \sim [P] - [O] = \sigma(P)$.

The geometric addition law: The chord-tangent description in (1) follows from the fact that three collinear points P, Q, R' on the plane cubic satisfy $P + Q + R' \sim 3O$: they are the

intersection of E with a line L, and L is linearly equivalent to the line $z = 0$, which meets E in $3O$ because z corresponds to the section 1 of $\mathcal{L}(3O)$. From $P + Q + R' \sim 3O$ we get $\sigma(P) + \sigma(Q) = [P] + [Q] - 2[O] = [3O - R'] - 2[O] = [O] - [R']$, and we need $\sigma(R) = [O] - [R']$, that is, $[R] - [O] = [O] - [R']$, giving $R + R' \sim 2O$. The line through O and R' meets E in $O + R' + R''$ with $O + R' + R'' \sim 3O$, so $R'' \sim 2O - R' \sim R$ and $R'' = R$ by injectivity of σ. For (2), the line through P and O meets E in $P + O + R''$ with $P + O + R'' \sim 3O$, so $\sigma(R'') = [O] - [P] = -\sigma(P)$ and $R'' = -P$.

Morphism property: Part (3) is not proved here. On the model (7.6), the line through $P = (x_0, y_0)$ and O is $x = x_0$, so by (2) the map $[-1]$ is the restriction of the linear automorphism $[x : y : z] \mapsto [x : -y - a_1x - a_3z : z]$ of $\mathbb{P}^2$, which preserves E, so it is a morphism. The chord-tangent construction expresses the coordinates of $P + Q$ as rational functions of those of P and Q, and showing that these define a morphism on all of the surface $E \times E$ is a separate argument, given in [94, Theorem III.3.6]. A second route goes through the functor of points (section 3.3): the divisor-theoretic construction, carried out for T-valued points (definition 3.3.1), needs the relative Picard functor of theorem 23.6.14, and the Yoneda lemma (theorem 0.4.22) then produces the morphism $E \times E \to E$. Granting (3), (E, O) is a group scheme, completing the proof.

The group law on an elliptic curve is *commutative*, because $\mathrm{Pic}^0(E)$ is an abelian group. An elliptic curve is therefore a smooth, connected, projective group scheme of dimension 1 over k, that is, an abelian variety of dimension 1 (*Abelian Varieties* [8]).

The chord-tangent construction also applies to the smooth locus of an irreducible singular plane cubic, and there it produces a linear algebraic group. Elliptic curves are smooth by definition, so the singular objects here are called singular cubic curves.

Let $C \subseteq \mathbb{P}^2_k$ be an irreducible cubic curve with a singular point P_{sing}, and assume $\mathrm{char} k \neq 2, 3$. A line not contained in C meets C in three points counted with multiplicity, and with multiplicity at least 2 at each singular point. So P_{sing} is the only singular point, and a line through two smooth points of C (or tangent at one) meets C in a third point that is again smooth. The chord-tangent recipe of theorem 7.6.3 therefore makes sense on the smooth locus $C_{\mathrm{reg}} = C \setminus \{P_{\mathrm{sing}}\}$, with a chosen smooth point O as identity. What changes is compactness: C_{reg} is not proper. The identification with the Picard group survives once divisors are taken to be Cartier divisors: $P \mapsto [P - O]$ is a bijection from C_{reg} onto the group $\mathrm{Pic}^0(C)$ of degree-zero line bundles on C, and the group law it transports is the chord-tangent law ([50, Example II.6.11.4] for the cusp, [50, Exercise II.6.7] for the node). The resulting group depends on the singularity type:

1. Node ($C\colon y^2 = x^3 + x^2$, say): the normalization of C is $\mathbb{P}^1$, and C is obtained from it by identifying the two preimages of the node. Removing the singular point leaves $C_{\mathrm{reg}} \cong \mathbb{P}^1 \setminus \{0, \infty\} \cong \mathbb{G}_m = \mathrm{Spec}\, k[t, t^{-1}]$, the *multiplicative group* (example 4.1.5), and the group law on the smooth locus is isomorphic to $(k^\times, \cdot)$.
2. Cusp ($C\colon y^2 = x^3$): the normalization is $\mathbb{P}^1$ with a single preimage of the cusp, and removing the singular point gives $C_{\mathrm{reg}} \cong \mathbb{G}_a = \mathrm{Spec}\, k[t]$, the *additive group* (example 4.1.4). The group law on the smooth locus is isomorphic to $(k, +)$.

Along a degeneration of an elliptic curve to a nodal cubic, and of a nodal cubic to a cuspidal one, the group of smooth points changes as

$$\underbrace{E}_{\text{abelian variety}} \quad \rightsquigarrow \quad \underbrace{\mathbb{G}_m}_{\text{node}} \quad \rightsquigarrow \quad \underbrace{\mathbb{G}_a}_{\text{cusp}}$$

The same trichotomy classifies reduction. Let E be an elliptic curve over a local field K, say $K = \mathbb{Q}_p$, given by a minimal Weierstrass equation. Reducing its coefficients modulo p gives a cubic curve $\overline{E}$ over the residue field $\mathbb{F}_p$, and the reduction type of E is determined by $\overline{E}$ and its smooth locus $\overline{E}_{\mathrm{reg}}$ ([20, Reduction Types]):

1. *Good reduction:* $\overline{E}$ is smooth, and $\overline{E}_{\mathrm{reg}} = \overline{E}$ is an elliptic curve over $\mathbb{F}_p$.
2. *Multiplicative (semistable) reduction:* $\overline{E}$ has a node, and $\overline{E}_{\mathrm{reg}}$ becomes isomorphic to $\mathbb{G}_m$ over $\mathbb{F}_{p^2}$. The reduction is *split* when $\overline{E}_{\mathrm{reg}} \cong \mathbb{G}_m$ over $\mathbb{F}_p$ and *non-split* otherwise, in which case $\overline{E}_{\mathrm{reg}}$ is a twist of $\mathbb{G}_m$.
3. *Additive (unstable) reduction:* $\overline{E}$ has a cusp, and $\overline{E}_{\mathrm{reg}} \cong \mathbb{G}_a$.

The *Néron model* of E over $\mathbb{Z}_p$ is a smooth group scheme over $\mathbb{Z}_p$ with generic fiber E, and the identity component of its special fiber is $\overline{E}_{\mathrm{reg}}$ ([93, Corollary IV.9.1]). The *conductor* of E records the reduction type: its exponent at p is 0, 1, or at least 2 according as the reduction is good, multiplicative or additive [20, The Conductor via the Galois Representation].

Different Weierstrass equations can define isomorphic elliptic curves, and over $\overline{k}$ a single invariant determines the isomorphism class.

Definition 7.6.4: The j-Invariant

Let E be an elliptic curve over k with $\mathrm{char} k \neq 2, 3$, given in short Weierstrass form $y^2 = x^3 + Ax + B$. The *j-invariant* of E is

$$j(E) \;=\; -1728 \cdot \frac{(4A)^3}{\Delta} \;=\; -1728 \cdot \frac{64A^3}{-16(4A^3 + 27B^2)} \;=\; 1728 \cdot \frac{4A^3}{4A^3 + 27B^2}$$

With the factor $1728 = 12^3$, the j-invariant equals c_4^3/Δ, where c_4 and Δ are polynomials with integer coefficients in the a_i of (7.6) (for the short form, $c_4 = -48A$). The formula $j = c_4^3/\Delta$ defines j in every characteristic, including 2 and 3 [20, The c-Invariants, The j-Invariant].

Proposition 7.6.5: j-Invariant Classifies Elliptic Curves

Let $k = \overline{k}$ with $\mathrm{char} k \neq 2, 3$.

1. Two elliptic curves E_1, E_2 over k are isomorphic (as curves with marked point) if and only if $j(E_1) = j(E_2)$.
2. For every $j_0 \in k$, there exists an elliptic curve E over k with $j(E) = j_0$.

In other words, the j-invariant defines a bijection between isomorphism classes of elliptic curves over k and the elements of k.

***Proof*:**
By the reduction above, every elliptic curve over k has a short Weierstrass model.

(1) Let $E\colon y^2 = x^3 + Ax + B$ and $E'\colon y'^2 = x'^3 + A'x' + B'$, and let $\psi\colon E \to E'$ be an isomorphism with $\psi(O) = O'$. Pulling back along ψ maps $H^0(E', \mathcal{L}(nO'))$ isomorphically onto $H^0(E, \mathcal{L}(nO))$ for every n. So $\psi^* x' = \alpha x + r$ and $\psi^* y' = \beta y + sx + t$ with $\alpha, \beta \in k^\times$ and $r, s, t \in k$. Substituting

into $y'^2 = x'^3 + A'x' + B'$ and using $y^2 = x^3 + Ax + B$ gives a relation among $1, x, x^2, x^3, y, xy$, which have the distinct pole orders $0, 2, 4, 6, 3, 5$ at O and are therefore linearly independent. Comparing coefficients of xy, y, x^3 and x^2 gives $2\beta s = 0$, $2\beta t = 0$, $\beta^2 = \alpha^3$ and $s^2 = 3\alpha^2 r$. As $\mathrm{char} k \neq 2, 3$, this forces $s = t = 0$ and then $r = 0$, and with $u = \beta/\alpha$ we get $\alpha = u^2$ and $\beta = u^3$. The coefficients of x and 1 then give $A' = u^4 A$ and $B' = u^6 B$, so

$$j(E') = 1728 \cdot \frac{4(u^4A)^3}{4(u^4A)^3 + 27(u^6B)^2} = 1728 \cdot \frac{4A^3u^{12}}{(4A^3 + 27B^2)u^{12}} = j(E)$$

Conversely, suppose $j(E) = j(E')$. Then $A^3B'^2 = A'^3B^2$, and $j = 0$ exactly when $A = 0$, while $j = 1728$ exactly when $B = 0$. If $A = A' = 0$, then $BB' \neq 0$, and we choose u with $u^6 = B'/B$. If $B = B' = 0$, then $AA' \neq 0$, and we choose u with $u^4 = A'/A$. If $ABA'B' \neq 0$, we choose u with $u^4 = A'/A$. Then $u^{12} = (A'/A)^3 = (B'/B)^2$, so $u^6 = \pm B'/B$, and replacing u by iu with $i^2 = -1$ if necessary gives $u^6 = B'/B$ without changing u^4. In each case $A' = u^4A$ and $B' = u^6B$, and $[x : y : z] \mapsto [u^2x : u^3y : z]$ is an isomorphism $E \to E'$ sending O to O'.

(2) For $j_0 \neq 0, 1728$, take $A = 3j_0(1728 - j_0)$ and $B = 2j_0(1728 - j_0)^2$. Then $4A^3 = 108j_0^3(1728 - j_0)^3$ and $27B^2 = 108j_0^2(1728 - j_0)^4$, so $4A^3 + 27B^2 = 108 \cdot 1728\, j_0^2(1728 - j_0)^3 \neq 0$ and $j = j_0$. For $j_0 = 0$, take $y^2 = x^3 + 1$, and for $j_0 = 1728$, take $y^2 = x^3 + x$. Both are nonsingular because $\mathrm{char} k \neq 2, 3$, completing the proof.

Over a perfect field k of characteristic different from 2 and 3 that is not algebraically closed, equality of j-invariants is necessary but need not be sufficient for isomorphism over k. Two elliptic curves over k with the same j-invariant become isomorphic over $\overline{k}$, and the curves over k that become isomorphic to E over $\overline{k}$, the *twists* of E, are classified by $H^1(\mathrm{Gal}(\overline{k}/k), \mathrm{Aut}_{\overline{k}}(E))$ [20, Twists are Classified by H^1].

7.6.6 The j-Line as $\mathcal{M}_{1,1}$ Since elliptic curves over $\overline{k}$ are classified by a single invariant $j \in k$, the coarse moduli space of elliptic curves is the affine line: $\mathcal{M}_{1,1}^{\mathrm{coarse}} \cong \mathbb{A}^1_k$. Elliptic curves have nontrivial automorphisms (at least the inversion $[-1]$, and more at $j = 0$ and $j = 1728$ when $\mathrm{char} k \neq 2, 3$), so the fine moduli space does not exist as a scheme. It exists as a Deligne-Mumford stack $\mathcal{M}_{1,1}$, whose coarse space is $\mathbb{A}^1$, a basic example of a moduli stack in *Moduli, Deformation Theory, and Stacks* [27].

Theorem 7.6.3 identifies $E(k)$ with $\mathrm{Pic}^0(E)$. For a smooth projective curve X of genus g, the group $\mathrm{Pic}^0(X)$ is the group of k-points of an abelian variety $\mathrm{Jac}(X)$ of dimension g, called the *Jacobian* of X:

$$\mathrm{Jac}(X)(k) \;\cong\; \mathrm{Pic}^0(X)$$

For $g = 1$ with a marked point O, the Jacobian is isomorphic to (X, O) itself, and on k-points this is theorem 7.6.3. For $g \geq 2$, the *Abel-Jacobi map*

$$\alpha \colon X \hookrightarrow \mathrm{Jac}(X), \qquad P \mapsto [P - O] \quad \text{(for a choice of base point } O\text{)}$$

is a closed immersion, and every morphism from X to an abelian variety A sending O to 0 factors uniquely as $h \circ \alpha$ with $h \colon \mathrm{Jac}(X) \to A$ a homomorphism (the *Albanese property* of the Jacobian, proved over $\mathbb{C}$ in [4, Theorem 11.4.1]). The other facts are proved in [8, The Jacobian Is an Abelian Variety, The Jacobian of an Elliptic Curve, The Curve Embeds in Its Jacobian].

7.6.7 Forward Reference: The Picard Scheme and Moduli The group $\mathrm{Pic}^0(X)$ is the group of k-points of a scheme. For a projective, geometrically integral k-scheme X with a k-point, the relative Picard functor $T \mapsto \mathrm{Pic}(X_T)/\pi_T^*\mathrm{Pic}(T)$ is represented by a group scheme $\mathrm{Pic}_{X/k}$, the *Picard scheme* (theorem 23.6.14), and for a smooth projective curve its identity component $\mathrm{Pic}^0_{X/k}$ is an abelian variety, the Jacobian.
Through the Jacobian, curves give principally polarized abelian varieties: the Torelli map $X \mapsto (\mathrm{Jac}(X), \Theta)$, where Θ is the theta divisor, is injective on isomorphism classes of curves of genus $g \geq 1$ [8, The Torelli Theorem].
The Néron-Severi group $\mathrm{NS}(X) = \mathrm{Pic}(X)/\mathrm{Pic}^0(X)$ of a curve is isomorphic to $\mathbb{Z}$ through the degree. For surfaces and higher-dimensional varieties it is a finitely generated abelian group that can have large rank, and for surfaces it is studied in section 8.1.

The nonconstant morphisms between elliptic curves that respect the origins are the isogenies.

Definition 7.6.8: Isogeny

An *isogeny* $\varphi\colon E_1 \to E_2$ between elliptic curves is a morphism of schemes that sends O_1 to O_2 and is nonconstant (hence surjective and finite, by proposition 7.1.6).

Every isogeny is a homomorphism of group schemes, $\varphi(P+Q) = \varphi(P) + \varphi(Q)$ [20, Isogenies are Group Homomorphisms][6].

Proposition 7.6.9: Multiplication by n

For any integer $n \neq 0$, the map $[n]\colon E \to E$ defined by $P \mapsto \underbrace{P + P + \cdots + P}_{n}$ (and $[-n] = [n] \circ [-1]$) is a finite morphism of degree n^2.

The map $[n]$ is a morphism by theorem 7.6.3(3). That its degree is n^2 in every characteristic, including $\mathrm{char} k \mid n$, is proved in [20, Degree of the Multiplication Map]. In particular $[n]$ is nonconstant, hence finite and surjective by proposition 7.1.6.

The *n-torsion subgroup* $E[n]$ is the kernel of $[n]$. As a group scheme it is finite of order (rank) $\deg[n] = n^2$, and its structure depends on the characteristic:

[6] The argument is rigidity. The map $h(P,Q) = \varphi(P+Q) - \varphi(P) - \varphi(Q)$ is a morphism $E_1 \times E_1 \to E_2$ by theorem 7.6.3(3), and $h(P, O_1) = O_2$ for every P. By the rigidity lemma [8, Rigidity Lemma], $h(P,Q) = h(O_1, Q) = O_2$ for all P, Q.

Proposition 7.6.10: Structure of the n-Torsion

Let E be an elliptic curve over $k = \overline{k}$.

1. If $\mathrm{char} k \nmid n$ (including $\mathrm{char} k = 0$): $E[n](\overline{k}) \cong (\mathbb{Z}/n\mathbb{Z})^2$ as abstract groups (and $E[n]$ is an étale group scheme over k).
2. If $\mathrm{char} k = p$ and $n = p^m$: the group scheme $E[p^m]$ has rank p^{2m}, but its group of $\overline{k}$-points is either $E[p^m](\overline{k}) \cong \mathbb{Z}/p^m\mathbb{Z}$ (the *ordinary* case) or $E[p^m](\overline{k}) \cong \{0\}$ (the *supersingular* case), depending on the Hasse invariant of E. In the supersingular case, the group scheme is connected (supported entirely at the origin).

The statements about $\overline{k}$-points are [20, Structure of the n-Torsion, p-Torsion Structure]. For $n = p^m n'$ with $p \nmid n'$ they combine to give $E[n](\overline{k}) \cong E[p^m](\overline{k}) \times E[n'](\overline{k})$.

The *endomorphism ring* $\mathrm{End}(E) = \mathrm{Hom}(E, E)$, consisting of the isogenies $E \to E$ and the zero map, is a ring under addition and composition, and it has one of three forms:

Proposition 7.6.11: Endomorphism Ring of an Elliptic Curve

Let E be an elliptic curve over $k = \overline{k}$. Then $\mathrm{End}(E)$ is isomorphic to one of the following:

1. $\mathbb{Z}$ (the generic case).
2. An order in an imaginary quadratic field $\mathbb{Q}(\sqrt{-d})$ (the *complex multiplication* or *CM* case). Over $\mathbb{C}$, with $E \cong \mathbb{C}/\Lambda$, this occurs exactly when the ratio τ of a basis of Λ is an imaginary quadratic number.
3. An order in a definite quaternion algebra over $\mathbb{Q}$. This occurs only in characteristic $p > 0$, exactly for the *supersingular* elliptic curves, and for $k = \overline{\mathbb{F}}_p$ the order is maximal in the quaternion algebra ramified exactly at p and ∞.

These are [20, Classification of Endomorphism Rings (Algebraic), Endomorphism Ring of Supersingular Curves, Classification of Endomorphism Rings (Analytic)].

7.6.12 Forward Reference: The Tate Module and ℓ-adic Representations Let E be an elliptic curve over a perfect field k, not necessarily algebraically closed, and fix a prime $\ell \neq \mathrm{char} k$. The *$\ell$-adic Tate module* of E is the limit

$$T_\ell(E) \;=\; \varprojlim_m E[\ell^m](\overline{k}) \;\cong\; \mathbb{Z}_\ell^2$$

where the isomorphism comes from proposition 7.6.10(1). It is a free $\mathbb{Z}_\ell$-module of rank 2 carrying a continuous action of $\mathrm{Gal}(\overline{k}/k)$, and the resulting representation $\rho_\ell\colon \mathrm{Gal}(\overline{k}/k) \to \mathrm{GL}_2(\mathbb{Z}_\ell)$ is a basic example of an *ℓ-adic Galois representation*.
When $k = \mathbb{F}_q$ is a finite field, the Frobenius element $\mathrm{Frob}_q \in \mathrm{Gal}(\overline{\mathbb{F}}_q/\mathbb{F}_q)$ acts on $T_\ell(E)$ as the q-power Frobenius endomorphism of E does, with characteristic polynomial $t^2 - a_q t + q$, where $a_q = q + 1 - |E(\mathbb{F}_q)|$ [20, Characteristic Polynomial of Frobenius, Determinant of an Endomorphism]. The *Riemann hypothesis for elliptic curves over finite fields*, proved by Hasse, states that $|a_q| \leq 2\sqrt{q}$ [20, Hasse's Theorem], or equivalently that both roots of $t^2 - a_q t + q$ have absolute value $\sqrt{q}$. It is the genus-1 case of the Weil conjectures, which are developed, with Deligne's proof, in *Étale Cohomology* [21].
For a curve X of higher genus g, the Tate module is replaced by the ℓ-adic cohomology group $H^1_{\text{ét}}(X_{\overline{k}}, \mathbb{Z}_\ell)$, a free $\mathbb{Z}_\ell$-module of rank $2g$. The Riemann hypothesis part of the Weil conjectures, proved by Deligne for smooth projective varieties over $\mathbb{F}_q$ of every dimension, states that the eigenvalues of Frobenius on $H^i_{\text{ét}}(X_{\overline{\mathbb{F}}_q}, \mathbb{Q}_\ell)$ have absolute value $q^{i/2}$. For $i = 1$ and $X = E$ this is Hasse's bound.

Example 7.6.13: Elliptic Curves over Number Fields
If E is an elliptic curve over a number field K (for example $K = \mathbb{Q}$), the group $E(K)$ of K-rational points is a finitely generated abelian group by the *Mordell-Weil theorem* [20, The Mordell-Weil Theorem]:

$$E(K) \;\cong\; \mathbb{Z}^r \oplus E(K)_{\text{tors}}$$

where $r \geq 0$ is the *Mordell-Weil rank* and $E(K)_{\text{tors}}$ is finite. No algorithm is known that provably computes r for every E. The *Birch and Swinnerton-Dyer conjecture* (one of the Millennium Prize Problems) predicts that r equals the order of vanishing of the L-function $L(E, s)$ at $s = 1$.

7.7 Further Topics on Curves

Four topics complete the account of curves: Castelnuovo's bound on the genus of a curve in $\mathbb{P}^r$, the behavior of cohomology in families of curves, the stable curves that compactify the moduli of curves, and curves over fields that are not algebraically closed.

The embedding theorem corollary 7.3.4 embeds every curve in some projective space, but it does not say which pairs (d, g) of degree and genus occur for curves in a given $\mathbb{P}^r$. Castelnuovo's bound gives the largest genus of a nondegenerate curve of degree d in $\mathbb{P}^r$.

Theorem 7.7.1: Castelnuovo's Bound

Let $X \subseteq \mathbb{P}^r$, $r \geq 2$, be a nondegenerate curve of degree d, that is, a curve not contained in any hyperplane. Write $d-1 = m(r-1)+\epsilon$ with $0 \leq \epsilon \leq r-2$ (Euclidean division). Then:

$$g(X) \;\leq\; \pi(d,r) \;:=\; \binom{m}{2}(r-1) + m\epsilon$$

The bound $\pi(d,r)$ is called the *Castelnuovo bound*, and curves attaining it are called *Castelnuovo curves* or *curves of maximal genus*. The bound is attained for every $d \geq r$, and for $d \geq 2r+1$ every Castelnuovo curve lies on a surface of degree $r-1$ in $\mathbb{P}^r$, the least degree of an irreducible surface not contained in a hyperplane.

Example 7.7.2: Castelnuovo's Bound in Low Dimension

1. For plane curves ($r=2$), $d-1 = m\cdot 1 + 0$, so $\pi(d,2) = \binom{d-1}{2} = \frac{(d-1)(d-2)}{2}$, the genus of a smooth plane curve of degree d (proposition 7.2.6). So smooth plane curves are Castelnuovo curves.
2. For space curves ($r=3$), $d-1 = 2m+\epsilon$ with $\epsilon \in \{0,1\}$. For a curve of degree 6 in $\mathbb{P}^3$, $d-1 = 5 = 2\cdot 2+1$ gives $\pi(6,3) = \binom{2}{2}\cdot 2 + 2\cdot 1 = 4$. So a nondegenerate curve of degree 6 in $\mathbb{P}^3$ has genus at most 4, and the canonical curve of a non-hyperelliptic curve of genus 4, of degree $2g-2=6$ in $\mathbb{P}^{g-1}=\mathbb{P}^3$ (theorem 7.3.8), attains the bound.

The proof chooses a hyperplane section D of X whose d points are in linearly general position, bounds $\ell(nD) - \ell((n-1)D)$ from below for each $n \geq 1$, and compares the sum with Riemann-Roch for large n. The case $r=3$ is [50, Theorem IV.6.4], and the general case is [1, Chapter III]. The Hilbert schemes that parametrize curves in $\mathbb{P}^r$ are constructed in *Moduli, Deformation Theory, and Stacks* [27].

7.7.1 Riemann-Roch in Families and Semicontinuity

The cohomology of line bundles on curves can be studied in *families*. Let $f\colon \mathcal{X} \to S$ be a flat projective morphism of Noetherian schemes whose geometric fibers are smooth curves of genus g, and let $\mathcal{L}$ be a line bundle on $\mathcal{X}$. Each point $s \in S$ gives a curve $X_s = f^{-1}(s)$ and a line bundle $\mathcal{L}_s = \mathcal{L}|_{X_s}$, and the question is how $h^0(X_s, \mathcal{L}_s) = \ell(\mathcal{L}_s)$ varies with s.

The Euler characteristic is locally constant. Both $\mathcal{L}$ and $\mathcal{O}_{\mathcal{X}}$ are flat over S, so by theorem 6.8.17(2) the functions $s \mapsto \chi(\mathcal{L}_s)$ and $s \mapsto \chi(\mathcal{O}_{X_s}) = 1-g$ are locally constant on S, and hence so is $\deg \mathcal{L}_s = \chi(\mathcal{L}_s) - \chi(\mathcal{O}_{X_s})$, by Riemann-Roch on the geometric fibers. The individual dimensions $h^i(X_s, \mathcal{L}_s)$ can jump, in a controlled direction:

1. By theorem 6.8.17(1), the function $s \mapsto h^i(X_s, \mathcal{L}_s)$ is upper semicontinuous: for each n, the set where $h^i(X_s, \mathcal{L}_s) \geq n$ is closed in S.
2. Since $\chi(\mathcal{L}_s) = h^0(X_s, \mathcal{L}_s) - h^1(X_s, \mathcal{L}_s)$ is locally constant, h^0 jumps up at a point exactly when h^1 does.

Grauert's theorem (theorem 6.8.19) complements this: if S is reduced and $h^i(X_s, \mathcal{L}_s)$ is constant on S, then $R^i f_* \mathcal{L}$ is locally free of that rank and its formation commutes with every base change from a locally Noetherian scheme, so its fiber at s is $H^i(X_s, \mathcal{L}_s)$.

Example 7.7.3: Semicontinuity for Curves
Let $\mathcal{X} \to S$ be a family as above with $g = 3$ and S irreducible, and let $\mathcal{L}$ have degree 3 on each fiber. Then $\chi(\mathcal{L}_s) = 3 + 1 - 3 = 1$ for all s. Suppose $\mathcal{L}_s$ is non-special for some s, that is, $h^1(X_s, \mathcal{L}_s) = \ell(K - D_s) = 0$ for a divisor D_s with $\mathcal{L}_s \cong \mathcal{L}(D_s)$. Then by theorem 6.8.17(1), the locus where $h^1 \geq 1$ is a proper closed subset of S, and off it $h^0 = 1$. At its points D_s is special, $h^1 \geq 1$ and $h^0 = 1 + h^1 \geq 2$. The hypothesis cannot be dropped: if $\mathcal{L}_s \cong \omega_{X_s}(-P_s)$ for a point P_s of each fiber, then $h^0 = g - 1 = 2$ on every fiber by theorem 7.3.8(1), so every fiber is special. Loci of this kind, where h^0 of a line bundle of fixed degree jumps, are the subject of *Brill-Noether theory*.

7.7.4 Forward Reference: Deformation Theory of Curves The tangent space to the deformation functor of a smooth curve X of genus g is $H^1(X, T_X)$, where $T_X = \Omega^\vee_{X/k}$ is the tangent sheaf. By Serre duality, $H^1(X, T_X) \cong H^0(X, \omega_X^{\otimes 2})^\vee$, and by Riemann-Roch

$$\dim H^0(X, \omega_X^{\otimes 2}) = \begin{cases} 0 & \text{if } g = 0, \\ 1 & \text{if } g = 1, \\ 3g - 3 & \text{if } g \geq 2 \end{cases}$$

For $g \geq 2$ this is the dimension $3g - 3$ of the moduli space $\mathcal{M}_g$. The obstructions to deformation lie in $H^2(X, T_X)$, which vanishes because $\dim X = 1$, so deformations of X are unobstructed. *Moduli, Deformation Theory, and Stacks* [27] makes this precise with Schlessinger's theorem and the cotangent complex.

7.7.5 Singular Curves in Moduli: Stable Curves and $\overline{\mathcal{M}}_g$ The moduli space $\mathcal{M}_g$ of smooth curves of genus $g \geq 2$ is not compact: its coarse moduli space is not proper. A family of smooth curves can degenerate, with smooth fibers acquiring singularities. Semicontinuity (theorem 6.8.17) controls how cohomology jumps, and the arithmetic genus stays constant in a flat family, because $\chi(\mathcal{O}_{X_s})$ is locally constant by theorem 6.8.17(2), but the fibers leave the class of smooth curves.
Compactifying $\mathcal{M}_g$ requires parametrizing more curves. The *Deligne-Mumford compactification* $\overline{\mathcal{M}}_g$ adds the singular *stable curves*, where a stable curve is a connected complete curve X of arithmetic genus g whose only singularities are *nodes* (ordinary double points) and whose automorphism group $\mathrm{Aut}(X)$ is finite.
Three facts single out nodes:

1. A node has $\delta = 1$ (box 7.2.9), so a rational curve with g nodes has $p_a = g$, the genus of the smooth curves it can be a limit of. A cusp also has $\delta = 1$, but admitting cusps would make limits non-unique. By the stable reduction theorem [27, Stable Reduction], a family of smooth curves of genus $g \geq 2$ over the generic point of a discrete valuation ring extends, after a finite extension of the ring, to a family of stable curves, and this extension is unique. A family with a cuspidal special fiber therefore also has a second limit, a stable one, after such an extension.

2. On a nodal curve X of arithmetic genus $g \geq 2$, the dualizing sheaf ω_X° (definition 6.5.1) is an ample line bundle if and only if $\mathrm{Aut}(X)$ is finite. So stable curves are exactly the nodal curves for which ω_X° is a polarization.

3. In a family of plane cubics degenerating an elliptic curve, a nodal fiber has smooth locus $\mathbb{G}_m$ (multiplicative reduction) and a cuspidal fiber has smooth locus $\mathbb{G}_a$ (additive reduction), as described in section 7.6. For the action of SL_3 on plane cubics, the nodal cubic is semistable and the cuspidal cubic is unstable in the sense of geometric invariant theory [77, Chapter 4, §2], matching the names *semistable* and *unstable* reduction.

Moduli, Deformation Theory, and Stacks constructs $\overline{\mathcal{M}}_g$ as a proper Deligne-Mumford stack and proves, following Knudsen and Mumford, that its coarse moduli space is a projective variety [27, The Coarse Space $\overline{M}_g$ is a Projective Variety]. Of the singular curves in box 7.2.9 and example 5.4.37, the nodal cubic with a smooth point marked is the one curve that $\overline{\mathcal{M}}_{1,1}$ adds to $\mathcal{M}_{1,1}$, and the cuspidal cubic is not stable.

7.7.2 Curves over Non-Algebraically-Closed Fields

The standing assumption of this chapter is $k = \overline{k}$. Over a general field k, three things change.

1. Rational points may not exist. A smooth projective geometrically integral curve of genus 0 over k is isomorphic to a conic in $\mathbb{P}^2_k$, and it is isomorphic to $\mathbb{P}^1_k$ if and only if it has a k-rational point [66, Proposition 7.4.1]. Riemann-Roch over k [66, Theorem 7.3.26] gives $\ell(P) = [\kappa(P) : k]+1$ for a closed point P of such a curve, so the argument of proposition 7.3.6 produces an isomorphism with $\mathbb{P}^1_k$ exactly when some P has $\kappa(P) = k$. Over $\mathbb{Q}$, whether a conic has a rational point is decided by the Hasse-Minkowski theorem (the local-global principle).

2. A curve of genus 1 without a k-rational point is not an elliptic curve, as it has no origin for the

group law. Such a curve C is a *torsor* (principal homogeneous space) for its Jacobian E, and its class as an E-torsor is an element of the Galois cohomology group $H^1(k, E)$ [20]. For k a number field, the Shafarevich-Tate group $Ш(E/k)$ classifies the torsors that have a point over every completion of k.

3. Over imperfect fields, a regular scheme need not be smooth (example 2.7.16), which complicates the theory of differentials and the adjunction formula.

Over a finite field $\mathbb{F}_q$, the genus bounds the number of rational points of a curve: a smooth projective geometrically integral curve of genus g over $\mathbb{F}_q$ has between $q+1-2g\sqrt{q}$ and $q+1+2g\sqrt{q}$ rational points. This is Weil's theorem (theorem 8.7.12), proved in section 8.7 with the intersection theory of the product of the curve with itself over $\overline{\mathbb{F}}_q$.

Riemann-Roch, obtained from Serre duality, computed the dimensions $\ell(D)$ and gave the embeddings by linear systems (corollary 7.3.4 and theorem 7.3.8). Hurwitz's formula, obtained from the sheaf of differentials, related the genera of curves under finite maps (theorem 7.4.5), and semicontinuity controlled how h^0 and h^1 vary in families (section 7.7.1). The genus alone classifies curves only in genus 0 (proposition 7.3.6): elliptic curves vary with j (proposition 7.6.5), and curves of genus $g \geq 2$ have $3g-3$ moduli (box 7.7.4).

8

Application: Algebraic Surfaces

Two features separate surfaces from curves. First, a divisor on a surface is a formal sum of curves, and two curves without a common component meet in finitely many points. Counting those points with multiplicity extends to a symmetric bilinear pairing on the Picard group of the surface, the intersection pairing, which has no counterpart on a curve. It is the first case of the intersection product of *Intersection Theory* [26], which also proves the Hirzebruch-Riemann-Roch and Grothendieck-Riemann-Roch theorems. Second, birational equivalence no longer implies isomorphism. Two smooth projective curves with isomorphic function fields are isomorphic (theorem 7.1.4(3)), but blowing up a closed point of a smooth projective surface produces a smooth projective surface that is birational to the original and not isomorphic to it. The contraction of (-1)-curves to a minimal surface, which reverses such blow-ups, is the two-dimensional case of the minimal model program of *Birational Geometry* [12].

Section 8.1 studies the Picard and Néron-Severi groups of a surface, and section 8.2 constructs the intersection pairing from Euler characteristics and proves the adjunction formula. Section 8.3 proves the Riemann-Roch theorem for surfaces and the Hodge index theorem, which determines the signature of the pairing in every characteristic, and states Noether's formula. Over $\mathbb{C}$ the Néron-Severi group embeds in $H^2(X;\mathbb{Z})$, and *Hodge Theory* [24] proves the Lefschetz $(1,1)$-theorem, which describes the image, and the analytic form of the Hodge index theorem. Section 8.4 constructs blow-ups, computes the intersection pairing on the blow-up of a surface at a point, and gives Castelnuovo's criterion for contracting a smooth rational curve of self-intersection -1. Section 8.5 treats ruled and rational surfaces, and section 8.6 sorts minimal surfaces by Kodaira dimension in the Enriques-Kodaira classification. For a curve of genus g defined over $\mathbb{F}_q$, section 8.7 applies the Hodge index theorem on the product of the curve with itself to prove Weil's bound $|N-(q+1)| \leq 2g\sqrt{q}$ for the number N of its points over $\mathbb{F}_q$.

8.1 Surfaces and the Néron-Severi Group

The intersection pairing of section 8.2 is defined on $\mathrm{Pic}\,(X)$, and it depends only on the image of a class in the Néron-Severi group $\mathrm{NS}(X)$, the quotient of $\mathrm{Pic}\,(X)$ by the classes algebraically equivalent to zero. This section defines surfaces, introduces the surfaces $\mathbb{P}^2$, $\mathbb{P}^1 \times \mathbb{P}^1$, the smooth surfaces in $\mathbb{P}^3$ and the Hirzebruch surfaces that recur through the chapter, and states the theorem of the base, by which $\mathrm{NS}(X)$ is finitely generated. It also defines the ample, nef, big and effective divisors on a surface.

The field k and every curve considered on its own are as in box 7.0.1. Curves lying on a surface X can be singular, and the irreducible ones are the prime divisors of X. A result that needs a curve $C \subseteq X$ to be nonsingular says so.

Definition 8.1.1: Surface

A *surface over* k is a Noetherian, integral, separated scheme X of dimension 2 and of finite type over k. The surface X is

1. *projective* if there exists a closed immersion $X \hookrightarrow \mathbb{P}^n_k$ for some n,
2. *nonsingular* (or *smooth*) if all local rings $\mathcal{O}_{X,x}$ are regular, or equivalently (over $k = \overline{k}$) if the structure morphism is smooth.

Unless otherwise stated, in this chapter a *surface* is a *smooth projective surface over* $k = \overline{k}$.

For curves properness implies projectivity (corollary 7.3.5), and the same holds for smooth surfaces: every proper smooth surface over k is projective, a theorem of Zariski quoted in [50, §V.1]. This book does not prove it, so projectivity is assumed, which keeps an ample line bundle available. In dimension 3 the implication fails (section 8.4.1).

Example 8.1.2: The Basic Surfaces

1. The projective plane $\mathbb{P}^2$ has $\mathrm{Pic}\,(\mathbb{P}^2) \cong \mathbb{Z}$, generated by the class H of a line, and a curve of degree d has class dH. Taking determinants in the Euler sequence (theorem 5.5.19) gives $\omega_{\mathbb{P}^2} \cong \mathcal{O}(-3)$, so the canonical class $K_{\mathbb{P}^2} = -3H$ is anti-ample.
2. The product $\mathbb{P}^1 \times \mathbb{P}^1$ is the simplest *ruled surface*: the first projection exhibits it as a family of copies of $\mathbb{P}^1$ parametrized by $\mathbb{P}^1$. Its Picard group is $\mathrm{Pic}\,(\mathbb{P}^1 \times \mathbb{P}^1) \cong \mathbb{Z}^2$, generated by the classes of the two rulings $F = \{p\} \times \mathbb{P}^1$ and $G = \mathbb{P}^1 \times \{q\}$. A divisor of *bidegree* (a, b) is one of class $aF + bG$, and the canonical class is $K = -2F - 2G$. This surface is not isomorphic to $\mathbb{P}^2$, since the Picard groups differ, but it is *birational* to $\mathbb{P}^2$: blowing up two distinct points of $\mathbb{P}^2$ and then contracting the strict transform of the line through them, a smooth rational curve of self-intersection -1, produces $\mathbb{P}^1 \times \mathbb{P}^1$ (section 8.4).
3. A smooth surface $S \subseteq \mathbb{P}^3$ of degree d has canonical class $K_S = (d-4)H$ by the adjunction formula (proposition 6.5.7), which separates three cases:
   (a) $d \leq 3$: K_S is anti-ample, and S (a plane, a quadric or a cubic surface) is rational.
   (b) $d = 4$: $K_S = 0$, and S is a K3 surface.
   (c) $d \geq 5$: K_S is ample, and S is of general type.

Over $\mathbb{C}$, a *very general* such surface with $d \geq 4$ has $\operatorname{Pic}(S) = \mathbb{Z}H$, by the Noether-Lefschetz theorem[a]. Special surfaces can have larger Picard groups (example 8.1.7).

4. For each $n \geq 0$, the nth *Hirzebruch surface* is $\mathbb{F}_n = \mathbb{P}(\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(-n))$, the projectivization of a rank-2 bundle on $\mathbb{P}^1$. It is a ruled surface with a section C_0 satisfying $C_0^2 = -n$ and fibers F with $F^2 = 0$ and $C_0 \cdot F = 1$. In particular $\mathbb{F}_0 = \mathbb{P}^1 \times \mathbb{P}^1$ and $\mathbb{F}_1 \cong \operatorname{Bl}_p \mathbb{P}^2$, the blow-up of $\mathbb{P}^2$ at a point (section 8.4).

[a] That is, the surfaces of degree $d \geq 4$ with $\operatorname{Pic}(S) \neq \mathbb{Z}H$ lie in a countable union of proper closed subsets of the space of all smooth surfaces of degree d. Here $\operatorname{Pic}(S) = \operatorname{NS}(S)$ because $H^1(S, \mathcal{O}_S) = 0$, so by theorem 8.1.6 the statement is $H^{1,1}(S) \cap H^2(S; \mathbb{Z}) = \mathbb{Z}H$. Its proof is Hodge-theoretic: see *Hodge Theory* [24, The Noether-Lefschetz Locus for Surfaces in $\mathbb{C}\mathrm{P}^3$].

8.1.3 Birational Models of Surfaces Every birational map between smooth projective curves extends to an isomorphism. For surfaces this fails: blowing up a closed point of a smooth surface X gives a smooth surface containing an *exceptional curve* $E \cong \mathbb{P}^1$ with $E^2 = -1$, birational to X (the blow-up is an isomorphism away from the point) and not isomorphic to it (section 8.4). A smooth projective surface therefore has many smooth projective models in its birational class, and the question is whether some of them are distinguished.
Contracting curves reverses blowing up. Castelnuovo's criterion (theorem 8.4.8) contracts any smooth rational curve E with $E^2 = -1$, each contraction lowers the Picard number by one, and so after finitely many contractions one reaches a *minimal surface*, one containing no such curve. When the Kodaira dimension (section 8.6.1) is ≥ 0, the minimal model in a birational class is unique. When it is $-\infty$ it is not: a rational surface is birational to $\mathbb{P}^2$ and to every Hirzebruch surface $\mathbb{F}_n$ with $n \neq 1$, and all of these are minimal.
In dimension ≥ 3 contracting curves can produce singular varieties, and the minimal model program has to allow singularities and *flips*. That theory is the subject of *Birational Geometry* [12].

Divisors on a surface behave as on any smooth variety. Let X be a smooth projective surface over $k = \overline{k}$. Every local ring $\mathcal{O}_{X,x}$ is regular, hence a UFD (proposition 2.7.27), so X is locally factorial (definition 2.4.30). By proposition 5.4.33 and theorem 5.4.44, Weil and Cartier divisors coincide and

$$\operatorname{CaCl} X \;\cong\; \operatorname{Cl} X \;\cong\; \operatorname{Pic} X$$

As with curves, divisors and line bundles are identified, and additive and multiplicative notation are used interchangeably.

A divisor on X is thus a formal sum $D = \sum n_i C_i$ of irreducible curves $C_i \subseteq X$ with $n_i \in \mathbb{Z}$, where on a curve it was a formal sum of points. The invertible sheaf $\mathcal{L}(D)$, its spaces of global sections, and the complete linear system $|D| \cong \mathbb{P}(H^0(X, \mathcal{L}(D)))$ of effective divisors linearly equivalent to D are defined as for curves.

For a curve, $\operatorname{Pic}(X) \cong \operatorname{Pic}^0(X) \oplus \mathbb{Z}$, where $\operatorname{Pic}^0(X)$ is the group of points of the Jacobian and the factor $\mathbb{Z}$ records the degree. On a surface the quotient of $\operatorname{Pic}(X)$ by $\operatorname{Pic}^0(X)$ is the Néron-Severi group, and its rank can exceed 1 (example 8.1.7).

Definition 8.1.4: Néron-Severi Group and Picard Number

Let X be a smooth projective variety. The case of interest in this chapter is a surface, but nothing below needs the dimension. The *Néron-Severi group* of X is the quotient

$$\mathrm{NS}(X) \;=\; \mathrm{Pic}\,(X)/\mathrm{Pic}^{\,0}(X)$$

where $\mathrm{Pic}^{\,0}(X)$ is the group of line bundles that are *algebraically equivalent* to zero (equivalently, the group of k-points of the identity component of the Picard scheme $\mathrm{Pic}_{X/k}$). The *Picard number* (or *rank of the Néron-Severi group*) is $\rho(X) = \mathrm{rk}\mathrm{NS}(X)$.

The group $\mathrm{Pic}\,(X)$ is in general not finitely generated: for an abelian surface, $\mathrm{Pic}^{\,0}$ is the group of points of a two-dimensional abelian variety (example 8.1.7). The quotient $\mathrm{NS}(X)$ is finitely generated.

Theorem 8.1.5: Theorem of the Base

Let X be a smooth projective variety over an algebraically closed field. Then $\mathrm{NS}(X)$ is a finitely generated abelian group. Its rank $\rho(X)$ is the *Picard number*, and over $\mathbb{C}$ it satisfies $\rho(X) \le h^{1,1}(X)$.

***Proof Cited*:**
This is the Néron-Severi theorem, and neither available proof is scheme-theoretic. Over $\mathbb{C}$, the exponential sequence $0 \to \mathbb{Z} \to \mathcal{O}_X \to \mathcal{O}_X^{\times} \to 0$ on the complex manifold $X(\mathbb{C})$ has a connecting map $\mathrm{Pic}\,(X) \to H^2(X;\mathbb{Z})$ with kernel $\mathrm{Pic}^{\,0}(X)$, so $\mathrm{NS}(X)$ embeds in the finitely generated group $H^2(X;\mathbb{Z})$. That argument needs the singular cohomology of $X(\mathbb{C})$ and its finite generation, which this book does not develop. The image consists of classes of type $(1,1)$ in the Hodge decomposition of corollary 6.9.10, which gives $\rho \le h^{1,1}$. Over an arbitrary algebraically closed field the theorem is due to Néron, by an arithmetic argument over a finitely generated field. The note to [50, Exercise V.1.7] gives references.

The bound $\rho \le h^{1,1}$ can be strict: a very general quartic surface in $\mathbb{P}^3_{\mathbb{C}}$ has $\rho = 1$ and $h^{1,1} = 20$ (examples 8.1.7 and 8.3.6). Over $\mathbb{C}$ the Lefschetz theorem describes exactly which cohomology classes are classes of divisors.

Theorem 8.1.6: Lefschetz Theorem on $(1,1)$-Classes

Let X be a smooth projective variety over $\mathbb{C}$. A class in $H^2(X;\mathbb{Z})$ is the class of a divisor if and only if its image in $H^2(X;\mathbb{C})$ lies in $H^{1,1}(X)$. More precisely, the cycle class map $\mathrm{NS}(X) \to H^2(X;\mathbb{Z})$ is injective with image $H^{1,1}(X) \cap H^2(X;\mathbb{Z})$.

***Proof Cited*:**
The proof is analytic. The connecting map $\mathrm{Pic}\,(X) \to H^2(X;\mathbb{Z})$ of the exponential sequence $0 \to \mathbb{Z} \to \mathcal{O}_X \to \mathcal{O}_X^{\times} \to 0$ has image the kernel of $H^2(X;\mathbb{Z}) \to H^2(X;\mathcal{O}_X)$, and Hodge theory identifies that kernel with the integral classes of type $(1,1)$. Both steps use the sheaf cohomology of the complex manifold $X(\mathbb{C})$ and the analytic form of the Hodge decomposition of corollary 6.9.10. A proof is in *Hodge Theory* [24, The Lefschetz $(1,1)$-Theorem]. The statement is the codimension-one case of the Hodge conjecture (box 8.3.14).

Example 8.1.7: Picard Groups of Basic Surfaces

1. $\mathrm{Pic}\,(\mathbb{P}^2) \cong \mathbb{Z}$, generated by the hyperplane class H. Here $\mathrm{Pic}^{\,0} = 0$, $\mathrm{NS} \cong \mathbb{Z}$ and $\rho = 1$.
2. $\mathrm{Pic}\,(\mathbb{P}^1 \times \mathbb{P}^1) \cong \mathbb{Z}^2$, generated by the two rulings F and G. Again $\mathrm{Pic}^{\,0} = 0$, $\mathrm{NS} \cong \mathbb{Z}^2$ and $\rho = 2$.
3. For a smooth quartic surface $S \subseteq \mathbb{P}^3$ (a K3 surface), $\mathrm{Pic}^{\,0}(S) = 0$ since $H^1(S, \mathcal{O}_S) = 0$, so $\mathrm{Pic}\,(S) = \mathrm{NS}(S)$. Over $\mathbb{C}$, a very general quartic has $\rho = 1$, while special quartics can have ρ as large as 20, the maximum for complex K3 surfaces because $h^{1,1} = 20$ (example 8.3.6). The Fermat quartic $x^4 + y^4 + z^4 + w^4 = 0$ attains it.
4. For a complex abelian surface A (a 2-dimensional abelian variety), $\mathrm{Pic}^{\,0}(A) \cong \widehat{A}(\mathbb{C})$ is the group of points of the dual abelian variety, which has dimension 2, and $1 \leq \rho \leq h^{1,1} = 4$.

On a curve a divisor is ample exactly when it has positive degree. On a surface positivity has several inequivalent forms. The intersection number $D \cdot C$ used below is defined in section 8.2.

1. A divisor D is *ample* if $\mathcal{O}_X(D)$ is ample in the sense of definition 5.3.30. By theorem 5.3.41, proposition 5.3.31 and lemma 5.3.33, this holds exactly when some positive multiple $\mathcal{O}_X(nD)$ is very ample, that is, when some $|nD|$ gives a closed immersion into projective space. By the Nakai-Moishezon criterion (theorem 8.2.11), D is ample if and only if $D^2 > 0$ and $D \cdot C > 0$ for every irreducible curve $C \subseteq X$.
2. A divisor D is *nef* ("numerically effective") if $D \cdot C \geq 0$ for every irreducible curve $C \subseteq X$.
3. A divisor D is *big* if $\ell(nD) \geq c\,n^2$ for some $c > 0$ and infinitely many $n \geq 1$. Quadratic growth is the maximum possible on a surface.
4. A divisor D is *effective* if $D \geq 0$ (all coefficients non-negative).

These notions recur in the Enriques-Kodaira classification (section 8.6). On a curve, ample means positive degree and nef means non-negative degree, but effectivity is not a condition on the degree: by lemma 7.2.2, a divisor of degree 0 is linearly equivalent to an effective divisor only if it is principal.

8.1.8 The Cone of Curves and Duality Ampleness and nefness are dual to the *cone of curves* $\mathrm{NE}(X)$, the convex cone in $\mathrm{Num}(X) \otimes \mathbb{R}$ (definition 8.2.5) spanned by the classes of irreducible curves. A divisor is nef exactly when its class pairs non-negatively with every element of $\mathrm{NE}(X)$, that is, when it lies in the dual cone $\mathrm{NE}(X)^\vee$, the *nef cone*. By *Kleiman's criterion*, a divisor is ample exactly when its class lies in the interior of the nef cone.
Mori's *Cone Theorem* describes the closure $\overline{\mathrm{NE}}(X)$: it is the sum of its part where $K_X \geq 0$ and of countably many rays, each spanned by the class of a rational curve C with $K_X \cdot C < 0$, and these rays accumulate only towards the hyperplane where K_X vanishes. Each such extremal ray is contracted by a morphism, and these contractions are the steps of the minimal model program of *Birational Geometry* [12].

8.2 Intersection Theory on Surfaces

This section attaches to any two divisors D_1, D_2 on a smooth projective surface an integer $D_1 \cdot D_2$, defined through Euler characteristics, proves that it is bilinear and depends only on linear equivalence classes, and shows that for curves without a common component it is the number of intersection points counted with multiplicity.

Definition 8.2.1: Intersection Number (Cohomological)

Let X be a smooth projective surface and D_1, D_2 divisors on X. The *intersection number* of D_1 and D_2 is the integer

$$D_1 \cdot D_2 \;=\; \chi(\mathcal{O}_X) - \chi(\mathcal{O}_X(-D_1)) - \chi(\mathcal{O}_X(-D_2)) + \chi(\mathcal{O}_X(-D_1 - D_2))$$

and $D^2 = D \cdot D$ is the *self-intersection* of D.

For effective D_1 and D_2 without a common component, the right-hand side is the Euler characteristic of the finite scheme $D_1 \cap D_2$, whose length counts the intersection points with multiplicity (proposition 8.2.2(5)).

Proposition 8.2.2: Properties of the Intersection Pairing

Let X be a smooth projective surface over $k = \overline{k}$.

1. The intersection number $D_1 \cdot D_2$ is $\mathbb{Z}$-bilinear in D_1 and D_2.
2. It is symmetric: $D_1 \cdot D_2 = D_2 \cdot D_1$.
3. It depends only on linear equivalence classes: if $D_1 \sim D_1'$ and $D_2 \sim D_2'$, then $D_1 \cdot D_2 = D_1' \cdot D_2'$.
4. If C_1 and C_2 are effective divisors with no common component that meet transversally, meaning that at each point of $C_1 \cap C_2$ their local equations generate the maximal ideal, then $C_1 \cdot C_2 = \#(C_1 \cap C_2)$, the number of intersection points.
5. If C_1 and C_2 are effective divisors with no common component, then
$$C_1 \cdot C_2 \;=\; \sum_{P \in C_1 \cap C_2} i_P(C_1, C_2)$$
where $i_P(C_1, C_2) = \dim_k \mathcal{O}_{X,P}/(f_1, f_2) \geq 1$ is the *local intersection multiplicity* at P, and f_1, f_2 are local equations of C_1 and C_2 at P.
6. If C is an effective divisor and D is any divisor, then $D \cdot C = \chi(\mathcal{O}_C) - \chi(\mathcal{O}_C \otimes \mathcal{O}_X(-D))$. If C is a smooth irreducible curve, then $D \cdot C = \deg(\mathcal{O}_X(D)|_C)$.

***Proof*:**
Step 1: (2), (3) and (6). The expression defining $D_1 \cdot D_2$ is symmetric in D_1 and D_2, which is (2). The Euler characteristic $\chi(\mathcal{O}_X(-D))$ depends only on the isomorphism class of $\mathcal{O}_X(-D)$,

which depends only on the linear equivalence class of D (theorem 5.4.44), and this gives (3). Now let C be an effective divisor. Its ideal sheaf is $\mathcal{O}_X(-C)$ (proposition 5.4.47), so there is an exact sequence

$$0 \to \mathcal{O}_X(-C) \to \mathcal{O}_X \to \mathcal{O}_C \to 0 \tag{8.1}$$

Tensoring with the invertible, hence flat, sheaf $\mathcal{O}_X(-D)$ gives

$$0 \to \mathcal{O}_X(-C-D) \to \mathcal{O}_X(-D) \to \mathcal{O}_C(-D) \to 0$$

where $\mathcal{O}_C(-D) = \mathcal{O}_C \otimes \mathcal{O}_X(-D)$. Additivity of χ (proposition 6.7.2) gives

$$\begin{aligned}\chi(\mathcal{O}_X(-C)) &= \chi(\mathcal{O}_X) - \chi(\mathcal{O}_C),\\ \chi(\mathcal{O}_X(-C-D)) &= \chi(\mathcal{O}_X(-D)) - \chi(\mathcal{O}_C(-D))\end{aligned}$$

and substituting into the definition,

$$\begin{aligned}D \cdot C &= \chi(\mathcal{O}_X) - \chi(\mathcal{O}_X(-D)) - \chi(\mathcal{O}_X(-C)) + \chi(\mathcal{O}_X(-C-D))\\ &= \chi(\mathcal{O}_C) - \chi(\mathcal{O}_C(-D))\end{aligned}$$

which is the first formula of (6). If C is a smooth irreducible curve, lemma 6.7.11 gives $\chi(\mathcal{O}_C(-D)) = \deg(\mathcal{O}_X(-D)|_C) + \chi(\mathcal{O}_C)$, and $\deg(\mathcal{O}_X(-D)|_C) = -\deg(\mathcal{O}_X(D)|_C)$ because the degree is additive and $\mathcal{O}_X(-D) \cong \mathcal{O}_X(D)^\vee$ (proposition 5.4.43). Hence $D \cdot C = \deg(\mathcal{O}_X(D)|_C)$, which completes (6).

Step 2: (5) and (4). Let C_1, C_2 be effective with no common component, let $P \in X$, and let $f_1, f_2 \in \mathcal{O}_{X,P}$ be local equations. The ring $\mathcal{O}_{X,P}$ is a UFD (proposition 2.7.27), and a prime element dividing both f_1 and f_2 would define an irreducible curve through P contained in both C_1 and C_2, hence a common component. So f_1 and f_2 have no common prime factor, and multiplication by f_1 is injective on $\mathcal{O}_{X,P}/(f_2)$: if $f_1 g \in (f_2)$ then f_2 divides g. Tensoring (8.1) for $C = C_1$ with $\mathcal{O}_{C_2}$ therefore gives an exact sequence

$$0 \to \mathcal{O}_{C_2}(-C_1) \to \mathcal{O}_{C_2} \to \mathcal{O}_{C_1 \cap C_2} \to 0 \tag{8.2}$$

where $C_1 \cap C_2$ is the closed subscheme with ideal sheaf $\mathcal{I}_{C_1} + \mathcal{I}_{C_2}$, whose stalk at P is $\mathcal{O}_{X,P}/(f_1, f_2)$. Its support is finite. Indeed, each irreducible component Γ of C_2 is an irreducible curve not contained in C_1 (otherwise Γ would be a component of C_1), so $\Gamma \cap C_1$ is a proper closed subset of the one-dimensional irreducible space Γ, hence a finite set of closed points. A coherent sheaf supported on finitely many closed points is flasque, its sections over an open set U being the product of its stalks at the points of the support lying in U. So it has no higher cohomology (corollary 6.1.7), and its global sections are the direct sum of its stalks, which gives $\chi(\mathcal{O}_{C_1 \cap C_2}) = \sum_P \dim_k \mathcal{O}_{X,P}/(f_1, f_2)$. Taking Euler characteristics in (8.2) and using (6) with $C = C_2$ and $D = C_1$,

$$C_1 \cdot C_2 = \chi(\mathcal{O}_{C_2}) - \chi(\mathcal{O}_{C_2}(-C_1)) = \chi(\mathcal{O}_{C_1 \cap C_2}) = \sum_{P \in C_1 \cap C_2} i_P(C_1, C_2)$$

which is (5). Each term is at least 1 because P lies in the support. If C_1 and C_2 meet transversally, then $(f_1, f_2) = \mathfrak{m}_P$ and $i_P = \dim_k \mathcal{O}_{X,P}/\mathfrak{m}_P = 1$, since k is algebraically closed, and this is (4).

Step 3: additivity against a fixed effective divisor. Fix an effective divisor C and write $\varphi_C(D) = D \cdot C$, which by Step 1 equals $\chi(\mathcal{O}_C) - \chi(\mathcal{O}_C(-D))$ and depends only on the linear equivalence

class of D. Let A be an effective divisor with no component in common with C. Tensoring (8.2), for $C_1 = A$ and $C_2 = C$, with $\mathcal{O}_X(-D)$ gives an exact sequence

$$0 \to \mathcal{O}_C(-A-D) \to \mathcal{O}_C(-D) \to \mathcal{O}_{A\cap C} \otimes \mathcal{O}_X(-D) \to 0$$

The last sheaf is supported on the finite set $A \cap C$, near each point of which $\mathcal{O}_X(-D)$ is free of rank one. It therefore has the same stalks as $\mathcal{O}_{A\cap C}$, and by Step 2 the same Euler characteristic $\chi(\mathcal{O}_{A\cap C}) = A \cdot C = \varphi_C(A)$. Hence $\chi(\mathcal{O}_C(-D)) - \chi(\mathcal{O}_C(-D-A)) = \varphi_C(A)$, that is,

$$\varphi_C(D+A) = \varphi_C(D) + \varphi_C(A) \tag{8.3}$$

for every divisor D and every effective A without a component in common with C.

Step 4: moving a divisor off C. Every divisor E is linearly equivalent to $A - B$ with A and B effective and without a component in common with C. Fix a very ample sheaf $\mathcal{O}_X(1)$ and a divisor H_1 with $\mathcal{O}_X(H_1) \cong \mathcal{O}_X(1)$. By theorem 5.3.26 there is an $n \geq 1$ such that $\mathcal{O}_X(E)(n)$ and $\mathcal{O}_X(n)$ are both generated by global sections. Pick a closed point x_j on each irreducible component Γ_j of C. For a globally generated invertible sheaf $\mathcal{L}$, the sections vanishing at x_j form a proper subspace of $H^0(X, \mathcal{L})$, and a vector space over the infinite field k is not a union of finitely many proper subspaces. So some $s \in H^0(X, \mathcal{L})$ vanishes at no x_j, and s can be taken nonzero (a globally generated invertible sheaf on the nonempty X has a nonzero section, which covers the case $C = 0$). Its divisor of zeros is an effective divisor in $|\mathcal{L}|$ (proposition 5.4.47) containing no Γ_j. Applying this to $\mathcal{L} = \mathcal{O}_X(E)(n)$ and to $\mathcal{L} = \mathcal{O}_X(n)$ gives effective $A \sim E + nH_1$ and $B \sim nH_1$ without a component in common with C, and $E \sim A - B$.

Step 5: (1). For fixed effective C and arbitrary D, E, write $E \sim A - B$ as in Step 4. Applying (8.3) to the sums $(D-B)+A$, $(D-B)+B$, $(-B)+A$ and $(-B)+B$ gives

$$\begin{aligned} \varphi_C(D+E) &= \varphi_C(D-B) + \varphi_C(A), & \varphi_C(D) &= \varphi_C(D-B) + \varphi_C(B), \\ \varphi_C(E) &= \varphi_C(-B) + \varphi_C(A), & 0 = \varphi_C(0) &= \varphi_C(-B) + \varphi_C(B) \end{aligned}$$

so $\varphi_C(D+E) = \varphi_C(D) + \varphi_C(A) - \varphi_C(B) = \varphi_C(D) + \varphi_C(E)$. Thus $D \mapsto D \cdot C$ is additive whenever C is effective.

To remove the effectivity, write $\chi(D)$ for $\chi(\mathcal{O}_X(D))$ and set $s(D_1, D_2, D_3) = (D_1 + D_2) \cdot D_3 - D_1 \cdot D_3 - D_2 \cdot D_3$. Expanding the definition,

$$s(D_1, D_2, D_3) = -\chi(0) + \sum_i \chi(-D_i) - \sum_{i<j} \chi(-D_i - D_j) + \chi(-D_1 - D_2 - D_3)$$

which is symmetric in D_1, D_2, D_3. The previous paragraph shows $s(D_1, D_2, C) = 0$ for C effective, so by symmetry and (3), s vanishes whenever one of its arguments is linearly equivalent to an effective divisor. Given arbitrary D_1, D_2, D_3, write $D_1 \sim A - B$ with A, B effective (Step 4 with $C = 0$). The vanishing of $s(A, D_2 - B, D_3)$ and of $s(B, D_2 - B, D_3)$ gives

$$(D_1 + D_2) \cdot D_3 = A \cdot D_3 + (D_2 - B) \cdot D_3, \qquad D_2 \cdot D_3 = B \cdot D_3 + (D_2 - B) \cdot D_3$$

and the case $D_2 = 0$ of these two equations, together with $0 \cdot D_3 = 0$, gives $D_1 \cdot D_3 = A \cdot D_3 - B \cdot D_3$. Subtracting, $(D_1 + D_2) \cdot D_3 = D_1 \cdot D_3 + D_2 \cdot D_3$. With (2) this is (1), completing the proof.

Example 8.2.3: Intersection Numbers on Basic Surfaces

1. Two distinct lines $L_1, L_2 \subseteq \mathbb{P}^2$, both of class H, meet transversally in one point, so $H^2 = 1$ by proposition 8.2.2(4). By bilinearity, curves of degrees d_1 and d_2 have intersection number $d_1 d_2$, and for curves without a common component proposition 8.2.2(5) turns this into Bézout's theorem ([30, Bézout's Theorem]).

2. On $\mathbb{P}^1 \times \mathbb{P}^1$ let $F = \{p\} \times \mathbb{P}^1$ and $G = \mathbb{P}^1 \times \{q\}$ be the two rulings. Then

$$F \cdot G = 1, \qquad F \cdot F = 0, \qquad G \cdot G = 0$$

   The curves F and G meet transversally in the single point (p, q). For $p' \neq p$ the fiber $F' = \{p'\} \times \mathbb{P}^1$ is linearly equivalent to F and disjoint from it, so $F^2 = F \cdot F' = 0$, and similarly $G^2 = 0$. Linearly equivalent effective divisors on a surface can therefore be disjoint.

3. If $C \subseteq \mathbb{P}^1 \times \mathbb{P}^1$ has class $aF + bG$, then

$$C \cdot F = b, \qquad C \cdot G = a, \qquad C^2 = 2ab$$

   For instance, the diagonal $\Delta \subseteq \mathbb{P}^1 \times \mathbb{P}^1$ has bidegree $(1, 1)$, so $\Delta^2 = 2$.

An ample divisor meets every curve positively, which is the "only if" half of the Nakai-Moishezon criterion (theorem 8.2.11).

Lemma 8.2.4: Ample Divisors Meet Curves Positively

Let H be an ample divisor on a smooth projective surface X.

1. $H \cdot C > 0$ for every irreducible curve $C \subseteq X$.
2. $H \cdot E \geq 0$ for every effective divisor E, with strict inequality if $E \neq 0$.
3. $H^2 > 0$.

***Proof*:**
By theorem 5.3.41 some multiple mH with $m \geq 1$ is very ample. Fix the corresponding closed immersion $X \hookrightarrow \mathbb{P}^N_k$. For a linear form λ not vanishing identically on X, the hyperplane section $X \cap V_+(\lambda)$ is an effective divisor linearly equivalent to mH (proposition 5.4.47).

(1) Choose a closed point $x \in C$ and a linear form λ with $\lambda(x) \neq 0$, and let $H' = X \cap V_+(\lambda)$. Then $C \not\subseteq H'$, so the effective divisors C and H' have no common component. They meet. Otherwise C is a closed subscheme of $X \cap D_+(\lambda)$, which is closed in the affine space $D_+(\lambda) \cong \mathbb{A}^N_k$, so C is affine. Being also proper and integral over $k = \overline{k}$, it has $\Gamma(C, \mathcal{O}_C) = k$ (theorem 3.5.33), so $C \cong \operatorname{Spec} k$ is a point, contradicting $\dim C = 1$. By proposition 8.2.2(5), $m\,(H \cdot C) = H' \cdot C = \sum_{P \in C \cap H'} i_P(C, H') \geq 1$, so $H \cdot C > 0$.

(2) Write $E = \sum n_i C_i$ with $n_i \geq 0$ and C_i irreducible curves. By bilinearity and (1), $H \cdot E = \sum n_i\,(H \cdot C_i) \geq 0$, with strict inequality if some $n_i > 0$.

(3) A hyperplane section $H' = X \cap V_+(\lambda)$ as in (1) is a nonzero divisor, since otherwise $X \subseteq D_+(\lambda)$ would be affine and the argument of (1), applied to X, would make X a point. So H' is a

nonzero effective divisor linearly equivalent to mH, and $m^2H^2 = (mH)\cdot H' = m\,(H\cdot H') > 0$ by (2), as claimed.

Numerical equivalence identifies divisors that the intersection pairing cannot distinguish.

Definition 8.2.5: Numerical Equivalence

A divisor D on a smooth projective surface X is *numerically equivalent to zero*, written $D \equiv 0$, if $D\cdot E = 0$ for every divisor E. Divisors D and D' are *numerically equivalent*, written $D \equiv D'$, if $D - D' \equiv 0$. The group of divisors modulo numerical equivalence is denoted $\mathrm{Num}(X)$.

Every divisor is a $\mathbb{Z}$-combination of irreducible curves, so by bilinearity $D \equiv 0$ if and only if $D\cdot C = 0$ for every irreducible curve C. Linearly equivalent divisors are numerically equivalent by proposition 8.2.2(3), so $\mathrm{Num}(X)$ is a quotient of $\mathrm{Pic}\,(X)$, and the intersection pairing descends to a nondegenerate symmetric pairing $\mathrm{Num}(X)\times\mathrm{Num}(X)\to\mathbb{Z}$. The group $\mathrm{Num}(X)$ is torsion-free: if $nD\equiv 0$ with $n\neq 0$, then $D\cdot E = 0$ for every E. A nonzero effective divisor E is never numerically equivalent to zero, since $E\cdot H > 0$ for H ample (lemma 8.2.4).

For a curve C on X the self-intersection C^2 can be positive, zero or negative, and for a smooth curve it is the degree of the normal bundle.

Proposition 8.2.6: Self-Intersection via the Normal Bundle

Let C be a smooth irreducible curve on a smooth projective surface X. Then

$$C^2 \;=\; \deg \mathcal{N}_{C/X}$$

where $\mathcal{N}_{C/X} = (\mathcal{I}_C/\mathcal{I}_C^2)^\vee$ is the normal sheaf, an invertible sheaf on C because C has codimension 1 in X (definition 5.5.32).

***Proof*:**
The ideal sheaf of C is $\mathcal{I}_C \cong \mathcal{O}_X(-C)$ (proposition 5.4.47), so $\mathcal{I}_C/\mathcal{I}_C^2 \cong \mathcal{I}_C\otimes\mathcal{O}_C \cong \mathcal{O}_X(-C)|_C$, and dualizing gives $\mathcal{N}_{C/X}\cong\mathcal{O}_X(C)|_C$. By proposition 8.2.2(6) with $D = C$, $C^2 = \deg(\mathcal{O}_X(C)|_C) = \deg\mathcal{N}_{C/X}$, as claimed.

The sign of C^2 separates three kinds of behaviour.

1. If $C^2 > 0$ and C is irreducible, the multiples of C move in large linear systems: $\ell(nC)\geq\chi(\mathcal{O}_X(nC))$ for $n\gg 0$, and the right-hand side grows like $n^2C^2/2$ (corollary 8.3.8, which applies because $C\cdot H > 0$ for H ample by lemma 8.2.4(1)). Lines in $\mathbb{P}^2$ have $L^2 = 1$.

2. Fibers of a morphism from X onto $\mathbb{P}^1$ have self-intersection 0, since two distinct fibers are linearly equivalent and disjoint. The rulings of $\mathbb{P}^1\times\mathbb{P}^1$ are an example (example 8.2.3).

3. If $C^2 < 0$ and C is irreducible, then C is the only effective divisor numerically equivalent to C (corollary 8.3.13), so it does not move in a linear system. The exceptional curve E of a blow-up, with $E^2 = -1$, is the basic example (section 8.4).

Castelnuovo's criterion (theorem 8.4.8) contracts every smooth rational curve of self-intersection -1 to a smooth point, and corollary 8.3.13 shows that an irreducible curve orthogonal to a divisor of positive square has negative self-intersection.

Example 8.2.7: Self-Intersection Numbers

1. Lines in $\mathbb{P}^2$ have $L^2 = 1$, and a curve of degree d has $C^2 = d^2$.
2. If $\pi\colon \widetilde{X} \to X$ is the blow-up of a point p and $E = \pi^{-1}(p)$ is the exceptional divisor, then $E^2 = -1$ (section 8.4).
3. For $n > 0$ the section $C_0 \subseteq \mathbb{F}_n$ with $C_0^2 = -n$ is the only effective divisor in its numerical class (corollary 8.3.13). For $n = 0$, $C_0^2 = 0$ and C_0 moves in a pencil of disjoint curves, one of the two rulings of $\mathbb{F}_0 = \mathbb{P}^1 \times \mathbb{P}^1$.
4. On an abelian surface A every irreducible curve C has $C^2 \geq 0$. For a general $a \in A$ the translate $C + a$ is an irreducible curve different from C. The translates of C form a family parametrized by the connected variety A, so $C + a$ is algebraically, hence numerically, equivalent to C [50, Exercise V.1.7], and $C^2 = C \cdot (C + a) \geq 0$ by proposition 8.2.2(5).

The adjunction formula expresses the canonical class of a curve on a surface in terms of the canonical class of the surface and the curve's self-intersection, and so computes the genus of a smooth curve from its divisor class.

Theorem 8.2.8: The Adjunction Formula

Let C be a smooth irreducible curve on a smooth projective surface X. Then

$$2g(C) - 2 \;=\; C \cdot (C + K_X)$$

where $g(C)$ is the genus of C and K_X is a canonical divisor of X. More precisely, $\omega_C \cong (\omega_X \otimes \mathcal{L}(C))|_C$, that is, $K_C \sim (K_X + C)|_C$.

***Proof*:**
The codimension-one case of proposition 5.5.33, applied to the smooth curve C in the smooth surface X, gives $\omega_C \cong (\omega_X \otimes \mathcal{L}(C))|_C$, which in divisor language is $K_C \sim (K_X + C)|_C$. Taking degrees on C and using proposition 8.2.2(6),

$$\deg K_C = \deg(\mathcal{O}_X(K_X)|_C) + \deg(\mathcal{O}_X(C)|_C) = K_X \cdot C + C^2 = C \cdot (C + K_X)$$

Since $\deg K_C = 2g(C) - 2$ (proposition 7.3.1), this is $2g(C) - 2 = C \cdot (C + K_X)$, as claimed.

The isomorphism is the case of proposition 5.5.33 for a curve on a surface (and proposition 6.5.7 covers subvarieties of projective space). The intersection pairing turns it into a formula for the genus of C in terms of the class of C alone.

Example 8.2.9: The Adjunction Formula in Action

1. Let $C \subseteq \mathbb{P}^2$ be a smooth curve of degree d. Then $C \sim dH$, so $C \cdot C = d^2$ and $C \cdot K_{\mathbb{P}^2} = C \cdot (-3H) = -3d$, and adjunction gives
$$2g - 2 = d^2 - 3d = d(d-3), \qquad g = \frac{(d-1)(d-2)}{2}$$
This is the genus formula of proposition 7.2.6, now recovered from the intersection pairing.

2. Let C be a smooth curve of bidegree (a, b) on $\mathbb{P}^1 \times \mathbb{P}^1$, where $K = -2F - 2G$. Then $C^2 = 2ab$ and $C \cdot K = (aF + bG) \cdot (-2F - 2G) = -2b - 2a$, so
$$2g - 2 = 2ab - 2a - 2b, \qquad g = (a-1)(b-1)$$
A smooth $(2,2)$-curve has $g = 1$, and a smooth $(3,3)$-curve has $g = 4$.

3. Let S be a K3 surface ($K_S = 0$) and $C \subseteq S$ a smooth irreducible curve. Adjunction gives $2g(C) - 2 = C^2$, so $g(C) = C^2/2 + 1$. In particular C^2 is even, and $C^2 \geq -2$ with equality if and only if $g(C) = 0$, that is, $C \cong \mathbb{P}^1$. Smooth rational curves on a K3 surface, which have $C^2 = -2$, are called (-2)-*curves* or *nodal curves*.

4. If $E \cong \mathbb{P}^1$ is the exceptional curve of the blow-up $\mathrm{Bl}_p X \to X$ of a smooth surface at a point, then $g(E) = 0$, and adjunction gives $-2 = E^2 + K_{\mathrm{Bl}_p X} \cdot E$. Section 8.4 shows that $K_{\mathrm{Bl}_p X} = \pi^* K_X + E$ and $(\pi^* K_X) \cdot E = 0$, so $K_{\mathrm{Bl}_p X} \cdot E = E^2$, hence $-2 = 2E^2$ and $E^2 = -1$.

8.2.10 Forward Reference: Chow Rings and the General Intersection Product
The intersection pairing on a smooth projective surface is the simplest case of the *intersection product* on the Chow ring of a smooth variety,
$$A^p(X) \otimes A^q(X) \to A^{p+q}(X)$$
where $A^p(X)$ is the group of codimension-p algebraic cycles modulo rational equivalence (definition 10.1.4). For a surface, $A^0(X) = \mathbb{Z}$ is generated by the class of X, $A^1(X) = \mathrm{Pic}\,(X)$, and $A^2(X)$ is the group of zero-cycles modulo rational equivalence, which carries a degree map $\deg\colon A^2(X) \to \mathbb{Z}$ sending the class of a closed point to 1. The intersection pairing is the composite $A^1(X) \times A^1(X) \to A^2(X) \xrightarrow{\deg} \mathbb{Z}$.
Intersection Theory [26] constructs the Chow ring of a smooth variety of any dimension, proves the *moving lemma* (which replaces cycles by rationally equivalent ones meeting properly), defines Chern classes as elements of $A^*(X)$, and proves the Grothendieck-Riemann-Roch theorem.

Positivity of the pairing on curves characterizes ample divisors.

Theorem 8.2.11: Nakai-Moishezon Criterion

Let D be a divisor on a smooth projective surface X. Then D is ample if and only if
$$D^2 > 0 \qquad \text{and} \qquad D \cdot C > 0 \ \text{ for every irreducible curve } C \subseteq X$$

***Proof Key ideas*:**
Necessity is proved in full by lemma 8.2.4(1) and (3). Sufficiency needs three inputs this book does not prove: that an invertible sheaf $\mathcal{L}$ on a projective curve, possibly singular and non-reduced, is ample when $\chi(\mathcal{L}|_{C_i}) - \chi(\mathcal{O}_{C_i}) > 0$ on each integral component C_i; that a proper morphism with finite fibers is finite (a consequence of theorem 3.4.38); and that the pullback of an ample sheaf along a finite morphism is ample. The argument is [50, Theorem V.1.10], and it runs as follows. A very ample divisor is linearly equivalent to an effective divisor H, nonzero because $H^2 > 0$ (lemma 8.2.4(3)), and $D \cdot H > 0$ by the hypothesis applied to the components of H. Together with $D^2 > 0$, corollary 8.3.8, proved below from Riemann-Roch without this theorem, makes some multiple of D effective, and D may be replaced by it. The restriction $\mathcal{O}_X(D)|_D$ satisfies $\chi(\mathcal{O}_{C_i}(D)) - \chi(\mathcal{O}_{C_i}) = D \cdot C_i > 0$ on each component C_i of D (proposition 8.2.2(6) applied to $-D$), hence is ample on the curve D, so $H^1(D, \mathcal{O}_X(nD)|_D) = 0$ for $n \gg 0$. The sequence $0 \to \mathcal{O}_X((n-1)D) \to \mathcal{O}_X(nD) \to \mathcal{O}_X(nD)|_D \to 0$ then makes $h^1(\mathcal{O}_X(nD))$ non-increasing, hence eventually constant, so $H^0(X, \mathcal{O}_X(nD)) \to H^0(D, \mathcal{O}_X(nD)|_D)$ is eventually surjective. Sections then generate $\mathcal{O}_X(nD)$ along D, and the section vanishing exactly on nD generates it off D. The resulting morphism $\varphi\colon X \to \mathbb{P}^M$ contracts no curve C, since a hyperplane missing $\varphi(C)$ would give a member of $|nD|$ disjoint from C, against $nD \cdot C > 0$. So φ has finite fibers, it is finite, and $\mathcal{O}_X(nD) = \varphi^*\mathcal{O}(1)$ is ample. Since D was replaced by a multiple, the original D has an ample multiple, and it is ample by lemma 5.3.33, as claimed.

On a curve the analogous statement is that a divisor is ample exactly when it has positive degree. On a projective variety X of any dimension, a divisor D is ample exactly when $D^{\dim V} \cdot V > 0$ for every closed subvariety $V \subseteq X$ of positive dimension [50, Theorem A.5.1], the intersection numbers being those of *Intersection Theory* [26].

8.3 Riemann-Roch and the Hodge Index Theorem

The Riemann-Roch theorem for curves (theorem 7.2.10) computes $\chi(\mathcal{L}(D))$ from $\deg D$ and the genus g. On a surface the intersection pairing takes the place of the degree, and the Euler characteristic becomes a quadratic function of D. Its constant term $\chi(\mathcal{O}_X)$ is computed over $\mathbb{C}$ by Noether's formula (section 8.3.2). When $D^2 > 0$ and $D \cdot H > 0$ for an ample divisor H, the quadratic growth of $\chi(\mathcal{O}_X(nD))$ in n makes nD effective for large n (corollary 8.3.8), and the Hodge index theorem (section 8.3.3) is deduced from this. Section 8.3.4 compares linear, algebraic and numerical equivalence of divisors through the Picard scheme.

8.3.1 The Riemann-Roch Theorem for Surfaces

Theorem 8.3.1: Riemann-Roch for Surfaces

Let X be a smooth projective surface over $k = \overline{k}$, and let D be a divisor on X. Then

$$\chi(\mathcal{L}(D)) \;=\; \frac{1}{2}\, D \cdot (D - K_X) \;+\; \chi(\mathcal{O}_X)$$

Equivalently, expanding the intersection product,

$$\chi(\mathcal{L}(D)) \;=\; \frac{D^2 - D \cdot K_X}{2} + \chi(\mathcal{O}_X)$$

For a curve of genus g, Riemann-Roch says $\chi(\mathcal{L}(D)) = \deg D + 1 - g = \deg D + \chi(\mathcal{O}_X)$, a linear function of D. On a surface $\chi(\mathcal{L}(D))$ is quadratic in D: it involves the self-intersection D^2 in addition to the linear term $D \cdot K_X$.

***Proof*:**
Here $\mathcal{L}(D) = \mathcal{O}_X(D)$. For a locally free sheaf on the two-dimensional smooth projective X, Serre duality (corollary 6.5.10) gives $H^i(X, \mathcal{O}_X(D)) \cong H^{2-i}(X, \mathcal{O}_X(K_X - D))^*$, so

$$\chi(\mathcal{O}_X(D)) = \sum_{i=0}^{2} (-1)^i\, h^{2-i}(\mathcal{O}_X(K_X - D)) = \chi(\mathcal{O}_X(K_X - D))$$

for every divisor D. In particular $\chi(\mathcal{O}_X(K_X)) = \chi(\mathcal{O}_X)$. Apply the definition of the intersection number to $-D$ and $D - K_X$:

$$(-D)\cdot(D-K_X) = \chi(\mathcal{O}_X) - \chi(\mathcal{O}_X(D)) - \chi(\mathcal{O}_X(K_X - D)) + \chi(\mathcal{O}_X(K_X)) = 2\chi(\mathcal{O}_X) - 2\chi(\mathcal{O}_X(D))$$

By bilinearity (proposition 8.2.2) the left-hand side is $-D \cdot (D - K_X)$, so $\chi(\mathcal{O}_X(D)) = \frac{1}{2}\, D \cdot (D - K_X) + \chi(\mathcal{O}_X)$, as we sought to show.

The proof uses only Serre duality and the bilinearity of the intersection number. The comparison of Euler characteristics on X with Euler characteristics on curves, which the proof of Riemann-Roch for curves carries out one point at a time, takes place in the proof of proposition 8.2.2. In every dimension the corresponding statement is the Hirzebruch-Riemann-Roch theorem, a case of Grothendieck-Riemann-Roch (*Intersection Theory* [26]).

Example 8.3.2: Riemann-Roch for Surfaces in Practice

1. On $\mathbb{P}^2$, $K_{\mathbb{P}^2} = -3H$ and $\chi(\mathcal{O}_{\mathbb{P}^2}) = 1$, since $H^i(\mathbb{P}^2, \mathcal{O}) = 0$ for $i > 0$ (theorem 6.3.1). For $D = dH$,
$$\chi(\mathcal{O}(d)) = \frac{d^2 - d(-3)}{2} + 1 = \frac{d^2 + 3d + 2}{2} = \binom{d+2}{2}$$
For $d \geq 0$ the higher cohomology of $\mathcal{O}(d)$ vanishes (theorem 6.3.1), and this is $\dim_k k[x, y, z]_d = \binom{d+2}{2}$.

2. On $\mathbb{P}^1 \times \mathbb{P}^1$, $K = -2F - 2G$ and $\chi(\mathcal{O}) = 1$. For $D = aF + bG$,

$$\chi(\mathcal{O}(a,b)) = \frac{2ab - (aF+bG)\cdot(-2F-2G)}{2} + 1 = \frac{2ab+2a+2b}{2} + 1 = (a+1)(b+1)$$

For $a, b \geq 0$ the Künneth formula gives $H^0(\mathbb{P}^1 \times \mathbb{P}^1, \mathcal{O}(a,b)) = H^0(\mathbb{P}^1, \mathcal{O}(a)) \otimes H^0(\mathbb{P}^1, \mathcal{O}(b))$, of dimension $(a+1)(b+1)$, and vanishing higher cohomology.

3. A smooth quartic surface $S \subseteq \mathbb{P}^3$ (a K3 surface) has $K_S = 0$, so

$$\chi(\mathcal{L}(D)) = \frac{D^2}{2} + \chi(\mathcal{O}_S)$$

and $\chi(\mathcal{O}_S) = 2$ (example 8.3.5). For an ample divisor D with $D^2 = 2d$, $\chi(\mathcal{L}(D)) = d + 2$.

By analogy with curves, the *arithmetic genus* of the surface X is

$$p_a(X) \;=\; (-1)^{\dim X}(\chi(\mathcal{O}_X) - 1) \;=\; \chi(\mathcal{O}_X) - 1$$

Since $h^0(\mathcal{O}_X) = 1$ (theorem 3.5.33), this is $p_a(X) = h^2(\mathcal{O}_X) - h^1(\mathcal{O}_X)$. Thus $\chi(\mathcal{O}_X) = 1 + p_a$, and Riemann-Roch becomes

$$\chi(\mathcal{L}(D)) = \frac{D\cdot(D - K_X)}{2} + 1 + p_a$$

Setting $D = K_X$ gives

$$\chi(\omega_X) = \frac{K_X^2 - K_X \cdot K_X}{2} + \chi(\mathcal{O}_X) = \chi(\mathcal{O}_X) \tag{8.4}$$

which is also the case $D = 0$ of the identity $\chi(\mathcal{O}_X(D)) = \chi(\mathcal{O}_X(K_X - D))$ from the proof of theorem 8.3.1.

The adjunction formula extends to effective divisors that may be singular, reducible or non-reduced. For such a divisor C, define the *arithmetic genus* by $p_a(C) = 1 - \chi(\mathcal{O}_C)$. Then

$$2p_a(C) - 2 \;=\; C\cdot(C + K_X) \tag{8.5}$$

Indeed, (8.1) gives $\chi(\mathcal{O}_C) = \chi(\mathcal{O}_X) - \chi(\mathcal{O}_X(-C))$, and theorem 8.3.1 for $-C$ gives $\chi(\mathcal{O}_X(-C)) = \frac{1}{2}C\cdot(C+K_X) + \chi(\mathcal{O}_X)$, so $2p_a(C) - 2 = -2\chi(\mathcal{O}_C) = C\cdot(C+K_X)$. When C is a smooth irreducible curve, $p_a(C) = g(C)$ and this is theorem 8.2.8.

8.3.2 Noether's Formula

Riemann-Roch expresses $\chi(\mathcal{L}(D))$ through intersection numbers and the single invariant $\chi(\mathcal{O}_X)$.

Theorem 8.3.3: Noether's Formula

Let X be a smooth projective surface over $\mathbb{C}$. Then

$$\chi(\mathcal{O}_X) \;=\; \frac{1}{12}\big(K_X^2 + \chi_{\text{top}}(X)\big)$$

where $\chi_{\text{top}}(X) = \sum_{i=0}^{4}(-1)^i b_i(X)$ is the topological Euler characteristic, the alternating sum of the Betti numbers of $X(\mathbb{C})$.

***Proof Key ideas*:**
The proof needs two results this book does not prove, both in [55]: the Hirzebruch-Riemann-Roch theorem (proved algebraically in *Intersection Theory* [26, Hirzebruch-Riemann-Roch]), and the equality of the degree of the top Chern class of the tangent bundle of a compact complex manifold with its topological Euler characteristic. Over any algebraically closed field, the first of these gives $\chi(\mathcal{O}_X) = \frac{1}{12}(K_X^2 + \deg c_2(T_X))$ by the computation below, and that statement is proved in *Intersection Theory* [26, Noether's Formula]. Granting both, Hirzebruch-Riemann-Roch for $\mathcal{O}_X$ gives $\chi(\mathcal{O}_X) = \int_X \mathrm{td}(T_X)$, and for a surface

$$\mathrm{td}(T_X) = 1 + \frac{1}{2}c_1(T_X) + \frac{1}{12}\big(c_1(T_X)^2 + c_2(T_X)\big)$$

Here $c_1(T_X) = -c_1(\Omega_X) = -K_X$ in $A^1(X)$, so $c_1(T_X)^2 = K_X^2$, and $\deg c_2(T_X) = \chi_{\mathrm{top}}(X)$. Taking the degree of the component in $A^2(X)$ gives $\chi(\mathcal{O}_X) = \frac{1}{12}(K_X^2 + \chi_{\mathrm{top}}(X))$, as claimed.

Over $\mathbb{C}$ the Hodge numbers $h^{p,q} = \dim H^q(X, \Omega_X^p)$ of a smooth projective surface satisfy $h^{p,q} = h^{q,p}$, $h^{p,q} = h^{2-p,2-q}$ and $b_k = \sum_{p+q=k} h^{p,q}$ (corollary 6.9.10, which rests on theorem 0.6.28 and theorem 6.9.2). For a surface this gives

$$b_0 = 1, \quad b_1 = 2h^{0,1}, \quad b_2 = h^{2,0} + h^{1,1} + h^{0,2} = 2h^{2,0} + h^{1,1},$$
$$b_3 = 2h^{0,1}, \quad b_4 = 1$$

so $\chi_{\mathrm{top}} = 2 - 4h^{0,1} + 2h^{2,0} + h^{1,1}$. The numbers $h^{0,1}$ and $h^{2,0}$ have algebraic counterparts over any algebraically closed field.

Definition 8.3.4: Surface Invariants

For a smooth projective surface X over $k = \overline{k}$:

1. The *irregularity* is $q = q(X) = \dim H^1(X, \mathcal{O}_X)$.
2. The *geometric genus* is $p_g = p_g(X) = \dim H^0(X, \omega_X)$, which equals $\dim H^2(X, \mathcal{O}_X)$ by Serre duality (corollary 6.5.10).
3. The *nth plurigenus* is $P_n = P_n(X) = \dim H^0(X, \omega_X^{\otimes n})$ for $n \geq 1$, so $P_1 = p_g$.

Over $\mathbb{C}$, $q = h^{0,1}$ and $p_g = h^{2,0} = h^{0,2}$.

Since $h^0(\mathcal{O}_X) = 1$, $\chi(\mathcal{O}_X) = 1 - q + p_g$ and $p_a(X) = p_g - q$.

Example 8.3.5: Noether's Formula in Practice

1. For $\mathbb{P}^2$, $K = -3H$, $K^2 = 9$ and $\chi_{\mathrm{top}} = 3$ (Betti numbers $1, 0, 1, 0, 1$). Noether's formula gives $\chi(\mathcal{O}) = \frac{9+3}{12} = 1$.
2. For $\mathbb{P}^1 \times \mathbb{P}^1$, $K = -2F - 2G$, $K^2 = 8$ and $\chi_{\mathrm{top}} = 4$ ($b_0 = b_4 = 1$, $b_2 = 2$, $b_1 = b_3 = 0$). Noether's formula gives $\chi(\mathcal{O}) = \frac{8+4}{12} = 1$.
3. A smooth quartic surface $S \subseteq \mathbb{P}^3$ has $K_S = 0$, so $K_S^2 = 0$ and $p_g = h^0(\mathcal{O}_S) = 1$. The sequence $0 \to \mathcal{O}_{\mathbb{P}^3}(-4) \to \mathcal{O}_{\mathbb{P}^3} \to \mathcal{O}_S \to 0$ and theorem 6.3.1 give $h^1(\mathcal{O}_S) = 0$, so $q = 0$ and $\chi(\mathcal{O}_S) = 1 - 0 + 1 = 2$. Over $\mathbb{C}$, Noether's formula then gives $\chi_{\mathrm{top}}(S) = 12 \cdot 2 - 0 = 24$, and since $b_1 = b_3 = 2q = 0$ the Betti numbers of S are $1, 0, 22, 0, 1$.

4. An abelian surface A has $K_A = 0$ (a translation-invariant 2-form trivializes ω_A), so $K^2 = 0$. The Betti numbers of the real 4-torus $A(\mathbb{C}) \cong \mathbb{C}^2/\Lambda$ are $1, 4, 6, 4, 1$, so $\chi_{\text{top}} = 0$, and Noether's formula gives $\chi(\mathcal{O}_A) = 0$, in agreement with $q = 2$, $p_g = 1$ and $\chi = 1 - 2 + 1 = 0$.

Over $\mathbb{C}$ the Hodge numbers of a smooth projective surface form its *Hodge diamond* (definition 0.6.29):

$$\begin{array}{ccccc} & & h^{0,0} & & \\ & h^{1,0} & & h^{0,1} & \\ h^{2,0} & & h^{1,1} & & h^{0,2} \\ & h^{2,1} & & h^{1,2} & \\ & & h^{2,2} & & \end{array} \quad = \quad \begin{array}{ccccc} & & 1 & & \\ & q & & q & \\ p_g & & h^{1,1} & & p_g \\ & q & & q & \\ & & 1 & & \end{array}$$

The symmetries are $h^{p,q} = h^{q,p}$ (Hodge symmetry) and $h^{p,q} = h^{2-p,2-q}$ (Serre duality). The diamond is determined by $(q, p_g, h^{1,1})$, subject to $h^{1,1} \geq \rho$ (theorem 8.1.5) and $h^{1,1} \geq 1$, the class of an ample divisor being a nonzero $(1,1)$-class.

Example 8.3.6: Hodge Diamonds of Basic Surfaces

1. The plane $\mathbb{P}^2$ has diamond $\begin{smallmatrix} & & 1 & & \\ & 0 & & 0 & \\ 0 & & 1 & & 0 \\ & 0 & & 0 & \\ & & 1 & & \end{smallmatrix}$, so $q = 0$, $p_g = 0$ and $h^{1,1} = 1 = \rho$.

2. A K3 surface has diamond $\begin{smallmatrix} & & 1 & & \\ & 0 & & 0 & \\ 1 & & 20 & & 1 \\ & 0 & & 0 & \\ & & 1 & & \end{smallmatrix}$, so $q = 0$, $p_g = 1$ and $h^{1,1} = 20$, with $1 \leq \rho \leq 20$.

3. An abelian surface has diamond $\begin{smallmatrix} & & 1 & & \\ & 2 & & 2 & \\ 1 & & 4 & & 1 \\ & 2 & & 2 & \\ & & 1 & & \end{smallmatrix}$, so $q = 2$, $p_g = 1$ and $h^{1,1} = 4$, with $1 \leq \rho \leq 4$.

4. A smooth quintic surface $S \subseteq \mathbb{P}^3$ is of general type, with $K_S = H$ and $K_S^2 = 5$. The sequence $0 \to \mathcal{O}(-5) \to \mathcal{O} \to \mathcal{O}_S \to 0$ gives $q = 0$ and $p_g = h^2(\mathcal{O}_S) = h^3(\mathcal{O}_{\mathbb{P}^3}(-5)) = 4$, so $\chi(\mathcal{O}_S) = 5$. Noether's formula gives $\chi_{\text{top}} = 60 - 5 = 55$, and then $h^{1,1} = \chi_{\text{top}} - 2 - 2p_g = 45$.

8.3.3 The Hodge Index Theorem

The intersection pairing descends to a nondegenerate symmetric bilinear form on $\text{Num}(X)$ (definition 8.2.5), and an ample class H has $H^2 > 0$ (lemma 8.2.4). The Hodge index theorem says that the form is negative definite on the orthogonal complement of H, which determines its signature. The proof below, due to Grothendieck [50, Theorem V.1.9], uses Riemann-Roch and Serre duality and no Hodge theory, so it holds in every characteristic.

Lemma 8.3.7: Vanishing of H^2 in Large Degree

Let H be an ample divisor on a smooth projective surface X. If D is a divisor with $D \cdot H > K_X \cdot H$, then $H^2(X, \mathcal{O}_X(D)) = 0$.

***Proof*:**
By Serre duality (corollary 6.5.10), $h^2(\mathcal{O}_X(D)) = h^0(\mathcal{O}_X(K_X - D))$. If this were nonzero, a nonzero section of $\mathcal{O}_X(K_X - D)$ would give an effective divisor $E \sim K_X - D$ (proposition 5.4.47), and lemma 8.2.4(2) with proposition 8.2.2(3) would give $(K_X - D)\cdot H = E \cdot H \geq 0$, contradicting $D \cdot H > K_X \cdot H$. Hence $H^2(X, \mathcal{O}_X(D)) = 0$, as claimed.

On a curve the analogous statement is the vanishing of $H^1(X, \mathcal{L}(D))$ for $\deg D > 2g - 2$ (proposition 7.3.2), with $D \cdot H$ in the role of the degree.

Corollary 8.3.8: Divisors of Positive Square Have Effective Multiples

Let H be an ample divisor on a smooth projective surface X, and let D be a divisor with $D \cdot H > 0$ and $D^2 > 0$. Then $\ell(nD) \geq \chi(\mathcal{O}_X(nD))$ for all $n \gg 0$, the right-hand side tends to ∞ with n, and nD is linearly equivalent to an effective divisor for all $n \gg 0$.

***Proof*:**
For $n\,(D \cdot H) > K_X \cdot H$ we have $nD \cdot H > K_X \cdot H$, so $h^2(\mathcal{O}_X(nD)) = 0$ by lemma 8.3.7, and $\ell(nD) = h^0(\mathcal{O}_X(nD)) \geq h^0 - h^1 = \chi(\mathcal{O}_X(nD))$. By theorem 8.3.1,

$$\chi(\mathcal{O}_X(nD)) = \frac{n^2 D^2 - n\, D \cdot K_X}{2} + \chi(\mathcal{O}_X)$$

which tends to ∞ with n because $D^2 > 0$. So $\ell(nD) > 0$ for $n \gg 0$, and a nonzero section of $\mathcal{O}_X(nD)$ gives an effective divisor linearly equivalent to nD (proposition 5.4.47), completing the proof.

Theorem 8.3.9: Hodge Index Theorem

Let X be a smooth projective surface over an algebraically closed field k of any characteristic, and let H be an ample divisor on X. If D is a divisor with $D \cdot H = 0$, then $D^2 \leq 0$, and $D^2 = 0$ if and only if $D \equiv 0$.

***Proof*:**
If $D \equiv 0$ then $D^2 = 0$. It remains to show that $D \cdot H = 0$ excludes $D^2 > 0$, and that $D \cdot H = 0$ and $D^2 = 0$ together force $D \equiv 0$.

Step 1: $D \cdot H = 0$ implies $D^2 \leq 0$. Suppose $D \cdot H = 0$ and $D^2 > 0$. Since H is ample, definition 5.3.30 applied to $\mathscr{F} = \mathcal{O}_X(D)$ gives an m_0 such that $\mathcal{O}_X(D + mH)$ is generated by global sections for all $m \geq m_0$. Fix $n > m_0$ and put $H' = D + nH$, so that $\mathcal{O}_X(H') = \mathcal{M} \otimes \mathcal{O}_X(H)$ with $\mathcal{M} = \mathcal{O}_X(D + (n-1)H)$ generated by global sections. For a coherent sheaf $\mathscr{F}$,

$$\mathscr{F} \otimes \mathcal{O}_X(H')^{\otimes r} \;\cong\; \mathcal{M}^{\otimes r} \otimes \left(\mathscr{F} \otimes \mathcal{O}_X(H)^{\otimes r}\right)$$

is a tensor product of sheaves generated by global sections once r is large, and products of generating sections generate the stalks of a tensor product, so it is generated by global sections. Hence H' is ample. Now $D \cdot H' = D^2 + n\,(D \cdot H) = D^2 > 0$, and corollary 8.3.8, applied to D and the ample divisor H', gives an $m \geq 1$ and an effective divisor $E \sim mD$. If $E = 0$, then $mD \sim 0$, so $D \equiv 0$ and $D^2 = 0$, which is false. So E is a nonzero effective divisor, and lemma 8.2.4(2)

gives $m\,(D \cdot H) = E \cdot H > 0$, contradicting $D \cdot H = 0$.

Step 2: $D \cdot H = 0$ and $D^2 = 0$ imply $D \equiv 0$. Suppose not, so that some divisor E has $D \cdot E \neq 0$. Put $E' = (H^2)E - (E \cdot H)H$. Then $E' \cdot H = 0$, and $D \cdot E' = (H^2)(D \cdot E) \neq 0$, because $D \cdot H = 0$ and $H^2 > 0$ (lemma 8.2.4(3)). For $t \in \mathbb{Z}$ the divisor $D_t = tD + E'$ satisfies $D_t \cdot H = 0$ and

$$D_t^2 = t^2 D^2 + 2t\,(D \cdot E') + E'^2 = 2t\,(D \cdot E') + E'^2$$

which is positive for a suitable integer t, since $D \cdot E' \neq 0$. This contradicts Step 1 applied to D_t, completing the proof.

The theorem determines the signature of the intersection form once $\mathrm{Num}(X)$ is known to have finite rank.

Corollary 8.3.10: Signature of the Intersection Form

Let X be a smooth projective surface, and suppose that $\mathrm{Num}(X)$ has finite rank r. Then the intersection form on $\mathrm{Num}(X) \otimes_{\mathbb{Z}} \mathbb{R}$ is nondegenerate of signature $(1, r-1)$.

***Proof*:**
Fix an ample divisor H, for instance one with $\mathcal{O}_X(H)$ very ample (proposition 5.3.31). Then $H^2 > 0$ by lemma 8.2.4(3). Let $V = \mathrm{Num}(X) \otimes \mathbb{Q}$ and $H^\perp = \{w \in V : w \cdot H = 0\}$. Every $v \in V$ decomposes as

$$v \;=\; \frac{v \cdot H}{H^2}\,H + \Big(v - \frac{v \cdot H}{H^2}\,H\Big)$$

with the second term in $H^\perp$, so $V = \mathbb{Q}H \oplus H^\perp$, an orthogonal decomposition. If $0 \neq w \in H^\perp$, some multiple mw with $m \geq 1$ is the class of a divisor D with $D \cdot H = 0$, and $D \not\equiv 0$ because its class maps to $mw \neq 0$ in V, so theorem 8.3.9 gives $w^2 = D^2/m^2 < 0$. The form is therefore negative definite on $H^\perp$. In particular no nonzero vector of $H^\perp$ is isotropic, so Gram-Schmidt over $\mathbb{Q}$ produces an orthogonal basis $e_2, \ldots, e_r$ of $H^\perp$ with every $e_i^2 < 0$. Then $H, e_2, \ldots, e_r$ is an orthogonal basis of V, and of $\mathrm{Num}(X) \otimes \mathbb{R} = V \otimes_{\mathbb{Q}} \mathbb{R}$, with $H^2 > 0$ and $e_i^2 < 0$ for $i \geq 2$, so the form on $\mathrm{Num}(X) \otimes \mathbb{R}$ is nondegenerate of signature $(1, r-1)$, as claimed.

The hypothesis always holds. Algebraically equivalent divisors are numerically equivalent [50, Exercise V.1.7], so $\mathrm{Num}(X)$ is a quotient of $\mathrm{NS}(X)$, finitely generated by theorem 8.1.5, and torsion-free, hence free of rank $r \leq \rho(X)$. Over $\mathbb{C}$, numerical and homological equivalence of divisors coincide [50, Appendix A, §5], and $\mathrm{NS}(X)$ embeds in $H^2(X;\mathbb{Z})$ (theorem 8.1.6), so the kernel of $\mathrm{NS}(X) \to \mathrm{Num}(X)$ is the torsion subgroup of $\mathrm{NS}(X)$, $r = \rho(X)$, and the form on $\mathrm{NS}(X) \otimes \mathbb{R}$ has signature $(1, \rho - 1)$.

8.3.11 Remark: The Analytic Proof over $\mathbb{C}$ Over $\mathbb{C}$ the theorem also follows from Hodge theory. The cup product on $H^{1,1}(X) \cap H^2(X;\mathbb{R})$ has signature $(1, h^{1,1}-1)$, with the class of an ample divisor in the positive direction (*Hodge Theory* [24, Hodge Index Theorem]), and on classes of divisors the cup product computes the intersection number. Neither input is proved in this book, and the proof of theorem 8.3.9 uses neither, which is why it holds in every characteristic. In characteristic p, corollary 8.3.12(1), applied on $C \times C$ with the sum of the two fibers through a point as the divisor of positive square, gives the Castelnuovo-Severi inequality, and from it Weil's bound on the number of rational points of a curve C defined over a finite field $\mathbb{F}_q$ (the product taken over $\overline{\mathbb{F}}_q$; section 8.7, following [50, Exercises V.1.9 and V.1.10]).

Corollary 8.3.12: Algebraic Index Inequality

Let C be a divisor on a smooth projective surface X with $C^2 > 0$.

1. If F is a divisor with $F \cdot C = 0$, then $F^2 \leq 0$, with equality if and only if $F \equiv 0$.
2. For every divisor D,
$$(C \cdot D)^2 \;\geq\; C^2 \cdot D^2$$
with equality if and only if $(C^2)\,D \equiv (C \cdot D)\,C$, that is, D is numerically proportional to C.

***Proof*:**
(1) Fix an ample divisor H. By theorem 8.3.9, $C \cdot H \neq 0$, since otherwise $C^2 \leq 0$. Put $G = (F \cdot H)\,C - (C \cdot H)\,F$. Then $G \cdot H = 0$, so $G^2 \leq 0$ by theorem 8.3.9, and since $F \cdot C = 0$,

$$G^2 = (F \cdot H)^2\,C^2 + (C \cdot H)^2\,F^2 \leq 0$$

As $C^2 > 0$ and $(C \cdot H)^2 > 0$, this gives $F^2 \leq 0$. If $F^2 = 0$, then $(F \cdot H)^2 C^2 \leq 0$ forces $F \cdot H = 0$, and theorem 8.3.9 applied to F gives $F \equiv 0$. Conversely $F \equiv 0$ gives $F^2 = 0$.

(2) Put $F = (C^2)\,D - (C \cdot D)\,C$. Then $F \cdot C = 0$ and

$$F^2 = (C^2)^2 D^2 - 2\,C^2 (C \cdot D)^2 + (C \cdot D)^2 C^2 = C^2\big(C^2 D^2 - (C \cdot D)^2\big)$$

By (1), $F^2 \leq 0$, and $C^2 > 0$ gives $C^2 D^2 \leq (C \cdot D)^2$. Equality holds if and only if $F^2 = 0$, which by (1) means $F \equiv 0$, that is, $(C^2)\,D \equiv (C \cdot D)\,C$, completing the proof.

Taking $C = H$ ample in (2) gives $(D^2)(H^2) \leq (D \cdot H)^2$ for every divisor D.

Corollary 8.3.13: Negative Self-Intersection Criterion

Let C be an irreducible curve on a smooth projective surface X.

1. If H is a divisor with $H^2 > 0$ and $C \cdot H = 0$, then $C^2 < 0$.
2. If $C^2 < 0$, then C is the only effective divisor numerically equivalent to C.

***Proof*:**
(1) By corollary 8.3.12(1), with H in the role of C there and C in the role of F, we get $C^2 \leq 0$, with equality only if $C \equiv 0$. A nonzero effective divisor is not numerically equivalent to zero (lemma 8.2.4(2)), so $C^2 < 0$.

(2) Let $C' \neq C$ be an effective divisor with $C' \equiv C$, and fix an ample divisor A. Write $C' = aC + C''$ with $a \geq 0$ and C'' effective, not having C as a component. Then $C \cdot C'' \geq 0$ by proposition 8.2.2(5). If $a = 0$, then $C^2 = C \cdot C' = C \cdot C'' \geq 0$, contradicting $C^2 < 0$. If $a \geq 1$, then $C'' \equiv (1-a)C$, so $C'' \cdot A = (1-a)(C \cdot A) \leq 0$, where $C \cdot A > 0$ by lemma 8.2.4(1). Since C'' is effective, lemma 8.2.4(2) forces $C'' \cdot A = 0$, hence $C'' = 0$ and $a = 1$, so $C' = C$, a contradiction. Hence C is the only effective divisor numerically equivalent to C, completing the proof.

In particular $|C| = \{C\}$ when C is irreducible with $C^2 < 0$: such a curve does not move in its linear system.

8.3.14 Forward Reference: The Hodge Conjecture and Higher-Dimensional Hodge Theory Over $\mathbb{C}$, theorem 8.3.9 is also a consequence of the Hodge-Riemann bilinear relations (box 8.3.11), which hold on every compact Kähler manifold. On a compact Kähler manifold of dimension n with Kähler class ω, they determine the signature of the form $(\alpha, \beta) \mapsto \int_X \alpha \wedge \beta \wedge \omega^{n-2}$ on the real $(1,1)$-classes, using the decomposition into primitive classes that the Hard Lefschetz theorem provides.
The *Hodge conjecture* asserts that for a smooth projective variety X over $\mathbb{C}$, every class in $H^{2p}(X;\mathbb{Q}) \cap H^{p,p}(X)$ is a $\mathbb{Q}$-linear combination of classes of algebraic cycles. For $p = 1$ this is the Lefschetz $(1,1)$ theorem (theorem 8.1.6), so the conjecture holds for surfaces. In general it is open, and it is one of the Clay Millennium Problems. Hodge theory and its relation to algebraic cycles are developed in *Hodge Theory* [24].

8.3.4 The Picard Scheme and Algebraic Equivalence

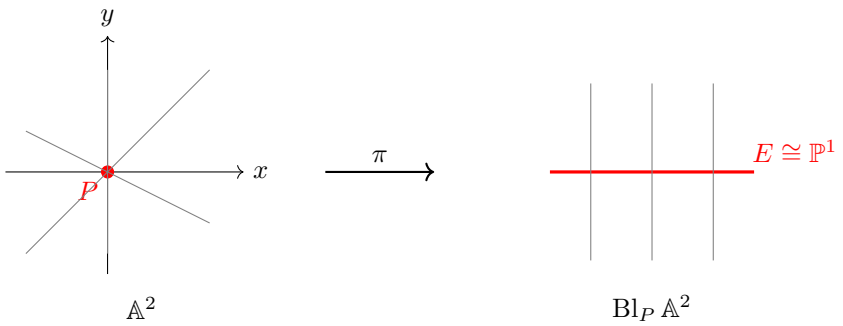
For a curve X, the line bundles of degree 0 are the k-points of the Jacobian $\mathrm{Jac}(X)$, an abelian variety. For a surface the corresponding object is the *Picard scheme* $\mathrm{Pic}_{X/k}$, a group scheme whose k-points form $\mathrm{Pic}(X)$. Over $\mathbb{C}$ its identity component $\mathrm{Pic}^0_{X/k}$ is an abelian variety of dimension $q = h^{0,1}(X)$ (the irregularity). In characteristic p the scheme $\mathrm{Pic}^0_{X/k}$ can be non-reduced (Igusa), and its reduction is an abelian variety of dimension at most q. The connected components of $\mathrm{Pic}_{X/k}$ are the cosets of $\mathrm{Pic}^0_{X/k}$, and they are indexed by the Néron-Severi group $\mathrm{NS}(X)$ of definition 8.1.4.

Three equivalence relations on divisors are in use, each coarser than the one before:

1. *Linear equivalence* ($\sim$): $D_1 \sim D_2$ if $D_1 - D_2 = \mathrm{div}(f)$. The classes form $\mathrm{Pic}(X)$.
2. *Algebraic equivalence* ($\sim_{\mathrm{alg}}$): the equivalence relation generated by declaring $D_1 \sim_{\mathrm{alg}} D_2$ when there are a connected variety T, points $t_1, t_2 \in T$, and a line bundle $\mathcal{L}$ on $X \times T$ with $\mathcal{L}|_{X \times \{t_i\}} \cong \mathcal{O}_X(D_i)$ for $i = 1, 2$. The classes form the Néron-Severi group $\mathrm{NS}(X) = \mathrm{Pic}(X)/\sim_{\mathrm{alg}}$.
3. *Numerical equivalence* ($\equiv$, definition 8.2.5). The classes form $\mathrm{Num}(X)$.

By the theorem of the base (theorem 8.1.5) the group $\mathrm{NS}(X)$ is finitely generated, and Matsusaka proved that numerical and algebraic equivalence agree up to torsion: the kernel of $\mathrm{NS}(X) \to \mathrm{Num}(X)$

is the torsion subgroup of $\mathrm{NS}(X)$, so $\mathrm{Num}(X) \cong \mathrm{NS}(X)/\text{torsion}$. If $q = 0$, then $\mathrm{Pic}^0_{X/k}$ is trivial, because its tangent space at the identity is $H^1(X, \mathcal{O}_X) = 0$. Linear and algebraic equivalence then coincide, and numerical equivalence differs from them only on the torsion of $\mathrm{Pic}(X)$. On an Enriques surface (section 8.6.3), for example, K_X is a nonzero torsion class that is numerically trivial.



8.4 Blow-ups

Blowing up a closed point of a smooth projective surface raises its Picard number by one (theorem 8.4.6(2) and (3)), which is why the blow-up is not isomorphic to the surface (box 8.1.3). By a theorem of Zariski (theorem 8.4.11), every birational morphism between smooth projective surfaces is a composition of blow-ups at points, and every birational map between them factors into blow-ups at points and their inverses [50, Theorem V.5.5].

The model case is the plane. Consider $\mathbb{A}^2_k$ with coordinates (x, y) and the origin $P = (0, 0)$. The *blow-up* of $\mathbb{A}^2$ at P replaces P by a copy of $\mathbb{P}^1$ parametrizing the *directions* through P. Every line through the origin has a well-defined direction $[x : y] \in \mathbb{P}^1$ (the vertical line included), and the blow-up has one point over the origin for each of these directions. Concretely, the blow-up is the closed subvariety

$$\mathrm{Bl}_P \mathbb{A}^2 \;=\; \{((x, y), [s : t]) \in \mathbb{A}^2 \times \mathbb{P}^1 : xt = ys\} \;\subseteq\; \mathbb{A}^2 \times \mathbb{P}^1$$

The projection $\pi\colon \mathrm{Bl}_P \mathbb{A}^2 \to \mathbb{A}^2$ onto the first factor is an isomorphism away from the origin, with inverse $(x, y) \mapsto ((x, y), [x : y])$ on $\mathbb{A}^2 \backslash \{(0, 0)\}$. Over the origin, the fiber $\pi^{-1}(0, 0) = \{(0, 0)\} \times \mathbb{P}^1 \cong \mathbb{P}^1$ contains every direction. This fiber is the *exceptional divisor* E.

The strict transforms of distinct lines through the origin, the closures of their preimages away from P, are disjoint and meet E at the distinct points given by their directions. So the blow-up separates curves through P with distinct tangent directions. In particular a node, two branches crossing at a point with distinct tangent lines, is resolved by one blow-up (example 8.4.7(2)). Example 3.1.32 exhibits the two branches of the same node in the completed local ring.

The same construction applies to any closed subscheme of a Noetherian scheme, with the Rees algebra of its ideal sheaf in place of the incidence equation $xt = ys$.

Definition 8.4.1: Blow-up

Let X be a Noetherian scheme and $\mathcal{I} \subseteq \mathcal{O}_X$ a coherent ideal sheaf defining a closed subscheme $Z \subseteq X$. The *blow-up of X along Z* (or *along $\mathcal{I}$*) is

$$\mathrm{Bl}_Z X \;=\; \mathrm{Proj}\left(\bigoplus_{n\geq 0} \mathcal{I}^n\right)$$

where $\bigoplus_{n\geq 0}\mathcal{I}^n$ is the *Rees algebra* of $\mathcal{I}$, the graded $\mathcal{O}_X$-algebra whose degree-n piece is the nth power of the ideal sheaf (with $\mathcal{I}^0 = \mathcal{O}_X$). The natural map $\pi\colon \mathrm{Bl}_Z X \to X$ is called the *blow-up morphism*. The *exceptional divisor* is the closed subscheme $E = \pi^{-1}(Z)$ of $\mathrm{Bl}_Z X$ defined by the inverse image ideal sheaf $\pi^{-1}\mathcal{I}\cdot\mathcal{O}_{\mathrm{Bl}_Z X}$. Its underlying set is the preimage of Z.

The Proj construction here is the *relative Proj* over X (theorem 5.3.49, which applies as the Rees algebra is generated in degree one): locally on an affine open $U = \operatorname{Spec} A$ of X with $\mathcal{I}|_U = \widetilde{I}$ for an ideal $I \subseteq A$, the blow-up restricts to $\operatorname{Proj}\bigoplus_{n\geq 0} I^n$, the classical blow-up algebra of I.

Proposition 8.4.2: Basic Properties of Blow-ups

Let $\pi\colon \mathrm{Bl}_Z X \to X$ be the blow-up of a Noetherian scheme X along a closed subscheme Z defined by $\mathcal{I}$.

1. π is proper, and projective over every affine open of X. If X admits an ample invertible sheaf, then π is projective.
2. π is an isomorphism over $X \setminus Z$: the restriction $\pi^{-1}(X\setminus Z) \xrightarrow{\sim} X \setminus Z$ is an isomorphism. If Z has codimension ≥ 1, then π is birational.
3. The inverse image ideal sheaf $\pi^{-1}\mathcal{I}\cdot\mathcal{O}_{\mathrm{Bl}_Z X}$ is invertible, so the exceptional divisor $E = V(\pi^{-1}\mathcal{I}\cdot\mathcal{O}_{\mathrm{Bl}_Z X})$ is an effective Cartier divisor.
4. If $f\colon Y \to X$ is a morphism such that $f^{-1}\mathcal{I}\cdot\mathcal{O}_Y$ is an invertible ideal sheaf, then f factors uniquely through π.

***Proof*:**

1. The Rees algebra is generated in degree one (example 5.3.48(2)) and $\mathcal{I}$ is coherent, so theorem 5.3.49 makes π proper and projective over every affine open of X. When X admits an ample invertible sheaf, π is projective by [50, Proposition II.7.10(b)].
2. Over the complement of Z, $\mathcal{I} = \mathcal{O}_X$, so $\mathcal{I}^n = \mathcal{O}_X$ for all n, and Proj of the polynomial algebra $\mathcal{O}_X[t]$ (in a single variable of degree 1) is X itself. If Z has codimension ≥ 1, it contains no irreducible component of X, so $X \setminus Z$ is dense in X. Its preimage $\pi^{-1}(X\setminus Z)$ is the complement of E, and it is dense in $\mathrm{Bl}_Z X$: by item (3), whose proof does not use this one, E is cut out on each chart by a nonzerodivisor of a Noetherian ring, and a nonzerodivisor lies in no minimal prime. So π restricts to an isomorphism between dense opens, and it is birational.
3. Let $U = \operatorname{Spec} A$ be an affine open with $\mathcal{I}|_U = \widetilde{I}$. The ring A is Noetherian (ex-

ample 2.2.32(2)), so $I = (a_0, \dots, a_m)$ for some $a_i \in A$, and $\pi^{-1}(U) = \operatorname{Proj} S$ for $S = \bigoplus_{n\geq 0} I^n t^n \subseteq A[t]$, covered by the charts $D_+(a_i t) = \operatorname{Spec} S_{(a_i t)}$ (lemma 2.3.2). In $S_{(a_i t)}$ each a_j equals $\big((a_j t)/(a_i t)\big)\, a_i$, so $IS_{(a_i t)} = a_i S_{(a_i t)}$. The element a_i is a nonzerodivisor of $S_{(a_i t)}$: if $a_i \cdot s/(a_i t)^n = 0$ with $s \in I^n t^n$, then $(a_i t)^N a_i s = a_i^{N+1} t^N s = 0$ in $A[t]$ for some N, so $a_i^{N+1} s = 0$, hence $(a_i t)^{N+1} s = 0$ and $s/(a_i t)^n = 0$. Thus $\pi^{-1}\mathcal{I} \cdot \mathcal{O}_{\operatorname{Bl}_Z X}$ is locally generated by a single nonzerodivisor, which is to say that it is invertible.

4. This is the universal property of blowing up, [50, Proposition II.7.14] or [96, § 22]. Its proof reduces to the affine case and applies theorem 5.3.43 to the generators of $f^{-1}\mathcal{I} \cdot \mathcal{O}_Y$, completing the proof.

By proposition 8.4.2(3), the ideal $\mathcal{I}$, which need not be locally principal, becomes locally principal on the blow-up, generated on each chart by a nonzerodivisor, and E is the effective Cartier divisor it cuts out.

When the centre is nonsingular and sits inside a nonsingular variety, the blow-up is again nonsingular. This is the case used below, for the blow-up of a surface at a point (theorem 8.4.6) and for a nonsingular base locus of a pencil (the paragraph after lemma 8.4.4).

Proposition 8.4.3: Blow-up Along a Nonsingular Centre

Let X be a nonsingular variety over an algebraically closed field k and let $Z \subseteq X$ be a nonsingular closed subvariety of codimension $d \geq 1$. Then $\operatorname{Bl}_Z X$ is a nonsingular variety of the same dimension as X, and the blow-down $\pi\colon \operatorname{Bl}_Z X \to X$ is proper and birational. If X is quasi-projective, then π is projective.

***Proof*:**
Properness and birationality are proposition 8.4.2(1) and (2), and $\operatorname{Bl}_Z X$ is separated and of finite type over k because π is proper and X is a variety. If X is quasi-projective, π is projective by [50, Proposition II.7.16(c)].

Step 1: $\operatorname{Bl}_Z X$ is a variety of dimension $n = \dim X$. Let $\operatorname{Spec} A \subseteq X$ be an affine open meeting Z, with $\mathcal{I}|_{\operatorname{Spec} A} = \widetilde{I}$ and $I = (h_1, \dots, h_m)$, every h_i taken nonzero (zero generators may be discarded). The blow-up over $\operatorname{Spec} A$ is Proj of the Rees algebra $S = \bigoplus_{n\geq 0} I^n t^n \subseteq A[t]$, generated in degree one by the $h_i t$, so it is covered by the charts $D_+(h_i t) = \operatorname{Spec} S_{(h_i t)}$. Here A is a domain, X being integral, so S is a graded subring of a domain and every $S_{(h_i t)}$ is a domain. Hence $\operatorname{Bl}_Z X$ is reduced. Moreover

$$A \;\subseteq\; S_{(h_i t)} \;=\; A\big[h_1/h_i, \dots, h_m/h_i\big] \;\subseteq\; A_{h_i} \;\subseteq\; \operatorname{Frac} A$$

the middle equality because S is generated in degree one by the $h_j t$. So each chart is a finitely generated k-domain with fraction field $\operatorname{Frac} A$ and therefore has dimension $\operatorname{trdeg}_k \operatorname{Frac} A = n$ by theorem 2.6.11. Over an affine open of X missing Z the blow-down is an isomorphism (proposition 8.4.2(2)), so those opens have dimension n too. As $\operatorname{Bl}_Z X$ is covered by charts of these two kinds, proposition 2.6.2 gives $\dim \operatorname{Bl}_Z X = n$.

For irreducibility, let $U = \pi^{-1}(X \setminus Z)$, isomorphic to $X \setminus Z$ by proposition 8.4.2(2) and hence irreducible and nonempty, X being a variety. On the chart $D_+(h_i t)$ the ideal $IS_{(h_i t)}$ is generated by h_i, since $h_j = h_i \cdot (h_j/h_i)$ there, so U meets that chart in $D(h_i)$, a nonempty open of an irreducible scheme and hence dense in it. So U is dense in every chart, hence dense in $\operatorname{Bl}_Z X$,

which is therefore the closure of an irreducible set and so irreducible (lemma 2.1.24(1)). Thus $\mathrm{Bl}_Z X$ is an integral scheme, birational to X.

Step 2: local generators with independent differentials. Fix a closed point $z \in Z$. Since X and Z are nonsingular, theorem 5.5.27 makes $\mathcal{I}/\mathcal{I}^2$ locally free of rank d and the conormal sequence $0 \to \mathcal{I}/\mathcal{I}^2 \to \Omega_{X/k} \otimes \mathcal{O}_Z \to \Omega_{Z/k} \to 0$ exact with all three terms locally free. A short exact sequence with locally free quotient is locally split (lemma 5.5.20), so it stays exact after $\otimes\, \kappa(w)$ at every point $w \in Z$. Choose $a_1, \dots, a_d \in \mathcal{I}$ whose classes form a basis of $\mathcal{I}/\mathcal{I}^2$ near z. After shrinking, they generate $\mathcal{I}$ by Nakayama, and since the conormal sequence stays exact after $\otimes\, \kappa(w)$, their differentials $da_1, \dots, da_d$ are linearly independent in $\Omega_{X/k} \otimes \kappa(w)$ at every closed point $w \in Z$ of that neighbourhood. Being members of a basis of a free module of rank $d \geq 1$ over a nonzero ring, each a_i is nonzero. Shrink further so that the neighbourhood is an affine $U_z = \operatorname{Spec} A$ realized as a closed subscheme $\operatorname{Spec} k[x_1, \dots, x_N]/(f_1, \dots, f_r)$ of $\mathbb{A}^N_k$. At a closed point of $\operatorname{Spec} A$ the local ring has dimension n by theorem 2.6.12, so nonsingularity of X and proposition 2.7.7 make the Jacobian of the f_i of rank $N - n$ there.

Step 3: the charts. The algebra S is generated in degree one by $a_1 t, \dots, a_d t$, so the charts $D_+(a_i t)$ cover $\pi^{-1}(U_z)$. By symmetry it is enough to treat $i = 1$. Since $I = (a_1, \dots, a_d)$, every element of I^n is an A-linear combination of degree-n monomials in the a_j, so

$$S_{(a_1 t)} \;=\; A\big[a_2/a_1,\ \dots,\ a_d/a_1\big] \;\subseteq\; A_{a_1}$$

Let $C = A[y_2, \dots, y_d]/(g_2, \dots, g_d)$ with $g_j = a_j - a_1 y_j$, and let $\varphi\colon C \to S_{(a_1 t)}$ send $y_j \mapsto a_j/a_1$. This is well defined and surjective. Presenting A as in Step 2 realizes $\operatorname{Spec} C$ as the closed subscheme of $\mathbb{A}^M_k$, $M = N + d - 1$, cut out by $f_1, \dots, f_r, g_2, \dots, g_d$, where each a_j is read through a polynomial lift, well defined modulo $(f_1, \dots, f_r)$. Every computation below is made modulo the span of $df_1, \dots, df_r$, so the choice of lift does not matter.

Step 4: $\operatorname{Spec} C$ is regular, and each of its components has dimension at least n. Let $P \in \operatorname{Spec} C$ be a closed point, lying over $Q \in \operatorname{Spec} A$. Since k is algebraically closed and P is closed, $\kappa(P) = k$. Then $k \subseteq \kappa(Q) \subseteq \kappa(P)$ forces $\kappa(Q) = k$, so Q is closed too. In $\Omega_{\mathbb{A}^M} \otimes \kappa(P)$, spanned by $dx_1, \dots, dx_N, dy_2, \dots, dy_d$, we have $dg_j = da_j - y_j(P)\, da_1 - a_1(Q)\, dy_j$. If $a_1(Q) \neq 0$ the dy-components of $dg_2, \dots, dg_d$ are $-a_1(Q)$ times the identity matrix, so these $d - 1$ forms are independent modulo the span of $df_1, \dots, df_r$, which involves no dy. If $a_1(Q) = 0$, then $a_j(Q) = a_1(Q) y_j(P) = 0$ for every j, so $Q \in Z$. There $dg_j = da_j - y_j(P)\, da_1$, and since $da_1, \dots, da_d$ are independent in $\Omega_{X/k} \otimes \kappa(Q)$, that is modulo the span of the df_i, reading off the coefficient of da_j shows $dg_2, \dots, dg_d$ are again independent modulo that span. Either way the Jacobian of $(f_1, \dots, f_r, g_2, \dots, g_d)$ at P has rank $(N - n) + (d - 1) = M - n$.

That rank computes the cotangent space. Because $\kappa(P) = k$ is separable over k, the map $\mathfrak{n}/\mathfrak{n}^2 \to \Omega_{\mathbb{A}^M/k} \otimes \kappa(P)$ is an isomorphism (proposition 5.5.10), where $\mathfrak{n}$ is the maximal ideal of P in $\mathbb{A}^M_k$. The surjection $\mathfrak{n}/\mathfrak{n}^2 \to \mathfrak{m}_P/\mathfrak{m}_P^2$ has kernel the span of the images of the defining equations, of dimension the Jacobian rank, so $\dim_k \mathfrak{m}_P/\mathfrak{m}_P^2 = M - (M - n) = n$ and hence $\dim \mathcal{O}_{C,P} \leq n$ by [15, Dimension and Embedding Dimension].

For the reverse, work inside $A[y_2, \dots, y_d]$. That ring is a finitely generated k-domain whose fraction field has transcendence degree $n + (d - 1)$ over k, so it has dimension $n + d - 1$ by theorem 2.6.11, and $\operatorname{Spec} C$ is cut out in it by the $d - 1$ equations $g_2, \dots, g_d$. So every irreducible component of $\operatorname{Spec} C$ has codimension at most $d - 1$ by corollary 2.6.15, hence dimension at least n by theorem 2.6.12. If W is a component through the closed point P, then applying theorem 2.6.12 to $\{P\} \subseteq W$ gives $\dim \mathcal{O}_{W,P} = \dim W \geq n$, so $\dim \mathcal{O}_{C,P} \geq n$. Therefore $\dim \mathcal{O}_{C,P} = n = \dim_k \mathfrak{m}_P/\mathfrak{m}_P^2$, which is regularity at P (definition 2.7.3). This holds at every

closed point, so $\operatorname{Spec} C$ is regular by box 5.5.24.

Step 5: the presentation is an isomorphism. By Step 2 the ring A is a domain and $a_1 \neq 0$. On the locus $a_1 \neq 0$ the equations $g_j = a_j - a_1 y_j$ say exactly that $y_j = a_j/a_1$, so $C_{a_1} \cong A_{a_1}$ and $\operatorname{Spec} C$ meets that locus in a copy of $\operatorname{Spec} A_{a_1}$: irreducible, and of dimension n, being a nonempty open of the n-dimensional irreducible $\operatorname{Spec} A$. On the complementary locus $a_1 = 0$ every a_j vanishes as well, so $C/(a_1) = (A/I)[y_2, \ldots, y_d]$. That ring is a finitely generated k-domain of transcendence degree $(n-d)+(d-1)$, using $\dim A/I = \dim Z = n-d$ from theorem 2.6.12, hence of dimension $n-1$ by theorem 2.6.11. By Step 4 every component of $\operatorname{Spec} C$ has dimension at least n, so none is contained in the locus $a_1 = 0$. Every component therefore meets the irreducible open $\{a_1 \neq 0\}$, and the argument of Step 1 makes $\operatorname{Spec} C$ irreducible. Being regular, $\operatorname{Spec} C$ is reduced (proposition 2.7.4), hence integral, so C is a domain, of dimension n because it contains the dense open $\operatorname{Spec} A_{a_1}$ of that dimension.

Now $\varphi\colon C \to S_{(a_1 t)}$ is a surjection onto a domain, itself of dimension n by Step 1. So $\ker\varphi$ is a prime $\mathfrak{p}$ with $\dim C/\mathfrak{p} = \dim C$, hence of codimension zero by theorem 2.6.12, hence zero. Thus $S_{(a_1 t)} \cong C$ is regular.

Step 6: globalization. Every closed point of Z has a neighbourhood U_z as in Step 2, and these cover Z. Over each, Steps 3 to 5 make the charts $D_+(a_i t)$ regular, and those charts cover $\pi^{-1}(U_z)$. Over the complement, $\pi^{-1}(X \setminus Z) \cong X \setminus Z$ is regular because X is. Every closed point of $\operatorname{Bl}_Z X$ lies over a closed point of X, so every closed point is covered by one of these cases. Regularity at closed points suffices (box 5.5.24), so $\operatorname{Bl}_Z X$ is regular. Being in addition an integral separated finite-type k-scheme, it is a nonsingular variety of dimension n, as claimed.

Two sections s_0, s_1 of an invertible sheaf $\mathcal{L}$ span a pencil when they are linearly independent, and theorem 5.3.43 turns them into the morphism $x \mapsto [s_0(x) : s_1(x)]$ to $\mathbb{P}^1$ away from the *scheme-theoretic base locus* $B = V(s_0, s_1)$ on which both vanish. Blowing up B extends this morphism to all of $\operatorname{Bl}_B X$, and the blow-up is the closure in $X \times \mathbb{P}^1$ of the graph of the morphism.

Lemma 8.4.4: The Blow-up as the Closure of a Graph

Let R be a ring, X an integral Noetherian R-scheme, $\mathcal{L}$ an invertible sheaf on X, and $s_0, s_1 \in \Gamma(X, \mathcal{L})$ two nonzero sections. Let $\mathcal{I} \subseteq \mathcal{O}_X$ be the image of

$$(s_0, s_1)\colon \mathcal{L}^\vee \oplus \mathcal{L}^\vee \longrightarrow \mathcal{O}_X, \qquad (\lambda, \mu) \longmapsto \lambda(s_0) + \mu(s_1)$$

a coherent ideal sheaf, let $B = V(s_0, s_1)$ be the closed subscheme of X it defines (proposition 5.1.34), and let $\pi\colon \widetilde{X} := \mathrm{Bl}_B X \to X$ be the blow-up along $\mathcal{I}$ (definition 8.4.1). Write $\mathbb{P}^1_R = \operatorname{Proj} R[T_0, T_1]$. The open $X \setminus B$ is nonempty and s_0, s_1 generate $\mathcal{L}$ over it, so theorem 5.3.43(2) gives an R-morphism

$$\varphi\colon X \setminus B \longrightarrow \mathbb{P}^1_R, \qquad x \longmapsto [s_0(x) : s_1(x)]$$

with $\varphi^*\mathcal{O}(1) \cong \mathcal{L}|_{X\setminus B}$ and $\varphi^* T_i = s_i$. Let $\Gamma_\varphi \subseteq (X \setminus B) \times_R \mathbb{P}^1_R \subseteq X \times_R \mathbb{P}^1_R$ be the image of (id, φ), the graph of φ, the first inclusion an open subscheme by proposition 3.2.5(1), applied to the projection to X. Then:

1. The $\mathcal{O}_{\widetilde{X}}$-submodule $\mathcal{M} \subseteq \pi^*\mathcal{L}$ generated by $\pi^* s_0$ and $\pi^* s_1$ is invertible and equals $(\mathcal{I}\mathcal{O}_{\widetilde{X}}) \cdot \pi^*\mathcal{L}$, so theorem 5.3.43(2) gives an R-morphism $g\colon \widetilde{X} \to \mathbb{P}^1_R$ with $g^*\mathcal{O}(1) \cong \mathcal{M}$ and $g^* T_i = \pi^* s_i$. Moreover π restricts to an isomorphism $\pi_W\colon W := \pi^{-1}(X\setminus B) \to X \setminus B$, and $g|_W = \varphi \circ \pi_W$.
2. The morphism $j := (\pi, g)\colon \widetilde{X} \to X \times_R \mathbb{P}^1_R$ is a closed immersion.
3. $\widetilde{X}$ is integral, and j identifies $\widetilde{X}$ with the closure $\overline{\Gamma_\varphi}$ of the graph in $X \times_R \mathbb{P}^1_R$, carrying its reduced induced structure (definition 3.1.26).

***Proof*:**

Step 1: the local model. Let $U = \operatorname{Spec} A \subseteq X$ be a nonempty affine open on which $\mathcal{L}$ is free with generator $e \in \mathcal{L}(U)$. Such opens cover X, since $\mathcal{L}$ is invertible and the affine opens form a basis. Write $s_i|_U = a_i e$ with $a_i \in A$. Under $\mathcal{L}^\vee|_U \cong \mathcal{O}_U$, $\lambda \mapsto \lambda(e)$, the map (s_0, s_1) becomes $\widetilde{(a_0, a_1)}\colon \widetilde{A^2} \to \widetilde{A}$, so $\mathcal{I}|_U = \widetilde{I}$ with $I = (a_0, a_1)$ (proposition 5.1.14(3)). Thus $\mathcal{I}$ is coherent, A being Noetherian (example 2.2.32(2)), and $B \cap U = V(I)$ (corollary 5.1.35), so $U \setminus B = D(a_0) \cup D(a_1)$ is the set of points at which some s_i generates $\mathcal{L}$. The ring A is a domain (definition 2.4.19) and $a_0 a_1 \neq 0$: if $a_i = 0$ then s_i vanishes on U, hence on every trivializing open V of $\mathcal{L}$, because $V \cap U$ is nonempty (X is irreducible) and $\mathcal{L}(V) \cong \mathcal{O}_X(V) \to \mathcal{O}_X(V \cap U)$ is injective (proposition 2.4.23), contradicting $s_i \neq 0$. In particular $X \setminus B \supseteq D(a_0) \neq \emptyset$.

By definition 8.4.1, example 5.3.48(2) and theorem 5.3.49(1), $\widetilde{U} := \pi^{-1}(U) \cong \operatorname{Proj} S$ over U, where $S = \bigoplus_{n\geq 0} I^n t^n \subseteq A[t]$ is the Rees algebra of I, a domain generated over A by $a_0 t$ and $a_1 t$. Hence $\widetilde{U}$ is covered by the charts $D_+(a_i t) = \operatorname{Spec} S_{(a_i t)}$ (lemma 2.3.2). The generators lie in degree one, so an element $s/(a_i t)^n$ of $S_{(a_i t)}$ with $s \in I^n t^n$ is a polynomial in a_{1-i}/a_i with coefficients in A, and conversely $a_{1-i}/a_i = (a_{1-i}t)/(a_i t)$ lies in $S_{(a_i t)}$. Hence

$$A \subseteq S_{(a_i t)} = A[a_{1-i}/a_i] \subseteq A_{a_i} \subseteq \operatorname{Frac}(A)$$

the inclusion $A \subseteq S_{(a_i t)}$ being $\pi^\#$ (example 3.1.11). Both charts are nonempty and they meet in $D_+(a_0 a_1 t^2) = \operatorname{Spec} S_{(a_0 a_1 t^2)}$, which is nonempty because $a_0 a_1 t^2 \neq 0$ in the domain S. In $S_{(a_i t)}$

we have $a_{1-i} = (a_{1-i}/a_i)\,a_i$, so $IS_{(a_it)} = a_i S_{(a_it)}$ is free of rank one on the nonzerodivisor a_i.

Step 2: the invertible sheaf $\mathcal{M}$ and the morphism g. On $\widetilde{U}$ the section π^*e generates $\pi^*\mathcal{L}$ and $\pi^*s_i = a_i\,\pi^*e$, so under $\pi^*\mathcal{L}|_{\widetilde{U}} \cong \mathcal{O}_{\widetilde{U}}$ the submodule $\mathcal{M}|_{\widetilde{U}}$ is the ideal sheaf generated by a_0, a_1, namely $I\mathcal{O}_{\widetilde{U}} = (\mathcal{I}\mathcal{O}_{\widetilde{X}})|_{\widetilde{U}}$, whose restriction to the chart $D_+(a_it)$ is $\widetilde{IS_{(a_it)}}$ (proposition 5.1.14(3),(7)), free of rank one on a_i by Step 1. Hence $\mathcal{M} = (\mathcal{I}\mathcal{O}_{\widetilde{X}})\cdot\pi^*\mathcal{L}$ is invertible and generated by π^*s_0, π^*s_1, and theorem 5.3.43(2) yields g. On the chart $D_+(a_kt) = \operatorname{Spec} S_{(a_kt)}$, where $\mathcal{M}$ is free on a_k, the section $\pi^*s_i = (a_i/a_k)\,a_k\,\pi^*e$ generates $\mathcal{M}$ at a point if and only if a_i/a_k is a unit there, that is, on $D(a_i/a_k) = D_+(a_it) \cap D_+(a_kt)$ (a homogeneous prime $\mathfrak{p} \in D_+(a_kt)$ contains a_it if and only if $a_i/a_k = (a_it)/(a_kt)$ lies in $(\mathfrak{p}S_{a_kt})_0$). Taking the union over $k = 0, 1$, the non-vanishing locus of π^*s_i in $\widetilde{U}$ is $D_+(a_it)$. The equality $\widetilde{U} \cap g^{-1}(D_+(T_i)) = D_+(a_it)$ follows from theorem 5.3.43(2) alone. In one direction, T_i generates $\mathcal{O}(1)$ over $D_+(T_i)$ (proposition 5.3.5) and $g^*T_i = \pi^*s_i$, so π^*s_i generates $\mathcal{M}$ over $g^{-1}(D_+(T_i))$. In the other, a point of $\mathbb{P}^1_R$ outside $D_+(T_i)$ lies in $D_+(T_{1-i})$, where $\mathcal{O}(1)$ is free on T_{1-i} (proposition 5.3.5) and T_i corresponds to the function T_i/T_{1-i}, whose non-vanishing locus is $D_+(T_i) \cap D_+(T_{1-i})$. So if $g(z) \notin D_+(T_i)$ then T_i does not generate $\mathcal{O}(1)$ at $g(z)$, its germ lies in $\mathfrak{m}_{g(z)}\mathcal{O}(1)_{g(z)}$, the germ of $g^*T_i = \pi^*s_i$ lies in $\mathfrak{m}_z\mathcal{M}_z$, because $g^\#$ is a local homomorphism, and z is outside the non-vanishing locus of π^*s_i. Finally, over $D_+(T_i)$ the section T_{1-i} equals $(T_{1-i}/T_i)\,T_i$ in $\mathcal{O}(1)$, so pulling back, $\pi^*s_{1-i} = g^\#(T_{1-i}/T_i)\,\pi^*s_i$ in $\mathcal{M}$. On $D_+(a_it)$, where $\mathcal{M}$ is free on $a_i\,\pi^*e$ and $\pi^*s_{1-i} = (a_{1-i}/a_i)(a_i\,\pi^*e)$, comparing coefficients of the generator gives $g^\#(T_{1-i}/T_i) = a_{1-i}/a_i \in S_{(a_it)}$.

Step 3: π over $X \setminus B$. Let $V = \operatorname{Spec} A' \subseteq X \setminus B$ be affine open. Then $\mathcal{I}|_V = \mathcal{O}_V$, since $\mathcal{I}_x = \mathcal{O}_{X,x}$ for $x \notin B$, so the Rees algebra restricts to $\widetilde{A'[t]}$ with t in degree one. A homogeneous prime of $A'[t]$ not containing $A'[t]_+ = tA'[t]$ omits t, so $\pi^{-1}(V) \cong \operatorname{Proj} A'[t] = D_+(t) = \operatorname{Spec}(A'[t]_t)_0 = \operatorname{Spec} A'$ over V, the structure map being induced by the identity $A' \to (A'[t]_t)_0 = A'$. Thus π is an isomorphism over each such V, and the local inverses glue (lemma 3.1.9) to an inverse of π_W. Pullback preserves surjections, so π^*s_0, π^*s_1 generate $\pi^*\mathcal{L}$ over W and $\mathcal{M}|_W = \pi^*\mathcal{L}|_W$. Hence $g|_W$ and $\varphi \circ \pi_W$ are R-morphisms $W \to \mathbb{P}^1_R$ pulling $(\mathcal{O}(1), T_0, T_1)$ back to $(\pi^*\mathcal{L}|_W, \pi^*s_0, \pi^*s_1)$, and the uniqueness in theorem 5.3.43(2) gives $g|_W = \varphi \circ \pi_W$.

Step 4: j is a closed immersion. A morphism that restricts to a closed immersion over every member of an open cover of the target is a closed immersion (lemma 5.3.39). Now the opens $V_{U,i} := U \times_R D_+(T_i) \cong \operatorname{Spec} A[T_{1-i}/T_i]$, for U as in Step 1 and $i = 0, 1$, cover $X \times_R \mathbb{P}^1_R$ (proposition 3.2.5(1), applied to each projection in turn), and $j^{-1}(V_{U,i}) = \pi^{-1}(U) \cap g^{-1}(D_+(T_i)) = D_+(a_it)$ by Step 2. The restriction $D_+(a_it) \to V_{U,i}$ of j is the morphism of affine schemes induced by the ring map $A[T_{1-i}/T_i] \to S_{(a_it)}$ that is $\pi^\#$, the inclusion, on A and sends T_{1-i}/T_i to $g^\#(T_{1-i}/T_i) = a_{1-i}/a_i$ (Steps 1 and 2). Its image is $A[a_{1-i}/a_i] = S_{(a_it)}$, so it is surjective and $j^{-1}(V_{U,i}) \to V_{U,i}$ is a closed immersion (proposition 3.1.24(2)). Hence j is a closed immersion.

Step 5: $\widetilde{X}$ is integral and $j(\widetilde{X}) = \overline{\Gamma_\varphi}$. Every chart $D_+(a_it) = \operatorname{Spec} S_{(a_it)}$ is the spectrum of a domain, so the stalks of $\mathcal{O}_{\widetilde{X}}$ have no nonzero nilpotents and $\widetilde{X}$ is reduced (proposition 2.4.15). Each $\widetilde{U}$ is irreducible: a nonempty open $O \subseteq \widetilde{U}$ meets one of the two irreducible charts in a nonempty open, which is dense in that chart and so meets the nonempty open $D_+(a_0a_1t^2)$ of it (Step 1). Two nonempty opens of $\widetilde{U}$ therefore meet $D_+(a_0a_1t^2)$ in nonempty opens of the irreducible chart $D_+(a_0t)$, and these intersect. Now $W \cong X \setminus B$ is a nonempty open of the irreducible X, hence irreducible, and $W \cap \widetilde{U} = \pi^{-1}(U \setminus B)$ is nonempty, π being an isomorphism over the nonempty $U \setminus B$ (Steps 1 and 3), and it is a nonempty open of the irreducible $\widetilde{U}$, hence

dense. The $\widetilde{U}$ cover $\widetilde{X}$, so W is dense in $\widetilde{X}$ and $\widetilde{X} = \overline{W}$ is irreducible, being the closure of an irreducible subspace (lemma 2.1.24(1)). Thus $\widetilde{X}$ is integral (proposition 2.4.26).

By Step 3, $j|_W = (\pi_W, \varphi \circ \pi_W) = (\mathrm{id}, \varphi) \circ \pi_W$ with π_W an isomorphism, so $j(W) = \Gamma_\varphi$. As j is a homeomorphism onto the closed set $j(\widetilde{X})$ and W is dense in $\widetilde{X}$, we get $j(\widetilde{X}) = \overline{j(W)} = \overline{\Gamma_\varphi}$. The closed subscheme $j(\widetilde{X}) \cong \widetilde{X}$ is reduced, and a reduced closed subscheme is determined by its underlying closed set (the uniqueness clause of proposition 3.1.25). Hence j identifies $\widetilde{X}$ with $\overline{\Gamma_\varphi}$ carrying its reduced induced structure, completing the proof.

When X is a nonsingular projective variety over an algebraically closed field $k = R$ and the base locus B is a nonsingular closed subvariety of codimension two, proposition 8.4.3 shows that $\overline{\Gamma_\varphi} = \mathrm{Bl}_B X$ is again a nonsingular variety, birational to X through π. This is the situation of a Lefschetz pencil, whose blow-up along the base locus is studied in *Hodge Theory* [24, The Fibration Attached to a Pencil]. Example 8.4.5 is the case $X = \mathbb{A}^2_k$, $\mathcal{L} = \mathcal{O}_X$, and $(s_0, s_1) = (x, y)$.

Example 8.4.5: Blow-up of $\mathbb{A}^2$ at the Origin

Take $X = \mathbb{A}^2_k = \operatorname{Spec} k[x, y]$ and $Z = V(x, y)$ (the origin), with $\mathcal{I} = (x, y)$. The Rees algebra $\bigoplus_{n\geq 0}(x, y)^n$ is the subring $k[x, y][xu, yu]$ of $k[x, y][u]$, and sending $s \mapsto xu$, $t \mapsto yu$ defines a surjection of graded rings

$$k[x, y, s, t] \longrightarrow \bigoplus_{n\geq 0}(x, y)^n, \qquad \deg s = \deg t = 1, \quad \deg x = \deg y = 0$$

whose kernel is generated by $xt - ys$ [50, Example II.7.12.1]. Hence $\mathrm{Bl}_P \mathbb{A}^2 = \operatorname{Proj} k[x, y, s, t]/(xt - ys)$, which is the closed subvariety of $\mathbb{A}^2 \times \mathbb{P}^1$ described at the start of section 8.4.

The exceptional divisor $E \cong \mathbb{P}^1$ is the fiber $\pi^{-1}(0, 0) = \operatorname{Proj} k[s, t]$. On the blow-up, the ideal (x, y) becomes the ideal sheaf $\mathcal{O}(-E)$, which is invertible (generated by x on the chart $s \neq 0$ and by y on the chart $t \neq 0$).

On a smooth projective surface X, the blow-up $\pi\colon \widetilde{X} = \mathrm{Bl}_P X \to X$ at a closed point P changes the Picard group, the intersection pairing and the canonical class in a way computed entirely from X.

Theorem 8.4.6: Intersection Theory on the Blow-up

Let $\pi\colon \widetilde{X} \to X$ be the blow-up of a smooth projective surface X at a closed point P, with exceptional divisor $E = \pi^{-1}(P)$. Then:

1. $\widetilde{X}$ is a smooth projective surface, and $E \cong \mathbb{P}^1$.
2. $\operatorname{Pic}(\widetilde{X}) \cong \operatorname{Pic}(X) \oplus \mathbb{Z} \cdot E$, the first summand embedded by π^*. Every divisor on $\widetilde{X}$ is linearly equivalent to $\pi^*D + mE$ for a unique class $D \in \operatorname{Pic}(X)$ and a unique $m \in \mathbb{Z}$.
3. The intersection numbers on $\widetilde{X}$ are determined by
$$E^2 = -1, \qquad (\pi^*D_1) \cdot (\pi^*D_2) = D_1 \cdot D_2, \qquad (\pi^*D) \cdot E = 0$$
for any $D, D_1, D_2 \in \operatorname{Pic}(X)$.
4. The canonical class satisfies
$$K_{\widetilde{X}} \;=\; \pi^*K_X + E$$
5. Let $C \subseteq X$ be an irreducible curve through P, with local equation f at P, and let $m = \operatorname{mult}_P(C)$ be the *multiplicity* of C at P, the largest integer with $f \in \mathfrak{m}_P^m$. The *strict transform* $\widetilde{C} \subseteq \widetilde{X}$, the closure of $\pi^{-1}(C \setminus \{P\})$, satisfies
$$\widetilde{C} \;=\; \pi^*C - mE, \qquad \widetilde{C} \cdot E = m, \qquad \widetilde{C}^2 = C^2 - m^2$$

***Proof*:**

1. A closed point of X is a nonsingular closed subvariety $\operatorname{Spec} k$ of codimension 2, so $\widetilde{X}$ is a nonsingular surface by proposition 8.4.3, and it is projective because X is [50, Proposition II.7.16(c)]. The exceptional divisor is the fiber $\widetilde{X} \times_X \operatorname{Spec} \kappa(P)$, and relative Proj commutes with base change (proposition 5.3.50). The pullback of the Rees algebra of the ideal of P to $\operatorname{Spec} \kappa(P)$ is $\bigoplus_{n\geq 0} \mathfrak{m}_P^n/\mathfrak{m}_P^{n+1} = \operatorname{gr}_{\mathfrak{m}_P} \mathcal{O}_{X,P}$, so
$$E \;\cong\; \operatorname{Proj} \operatorname{gr}_{\mathfrak{m}_P} \mathcal{O}_{X,P}$$
compatibly with the twisting sheaves. The local ring $\mathcal{O}_{X,P}$ is regular of dimension 2, so $\operatorname{gr}_{\mathfrak{m}_P} \mathcal{O}_{X,P} \cong k[t_1, t_2]$, with t_1, t_2 the classes of any two generators u, v of $\mathfrak{m}_P$ [15, Characterizations of a Regular Local Ring]. Therefore $E \cong \mathbb{P}^1$ with $\mathcal{O}_{\widetilde{X}}(1)|_E \cong \mathcal{O}_{\mathbb{P}^1}(1)$. Moreover $\mathcal{O}_{\widetilde{X}}(1)$ is the inverse image ideal sheaf of P [50, Proposition II.7.13(a)], which is $\mathcal{O}_{\widetilde{X}}(-E)$, so $\mathcal{O}_{\widetilde{X}}(E)|_E \cong \mathcal{O}_{\mathbb{P}^1}(-1)$.
2. The surfaces X and $\widetilde{X}$ are nonsingular, so Pic $=$ Cl on both. By proposition 5.4.18(3), restriction gives an exact sequence $\mathbb{Z} \to \operatorname{Cl}(\widetilde{X}) \to \operatorname{Cl}(\widetilde{X} \setminus E) \to 0$, the first map sending 1 to $[E]$, and π identifies $\widetilde{X} \setminus E$ with $X \setminus \{P\}$. Restriction $\operatorname{Cl}(X) \to \operatorname{Cl}(X \setminus \{P\})$ is an isomorphism by proposition 5.4.18(2), as P has codimension 2, and it factors as π^* followed by restriction to $\widetilde{X} \setminus E$. So π^* splits the sequence. Its first map is injective because $(mE) \cdot E = -m$ by item (3), whose proof does not use this one. Hence $\operatorname{Pic}(\widetilde{X}) = \pi^*\operatorname{Pic}(X) \oplus \mathbb{Z} \cdot E$.

3. The curve E is nonsingular, so proposition 8.2.6 and item (1) give $E^2 = \deg \mathcal{O}_{\widetilde{X}}(E)|_E = -1$. For $D \in \operatorname{Pic}(X)$, the restriction $\pi^*\mathcal{O}_X(D)|_E$ is pulled back from $\mathcal{O}_X(D)|_{\{P\}}$ along $E \to \operatorname{Spec}\kappa(P)$, so it is trivial, and $(\pi^*D)\cdot E = \deg(\pi^*\mathcal{O}_X(D)|_E) = 0$ by the formula $D'\cdot C = \deg(\mathcal{L}(D')|_C)$ for a divisor D' and a smooth irreducible curve C (proposition 8.2.2(6), applied with $C = E \cong \mathbb{P}^1$). For the third rule, every divisor on X is linearly equivalent to a difference of nonsingular curves avoiding P, and for D_1 and D_2 these curves can be chosen so that each curve of the first difference meets each curve of the second transversally, by a Bertini argument [50, Proposition V.3.2]. Since π is an isomorphism over $X \setminus \{P\}$, the preimages of such curves meet in the same points, again transversally, and proposition 8.2.2(1), (3) and (4) give $(\pi^*D_1)\cdot(\pi^*D_2) = D_1\cdot D_2$.

4. The sheaves $\omega_{\widetilde{X}}$ and $\pi^*\omega_X$ agree on $\widetilde{X}\setminus E$, which π maps isomorphically onto $X\setminus\{P\}$, so by the exact sequence in item (2), $K_{\widetilde{X}} = \pi^*K_X + aE$ for some $a\in\mathbb{Z}$. The adjunction formula (theorem 8.2.8) for $E\cong\mathbb{P}^1$ and item (3) give

$$-2 \;=\; E\cdot(E+K_{\widetilde{X}}) \;=\; -1+(\pi^*K_X)\cdot E + aE^2 \;=\; -1-a$$

so $a = 1$.

5. Let $\mathcal{I}_P$ be the ideal sheaf of P. Since $\mathfrak{m}_P$ is generated by two elements, there is an affine open $U = \operatorname{Spec}A$ containing P on which $\mathcal{I}_P$ is generated by two elements $u, v \in A$ and $C\cap U = V(f)$. The section f lies in $\mathcal{I}_P^m(U) = (u,v)^m$, because its image in $\mathcal{O}_X/\mathcal{I}_P^m$, a sheaf supported at P alone, has zero stalk at P. So $f = \sum_{i+j=m} a_{ij}\,u^iv^j$ with $a_{ij}\in A$. The leading form $f_m = \sum \bar{a}_{ij}\,t_1^it_2^j$, the image of f in $\mathfrak{m}_P^m/\mathfrak{m}_P^{m+1} \cong k[t_1,t_2]_m$, is nonzero because $f\notin\mathfrak{m}_P^{m+1}$. On the chart $D_+(ut) = \operatorname{Spec}A[v/u]$ of $\pi^{-1}(U)$, the exceptional divisor is $V(u)$, with coordinate ring $A[v/u]/(u) = k[s]$ for s the image of v/u (the chart $D_+(t_1)$ of $E = \operatorname{Proj}k[t_1,t_2]$), and

$$\pi^*f \;=\; u^mg, \qquad g \;=\; \sum_{i+j=m} a_{ij}\,(v/u)^j, \qquad g|_E \;=\; f_m(1,s)$$

The polynomial $f_m(1,s)$ is nonzero, since $f_m(t_1,t_2) = t_1^m f_m(1,t_2/t_1)$. So g does not vanish on E, and E, whose local equation is u, occurs in π^*C with multiplicity exactly m. Every other prime divisor of $\widetilde{X}$ is the closure of a prime divisor of $\widetilde{X}\setminus E\cong X\setminus\{P\}$, on which π^*C restricts to $C\setminus\{P\}$ with multiplicity one. Hence $\pi^*C = \widetilde{C} + mE$. By item (3), $\widetilde{C}\cdot E = (\pi^*C)\cdot E - mE^2 = m$ and $\widetilde{C}^2 = (\pi^*C)^2 - 2m\,(\pi^*C)\cdot E + m^2E^2 = C^2 - m^2$, as claimed.

Example 8.4.7: Blow-ups in Practice

1. Let $P\in\mathbb{P}^2$ and let H be the class of a line in $\mathbb{P}^2$. Then $\operatorname{Pic}(\operatorname{Bl}_P\mathbb{P}^2) = \mathbb{Z}H\oplus\mathbb{Z}E$ (identifying π^*H with H by abuse). A line through P has strict transform $\widetilde{L} = H-E$ with $\widetilde{L}^2 = 1-1 = 0$ and $\widetilde{L}\cdot E = 1$. A smooth conic through P has $\widetilde{C} = 2H-E$ with $\widetilde{C}^2 = 4-1 = 3$.

   The surface $\operatorname{Bl}_P\mathbb{P}^2$ is isomorphic to the Hirzebruch surface $\mathbb{F}_1$ (proposition 8.5.4(5)): the pencil of lines through P becomes a ruling of $\mathbb{F}_1$, and E is the negative section with $E^2 = -1$.

   The canonical class is $K_{\operatorname{Bl}_P\mathbb{P}^2} = \pi^*(-3H)+E = -3H+E$, so $K^2 = 9-1 = 8$. Over $\mathbb{C}$, replacing the point P by $E\cong\mathbb{P}^1$ raises the topological Euler characteristic by 1, to $\chi_{\text{top}} = 4$,

and Noether's formula (theorem 8.3.3) gives $\chi(\mathcal{O}_{\mathrm{Bl}_P \mathbb{P}^2}) = \frac{8+4}{12} = 1 = \chi(\mathcal{O}_{\mathbb{P}^2})$.

2. Let $\operatorname{char} k \neq 2$ and let $C\colon y^2 = x^3 + x^2$ be the nodal cubic in $\mathbb{A}^2$. Its singular point is the origin, where $\operatorname{mult}_0(C) = 2$. In the chart $y = xt$ of the blow-up of the origin, the total transform is $x^2(t^2 - x - 1) = 0$, so the strict transform $\widetilde{C}\colon t^2 = x + 1$ is smooth and meets $E = \{x = 0\}$ in the two points $t = \pm 1$, the directions of the two tangent lines $y = \pm x$. The other chart adds no point of $\widetilde{C} \cap E$, and $\widetilde{C}$ is smooth there too. One blow-up has *resolved* the singularity.

3. The cuspidal cubic $y^2 = x^3$ also has $\operatorname{mult}_0 = 2$. In the chart $y = xt$ the total transform is $x^2(t^2 - x) = 0$, so the strict transform $t^2 = x$ is already smooth, and it misses E in the other chart. It meets $E = \{x = 0\}$ only at $t = 0$, with $\widetilde{C} \cdot E = 2$ there, so $\widetilde{C}$ is tangent to E. One blow-up resolves the cusp, and making the total transform a divisor with normal crossings takes three blow-ups in all [50, Example V.3.9.1].

Blowing up a point of a smooth projective surface creates a (-1)-*curve*, a curve $E \cong \mathbb{P}^1$ with $E^2 = -1$ (theorem 8.4.6). Castelnuovo's criterion is the converse: every (-1)-curve on a smooth projective surface is the exceptional curve of a blow-up.

Theorem 8.4.8: Castelnuovo's Contractibility Criterion

Let X be a smooth projective surface and $E \subseteq X$ a smooth rational curve (i.e. $E \cong \mathbb{P}^1$) with $E^2 = -1$. Then there exists a smooth projective surface Y and a point $Q \in Y$ such that $X \cong \mathrm{Bl}_Q Y$, with E as the exceptional divisor. So E can be *contracted*: there exists a morphism $\pi\colon X \to Y$ that maps E to the point Q and restricts to an isomorphism $X \setminus E \to Y \setminus \{Q\}$.

***Proof Key ideas*:**
The proof that the image point is nonsingular uses the theorem on formal functions, which this book does not develop. The full argument is [50, Theorem V.5.7]. Choose a very ample divisor H on X with $H^1(X, \mathcal{O}_X(H)) = 0$ and $k = H \cdot E \geq 2$, and put $L = H + kE$, so that $L \cdot E = k - k = 0$. Since $\mathcal{O}_X(H + iE)|_E \cong \mathcal{O}_{\mathbb{P}^1}(k - i)$, induction on i gives $H^1(X, \mathcal{O}_X(H + iE)) = 0$ for $0 \leq i \leq k$, and from this the global sections of $\mathcal{O}_X(L)$ generate it along E as well as away from E. The resulting morphism to $\mathbb{P}^N$ maps E to a point Q, because $L \cdot E = 0$, and is an isomorphism of $X \setminus E$ onto the complement of Q in its image, because $|L|$ contains $|H| + kE$. Let Y be the normalization of the image. The theorem on formal functions identifies $\widehat{\mathcal{O}}_{Y,Q}$ with $\lim H^0(\mathcal{O}_{E_n})$, where E_n runs over the infinitesimal neighbourhoods of E. Since $E^2 = -1$, the conormal sheaf of E is $\mathcal{O}_{\mathbb{P}^1}(1)$, which makes each $H^0(\mathcal{O}_{E_n})$ a truncated power series ring $k[[u, v]]/(u, v)^n$. So $\widehat{\mathcal{O}}_{Y,Q} \cong k[[u, v]]$ and Y is nonsingular at Q. The morphism $X \to Y$ contracts exactly one curve, and in the factorization of birational morphisms (theorem 8.4.11, whose proof does not use this theorem) each blow-up accounts for one contracted curve, so $X \to Y$ is the blow-up of Q, as claimed.

The value $E^2 = -1$ is what makes Q nonsingular. A curve $E \cong \mathbb{P}^1$ with $E^2 \leq -2$ can still be contracted to a point of a projective surface [50, Exercise V.5.2], but that point is singular [50, Remark V.5.7.2]. Over $\mathbb{C}$, Grauert's theorem contracts any connected curve whose components have a negative definite intersection matrix, but only to a point of a complex analytic space: a curve of genus one with self-intersection -1 constructed by Hironaka [50, Example V.5.7.3] cannot be contracted to a point of an algebraic surface.

Corollary 8.4.9: Detecting (-1)-Curves

Let E be an irreducible curve on a smooth projective surface X. Then E is a (-1)-curve (i.e. $E \cong \mathbb{P}^1$ with $E^2 = -1$) if and only if

$$E^2 = -1 \qquad \text{and} \qquad K_X \cdot E = -1$$

Equivalently, $E^2 = -1$ and the arithmetic genus $p_a(E)$ is 0.

***Proof*:**
The adjunction formula for the integral curve E, (8.5), gives $2p_a(E) - 2 = E^2 + K_X \cdot E$, so when $E^2 = -1$ the conditions $K_X \cdot E = -1$ and $p_a(E) = 0$ are equivalent. If $E \cong \mathbb{P}^1$, then $p_a(E) = 1 - \chi(\mathcal{O}_{\mathbb{P}^1}) = 0$. Conversely, suppose $p_a(E) = 0$. By box 7.2.9, $p_a(E) = g(\widetilde{E}) + \sum_Q \delta_Q$, where $\widetilde{E}$ is the normalization, $g(\widetilde{E}) \geq 0$, and $\delta_Q \geq 1$ at every singular point Q, since the local ring there is not integrally closed. So E is nonsingular of genus 0, and $E \cong \mathbb{P}^1$ by proposition 7.3.6, completing the proof.

8.4.10 Forward Reference: Extremal Contractions and the MMP Castelnuovo's contractibility criterion is the surface case of the *extremal contractions* of the Minimal Model Program (MMP), developed in *Birational Geometry* [12].

1. The *Cone Theorem* (Mori) describes the K_X-negative part of the Mori cone $\overline{\mathrm{NE}}(X)$ by extremal rays spanned by rational curves. On a smooth projective surface such a ray is spanned by a (-1)-curve, by a fiber of a ruled surface $X \to C$ over a curve, or, when $X \cong \mathbb{P}^2$, by a line.

2. Each such ray corresponds to a *contraction morphism*: for a (-1)-curve, this is exactly the blow-down of Castelnuovo's criterion.

3. The process of successively contracting (-1)-curves terminates (since ρ decreases by 1 at each step) and produces a surface with no (-1)-curves.

In dimension ≥ 3 the contraction of an extremal ray can have a singular target. When it contracts no divisor, the canonical divisor of the target is not $\mathbb{Q}$-Cartier, and the MMP continues with a *flip*, a birational map that is an isomorphism in codimension one. Flips exist by Mori in dimension 3 and by Birkar-Cascini-Hacon-McKernan in every dimension.

The proof of theorem 8.4.8 uses the following theorem of Zariski.

Theorem 8.4.11: Factorization of Birational Morphisms

Let $f\colon X \to Y$ be a birational morphism between smooth projective surfaces. Then f is, up to an isomorphism $X \cong X_n$, a composition of finitely many blow-ups at closed points

$$X_n \xrightarrow{\pi_n} X_{n-1} \xrightarrow{\pi_{n-1}} \cdots \xrightarrow{\pi_1} X_0 = Y$$

where each π_i is the blow-up of X_{i-1} at a closed point, and n is the number of irreducible curves of X contracted by f.

***Proof Key ideas*:**
The proof uses Zariski's Main Theorem for birational transformations and a computation in local coordinates. The full argument is [50, Proposition V.5.3, Corollary V.5.4]. If f is not an isomorphism, its rational inverse is undefined at some closed point $Q \in Y$, and then f factors as $\pi_1 \circ f_1$ through the blow-up $\pi_1\colon \mathrm{Bl}_Q Y \to Y$. Only finitely many irreducible curves of X map to points under f, and f_1 maps one fewer of them to points, since exactly one of them maps onto the exceptional curve of π_1. After finitely many steps no curve is contracted, and a birational morphism contracting no curve has an inverse defined everywhere, so it is an isomorphism, completing the factorization.

In dimension ≥ 3 a birational morphism between nonsingular projective varieties need not be a composition of blow-ups along nonsingular centres [50, Remark V.5.4.4], and the minimal model program needs flips, birational maps that are morphisms in neither direction (*Birational Geometry* [12]).

8.4.1 Hironaka's Example

Every complete variety in the examples so far has been projective. For smooth curves the two notions coincide (proposition 7.1.7), and every smooth complete surface is projective as well, by a theorem of Zariski [50, Remark II.4.10.2]. In dimension three they differ: Hironaka's example below is a smooth complete threefold with no ample line bundle. It is built by blowing up two curves in opposite orders over two open sets and gluing the results. The two orders give different fibres over the two points where the curves meet, and comparing these fibres produces a nonzero effective 1-cycle whose degree is zero for every line bundle, which no ample line bundle allows.

Proposition 8.4.12: Hironaka's Example

Let X be a smooth projective threefold over an algebraically closed field, and let $C_1, C_2 \subseteq X$ be smooth curves meeting transversally at exactly two points P and Q, and nowhere else. Construct $\pi\colon M \to X$ by gluing two blow-ups:

- over $X \setminus \{Q\}$, blow up C_1 first, then the strict transform of C_2,
- over $X \setminus \{P\}$, blow up C_2 first, then the strict transform of C_1.

Over the overlap $X \setminus \{P, Q\}$ the two curves are disjoint, so the two orders give canonically isomorphic results and the pieces glue. Then M is a smooth complete threefold, and M is *not* projective.

***Proof*:**
Each piece of M is obtained from a smooth variety by blowing up two smooth curves in succession, because the strict transform of either curve under the blow-up of the other is isomorphic to the original curve [50, Corollary II.7.15], the inverse-image ideal being invertible on the smooth curve, so that blowing it up is an isomorphism (proposition 8.4.2(4) applied to the identity). So M is smooth by proposition 8.4.3. The morphism π is proper over each of the open sets $X \setminus \{Q\}$ and $X \setminus \{P\}$ (proposition 8.4.2(1)), and properness is local on the target, so π is proper and M is complete.
For a line bundle $\mathcal{L}$ on M and an integral complete curve $\gamma \subseteq M$, write $\mathcal{L} \cdot \gamma = \deg(\mathcal{L}|_\gamma)$, and extend this linearly to 1-cycles.

(a) A morphism from an integral scheme onto a nonsingular curve is flat [50, Proposition III.9.7].

(b) If $g\colon W \to T$ is a flat proper morphism onto a nonsingular connected curve T whose fibres have dimension 1, then for every line bundle $\mathcal{L}$ on W the number $\mathcal{L} \cdot [g^{-1}(t)]$ is independent of $t \in T$, where $[g^{-1}(t)]$ is the 1-cycle of the scheme-theoretic fibre, each component counted with its multiplicity (conservation of number, [38, § 10.2]).

For $c \in C_1 \setminus \{P, Q\}$ the fibre $\pi^{-1}(c)$ is a line ℓ_c, and ℓ denotes any one of these. Similarly m denotes the line $\pi^{-1}(c')$ over a point $c' \in C_2 \setminus \{P, Q\}$.
Step 1: the fibre over P. Over $X \setminus \{Q\}$ the morphism π is a composite $\alpha \circ \beta$, where $\alpha\colon X_1 \to X \setminus \{Q\}$ is the blow-up along C_1 and β is the blow-up of X_1 along the strict transform C_2' of C_2. The exceptional divisor $E_1 = \alpha^{-1}(C_1)$ is the projectivized normal bundle of C_1, a $\mathbb{P}^1$-bundle over $C_1 \setminus \{Q\}$, and $E_2 = \beta^{-1}(C_2')$ is likewise a $\mathbb{P}^1$-bundle over C_2' [50, Theorem II.8.24]. The curve C_2' meets the line $F_P = \alpha^{-1}(P)$ in a single point x: identifying F_P with the projectivized normal space of C_1 at P, the point x is the image of the tangent line of C_2 at P, which is not tangent to C_1 because the curves meet transversally. Hence $\pi^{-1}(P) = \beta^{-1}(F_P)$ is the union of two irreducible curves: ℓ_0, the closure of $\beta^{-1}(F_P \setminus \{x\})$, and $\ell_1 = \beta^{-1}(x)$, a fibre of $E_2 \to C_2'$.

Let Z be the closure of $\pi^{-1}(C_1 \setminus \{P, Q\})$ in $\pi^{-1}(X \setminus \{Q\})$, and let $g = \pi|_Z\colon Z \to C_1 \setminus \{Q\}$. Then Z is an integral surface, being the closure of a $\mathbb{P}^1$-bundle over an irreducible curve, g is proper and surjective, and g is flat by (a). Its fibre over $c \neq P$ is the line ℓ_c. Its fibre over P is cut out on Z by one equation, so every component of it has dimension 1, and it lies in $\ell_0 \cup \ell_1$. Thus $[g^{-1}(P)] = a\ell_0 + b\ell_1$ for integers $a, b \geq 0$, and in fact both are positive.

- The closed set $\beta(Z)$ contains $\alpha^{-1}(C_1 \setminus \{P, Q\})$, which is dense in the irreducible surface E_1, so $\beta(Z)$ contains F_P. As β is an isomorphism over $X_1 \setminus C_2'$ and $F_P \setminus \{x\}$ does not meet C_2', the surface Z contains $\beta^{-1}(F_P \setminus \{x\})$, hence contains ℓ_0. So $a \geq 1$.
- The exceptional divisor E_2 is an effective Cartier divisor (proposition 8.4.2(3)), and it is disjoint from ℓ_c for $c \neq P$ since $\pi(E_2) \subseteq C_2$. By (b) applied to $\mathcal{O}(E_2)$, $a\,\mathcal{O}(E_2) \cdot \ell_0 + b\,\mathcal{O}(E_2) \cdot \ell_1 = \mathcal{O}(E_2) \cdot \ell_c = 0$. The curve ℓ_0 is not contained in E_2, and it meets E_2 because $\beta(\ell_0)$ is closed and contains $F_P \setminus \{x\}$, hence contains x. So E_2 restricts to a nonzero effective Cartier divisor on ℓ_0, and $\mathcal{O}(E_2) \cdot \ell_0 > 0$. With $a \geq 1$ this forces $b \geq 1$.

The $\mathbb{P}^1$-bundle $E_2 \to C_2'$ is flat by (a), and its fibres include ℓ_1 and m. Applying (b) to it and to g gives, for every line bundle $\mathcal{L}$ on M,

$$\mathcal{L} \cdot \ell \;=\; a\,\mathcal{L} \cdot \ell_0 + b\,\mathcal{L} \cdot m$$

Step 2: the fibre over Q. Over $X \setminus \{P\}$ the roles of C_1 and C_2 are exchanged, and the same argument gives an irreducible curve $m_0 \subseteq \pi^{-1}(Q)$ and integers $a', b' \geq 1$ with

$$\mathcal{L} \cdot m \;=\; a'\,\mathcal{L} \cdot m_0 + b'\,\mathcal{L} \cdot \ell$$

for every line bundle $\mathcal{L}$ on M.

Step 3: no ample line bundle. Substituting Step 2 into Step 1, the 1-cycle

$$\gamma \;=\; a\ell_0 + ba'\,m_0 + (bb' - 1)\ell$$

satisfies $\mathcal{L} \cdot \gamma = 0$ for every line bundle $\mathcal{L}$ on M. It is effective because $bb' \geq 1$, and nonzero because $a \geq 1$. An ample line bundle $\mathcal{H}$ on M would restrict to an ample line bundle, of positive degree, on every integral curve, giving $\mathcal{H} \cdot \gamma \geq a\,\mathcal{H} \cdot \ell_0 > 0$. Hence M carries no ample line bundle and is not projective, as claimed.

The variety M is smooth and complete, so its failure to be projective comes from neither singularities nor non-completeness. It comes from the two orders of blowing up, which make the fibres over P and over Q asymmetric. A local computation shows that all four multiplicities a, b, a', b' equal 1, so that $\gamma = \ell_0 + m_0$, and that ℓ is algebraically equivalent to $\ell_0 + m$ and m to $m_0 + \ell$ [50, Appendix B, Example 3.4.1]. The proof above uses only that the multiplicities are positive. Hironaka's theorem on resolution of singularities [54] is a different result and is not proved in this book.

8.5 Ruled Surfaces and Rational Surfaces

The *ruled surfaces*, fibered over a curve with every fiber isomorphic to $\mathbb{P}^1$, and the *rational surfaces*, birational to $\mathbb{P}^2$, have Kodaira dimension $\kappa = -\infty$ (definition 8.6.1). Up to birational equivalence they are all the surfaces with $\kappa = -\infty$: such a surface is rational or birational to $C \times \mathbb{P}^1$ for a curve C [50, Theorem V.6.1].

Definition 8.5.1: Ruled Surface

A *ruled surface* over a smooth projective curve C is a smooth projective surface S together with a surjective morphism $p\colon S \to C$ whose fibers are all isomorphic to $\mathbb{P}^1$.

Every ruled surface is isomorphic over C to the projective bundle $\mathbb{P}(\mathscr{E}) = \underline{\mathrm{Proj}}_C(\mathrm{Sym}^\bullet \mathscr{E})$ of a locally free sheaf $\mathscr{E}$ of rank 2 on C (definition 5.3.51), whose fiber over $c \in C$ is $\mathbb{P}(\mathscr{E}(c)) \cong \mathbb{P}^1$, and conversely every such $\mathbb{P}(\mathscr{E})$ is a ruled surface [50, Proposition V.2.2]. Hartshorne's definition also requires a section of p, which exists by Tsen's theorem (see the note following that definition). In the convention of definition 5.3.51 (Grothendieck's), a point of $\mathbb{P}(\mathscr{E})$ over c is a one-dimensional *quotient* of $\mathscr{E}(c)$, and the sections σ of p correspond to the surjections $\mathscr{E} \twoheadrightarrow \mathcal{L}$ onto invertible sheaves on C, with $\mathcal{L} = \sigma^* \mathcal{O}_{\mathbb{P}(\mathscr{E})}(1)$ [50, Proposition V.2.6].

8.5.2 Warning: The Other $\mathbb{P}(\mathscr{E})$ The quotient convention of definition 5.3.51 is Grothendieck's and is used throughout this book. The opposite convention, under which $\mathbb{P}(\mathscr{E})$ is the bundle of one-dimensional *subspaces* of $\mathscr{E}$, is equally standard and is the one Fulton uses. *Intersection Theory* [26] follows it, since its Segre and Chern classes are built that way. The two differ by a dual, $\mathbb{P}_{\text{quot}}(\mathscr{E}) = \mathbb{P}_{\text{sub}}(\mathscr{E}^\vee)$, so a formula carried between the two books must be dualized. The point matters wherever $\mathcal{O}_{\mathbb{P}(\mathscr{E})}(1)$ appears: the pushforward $f_*\mathcal{O}(d) \cong \operatorname{Sym}^d \mathscr{E}$ of example 6.6.17(2) holds in this convention and acquires a dual in the other.

Two ruled surfaces $\mathbb{P}(\mathscr{E})$ and $\mathbb{P}(\mathscr{E}')$ over C are isomorphic (as surfaces over C) if and only if $\mathscr{E}' \cong \mathscr{E} \otimes \mathcal{L}$ for some invertible sheaf $\mathcal{L}$ on C [50, Proposition V.2.2]. Twisting by an invertible sheaf does not change the projectivization (example 5.3.55(3)), which is the "if" direction.

Over $\mathbb{P}^1$ every ruled surface is a Hirzebruch surface. A locally free sheaf of rank 2 on $\mathbb{P}^1$ splits as a direct sum of invertible sheaves (by the Birkhoff-Grothendieck theorem, whose rank-2 case is [50, Corollary V.2.14]), so $\mathscr{E} \cong \mathcal{O}(a) \oplus \mathcal{O}(b)$. Ordering the summands so that $a \geq b$ and twisting by $\mathcal{O}(-a)$ gives $\mathscr{E} \otimes \mathcal{O}(-a) \cong \mathcal{O} \oplus \mathcal{O}(-n)$ with $n = a - b \geq 0$, so every ruled surface over $\mathbb{P}^1$ is isomorphic to one of the following.

Definition 8.5.3: Hirzebruch Surface

For $n \geq 0$, the nth *Hirzebruch surface* is

$$\mathbb{F}_n \;=\; \mathbb{P}(\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(-n))$$

Proposition 8.5.4: Invariants of $\mathbb{F}_n$

The Hirzebruch surface $\mathbb{F}_n$ has the following properties:

1. $\operatorname{Pic}(\mathbb{F}_n) \cong \mathbb{Z} \cdot C_0 \oplus \mathbb{Z} \cdot F$, where F is the class of a fiber of $p\colon \mathbb{F}_n \to \mathbb{P}^1$ and C_0 is the section corresponding to the surjection $\mathcal{O} \oplus \mathcal{O}(-n) \twoheadrightarrow \mathcal{O}(-n)$ onto the second summand.
2. Intersection numbers: $F^2 = 0$, $C_0 \cdot F = 1$, $C_0^2 = -n$.
3. Canonical class: $K_{\mathbb{F}_n} = -2C_0 - (n+2)F$.
4. $\mathbb{F}_0 = \mathbb{P}^1 \times \mathbb{P}^1$ (with C_0 and F fibers of the two projections).
5. $\mathbb{F}_1 \cong \operatorname{Bl}_P \mathbb{P}^2$, with $C_0 = E$ (the exceptional divisor) and F the strict transform of a line through P.
6. For $n \geq 1$, C_0 is the unique irreducible curve with negative self-intersection on $\mathbb{F}_n$, and $\mathbb{F}_0$ has none. In particular, $\mathbb{F}_n \ncong \mathbb{F}_m$ for $n \neq m$.

***Proof*:**

1. For a ruled surface $p\colon S \to C$ with a section C_0, $\operatorname{Pic}(S) = \mathbb{Z} \cdot C_0 \oplus p^*\operatorname{Pic}(C)$ [50, Proposition V.2.3]. Here $\operatorname{Pic}(\mathbb{P}^1) = \mathbb{Z}$ is generated by the class of a point, whose pullback is F.
2. Two distinct fibers are disjoint and linearly equivalent, so $F^2 = 0$, and a section meets

each fiber in one point, transversally, so $C_0 \cdot F = 1$ [50, Proposition V.2.3]. A section D corresponding to a surjection $\mathscr{E} \twoheadrightarrow \mathcal{L}$ with kernel $\mathcal{N}$ satisfies $\mathcal{O}_S(D)|_D \cong \mathcal{L} \otimes \mathcal{N}^\vee$ under $D \cong C$ [50, Proposition V.2.6], so proposition 8.2.6 gives $D^2 = \deg \mathcal{L} - \deg \mathcal{N} = 2\deg \mathcal{L} - \deg \mathscr{E}$. For C_0 on $\mathbb{F}_n$, $\mathcal{L} = \mathcal{O}(-n)$ and $\deg \mathscr{E} = -n$, so $C_0^2 = -2n + n = -n$.

3. By item (1), $K_{\mathbb{F}_n} = aC_0 + bF$ for some $a, b \in \mathbb{Z}$. The fiber F and the section C_0 are smooth rational curves, so the adjunction formula (theorem 8.2.8) and item (2) give

$$-2 = F \cdot (F + K_{\mathbb{F}_n}) = a, \qquad -2 = C_0 \cdot (C_0 + K_{\mathbb{F}_n}) = -n - an + b$$

The first gives $a = -2$, and then the second reads $-2 = n + b$, so $b = -(n+2)$.

4. The sheaf $\mathcal{O} \oplus \mathcal{O}$ is free, so $\mathbb{F}_0 = \mathbb{P}^1_{\mathbb{P}^1} = \mathbb{P}^1 \times \mathbb{P}^1$ with p the first projection (example 5.3.55(1)). The section corresponding to the quotient onto a summand is a fiber of the second projection.

5. The blow-up $\mathrm{Bl}_P \mathbb{P}^2$ is the closed subvariety of $\mathbb{P}^2 \times \mathbb{P}^1$ described in example 4.7.12. Its second projection to $\mathbb{P}^1$ has as fibers the strict transforms of the lines through P, each isomorphic to $\mathbb{P}^1$. So $\mathrm{Bl}_P \mathbb{P}^2$ is a ruled surface over $\mathbb{P}^1$, hence isomorphic to some $\mathbb{F}_m$. The curve E is irreducible with $E^2 = -1$ (theorem 8.4.6), so item (6), proved below without using this one, forces $m = 1$ and $C_0 = E$. The class F is that of a fiber.

6. Let $C \neq C_0$ be an irreducible curve, with class $aC_0 + bF$. Then $a = C \cdot F \geq 0$: if C is a fiber then $a = 0$, and otherwise C and a fiber are distinct irreducible curves, so proposition 8.2.2(5) applies. Likewise $b - an = C \cdot C_0 \geq 0$. Hence $C^2 = -a^2 n + 2ab = a^2 n + 2a(b - an) \geq 0$. So for $n \geq 1$ the curve C_0, with $C_0^2 = -n$, is the only irreducible curve of negative self-intersection, and $\mathbb{F}_0$ has none. The self-intersection of that curve recovers n from $\mathbb{F}_n$, which proves the last assertion and completes the proof.

Example 8.5.5: Ruled Surfaces over Higher-Genus Curves

If C has genus $g \geq 1$, rank-2 bundles on C need not split, and the ruled surfaces $\mathbb{P}(\mathscr{E}) \to C$ vary in positive-dimensional families.

8.5.1 Rational Surfaces

Definition 8.5.6: Rational Surface

A smooth projective surface X is *rational* if it is birational to $\mathbb{P}^2$.

Contracting (-1)-curves one at a time (theorem 8.4.8) stops, because the Picard number drops by one at each step (theorem 8.4.6(2) and (3)), and takes a rational surface X to a rational surface without (-1)-curves. Such a surface is $\mathbb{P}^2$ or some $\mathbb{F}_n$ with $n \neq 1$ [50, Example V.5.8.2, Remark V.5.8.4]. Reversing the contractions, every rational surface is obtained from $\mathbb{P}^2$ or from some $\mathbb{F}_n$ by a sequence of blow-ups at points.

Example 8.5.7: Rational Surfaces in Practice

1. $\mathbb{P}^2$ itself and all $\mathbb{F}_n$ (including $\mathbb{P}^1 \times \mathbb{P}^1 = \mathbb{F}_0$).

2. The blow-up of $\mathbb{P}^2$ at $r \leq 8$ points in *general position* (no three collinear, no six on a conic, no eight on a cubic that is singular at one of them) has $K^2 = 9 - r$ and $-K$ ample, so it is a *del Pezzo surface*, a surface with $-K$ ample.

3. A smooth cubic surface $S \subseteq \mathbb{P}^3$ is isomorphic to $\mathrm{Bl}_{P_1,\dots,P_6} \mathbb{P}^2$ (the blow-up of $\mathbb{P}^2$ at 6 points in general position). It has $K_S = -H$ (the hyperplane class), $K^2 = 3$, and $\rho = 7$. The 27 lines on S correspond to the 6 exceptional divisors E_i, the 15 strict transforms $\widetilde{L_{ij}}$ of the lines through pairs of blown-up points, and the 6 strict transforms $\widetilde{Q_i}$ of the conics through 5 of the 6 points. Each line ℓ satisfies $\ell^2 = -1$ and $K \cdot \ell = -1$, so every line is a (-1)-curve. The permutations of the 27 lines that preserve their incidences form a group of order 51840, isomorphic to the Weyl group $W(E_6)$ [50, § V.4].

The irregularity q and the second plurigenus P_2 (definition 8.3.4) vanish for $\mathbb{P}^2$ and are birational invariants, so they vanish on every rational surface. Castelnuovo proved the converse.

Theorem 8.5.8: Castelnuovo's Rationality Criterion

A smooth projective surface X over $\mathbb{C}$ is rational if and only if $q(X) = 0$ and $P_2(X) = 0$ (irregularity zero and second plurigenus zero).

For the "only if" direction, a blow-up at a point does not change q [50, Remark V.3.5.1], so [50, Theorem V.5.5] makes q a birational invariant, and the argument of [50, Theorem II.8.19] for the geometric genus applies unchanged to P_2. The "if" direction is not proved in this book. A proof over $\mathbb{C}$ is in Griffiths and Harris [41, Rational Surfaces II, the Castelnuovo-Enriques Theorem]. Over an algebraically closed field of any characteristic the theorem holds in the form $p_a = P_2 = 0$, the case of positive characteristic being Zariski's [50, Theorem V.6.2]. The two forms agree because $P_2 = 0$ forces $p_g = 0$, and then $p_a = p_g - q = -q$.

8.6 The Enriques-Kodaira Classification

Castelnuovo and Enriques classified smooth projective surfaces in the early twentieth century, Kodaira completed the classification over $\mathbb{C}$ in the 1960s, and Mumford and Bombieri extended it to characteristic p. The classification sorts surfaces by their *Kodaira dimension*, which measures the growth of the spaces of pluricanonical forms, and it works with one representative of each birational class: a minimal surface, reached by contracting (-1)-curves with theorem 8.4.8. The same two steps, a birational invariant and a reduction to minimal models, organize the classification of varieties in higher dimension (*Birational Geometry* [12]). The section also states Kodaira vanishing and its extension by Kawamata and Viehweg to nef and big divisors, a class that contains the canonical divisor of every minimal surface of general type (section 8.6.5).

8.6.1 Kodaira Dimension

Definition 8.6.1: Kodaira Dimension

Let X be a smooth projective variety of dimension d over k. For each $n \geq 1$, the *nth plurigenus* is $P_n(X) = \dim_k H^0(X, \omega_X^{\otimes n})$. The *Kodaira dimension* $\kappa(X)$ is defined by the growth rate of P_n:

$$\kappa(X) = \begin{cases} -\infty & \text{if } P_n = 0 \text{ for all } n \geq 1, \\ \min\left\{ j \geq 0 : \limsup_{n\to\infty} \dfrac{P_n}{n^j} < \infty \right\} & \text{otherwise.} \end{cases}$$

By a theorem of Iitaka, $\kappa(X)$ is also the dimension of the image of the *pluricanonical map* $\varphi_{|nK_X|} \colon X \dashrightarrow \mathbb{P}^{P_n - 1}$ for n sufficiently large and divisible (or $-\infty$ if all $P_n = 0$).

For a surface, $\kappa \in \{-\infty, 0, 1, 2\}$:

1. $\kappa = -\infty$: $P_n = 0$ for all n, that is, no positive multiple of K_X is linearly equivalent to an effective divisor.
2. $\kappa = 0$: $P_n \in \{0, 1\}$ for every n, and $P_n = 1$ for some n. On a minimal surface (definition 8.6.2) the canonical class is then numerically trivial (section 8.6.3).
3. $\kappa = 1$: P_n grows linearly in n, and for n sufficiently divisible the image of the pluricanonical map is a curve, so the map fibres the surface over a curve.
4. $\kappa = 2$: P_n grows quadratically in n, and the pluricanonical map is birational onto its image for $n \gg 0$. These are the *surfaces of general type*.

The plurigenera, and hence the Kodaira dimension, are birational invariants of smooth projective varieties. The proof of theorem 5.5.31 applies with $\omega_X^{\otimes n}$ in place of ω_X: Step 2 takes the nth tensor power of the map $f^*\omega_{X'} \to \omega_V$, which is still an isomorphism on a dense open set, and Step 3 extends sections of any invertible sheaf across a closed subset of codimension at least 2. So if X and Y are birational smooth projective varieties, then $P_n(X) = P_n(Y)$ for every $n \geq 1$, and $\kappa(X) = \kappa(Y)$.

8.6.2 Minimal Models

Definition 8.6.2: Minimal Surface

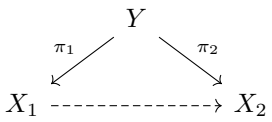
A smooth projective surface X is *minimal* if it contains no (-1)-curves (smooth rational curves E with $E^2 = -1$). Equivalently, X is not the blow-up of a smooth projective surface at a point: such a blow-up contains its exceptional curve, a (-1)-curve (theorem 8.4.6), and every (-1)-curve can be contracted (theorem 8.4.8).

Theorem 8.6.3: Existence and Uniqueness of Minimal Models

Let X be a smooth projective surface.

1. *Existence.* There is a birational morphism from X to a minimal surface, obtained by successively contracting (-1)-curves (theorem 8.4.8). The process terminates since the Picard number ρ drops by 1 at each step.

2. *Uniqueness for $\kappa \geq 0$.* If $\kappa(X) \geq 0$, any two minimal surfaces birational to X are isomorphic, so X has a unique minimal model.



3. *Non-uniqueness for $\kappa = -\infty$.* If X is rational, its minimal models are $\mathbb{P}^2$ and the Hirzebruch surfaces $\mathbb{F}_n$ with $n \neq 1$. If X is birational to $C \times \mathbb{P}^1$ for a smooth projective curve C of genus $g(C) \geq 1$, its minimal models are the ruled surfaces $\mathbb{P}(\mathscr{E}) \to C$ of definition 8.5.1. In both cases there are infinitely many, pairwise non-isomorphic.

By Enriques' theorem (section 8.6.3), the two cases in (3) are all the surfaces with $\kappa = -\infty$. The surface $\mathbb{F}_1$ does not appear in (3) because its section C_0 is a (-1)-curve (proposition 8.5.4). The proof below omits two inputs that this book does not prove, the elimination of indeterminacy of a birational map between surfaces and the factorization of a birational morphism through the contraction of a curve it contracts, both in [50, § V.5], and it omits the proof that the lists in (3) are complete [50, Remark V.5.8.4].

***Proof Key ideas*:**
(1) is theorem 8.4.8 applied repeatedly. Each contraction lowers ρ by one (theorem 8.4.6), and $\rho \geq 1$ on a projective surface, so the process stops.

For (2), a minimal surface X_1 with $\kappa(X_1) \geq 0$ has K_{X_1} nef. Suppose C is an irreducible curve with $K_{X_1} \cdot C < 0$, and choose $n \geq 1$ and an effective $D \in |nK_{X_1}|$, which exists as $\kappa \geq 0$. Writing $D = aC + D'$ with D' effective and not containing C, the inequality $D \cdot C < 0$ forces $a \geq 1$ and $C^2 < 0$, because $D' \cdot C \geq 0$. Adjunction (8.5) gives $2p_a(C) - 2 = C^2 + K_{X_1} \cdot C \leq -2$, so $p_a(C) = 0$ and $C^2 = K_{X_1} \cdot C = -1$. An integral curve with $p_a = 0$ is smooth and rational [50, Exercise IV.1.8], so C is a (-1)-curve, contradicting minimality.

Now let X_1 and X_2 be minimal surfaces birational to X, and resolve the birational map between them by a smooth projective surface Y:

By theorem 8.4.11 each π_i is a composite of blow-ups at points, so iterating theorem 8.4.6(4) gives $K_Y = \pi_2^* K_{X_2} + Z_2$ with Z_2 effective and supported on the curves contracted by π_2. If π_1 is not an isomorphism, let $E \subseteq Y$ be the exceptional curve of its last blow-up, so that $K_Y \cdot E = -1$. If π_2 did not contract E, then $Z_2 \cdot E \geq 0$ and $\pi_2^* K_{X_2} \cdot E = K_{X_2} \cdot \pi_{2*} E \geq 0$ by nefness, so $K_Y \cdot E \geq 0$, a contradiction. Hence π_2 contracts E as well, both π_i factor through the contraction of E, and induction on the number of blow-ups in π_1 reduces to the case where π_1 is an isomorphism. Then $\pi_2 \circ \pi_1^{-1} \colon X_1 \to X_2$ is a birational morphism from a minimal surface, which is an isomorphism because otherwise X_1 would contain the (-1)-curve of its last blow-up.

For (3), the surfaces listed are minimal: $\mathbb{P}^2$ and $\mathbb{F}_0$ contain no curve of negative self-intersection,

the only such curve on $\mathbb{F}_n$ for $n \geq 2$ is C_0, with $C_0^2 = -n$ (proposition 8.5.4), and on a ruled surface over a curve of genus $g \geq 1$ every rational curve maps to a point of the base, so it is a fibre and has self-intersection 0. They are birational to one another, and there are infinitely many pairwise non-isomorphic ones: the $\mathbb{F}_n$ are distinguished by n (proposition 8.5.4), and over C the surfaces $\mathbb{P}(\mathcal{O}_C \oplus \mathcal{O}_C(-D))$ with $\deg D = e \geq 0$ by the invariant e [50, § V.2], which gives non-uniqueness, completing the sketch.

8.6.3 Overview of the Classification

Over $\mathbb{C}$, the Enriques-Kodaira classification sorts minimal surfaces into four classes by κ and divides the class $\kappa = 0$ into four types. The ground field is $\mathbb{C}$ from here to the end of section 8.6.4, and box 8.6.7 records what changes in characteristic p. The main theorems below are stated, with references for their proofs, in [50, § V.6].

A minimal surface with $\kappa = -\infty$ is either $\mathbb{P}^2$ or a ruled surface $\mathbb{P}(\mathscr{E}) \to C$ over a smooth projective curve C of genus $g \geq 0$ (definition 8.5.1), and Enriques' theorem identifies the class among all surfaces [50, Theorem V.6.1]:

$$\kappa(X) = -\infty \iff P_{12}(X) = 0 \iff X \text{ is birational to } C \times \mathbb{P}^1 \text{ for a smooth projective curve } C$$

The genus of C equals the irregularity $q(X)$, and X is rational exactly when $g(C) = 0$.

Minimal surfaces with $\kappa = 0$ satisfy $12K_X \sim 0$, so K_X is numerically trivial ($K_X \cdot C = 0$ for every curve C) and has order dividing 12 in $\operatorname{Pic}(X)$. They fall into exactly four families, distinguished by the irregularity q and the geometric genus p_g [50, Theorem V.6.3].

1. *Abelian surfaces* ($q = 2$, $p_g = 1$, $K_X \sim 0$) are the two-dimensional abelian varieties. For each of them $X(\mathbb{C})$ is a complex torus $\mathbb{C}^2/\Lambda$ for a lattice Λ of rank 4, the group law is addition on the torus, $h^{1,1} = 4$, and $\chi(\mathcal{O}_X) = 0$ (example 8.3.5).

2. *K3 surfaces* ($q = 0$, $p_g = 1$, $K_X \sim 0$) are defined by $K_X \sim 0$ and $q = 0$. They are simply connected, with $h^{1,1} = 20$ and $\chi(\mathcal{O}_X) = 2$, and a smooth quartic surface in $\mathbb{P}^3$ is one (example 8.3.5). Example 8.6.4 collects more of their properties.

3. *Enriques surfaces* ($q = 0$, $p_g = 0$, $K_X \not\sim 0$, $2K_X \sim 0$) are exactly the quotients of K3 surfaces by a fixed-point-free involution. They have $\chi(\mathcal{O}_X) = 1$ and $h^{1,1} = 10$.

4. *Bielliptic surfaces*, also called hyperelliptic surfaces ($q = 1$, $p_g = 0$), are the quotients $(E_1 \times E_2)/G$ in which E_1 and E_2 are elliptic curves and G is a finite group acting on E_1 by translations and on E_2 with $E_2/G \cong \mathbb{P}^1$. The projections give two fibrations: $X \to E_1/G$, onto an elliptic curve, with every fibre isomorphic to E_2, and $X \to E_2/G \cong \mathbb{P}^1$, with general fibre E_1. Here $\chi(\mathcal{O}_X) = 0$, $h^{1,1} = 2$, and K_X has order 2, 3, 4 or 6 in $\operatorname{Pic}(X)$.

Example 8.6.4: K3 Surfaces: A Closer Look
Huybrechts [57] treats all four items.

1. Smooth quartic surfaces in $\mathbb{P}^3$, smooth complete intersections of type $(2,3)$ in $\mathbb{P}^4$ and of type $(2,2,2)$ in $\mathbb{P}^5$, double covers of $\mathbb{P}^2$ branched along a smooth sextic curve, and Kummer surfaces (the minimal resolutions of $A/\{\pm 1\}$ for an abelian surface A) are K3 surfaces.

2. All complex K3 surfaces, projective or not, are deformation-equivalent as complex manifolds (Kodaira), and their local deformation spaces are 20-dimensional. The projective ones form countably many 19-dimensional families, indexed by the degree $2d$ of a primitive polarization, and a very general complex K3 surface is not projective.

3. With its intersection form, $H^2(S,\mathbb{Z})$ is the even unimodular lattice $U^{\oplus 3} \oplus E_8(-1)^{\oplus 2}$ of signature $(3,19)$, so $b_2(S) = 22$. By the global Torelli theorem, two complex K3 surfaces S and S' are isomorphic if and only if there is an isometry $H^2(S,\mathbb{Z}) \cong H^2(S',\mathbb{Z})$ that respects the Hodge decompositions (Piatetski-Shapiro and Shafarevich for projective K3 surfaces, Burns and Rapoport in general). The periods of K3 surfaces lie in the period domain $\mathrm{SO}(3,19)/(\mathrm{SO}(2)\times\mathrm{SO}(1,19))$.

4. Every projective complex K3 surface contains infinitely many rational curves. The last cases were proved by Chen, Gounelas and Liedtke in 2022, after work of Bogomolov, Hassett and Tschinkel and of Li and Liedtke. Since $K_S = 0$, adjunction (8.5) gives $C^2 = 2p_a(C) - 2 \geq -2$ for an integral curve $C \subseteq S$, with $C^2 = -2$ exactly for the smooth rational curves.

A minimal surface with $\kappa = 1$ is *properly elliptic*: it admits a fibration $f\colon X \to C$ onto a smooth projective curve whose general fibre is a smooth curve of genus 1 [50, Theorem V.6.4], and f is the Iitaka fibration, the map given by $|nK_X|$ for n sufficiently divisible. Kodaira's *canonical bundle formula* describes K_X through the fibration:

$$K_X \sim f^*(K_C + \mathcal{L}) + \sum_i (m_i - 1)F_i$$

where $\mathcal{L}$ is a line bundle on C of degree $\chi(\mathcal{O}_X)$, and the sum runs over the *multiple fibres* $f^*(c_i) = m_i F_i$ with $m_i \geq 2$. Since $m_i F_i = f^*(c_i)$, a suitable multiple of K_X is the pullback of a divisor on C whose degree is a positive multiple of

$$2g(C) - 2 + \chi(\mathcal{O}_X) + \sum_i \left(1 - \frac{1}{m_i}\right)$$

and $\kappa(X) = 1$ exactly when this number is positive. Elliptic surfaces connect to the arithmetic of elliptic curves over function fields, through the Mordell-Weil group of the generic fibre, and to Kodaira's classification of the singular fibres of elliptic fibrations.

A surface is of *general type* if $\kappa = 2$. Then K_X is big, P_n grows like n^2, and the pluricanonical map $\varphi_{|nK_X|}$ is birational onto its image for some n [50, Theorem V.6.5], and Bombieri proved that every $n \geq 5$ works. The numerical invariants of a minimal surface of general type satisfy three inequalities, proved in the chapter on surfaces of general type of Barth, Hulek, Peters and Van de Ven, *Compact Complex Surfaces*.

Theorem 8.6.5: Geography of Surfaces of General Type

Let X be a minimal surface of general type over $\mathbb{C}$.

1. *Bogomolov-Miyaoka-Yau inequality.* $K_X^2 \leq 9\chi(\mathcal{O}_X)$, with equality if and only if the universal cover of $X(\mathbb{C})$ is the unit ball in $\mathbb{C}^2$.
2. *Noether inequality.* $p_g(X) \leq \frac{1}{2}K_X^2 + 2$. Since $\chi(\mathcal{O}_X) = 1 - q + p_g \leq 1 + p_g$, this gives $K_X^2 \geq 2\chi(\mathcal{O}_X) - 6$.
3. $K_X^2 \geq 1$ and $\chi(\mathcal{O}_X) \geq 1$.

The region of the (K^2, χ)-plane cut out by these inequalities is the *geography* of minimal surfaces of general type, and which of its lattice points are realized by such surfaces is not completely known. Horikawa classified the surfaces with $K^2 = 2p_g - 4$: their canonical map has degree 2 onto a rational surface. The surfaces with $K^2 = 9\chi$ are the ball quotients of item (1).

Example 8.6.6: Surfaces of General Type

1. A smooth surface $S \subseteq \mathbb{P}^3$ of degree $d \geq 5$ has $K_S = (d-4)H$ (proposition 6.5.7) and $K_S^2 = d(d-4)^2$. The sequence $0 \to \mathcal{O}_{\mathbb{P}^3}(-d) \to \mathcal{O}_{\mathbb{P}^3} \to \mathcal{O}_S \to 0$ gives $q = 0$ and $p_g = \binom{d-1}{3}$, so $\chi(\mathcal{O}_S) = 1 + \binom{d-1}{3}$. For $d = 5$ this is $K^2 = 5$, $p_g = 4$ and $\chi = 5$, as in example 8.3.6, and both inequalities hold: $5 \leq 9 \cdot 5$ and $4 \leq \frac{5}{2} + 2$.
2. For smooth projective curves C_1, C_2 of genera $g_1, g_2 \geq 2$, the product $X = C_1 \times C_2$ has $K_X = p_1^* K_{C_1} + p_2^* K_{C_2}$, $K^2 = 8(g_1 - 1)(g_2 - 1)$ and $\chi(\mathcal{O}_X) = (g_1 - 1)(g_2 - 1)$, so $K^2/\chi = 8$ for every such product.
3. The *Godeaux surface* is the quotient of the Fermat quintic $\{x_0^5 + \cdots + x_3^5 = 0\} \subseteq \mathbb{P}^3$ by the group of order 5 generated by $(x_0 : x_1 : x_2 : x_3) \mapsto (x_0 : \zeta x_1 : \zeta^2 x_2 : \zeta^3 x_3)$, for ζ a primitive fifth root of unity. Every nontrivial element of the group has four distinct eigenvalues, so its only fixed points in $\mathbb{P}^3$ are the coordinate points, which do not lie on the quintic, and the action is free. The quotient map is therefore étale of degree 5, which divides K^2 and χ by 5: the Godeaux surface has $K^2 = 1$ and $\chi = 1$, the smallest values allowed by theorem 8.6.5(3).

8.6.4 The Classification Table

The table lists the irregularity, the geometric genus and K^2 of each class of minimal surfaces over $\mathbb{C}$.

κ	q	p_g	K^2	Type
$-\infty$	any	0	$8(1-q)$, or 9 for $\mathbb{P}^2$	Ruled / Rational
0	2	1	0	Abelian surface
0	0	1	0	K3 surface
0	0	0	0	Enriques surface ($2K \sim 0$)
0	1	0	0	Bielliptic surface
1	any	any	0	Properly elliptic surface
2	any	any	> 0	General type

1. On a minimal surface the canonical class becomes more positive as κ increases. For $\kappa = -\infty$ it is not nef: $K_X \cdot F = -2$ for a fibre F of a ruling, and $K_{\mathbb{P}^2} = -3H$. For $\kappa = 0$ it is numerically trivial. For $\kappa = 1$ it is nef with $K_X^2 = 0$, and by the canonical bundle formula a multiple of it is the pullback of a divisor of positive degree on the base curve. For $\kappa = 2$ it is nef and big.
2. The self-intersection K^2 of a minimal surface is 0 for $\kappa = 0$ and $\kappa = 1$, and positive for $\kappa = 2$. For $\kappa = -\infty$ it is $8(1-q)$ for a ruled surface over a curve of genus q, and 9 for $\mathbb{P}^2$.
3. The pair (q, p_g) distinguishes the four types with $\kappa = 0$. For $\kappa = 1$ and $\kappa = 2$ more invariants are needed: the elliptic fibration and its multiple fibres, and the position in the geography, respectively.

8.6.7 Forward Reference: The Classification in Higher Dimensions and Positive Characteristic The Enriques-Kodaira classification of surfaces is the prototype for the *classification of algebraic varieties* in all dimensions, which also sorts varieties by Kodaira dimension and uses the Minimal Model Program to reduce to minimal models. *Birational Geometry* [12] develops this program:

1. The *cone theorem* and the *contraction theorem* generalize the theory of (-1)-curves to extremal rays of the Mori cone in any dimension.
2. *Flips* are needed when an extremal contraction is small, that is, contracts no divisor. This never happens on surfaces and does happen in every dimension ≥ 3.
3. The *abundance conjecture*, a theorem in dimension at most 3 and open in general, predicts that the canonical class of a minimal variety is semi-ample.

Bombieri and Mumford extended the classification of surfaces to characteristic $p > 0$, and new phenomena appear there. With $\kappa = 0$ there are quasi-hyperelliptic surfaces (in characteristics 2 and 3), K3 surfaces of Picard number 22 (the supersingular K3 surfaces, impossible over $\mathbb{C}$, where $\rho \leq h^{1,1} = 20$), and in characteristic 2 Enriques surfaces with $K_X \sim 0$. For general type, the Bogomolov-Miyaoka-Yau inequality $K^2 \leq 9\chi$ fails in characteristic p, and Bombieri's proof that $|5K_X|$ gives a birational map uses vanishing theorems that fail in characteristic p (theorem 8.6.8 and the remark after it). Ekedahl studied pluricanonical maps in characteristic p by other methods.

8.6.5 Vanishing Theorems

Kodaira vanishing and its extension by Kawamata and Viehweg control the higher cohomology of positive line bundles. Neither is proved in this book. Kodaira proved the first with harmonic forms, Deligne and Illusie gave an algebraic proof by reduction to characteristic p [34], and Kawamata-Viehweg vanishing is deduced from Kodaira vanishing by cyclic covering constructions.

Theorem 8.6.8: Kodaira Vanishing

Let X be a smooth projective variety over $\mathbb{C}$ and $\mathcal{L}$ an ample line bundle on X. Then

$$H^i(X, \omega_X \otimes \mathcal{L}) = 0 \qquad \text{for all } i > 0$$

Equivalently (by Serre duality), $H^i(X, \mathcal{L}^{-1}) = 0$ for $i < \dim X$.

The theorem is [50, Remark III.7.15]. The hypothesis $k = \mathbb{C}$ (more generally, characteristic 0) is needed: Raynaud constructed, in every characteristic $p > 0$, a smooth projective surface with an ample line bundle $\mathcal{L}$ such that $H^1(X, \mathcal{L}^{-1}) \neq 0$. In characteristic p Kodaira vanishing does hold for a smooth projective X of dimension at most p that lifts to the ring $W_2(k)$ of Witt vectors of length 2, by the theorem of Deligne and Illusie.

For a surface, Kodaira vanishing gives $H^1(X, \omega_X \otimes \mathcal{L}) = H^2(X, \omega_X \otimes \mathcal{L}) = 0$ for $\mathcal{L}$ ample, so Riemann-Roch for surfaces (theorem 8.3.1) computes the dimension of the space of sections:

$$h^0(X, \omega_X \otimes \mathcal{L}) = \chi(\omega_X \otimes \mathcal{L}) = \frac{D \cdot (D + K_X)}{2} + \chi(\mathcal{O}_X)$$

where D is a divisor with $\mathcal{L} \cong \mathcal{O}_X(D)$.

Theorem 8.6.9: Kawamata-Viehweg Vanishing

Let X be a smooth projective variety over $\mathbb{C}$ and D a nef and big divisor on X. Then

$$H^i(X, \omega_X \otimes \mathcal{L}(D)) = 0 \qquad \text{for all } i > 0$$

Kawamata and Viehweg proved this in 1982. It extends Kodaira vanishing from ample to nef and big divisors, and the extension is needed already for surfaces: on a minimal surface of general type the canonical divisor is nef and big (by the first paragraph of the proof of part (2) of theorem 8.6.3), and it fails to be ample exactly when X contains a smooth rational curve C with $C^2 = -2$. Indeed, if $K_X \cdot C = 0$ for an irreducible curve C, then $C^2 < 0$ by corollary 8.3.12 (as $K_X^2 > 0$), and adjunction (8.5) gives $2p_a(C) - 2 = C^2 < 0$, so $p_a(C) = 0$ and $C^2 = -2$. If no such curve exists, K_X is ample by theorem 8.2.11.

8.6.10 Forward Reference: Vanishing Theorems in the MMP Kawamata-Viehweg vanishing and its extensions (Nadel vanishing, Kollár vanishing) are the main technical input of the Minimal Model Program, and *Birational Geometry* [12] uses them to prove the following theorems, stated here for a smooth projective variety X over $\mathbb{C}$ (they hold more generally when X has klt singularities).

1. The *basepoint-free theorem* (Kawamata, Shokurov): if D is a nef Cartier divisor and $aD - K_X$ is nef and big for some $a > 0$, then $|mD|$ is base-point-free for all $m \gg 0$.
2. The *rationality theorem* (Kawamata): if K_X is not nef and H is ample, then $r = \max\{t \in \mathbb{R} : H + tK_X \text{ is nef}\}$ is a rational number.
3. The *non-vanishing theorem* (Shokurov): if D is a nef Cartier divisor and $aD - K_X$ is nef and big for some $a > 0$, then $H^0(X, \mathcal{O}_X(mD)) \neq 0$ for all $m \gg 0$.

In these proofs, vanishing of the higher cohomology lets Riemann-Roch compute dimensions of spaces of sections, as in the surface computation after theorem 8.6.8.

8.7 Application: Counting Points on Curves over Finite Fields

A system of homogeneous polynomial equations with coefficients in a finite field $\mathbb{F}_q$ has finitely many solutions in $\mathbb{P}^m(\mathbb{F}_q)$. When the equations cut out a smooth projective curve C_0, the number N of solutions is controlled by the genus g of the curve: the projective line has exactly $q+1$ points over $\mathbb{F}_q$, and every curve of genus g has $q+1$ points up to an error of at most $2g\sqrt{q}$. Hasse proved this for $g = 1$ in the 1930s, and Weil proved it for every g in 1948. We prove Weil's theorem with the surface theory of this chapter. The points of C_0 over $\mathbb{F}_q$ are the fixed points of the q-power Frobenius morphism F of the curve C obtained from C_0 by extending scalars to $\overline{\mathbb{F}}_q$. Their number is the intersection number of the graph of F with the diagonal on the surface $C \times C$, and the Hodge index theorem (theorem 8.3.9), which holds in every characteristic, bounds that intersection number in terms of g and q. Over a number field the number of points can be infinite, and section 8.7.1 records how the Euler characteristic of the curve governs the finiteness of its integral points.

Only the curve C_0 and its points are defined over $\mathbb{F}_q$. The curve C and the surface $C \times C$ are defined over the algebraically closed field $\overline{\mathbb{F}}_q$, where the conventions of box 7.0.1 hold.

8.7.1 Conventions Throughout this section $q = p^r$ is a power of a prime p, and $k = \overline{\mathbb{F}}_q$ is an algebraic closure of $\mathbb{F}_q$. For $n \geq 1$, $\mathbb{F}_{q^n}$ is the subfield of k formed by the q^n roots of $T^{q^n} - T$. The letter C_0 denotes a projective $\mathbb{F}_q$-scheme whose base change $C = C_0 \times_{\mathbb{F}_q} k$ is a curve over k in the sense of box 7.0.1: integral, of dimension 1, complete and nonsingular. The *genus* of C_0 is $g = g(C)$.

A closed immersion $C_0 \hookrightarrow \mathbb{P}^m_{\mathbb{F}_q}$ is fixed. On a standard chart $D_+(x_j) = \operatorname{Spec} \mathbb{F}_q[y]$, where y is the tuple of the m coordinates x_i/x_j with $i \neq j$, the closed subscheme $C_0 \cap D_+(x_j)$ is $\operatorname{Spec}(\mathbb{F}_q[y]/I_j)$ for an ideal I_j (proposition 3.1.24(1)), and $C \cap D_+(x_j) = \operatorname{Spec}(k[y]/I_j k[y])$, because $(\mathbb{F}_q[y]/I_j) \otimes_{\mathbb{F}_q} k \cong k[y]/I_j k[y]$. By theorem 0.1.12(3) the closed points of $C \cap D_+(x_j)$ are the points $a \in k^m$ at which every element of I_j vanishes, so every closed point of C has homogeneous coordinates $[a_0 : \cdots : a_m]$. For a subfield $L \subseteq k$ containing $\mathbb{F}_q$, $C_0(L)$ denotes the set of closed points of C that have homogeneous coordinates in L, and

$$N_n = \#C_0(\mathbb{F}_{q^n}), \qquad N = N_1$$

The set $C_0(\mathbb{F}_q)$ is in bijection with the set of $\mathbb{F}_q$-rational points of C_0, the points z with $\kappa(z) = \mathbb{F}_q$. Such a point of $C_0 \cap D_+(x_j)$ is the kernel of a surjection $\mathbb{F}_q[y]/I_j \to \mathbb{F}_q$, which is determined by the images $a \in \mathbb{F}_q^m$ of the coordinates, and a is a zero of every element of I_j, that is, a closed point of C with coordinates in $\mathbb{F}_q$. Conversely, every such closed point a defines the surjection $\mathbb{F}_q[y]/I_j \to \mathbb{F}_q$, $y \mapsto a$. In particular N does not depend on the embedding.

Raising the homogeneous coordinates of a closed point of C to the q-th power fixes exactly the points of $C_0(\mathbb{F}_q)$, and this operation comes from the q-th power map on the functions of C_0.

Definition 8.7.2: The q-Power Frobenius Morphism

The *q-power absolute Frobenius* of C_0 is the morphism $\Phi\colon C_0 \to C_0$ that is the identity on the underlying topological space and is $h \mapsto h^q$ on $\mathcal{O}_{C_0}$. The *q-power Frobenius* of C is the morphism of k-schemes

$$F = \Phi \times_{\mathbb{F}_q} \mathrm{id}_k \colon C = C_0 \times_{\mathbb{F}_q} k \longrightarrow C_0 \times_{\mathbb{F}_q} k = C$$

The map $h \mapsto h^q$ is a ring endomorphism of each $\mathcal{O}_{C_0}(V)$, because q is a power of the characteristic p, and it commutes with restriction. On stalks it is a local homomorphism, since h^q lies in a prime ideal exactly when h does. It fixes every $c \in \mathbb{F}_q$, as $c^q = c$, so Φ is a morphism of $\mathbb{F}_q$-schemes and its fiber product with id_k over $\mathbb{F}_q$ is defined. On an affine open $U_0 = \operatorname{Spec} A_0$ of C_0, the morphism Φ restricts to Spec of the ring map $a \mapsto a^q$: this map is the identity on prime ideals, and on each $D(b)$ it is $a/b^n \mapsto a^q/b^{qn}$. Hence on the affine open $U = U_0 \times_{\mathbb{F}_q} k = \operatorname{Spec}(A_0 \otimes_{\mathbb{F}_q} k)$ of C, the morphism F restricts to Spec of the k-algebra endomorphism

$$F^{\#}\colon A_0 \otimes_{\mathbb{F}_q} k \longrightarrow A_0 \otimes_{\mathbb{F}_q} k, \qquad a \otimes \lambda \longmapsto a^q \otimes \lambda \tag{8.6}$$

The q-th power map $h \mapsto h^q$ on $\mathcal{O}_C$ sends a constant $\lambda \in k$ to λ^q, so it is not a morphism of k-schemes. The morphism F raises to the q-th power only the functions that come from C_0, and it is k-linear. Under the identification of C with its Frobenius twist, which holds because C comes from $\mathbb{F}_q$, it is the k-linear Frobenius morphism of [50, Remark IV.2.4.1 and Exercise V.1.10] for the power q.

Example 8.7.3: The Frobenius of the Projective Line

Let $C_0 = \mathbb{P}^1_{\mathbb{F}_q}$, so that $C = \mathbb{P}^1_k$. On the chart $D_+(x_0) = \operatorname{Spec} \mathbb{F}_q[t]$ with $t = x_1/x_0$, (8.6) is the k-algebra map $k[t] \to k[t]$, $t \mapsto t^q$. The closed point $t = c$ corresponds to the kernel of $t \mapsto c$, and composing with $t \mapsto t^q$ gives $t \mapsto c^q$, so F sends it to $t = c^q$. On the other chart the same computation applies, and in homogeneous coordinates $F[a_0 : a_1] = [a_0^q : a_1^q]$. The point $[1 : c]$ is fixed exactly when $c^q = c$, that is, when $c \in \mathbb{F}_q$, and $[0 : 1]$ is fixed, so F has $q + 1 = \#\mathbb{P}^1(\mathbb{F}_q)$ fixed points. Every $c \in k$ has a unique q-th root in k, so F is a bijection on closed points. On function fields F induces the map $k(t) \to k(t)$, $t \mapsto t^q$, whose image is $k(t^q) = k(t)^q$, the subfield of q-th powers.

The degree of a finite morphism of curves is the degree of an extension of function fields (definition 7.1.8). For $\mathbb{P}^1$ the extension is $k(t)$ over its subfield of q-th powers. Over a perfect field, the function field of every curve has degree q over its subfield of q-th powers.

Lemma 8.7.4: A Function Field Has Degree q over Its q-th Powers

Let k be a perfect field of characteristic $p > 0$, let q be a power of p, and let K be a finitely generated field extension of k of transcendence degree 1. Then $K^q = \{h^q : h \in K\}$ is a subfield of K containing k, and $[K : K^q] = q$.

***Proof*:**

The map $\mathrm{Fr}\colon K \to K$, $h \mapsto h^q$, is an injective ring homomorphism, so its image K^q is a subfield of K isomorphic to K. It contains $k = k^q$, since k is perfect.

Choose $t \in K$ transcendental over k. The extension $K/k(t)$ is finitely generated and algebraic, hence finite, of some degree n. The isomorphism $\mathrm{Fr}\colon K \to K^q$ carries $k(t)$ onto $k^q(t^q) = k(t^q)$, so $[K^q : k(t^q)] = n$. The element t is a root of $T^q - t^q \in k(t^q)[T]$, so $[k(t) : k(t^q)] \leq q$. The powers $1, t, \ldots, t^{q-1}$ are linearly independent over $k(t^q)$: after clearing denominators, a relation $\sum_{i=0}^{q-1} c_i t^i = 0$ has coefficients $c_i \in k[t^q]$, every monomial occurring in $c_i t^i$ has exponent congruent to i modulo q, and since t is transcendental the relation holds in the polynomial ring $k[t]$, so each $c_i t^i$ vanishes and every c_i is zero. Hence $[k(t) : k(t^q)] = q$. Computing $[K : k(t^q)]$ through the two towers $K \supseteq K^q \supseteq k(t^q)$ and $K \supseteq k(t) \supseteq k(t^q)$ gives

$$[K : K^q] \cdot n = [K : k(t^q)] = n \cdot q$$

so $[K : K^q] = q$, as claimed.

For transcendence degree d the same two towers, built on a transcendence basis $t_1, \ldots, t_d$, give $[K : K^q] = q^d$.

Proposition 8.7.5: Fixed Points, Degree and Differential of the Frobenius

Let $F\colon C \to C$ be the q-power Frobenius.

1. For every closed point $[a_0 : \cdots : a_m]$ of C,
$$F[a_0 : \cdots : a_m] = [a_0^q : \cdots : a_m^q]$$
The closed points fixed by F are exactly the points of $C_0(\mathbb{F}_q)$, so F has exactly N fixed closed points.
2. F is a finite surjective morphism of degree q, and the map $F^*\colon K(C) \to K(C)$ it induces on the function field has image $K(C)^q$.
3. For every closed point x of C and every $h \in \mathcal{O}_{C,F(x)}$, the differential $d(F^\# h) \in \Omega_{C/k,x}$ is zero. Equivalently, the map $F^*\Omega_{C/k} \to \Omega_{C/k}$ of the cotangent sequence (proposition 5.5.17) is zero.

***Proof*:**
Let $U_0 = \operatorname{Spec} A_0$ be a nonempty affine open of C_0 and $U = \operatorname{Spec} A$ with $A = A_0 \otimes_{\mathbb{F}_q} k$. By (8.6), F maps U into U and is given there by $F^\#(a \otimes \lambda) = a^q \otimes \lambda$.

(1) Take $U_0 = C_0 \cap D_+(x_j)$, so $A_0 = \mathbb{F}_q[y]/I_j$ and $A = k[y]/I_j k[y]$, with $F^\#(y_i) = y_i^q$ for each coordinate. A closed point a of U, with $a_j = 1$, corresponds to the kernel of the evaluation $\operatorname{ev}_a\colon A \to k$, $y_i \mapsto a_i$ (theorem 0.1.12(3)). Its image $F(a)$ corresponds to the prime ideal $(F^\#)^{-1}(\ker \operatorname{ev}_a) = \ker(\operatorname{ev}_a \circ F^\#)$, and $\operatorname{ev}_a \circ F^\#$ is the k-algebra map with $y_i \mapsto a_i^q$. So $F(a)$ is the point with coordinates a_i^q, which in homogeneous coordinates is $[a_0^q : \cdots : a_m^q]$, since $a_j = 1 = a_j^q$. The point a is fixed exactly when $a_i^q = a_i$ for every i. The q elements of $\mathbb{F}_q$ are roots of $T^q - T$, because $c^{q-1} = 1$ for $c \in \mathbb{F}_q^\times$, and the polynomial has at most q roots in k, so its roots are exactly the elements of $\mathbb{F}_q$. Hence a is fixed if and only if every a_i lies in $\mathbb{F}_q$, that is, $a \in C_0(\mathbb{F}_q)$. The charts $D_+(x_j)$ cover C, which proves (1).

(2) The Frobenius $\sigma\colon k \to k$, $\lambda \mapsto \lambda^q$, is a field automorphism fixing $\mathbb{F}_q$ pointwise: it is injective, and surjective because $T^q - \lambda$ has a root in the algebraically closed field k. So $\psi = \mathrm{id}_{A_0} \otimes \sigma^{-1}$ is a ring automorphism of A. For $h = \sum_i a_i \otimes \lambda_i$, the q-th power map is additive in characteristic p, so
$$\psi(h)^q = \sum_i a_i^q \otimes \lambda_i = F^\#(h)$$
The ring A is a domain, as C is integral, so $F^\#(h) = 0$ forces $\psi(h) = 0$ and $h = 0$. Thus $F^\#$ is injective, F maps the generic point of C to itself, and F is not constant. By proposition 7.1.6, F is finite and surjective. The map F^* on $K = K(C) = \operatorname{Frac} A$ extends $F^\#$, and $F^\#(A) = \psi(A)^q = A^q$, so $F^*K = \operatorname{Frac}(A^q) = K^q$. The field K is finitely generated of transcendence degree 1 over the perfect field k (theorem 2.6.11), so definition 7.1.8 and lemma 8.7.4 give $\deg F = [K : F^*K] = [K : K^q] = q$.

(3) Let x be a closed point and choose U_0 with $x \in U$. Then $F(x) \in U$, and $F^\#\colon \mathcal{O}_{C,F(x)} \to \mathcal{O}_{C,x}$ is the map induced by $F^\#\colon A \to A$ on localizations. An element of $\mathcal{O}_{C,F(x)}$ has the form $h = a/b$ with $a, b \in A$ and b outside the prime ideal of $F(x)$. Since $F^\#$ is local, $\psi(b)^q = F^\# b$ is a unit of $\mathcal{O}_{C,x}$, hence so is $\psi(b)$, and $F^\# h = \psi(a)^q/\psi(b)^q = u^q$ with $u = \psi(a)/\psi(b)$. Hence $d(F^\# h) = q\, u^{q-1}\, du = 0$, because $q = 0$ in k. The map $F^*\Omega_{C/k} \to \Omega_{C/k}$ sends $F^*(dh)$ to

$d(F^{\#}h)$ (proposition 5.5.5), and the elements $F^*(dh)$ generate $F^*\Omega_{C/k}$, so the map is zero, completing the proof.

As on $\mathbb{P}^1$, the morphism F is a bijection on closed points: coordinatewise q-th roots invert the formula of (1), and they preserve the zero set of each I_j, because an element h of I_j has coefficients c with $c^q = c$, so that $h(b)^q = h(b^q)$ for every $b \in k^m$. Nevertheless F has degree q, so over each closed point there is a single point, with ramification index q (proposition 7.1.9). The extension K/K^q is purely inseparable, and (3) is the vanishing of (7.3) for the inseparable morphism F (box 7.4.4).

By proposition 8.7.5(1), N is the number of closed points x with $F(x) = x$, that is, the number of points where the graph of F meets the diagonal of the surface $C \times C$.

Proposition 8.7.6: The Product of Two Curves

Let C and C' be curves over k, and let $X = C \times C' = C \times_k C'$, with projections p_1 and p_2.

1. X is a surface: a smooth projective surface over k in the sense of definition 8.1.1.
2. The map
$$\alpha\colon p_1^*\Omega_{C/k} \oplus p_2^*\Omega_{C'/k} \longrightarrow \Omega_{X/k}$$
whose two components are the first maps of the cotangent sequences (proposition 5.5.17) of p_1 and p_2, is an isomorphism.
3. $\omega_X \cong p_1^*\omega_C \otimes p_2^*\omega_{C'}$.
4. Let P be a closed point of X, with $x = p_1(P)$ and $y = p_2(P)$. For $h \in \mathcal{O}_{C,x}$ and $h' \in \mathcal{O}_{C',y}$ write $h \otimes 1 = p_1^{\#}h$ and $1 \otimes h' = p_2^{\#}h'$ in $\mathcal{O}_{X,P}$, and write $dh(x)$ for the image of dh in $\Omega_{C/k,x} \otimes \kappa(x)$, and likewise $dh'(y)$. There is an isomorphism of k-vector spaces
$$\mathfrak{m}_P/\mathfrak{m}_P^2 \;\cong\; \big(\Omega_{C/k,x} \otimes \kappa(x)\big) \oplus \big(\Omega_{C'/k,y} \otimes \kappa(y)\big)$$
sending the class of $h \otimes 1 + 1 \otimes h'$, for $h \in \mathfrak{m}_x$ and $h' \in \mathfrak{m}_y$, to $(dh(x), dh'(y))$. Each summand is one-dimensional, spanned by $dt(x)$, respectively $dt'(y)$, for uniformizers t at x and t' at y.

***Proof*:**

Step 1: (1). The curves C and C' are regular, hence smooth over the perfect field k (theorem 2.7.15), of relative dimension 1, since by proposition 2.7.12 the relative dimension of a smooth morphism to $\operatorname{Spec} k$ is the dimension of its source. By proposition 2.7.11(3), X is smooth over k of relative dimension 2. So X has pure dimension 2 (proposition 2.7.12) and is regular (theorem 2.7.15), and it is integral, separated and of finite type over k by proposition 3.7.10. Choose closed immersions $C \hookrightarrow \mathbb{P}^m_k$ and $C' \hookrightarrow \mathbb{P}^{m'}_k$ (proposition 7.1.7). The morphisms $C \times C' \to \mathbb{P}^m_k \times C'$ and $\mathbb{P}^m_k \times C' \to \mathbb{P}^m_k \times \mathbb{P}^{m'}_k$ are base changes of these closed immersions, hence closed immersions (proposition 3.2.5(2)), and the Segre embedding $\mathbb{P}^m_k \times \mathbb{P}^{m'}_k \to \mathbb{P}^M_k$ is a closed immersion (example 5.3.45(5)). The composite is a closed immersion (proposition 3.1.24(3)), so X is projective.

Step 2: (2). By proposition 5.5.25, $\Omega_{X/k}$ is locally free of rank 2, and the source of α is a direct sum of two invertible sheaves. Let $U = \operatorname{Spec} A \subseteq C$ and $U' = \operatorname{Spec} B \subseteq C'$ be affine opens.

Then $U \times U' = \operatorname{Spec}(A \otimes_k B)$, such opens cover X, and $\Omega_{X/k}|_{U\times U'}$ is the sheaf associated to $\Omega_{A\otimes_k B/k}$ (proposition 5.5.15). On $U \times U'$ the first component of α sends $da \otimes c$ to $c\,d(a \otimes 1)$ and the second sends $db \otimes c$ to $c\,d(1 \otimes b)$ (proposition 5.5.5). The module $\Omega_{A\otimes_k B/k}$ is generated by the differentials of the elements of $A \otimes_k B$ (definition 5.5.2, Construction 1), and by the Leibniz rule

$$d(a \otimes b) = (1 \otimes b)\, d(a \otimes 1) + (a \otimes 1)\, d(1 \otimes b)$$

so α is surjective. At a point P of X, α_P is then a surjection $\mathcal{O}_{X,P}^2 \to \mathcal{O}_{X,P}^2$ of free modules. It has a right inverse β, the target being free, and $\det(\alpha_P)\det(\beta) = 1$, so $\det(\alpha_P)$ is a unit and α_P is an isomorphism. Hence α is an isomorphism.

Step 3: (3). For a curve $\omega_C = \Omega_{C/k}$, and $\omega_X = \bigwedge^2 \Omega_{X/k}$ (definition 5.5.28). Put $\mathcal{L}_1 = p_1^*\omega_C$ and $\mathcal{L}_2 = p_2^*\omega_{C'}$. The bilinear map $(s_1, s_2) \mapsto s_1 \wedge s_2$ induces $\mathcal{L}_1 \otimes \mathcal{L}_2 \to \bigwedge^2(\mathcal{L}_1 \oplus \mathcal{L}_2)$. Where $\mathcal{L}_1$ and $\mathcal{L}_2$ are free on generators u_1 and u_2, the sheaf $\mathcal{L}_1 \oplus \mathcal{L}_2$ is free on u_1, u_2, its second exterior power is free on $u_1 \wedge u_2$, and the map sends the generator $u_1 \otimes u_2$ to it. So the map is an isomorphism, and with (2) it gives $\omega_X \cong \bigwedge^2(\mathcal{L}_1 \oplus \mathcal{L}_2) \cong \mathcal{L}_1 \otimes \mathcal{L}_2$.

Step 4: (4). The residue fields $\kappa(P)$, $\kappa(x)$, $\kappa(y)$ are all k. By proposition 5.5.10, the map $\mathfrak{m}_P/\mathfrak{m}_P^2 \to \Omega_{X/k,P} \otimes \kappa(P)$ sending the class of u to $du \otimes 1$ is an isomorphism. Composing with the inverse of $\alpha_P \otimes \kappa(P)$ and using $(p_1^*\Omega_{C/k})_P \otimes \kappa(P) = \Omega_{C/k,x} \otimes \kappa(x)$, and likewise for p_2, gives the isomorphism of (4). Under it $d(h \otimes 1) = \alpha(p_1^* dh, 0)$ goes to $(dh(x), 0)$ and $d(1 \otimes h')$ to $(0, dh'(y))$. The same proposition on C identifies $\Omega_{C/k,x} \otimes \kappa(x)$ with $\mathfrak{m}_x/\mathfrak{m}_x^2$, which is spanned by the class of t, so it is spanned by $dt(x)$, and likewise for C', completing the proof.

The proposition is the algebraic form of the splitting of the cotangent space of a product into the cotangent spaces of its factors, and (3) says that a canonical divisor of $C \times C'$ is $p_1^*K_C + p_2^*K_{C'}$.

From now on C is a curve of genus g and $X = C \times C$. For a closed point P of C, the fibers of p_1 and p_2 over P are

$$e = P \times_k C = \{P\} \times C, \qquad f = C \times_k P = C \times \{P\}$$

For a morphism $\varphi\colon C \to C$, the morphism $\gamma_\varphi = (\mathrm{id}_C, \varphi)\colon C \to X$ is a closed immersion (proposition 3.5.9, C being separated over k), and its image Γ_φ is the *graph* of φ. Its closed points are the $(x, \varphi(x))$. The graph $\Delta = \Gamma_{\mathrm{id}_C}$ is the diagonal. The fiber f is the graph of the constant morphism c_P with value P.

Proposition 8.7.7: Intersection Numbers of Fibers and Graphs

Let P be a closed point of C, let e and f be the fibers over P, and let $\varphi\colon C \to C$ be a finite morphism of degree d.

1. The fibers e and f are smooth irreducible curves on X, with $\mathcal{O}_X(e) \cong p_1^*\mathcal{L}(P)$ and $\mathcal{O}_X(f) \cong p_2^*\mathcal{L}(P)$, and
$$e^2 = f^2 = 0, \qquad e \cdot f = 1$$
2. The graph Γ_φ is a smooth irreducible curve isomorphic to C, and
$$\Gamma_\varphi \cdot e = 1, \qquad \Gamma_\varphi \cdot f = d$$
3. $\Gamma_\varphi^2 = d(2-2g)$. In particular $\Delta^2 = 2 - 2g$.

***Proof*:**
Step 1: degrees along graphs. Let $\psi\colon C \to C$ be a morphism. Its graph Γ_ψ is a closed subscheme isomorphic to C through γ_ψ, hence a smooth irreducible curve on X. For a divisor D on X, proposition 8.2.2(6) and this isomorphism give

$$D \cdot \Gamma_\psi = \deg\bigl(\gamma_\psi^* \mathcal{O}_X(D)\bigr) \tag{8.7}$$

For an invertible sheaf $\mathcal{L}$ on C: if ψ is finite of degree d_ψ, then $\deg \psi^*\mathcal{L} = d_\psi \deg \mathcal{L}$, because $\mathcal{L} \cong \mathcal{L}(D_0)$ for a divisor D_0 (corollary 5.4.45), $\psi^*\mathcal{L}(D_0) \cong \mathcal{L}(\psi^* D_0)$ (as shown before (7.4)), and $\deg \psi^* D_0 = d_\psi \deg D_0$ (proposition 7.1.9). If $\psi = c_P$ is constant, then ψ factors through $\operatorname{Spec} k$, on which every invertible sheaf is trivial, so $\deg \psi^*\mathcal{L} = 0$.

Step 2: (1). The point P is an effective Cartier divisor on C with ideal sheaf $\mathcal{I}_P \cong \mathcal{L}(-P)$ (proposition 5.4.47(1)), and it is flat over $\operatorname{Spec} k$, as every module over a field is. The fiber $e = P \times_k C$ is its base change along the second factor $C \to \operatorname{Spec} k$, and the projection from $X = C \times_k C$ to the factor containing P is p_1. By proposition 5.4.31, e is an effective Cartier divisor on X with $\mathcal{I}_e \cong p_1^*\mathcal{I}_P$, so $\mathcal{O}_X(-e) \cong p_1^*\mathcal{L}(-P)$, and dualizing gives $\mathcal{O}_X(e) \cong p_1^*\mathcal{L}(P)$. Exchanging the factors, $\mathcal{O}_X(f) \cong p_2^*\mathcal{L}(P)$. The closed immersion $f = C \times_k P \hookrightarrow X$, composed with the isomorphism $C \cong C \times_k P$, is $\gamma_{c_P} = (\mathrm{id}_C, c_P)\colon x \mapsto (x, P)$, and in the same way e is the image of the closed immersion $\varepsilon = (c_P, \mathrm{id}_C)\colon x \mapsto (P, x)$. Both fibers are smooth irreducible curves isomorphic to C, and (8.7), together with its analogue for ε, gives

$$\begin{aligned} f^2 &= \deg \gamma_{c_P}^* p_2^* \mathcal{L}(P) = \deg c_P^* \mathcal{L}(P) = 0, \\ e \cdot f &= \deg \gamma_{c_P}^* p_1^* \mathcal{L}(P) = \deg \mathcal{L}(P) = 1, \\ e^2 &= \deg \varepsilon^* p_1^* \mathcal{L}(P) = \deg c_P^* \mathcal{L}(P) = 0 \end{aligned}$$

using $p_1 \circ \gamma_{c_P} = \mathrm{id}_C = p_2 \circ \varepsilon$ and $p_2 \circ \gamma_{c_P} = c_P = p_1 \circ \varepsilon$.

Step 3: (2). Since $p_1 \circ \gamma_\varphi = \mathrm{id}_C$ and $p_2 \circ \gamma_\varphi = \varphi$, (8.7) and Step 1 give

$$\Gamma_\varphi \cdot e = \deg \mathcal{L}(P) = 1, \qquad \Gamma_\varphi \cdot f = \deg \varphi^* \mathcal{L}(P) = d$$

Step 4: (3). Let K_X be a canonical divisor of X. By proposition 8.7.6(3), $\mathcal{O}_X(K_X) \cong p_1^*\omega_C \otimes p_2^*\omega_C$, so by (8.7), Step 1 and proposition 7.3.1,

$$K_X \cdot \Gamma_\varphi = \deg \omega_C + \deg \varphi^* \omega_C = (2g-2) + d(2g-2)$$

The curve $\Gamma_\varphi \cong C$ has genus g, and the adjunction formula (theorem 8.2.8) gives

$$2g - 2 = \Gamma_\varphi^2 + K_X \cdot \Gamma_\varphi = \Gamma_\varphi^2 + (1+d)(2g-2)$$

so $\Gamma_\varphi^2 = -d(2g-2) = d(2-2g)$. The diagonal is the case $\varphi = \mathrm{id}_C$, $d = 1$, completing the proof.

As sets, Γ_φ meets the fiber e of the first projection in the single point $(P, \varphi(P))$, and the fiber f of the second projection in the points (x, P) with $x \in \varphi^{-1}(P)$, of which there are d counted with ramification. For $g \geq 2$ the diagonal has negative self-intersection, so by corollary 8.3.13(2) it is the only effective divisor in its numerical class.

The intersection number $\Gamma_F \cdot \Delta$ is a sum of local intersection multiplicities (proposition 8.2.2(5)), and computing those requires a local equation of each graph.

Lemma 8.7.8: Local Equation of a Graph

Let $\varphi\colon C \to C$ be a morphism, x a closed point of C, $y = \varphi(x)$, $P = (x, y)$, and t a uniformizer at y. Then the ideal of Γ_φ in $\mathcal{O}_{X,P}$ is generated by

$$1 \otimes t - \varphi^{\#} t \otimes 1$$

Under the isomorphism of proposition 8.7.6(4), the class of this element in $\mathfrak{m}_P/\mathfrak{m}_P^2$ is $\big(-d(\varphi^{\#}t)(x),\, dt(y)\big)$, whose second component is nonzero.

***Proof*:**

Write $g_P = 1\otimes t - \varphi^{\#}t \otimes 1$ and let $J \subseteq \mathcal{O}_{X,P}$ be the ideal of Γ_φ. Choose an affine open $V = \operatorname{Spec} B$ containing y with $t \in B$, and an affine open $U = \operatorname{Spec} A$ containing x with $\varphi(U) \subseteq V$. Then $\gamma_\varphi^{-1}(U \times V) = U$, and $\gamma_\varphi|_U\colon U \to U \times V = \operatorname{Spec}(A \otimes_k B)$ is Spec of the surjection $A \otimes_k B \to A$, $a \otimes b \mapsto a\,\varphi^{\#}(b)$. So $\Gamma_\varphi \cap (U \times V)$ is the closed subscheme defined by the kernel of this surjection, which contains $1 \otimes t - \varphi^{\#}t \otimes 1$, and $g_P \in J$.

Here $t \in \mathfrak{m}_y$ and $\varphi^{\#}t \in \mathfrak{m}_x$, as $(\varphi^{\#}t)(x) = t(\varphi(x)) = t(y) = 0$, so proposition 8.7.6(4) applies with $h = -\varphi^{\#}t$ and $h' = t$, and gives the class $\big(-d(\varphi^{\#}t)(x), dt(y)\big)$. Its second component is nonzero because $dt(y)$ spans $\Omega_{C/k,y} \otimes \kappa(y)$. In particular $g_P \notin \mathfrak{m}_P^2$ and $g_P \neq 0$.

The local ring $\mathcal{O}_{X,P}$ is regular of dimension 2 (proposition 8.7.6(1) and theorem 2.6.12), hence a unique factorization domain (proposition 2.7.27). The ideal J is prime, and $\mathcal{O}_{X,P}/J \cong \mathcal{O}_{C,x}$ through γ_φ, a discrete valuation ring, so $J \neq \mathfrak{m}_P$. The element g_P is a nonzero nonunit of the prime ideal J, so one of its prime factors π lies in J. The chain $0 \subsetneq (\pi) \subseteq J \subsetneq \mathfrak{m}_P$ of prime ideals in a local ring of dimension 2 forces $(\pi) = J$. Write $g_P = \pi u$. If $u \in \mathfrak{m}_P$ then $g_P \in \mathfrak{m}_P^2$, which is false, so u is a unit and $J = (g_P)$, as claimed.

Proposition 8.7.9: The Rational Points as an Intersection Number

Let $\Gamma_F \subseteq X = C \times C$ be the graph of the q-power Frobenius and Δ the diagonal. Then Γ_F and Δ meet transversally, and

$$\Gamma_F \cdot \Delta = N$$

***Proof*:**

By proposition 8.7.5(2), F is finite of degree $q \geq 2$, so proposition 8.7.7(2) gives $\Gamma_F \cdot f = q$ while $\Delta \cdot f = 1$. Hence $\Gamma_F \neq \Delta$, and the two irreducible curves have no common component. The closed points of Γ_F are the $(x, F(x))$ and those of Δ are the (x, x), so the closed points of $\Gamma_F \cap \Delta$ are the (x, x) with $F(x) = x$. By proposition 8.7.5(1) there are N of them, and by the proof of proposition 8.2.2(5) the intersection consists of closed points only.

Let $P = (x, x)$ with $F(x) = x$, and let t be a uniformizer at x. By lemma 8.7.8, applied to id_C and to F, local equations of Δ and Γ_F at P are

$$\delta = 1 \otimes t - t \otimes 1, \qquad \gamma = 1 \otimes t - F^{\#}t \otimes 1$$

and their classes in $\mathfrak{m}_P/\mathfrak{m}_P^2$ are $(-dt(x), dt(x))$ and $(-d(F^{\#}t)(x), dt(x))$. By proposition 8.7.5(3), $d(F^{\#}t) = 0$, so the second class is $(0, dt(x))$. As $dt(x) \neq 0$, the two classes are linearly independent, so they span the two-dimensional space $\mathfrak{m}_P/\mathfrak{m}_P^2$, and by Nakayama's lemma δ and

γ generate $\mathfrak{m}_P$. So Γ_F and Δ meet transversally at every point of $\Gamma_F \cap \Delta$, and proposition 8.2.2(4) gives $\Gamma_F \cdot \Delta = \#(\Gamma_F \cap \Delta) = N$, as claimed.

For a smooth map $\theta\colon M \to M$ of a compact oriented manifold, the Lefschetz number is the oriented intersection number of the diagonal with the graph of θ, and when $d\theta_p - \mathrm{id}$ is invertible at every fixed point p, the Lefschetz-Hopf theorem expresses it as a sum of local contributions ± 1, one for each fixed point (*Differential Topology* [80, Lefschetz Number, The Lefschetz-Hopf Theorem]). Proposition 8.7.9 is the algebraic counterpart for F: its differential vanishes, so $dF - \mathrm{id} = -\mathrm{id}$ is invertible at every fixed point, and each fixed point contributes local intersection multiplicity 1.

Example 8.7.10: The Graph of Frobenius on $\mathbb{P}^1 \times \mathbb{P}^1$

Let $C_0 = \mathbb{P}^1_{\mathbb{F}_q}$ as in example 8.7.3, so that $g = 0$ and $X = \mathbb{P}^1_k \times \mathbb{P}^1_k$. The fibers e and f are members of the two rulings, and $\operatorname{Pic} X = \mathbb{Z}e \oplus \mathbb{Z}f$ (example 8.1.7(2)). Write $\Gamma_F \sim \alpha e + \beta f$. Since $e^2 = f^2 = 0$ and $e \cdot f = 1$, the numbers $\Gamma_F \cdot e = 1$ and $\Gamma_F \cdot f = q$ of proposition 8.7.7(2) give $\beta = 1$ and $\alpha = q$, so $\Gamma_F \sim qe + f$. In the same way $\Delta \sim e + f$, and

$$\Gamma_F \cdot \Delta = (qe + f) \cdot (e + f) = q + 1, \qquad \Gamma_F^2 = 2q, \qquad \Delta^2 = 2$$

This agrees with proposition 8.7.9 and $\#\mathbb{P}^1(\mathbb{F}_q) = q + 1$, with proposition 8.7.7(3) for $g = 0$, and with the self-intersection 2 of a curve of bidegree $(1, 1)$ (example 8.2.3(3)).

The Hodge index theorem bounds the self-intersection of every divisor on X by its intersection numbers with the two fibers, in an inequality due to Castelnuovo and Severi.

Theorem 8.7.11: Castelnuovo-Severi Inequality

Let C be a curve, $X = C \times C$, P a closed point of C, and e and f the fibers over P. For a divisor D on X put $a = D \cdot e$ and $b = D \cdot f$. Then

$$D^2 \;\le\; 2ab$$

with equality if and only if $D \equiv be + af$.

***Proof*:**

Put $D' = D - be - af$. By proposition 8.7.7(1), $e^2 = f^2 = 0$ and $e \cdot f = 1$, so

$$D' \cdot e = a - b\,e^2 - a\,(f \cdot e) = 0, \qquad D' \cdot f = b - b\,(e \cdot f) - a\,f^2 = 0$$

and therefore $D' \cdot (e + f) = 0$, while $(e + f)^2 = 2 > 0$. By corollary 8.3.12(1), applied to the divisor $e + f$ of positive square and to the divisor D' orthogonal to it, $D'^2 \le 0$, with equality if and only if $D' \equiv 0$. Expanding,

$$D'^2 = D^2 - 2b\,(D \cdot e) - 2a\,(D \cdot f) + b^2 e^2 + 2ab\,(e \cdot f) + a^2 f^2 = D^2 - 2ab - 2ab + 2ab = D^2 - 2ab$$

so $D^2 \le 2ab$, with equality if and only if $D \equiv be + af$, as claimed.

The proof uses only that $e + f$ has positive square. On $\mathbb{P}^1 \times \mathbb{P}^1$ every divisor is linearly equivalent to $be + af$, because $\operatorname{Pic}(\mathbb{P}^1 \times \mathbb{P}^1) = \mathbb{Z}e \oplus \mathbb{Z}f$, so equality holds for all D, as in example 8.2.3(3). For $g \ge 1$ the inequality is strict for the diagonal, since $\Delta \cdot e = \Delta \cdot f = 1$ while $\Delta^2 = 2 - 2g < 2$.

Applied to the divisors $r\Gamma_F + s\Delta$, the inequality becomes a family of quadratic inequalities whose only unknown is N.

Theorem 8.7.12: The Weil Bound for Curves over Finite Fields

Let C_0 be as in box 8.7.1, of genus g, and let $N = \#C_0(\mathbb{F}_q)$. Then

$$\big|N - (q+1)\big| \;\le\; 2g\sqrt{q}$$

***Proof*:**
Step 1: a quadratic form. Fix a closed point P of C, let e and f be the fibers over P, and write $\Gamma = \Gamma_F$. By proposition 8.7.7, applied to F (finite of degree q by proposition 8.7.5(2)) and to id_C, and by proposition 8.7.9,

$$\Gamma\cdot e = \Delta\cdot e = \Delta\cdot f = 1, \qquad \Gamma\cdot f = q, \qquad \Gamma^2 = q(2-2g), \qquad \Delta^2 = 2-2g, \qquad \Gamma\cdot\Delta = N$$

For integers r and s let $D = r\Gamma + s\Delta$. Then $a = D\cdot e = r+s$, $b = D\cdot f = qr+s$, and

$$D^2 = q(2-2g)\,r^2 + 2N\,rs + (2-2g)\,s^2, \qquad 2ab = 2q\,r^2 + 2(q+1)\,rs + 2\,s^2$$

By theorem 8.7.11, $D^2 \le 2ab$. Subtracting and dividing by 2,

$$gq\,r^2 + (q+1-N)\,rs + g\,s^2 \;\ge\; 0 \qquad \text{for all } r,s\in\mathbb{Z} \tag{8.8}$$

Step 2: the discriminant. Put $B = q+1-N$. If $g=0$, then (8.8) at $(r,s)=(1,-B)$ reads $-B^2\ge 0$, so $B=0$. If $g\ge 1$, then at $(r,s)=(B,-2gq)$ it reads

$$gq\,B^2 - 2gq\,B^2 + 4g^3q^2 = gq\,(4g^2q - B^2) \;\ge\; 0$$

and $gq>0$ gives $B^2\le 4g^2q$. In both cases $|N-(q+1)| = |B| \le 2g\sqrt{q}$, as we sought to show.

Applied over the extensions of $\mathbb{F}_q$, theorem 8.7.12 bounds every N_n.

Corollary 8.7.13: The Weil Bound over Every Finite Extension

Let C_0 be as in box 8.7.1, of genus g. For every $n\ge 1$,

$$\big|N_n - (q^n+1)\big| \;\le\; 2g\,q^{n/2}$$

***Proof*:**
Let $C_0' = C_0 \times_{\mathbb{F}_q} \mathbb{F}_{q^n}$, a closed subscheme of $\mathbb{P}^m_{\mathbb{F}_{q^n}}$ whose chart ideals are generated by the same I_j. Its base change $C_0' \times_{\mathbb{F}_{q^n}} k$ is $C_0 \times_{\mathbb{F}_q} k = C$, as $(A_0 \otimes_{\mathbb{F}_q} \mathbb{F}_{q^n}) \otimes_{\mathbb{F}_{q^n}} k \cong A_0 \otimes_{\mathbb{F}_q} k$ on each chart, and k is an algebraic closure of $\mathbb{F}_{q^n}$. So C_0' satisfies the conventions of box 8.7.1 over $\mathbb{F}_{q^n}$, with the same curve C and genus g, and its $\mathbb{F}_{q^n}$-points are the closed points of C with coordinates in $\mathbb{F}_{q^n}$, which number N_n. Theorem 8.7.12 for C_0', with q^n in place of q, gives $|N_n - (q^n+1)| \le 2g\sqrt{q^n}$, as claimed.

In particular $N_n/q^n \to 1$, so for large n the number of points of C_0 over $\mathbb{F}_{q^n}$ is close to that of $\mathbb{P}^1$. Over a single field the theorem forces rational points when q is large compared with g.

Corollary 8.7.14: Curves over Large Finite Fields Have Rational Points

Let C_0 be as in box 8.7.1, of genus g. If $q+1 > 2g\sqrt{q}$, which holds whenever $q \geq 4g^2$, then $C_0(\mathbb{F}_q)$ is nonempty. In particular $C_0(\mathbb{F}_q)$ is nonempty when $g \leq 1$.

***Proof*:**

By theorem 8.7.12, $N \geq q+1-2g\sqrt{q} > 0$. If $q \geq 4g^2$, then $2g\sqrt{q} \leq \sqrt{q}\cdot\sqrt{q} = q < q+1$. For $g=0$ the condition is $q+1>0$, and for $g=1$ it is $(\sqrt{q}-1)^2 > 0$, which holds since $q \geq 2$, completing the proof.

For $g=2$ the condition $q+1 > 4\sqrt{q}$ is $\sqrt{q} > 2+\sqrt{3}$, that is, $q > 7+4\sqrt{3} \approx 13.9$, and the least prime power in that range is 16, so every curve of genus 2 over $\mathbb{F}_q$ with $q \geq 16$ has a rational point. For $g=0$ the theorem gives $N = q+1$ exactly, the number of points of $\mathbb{P}^1_{\mathbb{F}_q}$. For $g=1$ the curve C_0 has a rational point O by corollary 8.7.14, so (C_0, O) is an elliptic curve over $\mathbb{F}_q$, and the theorem is Hasse's bound $|q+1-N| \leq 2\sqrt{q}$ of box 7.6.12, proved in *Elliptic Curves* [20, Hasse's Theorem].

For a plane curve the genus is determined by the degree (proposition 7.2.6), so the bound depends only on the degree and q once the curve is known to be smooth, and smoothness can be checked on the partial derivatives of the equation.

Lemma 8.7.15: A Plane Curve with Nowhere-Vanishing Gradient Is Smooth

Let $G \in k[x,y,z]$ be homogeneous of degree $d \geq 1$, and suppose that $\partial G/\partial x$, $\partial G/\partial y$ and $\partial G/\partial z$ have no common zero in $\mathbb{P}^2(k)$. Then $V_+(G) \subseteq \mathbb{P}^2_k$ is a smooth projective curve of genus $(d-1)(d-2)/2$.

***Proof*:**

Step 1: $V_+(G)$ is integral of dimension 1. A homogeneous $H \in k[x,y,z]$ of positive degree has a zero in $\mathbb{P}^2(k)$: either $H(x,y,0) = 0$, and every $[a:b:0]$ is a zero, or $H(x,y,0)$ is a nonzero binary form, which is a product of linear forms over the algebraically closed field k and vanishes at some $[a:b:0]$. Suppose $G = G_1G_2$ with G_1 and G_2 homogeneous of positive degree. They have a common zero: a zero of a common irreducible factor if they have one, and otherwise one of the $\deg G_1 \cdot \deg G_2 > 0$ intersection points counted by Bézout's theorem (*Classical Algebraic Geometry* [30, Bézout's Theorem]). At a common zero, the product rule $\partial G = G_1\,\partial G_2 + G_2\,\partial G_1$ makes all three partial derivatives of G vanish, against the hypothesis. So G is irreducible, (G) is a prime ideal, and $V_+(G)$ is integral. It is nonempty, and by lemma 3.7.11, applied to $\mathbb{P}^2_k$, it has dimension 1. Being closed in $\mathbb{P}^2_k$, it is projective and complete.

Step 2: nonsingularity. Let a be a closed point of $V_+(G)$. Permuting the variables, we may assume a lies in $D_+(z)$, with affine coordinates (a_1, a_2). There $V_+(G)$ is $\operatorname{Spec} k[x,y]/(g)$ with $g(x,y) = G(x,y,1)$, and $\partial g/\partial x(a) = \partial G/\partial x(a_1,a_2,1)$ and $\partial g/\partial y(a) = \partial G/\partial y(a_1,a_2,1)$. These do not both vanish: Euler's identity $x\,\partial G/\partial x + y\,\partial G/\partial y + z\,\partial G/\partial z = dG$, which holds monomial by monomial, evaluated at $(a_1,a_2,1)$, where G vanishes, would otherwise force $\partial G/\partial z(a_1,a_2,1) = 0$ as well. So the Jacobian matrix of g has rank 1 at a. The local ring of $V_+(G)$ at a has dimension 1 (theorem 2.6.12), and $1 = 2-1$, so $V_+(G)$ is regular at a by

proposition 2.7.7. Regularity at every closed point gives regularity everywhere (box 5.5.24), so $V_+(G)$ is a smooth projective curve, and proposition 7.2.6 gives its genus, as claimed.

Corollary 8.7.16: Points on Smooth Plane Curves

Let $G \in \mathbb{F}_q[x,y,z]$ be homogeneous of degree d, suppose that $V_+(G) \subseteq \mathbb{P}^2_k$ is a smooth curve (by lemma 8.7.15, this holds when the partial derivatives of G have no common zero in $\mathbb{P}^2(k)$), and let $C_0 = V_+(G) \subseteq \mathbb{P}^2_{\mathbb{F}_q}$. Then

$$\left|N - (q+1)\right| \;\leq\; (d-1)(d-2)\sqrt{q}$$

***Proof*:**
The scheme C_0 is projective over $\mathbb{F}_q$, and on each chart its base change to k is cut out by the same equation, so $C = V_+(G) \subseteq \mathbb{P}^2_k$, a smooth curve of genus $(d-1)(d-2)/2$ by proposition 7.2.6. Theorem 8.7.12 gives the bound, as claimed.

The bound of theorem 8.7.12 cannot be improved in general: for every square q there is a plane curve that attains the upper bound.

Example 8.7.17: The Hermitian Curve Attains the Bound
Let Q be a power of p, let $q = Q^2$, and let $C_0 = V_+(G) \subseteq \mathbb{P}^2_{\mathbb{F}_q}$ with

$$G = x^{Q+1} + y^{Q+1} + z^{Q+1}$$

the *Hermitian curve*. Since $Q+1 = 1$ in k, the partial derivatives of G are x^Q, y^Q and z^Q, which have no common zero in $\mathbb{P}^2(k)$. By lemma 8.7.15, $C = V_+(G) \subseteq \mathbb{P}^2_k$ is a smooth curve of genus $g = Q(Q-1)/2$, and, as in the proof of corollary 8.7.16, C_0 satisfies the conventions of box 8.7.1.

The count uses the map $u \mapsto u^{Q+1}$ on $\mathbb{F}_q$. The group $\mathbb{F}_q^\times$ is cyclic of order $Q^2-1 = (Q-1)(Q+1)$, so this map sends it onto its unique subgroup of order $Q-1$, which is $\mathbb{F}_Q^\times$, with fibers of $Q+1$ elements. Hence for $c \in \mathbb{F}_Q$ the equation $u^{Q+1} = c$ has one solution $u \in \mathbb{F}_q$ if $c = 0$ and $Q+1$ solutions if $c \neq 0$.

1. Points $[a:b:1]$. Put $s = a^{Q+1}$ and $t = b^{Q+1}$, so that $s,t \in \mathbb{F}_Q$ and $s+t = -1$. The pairs $(s,t) = (0,-1)$ and $(-1,0)$ contribute $Q+1$ solutions (a,b) each, and each of the $Q-2$ values $s \in \mathbb{F}_Q \setminus \{0,-1\}$ contributes $(Q+1)^2$. The total is $2(Q+1) + (Q-2)(Q+1)^2 = (Q+1)(Q^2-Q) = Q^3 - Q$.
2. Points $[a:b:0]$. Here $b \neq 0$, and with $b = 1$ the condition is $a^{Q+1} = -1$, which has $Q+1$ solutions.

So $N = Q^3 - Q + Q + 1 = Q^3 + 1$, while

$$q + 1 + 2g\sqrt{q} = Q^2 + 1 + Q(Q-1)\cdot Q = Q^3 + 1$$

The Hermitian curve attains the upper bound of theorem 8.7.12. For $Q = 2$ it is the plane cubic $x^3 + y^3 + z^3 = 0$ over $\mathbb{F}_4$, of genus 1, with $9 = 4 + 1 + 2\cdot 2$ points, and for $Q = 3$ it is a plane quartic of genus 3 over $\mathbb{F}_9$ with $28 = 9 + 1 + 6\cdot 3$ points.

Taken together for all n, the bounds of corollary 8.7.13 are equivalent to the statement that the $2g$ eigenvalues of the q-power Frobenius on the first ℓ-adic cohomology group of C have absolute value $\sqrt{q}$, which is the Riemann hypothesis of theorem 8.7.18 for a curve. Weil formulated these conjectures in 1949 for every smooth projective variety over $\mathbb{F}_q$.

Theorem 8.7.18: The Weil Conjectures (Dwork, Grothendieck, Deligne)

Let X be a smooth projective variety of dimension n over $\mathbb{F}_q$, let $\overline{X} = X \times_{\mathbb{F}_q} \overline{\mathbb{F}}_q$, let ℓ be a prime not dividing q, and let F be the endomorphism of $H^i = H^i(\overline{X}, \mathbb{Q}_\ell)$ induced by the q-power Frobenius morphism of $\overline{X}$. Write $Z(X,t) = \exp\left(\sum_{m=1}^{\infty} \frac{\#X(\mathbb{F}_{q^m})}{m} t^m\right)$.

1. *Rationality.* $Z(X,t) = \prod_{i=0}^{2n} P_i(t)^{(-1)^{i+1}}$ with $P_i(t) = \det(1 - tF \,|\, H^i)$. In particular $Z(X,t) \in \mathbb{Q}(t)$.
2. *Functional equation.* $Z(X, q^{-n}t^{-1}) = \pm\, q^{nE/2}\, t^E\, Z(X,t)$, where $E = \sum_i (-1)^i \dim H^i$.
3. *Riemann hypothesis.* The eigenvalues of F on H^i are algebraic numbers all of whose complex conjugates have absolute value $q^{i/2}$.

Dwork proved rationality in 1960 by p-adic analysis, and Grothendieck proved rationality and the functional equation in 1964-1965 from the Lefschetz trace formula and Poincaré duality in étale cohomology. Deligne proved the Riemann hypothesis in 1974 [33]. *Étale Cohomology* [21] develops étale cohomology and gives Deligne's proof.

8.7.1 Arithmetic Surfaces and Integral Points

The theory of surfaces has an arithmetic counterpart over the rings of integers of number fields. An *arithmetic surface* is a 2-dimensional integral Noetherian scheme $\mathcal{X}$ equipped with a proper flat morphism

$$\pi \colon \mathcal{X} \to \operatorname{Spec} \mathcal{O}_K$$

where $\mathcal{O}_K$ is the ring of integers of a number field K. The generic fiber $\mathcal{X}_\eta = \mathcal{X} \times_{\mathcal{O}_K} K$ is a curve over K. The fiber $\mathcal{X}_\mathfrak{p} = \mathcal{X} \times_{\mathcal{O}_K} \mathcal{O}_K/\mathfrak{p}$ over a maximal ideal $\mathfrak{p}$ is a proper one-dimensional scheme over the finite field $\mathcal{O}_K/\mathfrak{p}$, which may be singular, reducible or non-reduced. An arithmetic surface is thus a family of curves over $\operatorname{Spec} \mathcal{O}_K$: the generic fiber is a curve over a number field, and the closed fibers are its reductions modulo the primes of $\mathcal{O}_K$.

Example 8.7.19: Arithmetic Surfaces in Practice

1. The projective line $\mathcal{X} = \mathbb{P}^1_{\mathbb{Z}}$, with $\pi \colon \mathbb{P}^1_{\mathbb{Z}} \to \operatorname{Spec} \mathbb{Z}$, has generic fiber $\mathbb{P}^1_{\mathbb{Q}}$ and fiber $\mathbb{P}^1_{\mathbb{F}_p}$ over (p).
2. Let $E \colon y^2 = x^3 - x$ over $\mathbb{Q}$, and let $\mathcal{E} \subseteq \mathbb{P}^2_{\mathbb{Z}}$ be the closed subscheme defined by $y^2 z = x^3 - xz^2$. The polynomial is irreducible and its coefficients have no common prime factor, so $\mathcal{E}$ is integral and $\mathbb{Z}[x,y,z]/(y^2z - x^3 + xz^2)$ has no $\mathbb{Z}$-torsion, which makes $\mathcal{E}$ flat over $\operatorname{Spec} \mathbb{Z}$. It is an arithmetic surface with generic fiber E. Its fiber over an odd prime p is the curve $y^2z = x^3 - xz^2$ over $\mathbb{F}_p$, an elliptic curve since the discriminant 64 of the Weierstrass equation is a unit modulo p. Its fiber over 2 is the curve $y^2 z = x(x+z)^2$ over $\mathbb{F}_2$, which is singular at the point $(1:0:1)$, reflecting the bad reduction of E at 2. The Néron model of E is a

different object: it is smooth over $\mathbb{Z}$, so none of its fibers is singular, and since E has bad reduction at 2 it is not proper over $\mathbb{Z}$.

Intersection theory on arithmetic surfaces is *Arakelov theory*, introduced by Arakelov in 1974. The scheme $\operatorname{Spec} \mathcal{O}_K$ has no points corresponding to the archimedean places of K, and Arakelov theory adds data at these places: an Arakelov divisor carries a real coefficient for each archimedean place, and line bundles carry Hermitian metrics on the Riemann surfaces $\mathcal{X}_\sigma(\mathbb{C})$ for the embeddings $\sigma\colon K \to \mathbb{C}$. The resulting intersection pairing

$$\widehat{\operatorname{Div}}(\mathcal{X}) \times \widehat{\operatorname{Div}}(\mathcal{X}) \to \mathbb{R}$$

is the arithmetic counterpart of the intersection pairing on a surface, and it takes values in $\mathbb{R}$ because of the archimedean contributions. Arakelov proved an arithmetic adjunction formula, Faltings an arithmetic Riemann-Roch theorem, and Faltings and Hriljac the arithmetic Hodge index theorem. Gillet and Soulé proved an arithmetic Riemann-Roch theorem in all dimensions. Vojta's 1991 proof of the Mordell conjecture (Faltings' theorem that a curve of genus at least 2 over a number field has finitely many rational points) uses Arakelov intersection theory and the arithmetic Riemann-Roch theorem of Gillet and Soulé. Faltings' original proof of 1983 used different methods.

Over $\mathbb{F}_q$ every curve has finitely many points, and the genus bounds their number. The Euler characteristic of the associated complex Riemann surface determines whether the set of integral points becomes infinite after the field and the allowed denominators are enlarged.

8.7.20 Integral Points and the Euler Characteristic Let K be a number field, S a finite set of places of K containing the archimedean ones, and $\mathcal{O}_{K,S}$ the ring of S-integers. Let $C^\circ \subseteq \mathbb{A}^m_K$ be a smooth geometrically integral affine curve cut out by polynomials with coefficients in $\mathcal{O}_{K,S}$, let C be the smooth projective curve containing C° as a dense open subscheme, of genus g, and let $s \geq 1$ be the number of points of $C \setminus C^\circ$ over $\overline{K}$. The *S-integral points* of C° are the points of $C^\circ(K)$ whose coordinates lie in $\mathcal{O}_{K,S}$. For a smooth projective geometrically integral curve C over K, put $C^\circ = C$ and $s = 0$, and let all of $C(K)$ play the role of the S-integral points. For every embedding $K \hookrightarrow \mathbb{C}$, the space $C^\circ(\mathbb{C})$ is a compact Riemann surface of genus g with s points removed, and its topological Euler characteristic is

$$\chi = 2 - 2g - s$$

If $\chi \geq 0$, the set of S-integral points can be finite, and it becomes infinite once K is replaced by a suitable finite extension and S by a suitable larger set. If $\chi < 0$, it is finite for every number field and every S.

1. $\chi > 0$, that is, $g = 0$ and $s \leq 1$. For $C = \mathbb{P}^1_K$ the set $C(K)$ is infinite, and the S-integral points of the affine line $\mathbb{A}^1_K = \mathbb{P}^1_K \setminus \{\infty\}$ form the infinite set $\mathcal{O}_{K,S}$.
2. $\chi = 0$, that is, $(g, s) = (0, 2)$ or $(1, 0)$. The S-integral points of $\mathbb{G}_m = \mathbb{P}^1_K \setminus \{0, \infty\}$, embedded in $\mathbb{A}^2_K$ as $xy = 1$, form the unit group $\mathcal{O}^\times_{K,S}$, a finitely generated abelian group of rank $\#S - 1$ by Dirichlet's unit theorem in its S-unit form (for S the set of archimedean places, *Algebraic Number Theory* [11, Dirichlet Unit Theorem]). It is finite for $K = \mathbb{Q}$ and S the archimedean place, where it is $\mathbb{Z}^\times = \{\pm 1\}$. For an elliptic curve E over K, the group $E(K)$ is finitely generated (*Elliptic Curves* [20, The Mordell-Weil Theorem]), and its rank can be 0, while it is positive over a suitable finite extension of K.
3. $\chi < 0$. If $s \geq 1$, the set of S-integral points of C° is finite. Siegel proved this for integral points in 1929 (reprinted in [92]), and Lang proved it for S-integral points in 1960 [63], after Mahler's case of genus 1 over $\mathbb{Q}$ (1934) [67]. For an elliptic curve minus its origin, given by a Weierstrass equation, this is *Elliptic Curves* [20, Siegel's Theorem (S-Integral Version)]. If $s = 0$, then $g \geq 2$, and $C(K)$ is finite. Mordell conjectured this in 1922 [74] and Faltings proved it in 1983 [36].

Exercise 8.7.1

1. Let C be a curve of genus g and $\Delta \subseteq C \times C$ the diagonal, with ideal sheaf $\mathcal{I}_\Delta$. Show that the conormal sheaf $\mathcal{I}_\Delta/\mathcal{I}^2_\Delta$ corresponds to $\Omega_{C/k}$ under the isomorphism $C \cong \Delta$ given by the diagonal morphism (definition 5.5.14), and use proposition 8.2.6 to give a second proof that $\Delta^2 = 2 - 2g$.
2. Let $\sigma \neq \mathrm{id}_C$ be an automorphism of a curve C of genus g.
    1. Apply theorem 8.7.11 to $D = \Gamma_\sigma + \Delta$ to show that $\Gamma_\sigma \cdot \Delta \leq 2g + 2$, and deduce that σ has at most $2g + 2$ fixed points.
    2. Let C be hyperelliptic, with $\mathrm{char} k \neq 2$, and let ι be its hyperelliptic involution, whose fixed points are the $2g + 2$ Weierstrass points (definition 7.5.3). Show that $\Gamma_\iota \cdot \Delta = 2g + 2$ and that Γ_ι meets Δ transversally.

3. Let $q \equiv 2 \pmod 3$ and $C_0 = V_+(x^3 + y^3 + z^3) \subseteq \mathbb{P}^2_{\mathbb{F}_q}$. Show that C_0 satisfies the conventions of box 8.7.1 with $g = 1$, and that $N = q + 1$. (*Hint:* $u \mapsto u^3$ is a bijection of $\mathbb{F}_q$.) Compare with theorem 8.7.12.

4. Let C_0 be as in box 8.7.1. Show that for every sufficiently large n there is a closed point of C whose homogeneous coordinates can be chosen in $\mathbb{F}_{q^n}$ but not in $\mathbb{F}_{q^d}$ for any proper divisor d of n. (*Hint:* compare N_n with $\sum_{d \mid n,\, d<n} N_d$ using corollary 8.7.13.)

5. Let $C_0 = V_+(G) \subseteq \mathbb{P}^2_{\mathbb{F}_q}$ be as in corollary 8.7.16, of degree d, and suppose that $C_0(\mathbb{F}_q)$ is all of $\mathbb{P}^2(\mathbb{F}_q)$. Show that $(d-1)(d-2) \geq q^{3/2}$, and deduce that no smooth plane cubic over $\mathbb{F}_q$ passes through every point of $\mathbb{P}^2(\mathbb{F}_q)$.

9

What Next?

Sheaves, schemes, quasi-coherent sheaves and their cohomology, built in chapters 1 to 3, 5 and 6, were applied in chapters 7 and 8 to curves and surfaces over an algebraically closed field. Those two chapters worked under four restrictions. The varieties studied had dimension one or two, apart from Hironaka's threefold (section 8.4.1). No moduli space was constructed: $\mathcal{M}_g$ and $\overline{\mathcal{M}}_g$ are described without proof (boxes 7.2.8 and 7.7.5), and families of curves entered through semicontinuity (section 7.7.1) and through the fibrations of ruled, elliptic and arithmetic surfaces. The ground field was algebraically closed, with sections 7.7.2 and 8.7 the main exceptions. The cohomology computed was the cohomology of coherent sheaves, and the singular cohomology of $X(\mathbb{C})$ entered the two chapters only through cited results such as theorem 8.1.6.

Intersection theory and Riemann-Roch in every dimension. On a smooth variety X of dimension n, the classes of subvarieties of every codimension modulo rational equivalence form the Chow ring $A^*(X)$, and the intersection pairing of a surface is its product $A^1(X) \times A^1(X) \to A^2(X)$ followed by the degree (box 8.2.10). Riemann-Roch generalizes to the Hirzebruch-Riemann-Roch theorem, which expresses $\chi(\mathscr{E})$ for a vector bundle $\mathscr{E}$ through the Chern classes of $\mathscr{E}$ and of the tangent bundle of X. For line bundles on a curve and on a surface it gives theorem 7.2.10 and theorem 8.3.1, and the proof of Noether's formula (theorem 8.3.3) applies it to $\mathcal{O}_X$. The Grothendieck-Riemann-Roch theorem extends it to a proper morphism. *Intersection Theory* [26] constructs the Chow ring and Chern classes and proves both theorems. Fulton's *Intersection Theory* is the standard reference, and Eisenbud and Harris's *3264 and All That* develops the subject through enumerative problems.

Birational geometry and the minimal model program. On a surface, contracting (-1)-curves (theorem 8.4.8) reaches a minimal model, which is unique when $\kappa \geq 0$ (theorem 8.6.3), and every surface in the process is smooth. From dimension three on, the contraction of a K_X-negative extremal ray can have a singular image, and when it contracts no divisor the canonical divisor of the image is not $\mathbb{Q}$-Cartier, so the program admits mild singularities and continues by a flip (box 8.4.10). Flips exist in every dimension (Birkar, Cascini, Hacon and McKernan, 2010), their termination is known in dimension three and open in general, and the abundance conjecture of box 8.6.7 is open from

dimension four on. *Birational Geometry* [12] develops the cone and contraction theorems, flips, and the vanishing theorems used to prove them (box 8.6.10). Kollár and Mori's *Birational Geometry of Algebraic Varieties* is the standard text, and Debarre's *Higher-Dimensional Algebraic Geometry* treats the rational curves that span the extremal rays of the cone theorem.

Toric varieties. The surfaces $\mathbb{P}^2$, $\mathbb{P}^1 \times \mathbb{P}^1$ and $\mathbb{F}_n$ of example 8.1.2 each contain the torus $\mathbb{G}_m^2$ as a dense open subset, and the action of $\mathbb{G}_m^2$ on itself by translation extends to the whole surface. Varieties with this property are *toric*. They exist in every dimension, and a normal toric variety of dimension n is determined by a fan of cones in $\mathbb{R}^n$. Its divisors, Picard group, intersection numbers and cohomology are computed from the fan, and so is projectivity: a complete toric variety is projective exactly when its fan is the normal fan of a polytope, and, as with Hironaka's threefold (section 8.4.1), completeness does not imply projectivity: some complete toric threefolds are not projective. *Toric Geometry* [28] develops the theory. Fulton's *Introduction to Toric Varieties* is a short introduction, and Cox, Little and Schenck's *Toric Varieties* is a comprehensive account.

Abelian varieties and Jacobians. Theorem 7.6.3 identified an elliptic curve E with $\mathrm{Pic}^0(E)$. For a curve X of genus $g \geq 2$, the group $\mathrm{Pic}^0(X)$ is the group of points of the Jacobian $\mathrm{Jac}(X)$, a projective group variety of dimension g into which X embeds by the Abel-Jacobi map, and by the Torelli theorem $\mathrm{Jac}(X)$ with its theta divisor determines X. The complete connected group varieties are the *abelian varieties*. They are commutative and projective, and those of dimension 1 are the elliptic curves. *Abelian Varieties* [8] develops them over an arbitrary field, with the theorem of the cube, the dual abelian variety, polarizations, Jacobians and the Torelli theorem. Mumford's *Abelian Varieties* is the standard text, and Birkenhake and Lange's *Complex Abelian Varieties* treats the theory over $\mathbb{C}$.

Moduli of curves and stacks. Curves of genus $g \geq 2$ depend on $3g-3$ parameters (box 7.7.4), and elliptic curves are classified by the j-line (box 7.6.6). Some curves of every genus have nontrivial automorphisms, so no scheme represents the moduli functor of curves of genus g, and for $g \geq 2$ the moduli problem is a Deligne-Mumford stack $\mathcal{M}_g$ (box 7.2.8). Its coarse moduli space is not proper, and the Deligne-Mumford compactification $\overline{\mathcal{M}}_g$ adds the stable curves of box 7.7.5. *Moduli, Deformation Theory, and Stacks* [27] constructs Hilbert schemes, Picard schemes and $\overline{\mathcal{M}}_g$, and develops the deformation theory behind the count $3g-3$. Harris and Morrison's *Moduli of Curves* is the standard introduction, and Arbarello, Cornalba and Griffiths's *Geometry of Algebraic Curves, Volume II* is the comprehensive reference.

The arithmetic of elliptic curves. Over a field that is not algebraically closed, a curve of genus 1 can have no rational point, and it is then a torsor under its Jacobian E, with a class in $H^1(k, E)$ (section 7.7.2). Over a number field K the group $E(K)$ is finitely generated (example 7.6.13), the Birch and Swinnerton-Dyer conjecture predicts its rank from the L-function of E, and the Galois action on the Tate module (box 7.6.12) is a basic example of an ℓ-adic Galois representation. *Elliptic Curves* [20] develops the Mordell-Weil and Siegel theorems, Selmer and Shafarevich-Tate groups, and complex multiplication. Silverman's *The Arithmetic of Elliptic Curves* is the standard text, and his *Advanced Topics in the Arithmetic of Elliptic Curves* continues it.

Étale cohomology and the Weil conjectures. Section 8.7 bounded the number of points of a curve over $\mathbb{F}_q$ by the Hodge index theorem on the product of the curve with itself, and the bounds over all the extensions $\mathbb{F}_{q^n}$ together are equivalent to the Riemann hypothesis of the Weil conjectures (theorem 8.7.18) for curves. For a variety X of higher dimension, an argument of the same kind on $X \times X$ requires Grothendieck's standard conjectures, which are open. The Weil conjectures were proved with ℓ-adic étale cohomology, which attaches to a variety over $\overline{\mathbb{F}}_q$ cohomology groups with coefficients in $\mathbb{Q}_\ell$ and a Lefschetz trace formula for the Frobenius morphism. *Étale Cohomology* [21]

develops the étale site, the étale fundamental group of box 7.4.10, ℓ-adic cohomology and Deligne's proof. Milne's *Étale Cohomology* is the standard reference, and Freitag and Kiehl's *Étale Cohomology and the Weil Conjecture* is organized around Deligne's theorem.

Hodge theory and the Hodge conjecture. Over $\mathbb{C}$ the Néron-Severi group of a surface is identified with the integral cohomology classes of type $(1,1)$ (theorem 8.1.6), and the Hodge decomposition (corollary 6.9.10) gives the Hodge diamond of a surface (example 8.3.6). On a compact Kähler manifold of any dimension the Hard Lefschetz theorem and the Hodge-Riemann bilinear relations hold, and on a surface the second gives the Hodge index theorem over $\mathbb{C}$ (box 8.3.14). The Hodge conjecture asks whether every rational cohomology class of type (p,p) on a smooth projective complex variety is a rational combination of classes of subvarieties of codimension p. Its case $p = 1$ is theorem 8.1.6, and it is open in general. *Hodge Theory* [24] develops the Hodge decomposition, the Hard Lefschetz theorem and the Hodge-Riemann relations, and proves the Lefschetz $(1,1)$-theorem. Voisin's *Hodge Theory and Complex Algebraic Geometry* is the standard modern text, and Griffiths and Harris's *Principles of Algebraic Geometry* the classical one.

Derived categories of coherent sheaves. Sheaf cohomology consists of the right derived functors of global sections (chapter 6), and for a smooth projective variety Serre duality, used in the proofs of theorem 7.2.10 and theorem 8.3.1, is the case of the structure morphism $X \to \operatorname{Spec} k$ of Grothendieck duality, a statement about derived categories. The bounded derived category $D^b(\mathbf{Coh}X)$ of coherent sheaves is an invariant of X, and it does not always determine X. By Mukai's theorem an abelian variety and its dual, which need not be isomorphic, have equivalent derived categories through the Fourier-Mukai transform. By the Bondal-Orlov theorem a smooth projective variety whose canonical divisor is ample or anti-ample is determined by its derived category. Derived categories of abelian categories are constructed in *Homological Algebra* [25], and *Derived Algebraic Geometry* [19] develops derived categories of coherent sheaves, Fourier-Mukai transforms and the Bondal-Orlov theorem. Huybrechts's *Fourier-Mukai Transforms in Algebraic Geometry* is the standard introduction.

Part I

The Chow Group

Cycles are easy to write down and useless as they stand: the group of formal integer combinations of subvarieties is enormous, is not an invariant of anything, and admits no product. This part cuts it down to something that is. Rational equivalence identifies two cycles when one sweeps out to the other in a family over $\mathbb{P}^1$, and the quotient, the Chow group, turns out to carry exactly the structure the classical geometers were assuming when they deformed a configuration and trusted the count. Proper pushforward and flat pullback make it functorial, the localization sequence and homotopy invariance make it computable, and intersecting with a divisor gives the first operation that lowers dimension. That last operation, the first Chern class, is the seed of everything the rest of the book builds.

9.0.1 Convention: Standing Hypotheses Throughout the book a scheme is a *separated* scheme of finite type over a fixed algebraically closed field $\overline{k}$; such a scheme is called an *algebraic scheme*. A point is a closed point unless stated otherwise, a subvariety of a scheme is a closed integral subscheme, and a *variety* is a reduced and irreducible algebraic scheme, hence separated. Separatedness is folded in here rather than carried statement by statement because it is exactly the condition making the diagonal $\delta\colon X \to X \times X$ a closed immersion, and from chapter 14 onward every intersection product is built by pulling back along that diagonal. A non-separated example such as the line with a doubled origin is excluded by this convention, not by hypothesis.

9.0.2 Convention: $\mathbb{P}(E)$ Is the Bundle of Lines For a vector bundle E on X, this book writes $\mathbb{P}(E)$ for the bundle of one-dimensional *subspaces* of E: the fibre over x is the space of lines in E_x. This is Fulton's convention.

Algebraic Geometry [9] uses Grothendieck's opposite convention, under which $\mathbb{P}(\mathscr{E}) = \operatorname{Proj}(\operatorname{Sym}^\bullet \mathscr{E})$ parametrizes one-dimensional *quotients* of the fibres. The two are related by a dual: the bundle written $\mathbb{P}(E)$ here is the one written $\mathbb{P}(E^\vee)$ there, and a formula transported between the two must be dualized. The Segre classes of Chapter 10 onward are defined by pushing forward powers of $c_1(\mathcal{O}_{\mathbb{P}(E)}(1))$, so reading such a formula in the wrong convention silently computes the classes of $E^\vee$ instead of E.

10

Rational Equivalence

Recall from [30, Plane Curve] that we had to define *projective plane curves* to be an equivalence relation on homogeneous polynomials of $k[x, y, z]$ up to a constant ($f \sim g$ if and only if $f = \alpha g$). This was specifically done keep track of multiplicity information. By the correspondence between homogeneous and affine curves, we can without loss of generality work with $[f(x, y)], [g(x, y)] \in k[x, y]$ and choose any representative; we shall simply call these *plane curves*. Given a choice of plane curves f, g let F, G denote the resulting variety. The intersection of two (affine or projective) plane curves F, G at P was defined as:

$$i(P, f \cdot g) = \dim_k \frac{\mathcal{O}_{\mathbb{A}^2_k, P}}{(f, g)} = \dim_k \mathcal{O}_{Z,P}$$

where $Z = \mathcal{Z}(f, g)$. The properties recorded there are:

1. (commutative on intersection): $i(P, F \cdot G) = i(P, G \cdot F)$
2. (additive on intersection): if $F_1 + F_2$ is the curve defined by $f_1 f_2$, then $i(P, (F_1 + F_2) \cdot G) = i(P, F_1 \cdot G) + i(P, F_2 \cdot G)$
3. (invariance of representation): if F' is given by $f + gh$ for some $h \in k[x, y]$:
$$i(P, F' \cdot G) = i(P, F \cdot G)$$
4. If F, G have have a common component through P (i.e. the dimension of the irreducible variety in $F \cap G$ containing p is greater than 0), then $i(P, F \cdot G) = \infty$. Otherwise, $i(P, F \cdot G) \in \mathbb{N}_{\geq 0}$.
5. If $P \notin F \cap G$:
$$i(P, F \cdot G) = 0$$
6. if $f(x, y) = x - a$ and $g(x, y) = y - b$ (more generally $\frac{\partial(f,g)}{\partial(x,y)} \neq 0$ at p) then:
$$i(P, F \cdot G) = 1$$

7. If F has no common component with G and H and P is a simple point of F, then $i(P, G \cdot H) \geq \min\big(i(P, F \cdot G),\ i(P, F \cdot H)\big)$. This one is not in the cited source, whose nearest statement is about the sum of forms $g + h$ rather than the product gh; it follows from the total ordering of the ideals of the discrete valuation ring $\mathcal{O}_{\mathbb{A}^2_k, P}/(f)$.

10.1 Cycles and Rational Equivalence

The classical intersection number recalled above attaches an integer to a pair of plane curves meeting at a point. Turning that local count into a theory valid on any variety and in every dimension calls for a home for "formal combinations of subvarieties" together with an equivalence relation flexible enough to make intersection numbers well defined. That home is the Chow group, the higher-dimensional descendant of the divisor class group of definition 5.4.8: where the divisor class group records codimension-one subvarieties modulo the divisors of rational functions, the Chow group records subvarieties of *every* dimension modulo the same mechanism.

This section builds the three objects in turn, the group of cycles $Z_k(X)$, the subgroup $\mathrm{Rat}_k(X)$ of cycles rationally equivalent to zero, and the quotient $A_k(X)$. Throughout the chapter X is an algebraic scheme (a scheme of finite type over the algebraically closed field $\overline{k}$), a *subvariety* means a closed integral subscheme, and a point means a closed point unless stated otherwise.

The construction rests on the order of vanishing of a rational function along a codimension-one subvariety, introduced for divisors in section 5.4. On a variety W a prime divisor is a codimension-one subvariety V, and the local ring $\mathcal{O}_{W,V}$ is a one-dimensional local domain with fraction field the function field $k(W)$. When W is regular in codimension one this ring is a discrete valuation ring and its valuation ν_V records orders of vanishing (definition 5.4.7); the length-theoretic definition below removes the regularity hypothesis, which matters as soon as W is an arbitrary subvariety of X.

Definition 10.1.1: Order Along a Subvariety

Let W be a variety and $V \subseteq W$ a codimension-one subvariety, and set $A = \mathcal{O}_{W,V}$, a one-dimensional local domain with fraction field $k(W)$. For nonzero $a \in A$ the quotient $A/(a)$ has finite length, and the *order of a along V* is

$$\operatorname{ord}_V(a) = \operatorname{length}_A\big(A/(a)\big)$$

Because $\operatorname{ord}_V(ab) = \operatorname{ord}_V(a) + \operatorname{ord}_V(b)$, this extends to a homomorphism $\operatorname{ord}_V \colon k(W)^* \to \mathbb{Z}$ by $\operatorname{ord}_V(a/b) = \operatorname{ord}_V(a) - \operatorname{ord}_V(b)$.

When $\mathcal{O}_{W,V}$ is a discrete valuation ring, in particular whenever W is normal, this length equals the valuation $\nu_V(a)$, so definition 10.1.1 agrees with the order function of section 5.4. For a fixed $r \in k(W)^*$ the integer $\operatorname{ord}_V(r)$ vanishes for all but finitely many V, so each sum $\sum_V \operatorname{ord}_V(r)[V]$ below is finite. For W regular in codimension one this is lemma 5.4.6; for a general W, where the order is the length-theoretic one just defined, it is [38, Appendix B.4.3].

Definition 10.1.2: [Algebraic] Cycle

Let X be an algebraic scheme. A *k-cycle* on X is a finite formal $\mathbb{Z}$-linear combination $\sum_i n_i[V_i]$ of k-dimensional subvarieties $V_i \subseteq X$ with $n_i \in \mathbb{Z}$. The k-cycles form the free abelian group

$$Z_k(X) = \bigoplus_{\dim V = k} \mathbb{Z}\,[V]$$

on the set of k-dimensional subvarieties of X, and the group of all cycles is $Z_*(X) = \bigoplus_{k \geq 0} Z_k(X)$.

A cycle remembers only which subvarieties occur and with what integer multiplicity; it detects neither embedded nor nonreduced structure, a point made precise by the equality $Z_k(X) = Z_k(X_{\mathrm{red}})$. Two cases sit at the extremes. A 0-cycle is a finite formal sum of closed points. At the top, if X has dimension n with n-dimensional irreducible components $X_1, \dots, X_r$, then $Z_n(X)$ is free on $[X_1], \dots, [X_r]$.

The *fundamental cycle* of X ranges over *all* irreducible components $X_1, \dots, X_t$, of whatever dimension:

$$[X] = \sum_{i=1}^{t} \mathrm{length}_{\mathcal{O}_{X,X_i}}\left(\mathcal{O}_{X,X_i}\right)[X_i] \;\in\; Z_*(X)$$

weighting each component by the multiplicity with which X carries it, and reducing to $\sum_i [X_i]$ when X is reduced. When X is equidimensional the sum is concentrated in degree n; in general it is not, and it must not be truncated to the top-dimensional components. A scheme such as the union of a plane and a line meeting it in a point carries a fundamental cycle with a 2-dimensional and a 1-dimensional term, and discarding the line would make the Segre classes of chapter 12 disagree with the standard ones on exactly such a base.

The one construction that produces relations among cycles is the divisor of a rational function. Given a $(k+1)$-dimensional subvariety $W \subseteq X$ and a nonzero $r \in k(W)^*$, its *divisor* is the k-cycle

$$[\mathrm{div}(r)] = \sum_{V} \mathrm{ord}_V(r)\,[V] \in Z_k(X)$$

the sum running over the codimension-one subvarieties V of W, each of which is a k-dimensional subvariety of X. The sum is finite, by [38, Appendix B.4.3] in general and by lemma 5.4.6 when W is regular in codimension one, and $[\mathrm{div}(rs)] = [\mathrm{div}(r)] + [\mathrm{div}(s)]$ because ord_V is a homomorphism.

Definition 10.1.3: Rational Equivalence

A k-cycle $\alpha \in Z_k(X)$ is *rationally equivalent to zero*, written $\alpha \sim 0$, if there are finitely many $(k+1)$-dimensional subvarieties $W_i \subseteq X$ and rational functions $r_i \in k(W_i)^*$ with

$$\alpha = \sum_i [\mathrm{div}(r_i)]$$

Two k-cycles are *rationally equivalent*, written $\alpha \sim \beta$, when $\alpha - \beta \sim 0$. The cycles rationally equivalent to zero form a subgroup $\mathrm{Rat}_k(X) \leq Z_k(X)$: it is closed under addition by definition and under negation because $[\mathrm{div}(r^{-1})] = -[\mathrm{div}(r)]$.

Geometrically, a subvariety W together with a rational function r presents $[\operatorname{div}(r)]$ as the difference between the zeros and the poles of r, that is, between the fibers over 0 and ∞ of the rational map $r\colon W \dashrightarrow \mathbb{P}^1$. Rational equivalence is thus the relation generated by sweeping one cycle to another through a family parametrized by the line. In the one codimension seen before, $k = n-1$ on an n-dimensional variety, a cycle is a Weil divisor and rational equivalence is exactly the linear equivalence of definition 5.4.8; the Chow group below carries $\operatorname{Cl} X$ to all dimensions at once.

Definition 10.1.4: Chow Group

The *k-th Chow group* of an algebraic scheme X is the quotient

$$A_k(X) = Z_k(X)/\operatorname{Rat}_k(X)$$

Its elements are *k-cycle classes*, and the class of a cycle α is written $[\alpha]$, or simply α when no confusion results. The *total Chow group* is

$$A_*(X) = \bigoplus_{k\geq 0} A_k(X) = Z_*(X)/\operatorname{Rat}_*(X), \qquad \operatorname{Rat}_*(X) = \bigoplus_{k\geq 0} \operatorname{Rat}_k(X)$$

Following the cohomological convention, much of the literature grades by codimension, writing $A^p(X) = A_{n-p}(X)$ or $CH^p(X)$ when X is equidimensional of dimension n; the two indexings carry the same information, and definition 10.1.4 is the promised general form of the construction previewed for surfaces in box 8.2.10. A cycle $\sum_i n_i[V_i]$ is *positive* (or *effective*) if it is nonzero with every $n_i \geq 0$, and a cycle class is positive if it has a positive representative. Positivity is the algebraic trace of an actual geometric subvariety, and deciding which classes are positive is among the central difficulties of the subject.

Passing to the quotient collapses exactly the ambiguity that a complete variety imposes on its points.

Example 10.1.5: Zero-Cycles on the Line

On $X = \mathbb{P}^1$ any two closed points are rationally equivalent. Write t for the affine coordinate and ∞ for the point at infinity. Distinct points $p, q \in \mathbb{A}^1 \subseteq \mathbb{P}^1$ are cut out by $t-p$ and $t-q$, and the rational function $r = (t-p)/(t-q)$ has

$$\operatorname{ord}_p(r) = 1, \qquad \operatorname{ord}_q(r) = -1, \qquad \operatorname{ord}_x(r) = 0 \text{ for } x \neq p, q$$

since r takes the finite nonzero value 1 at ∞. Hence $[\operatorname{div}(r)] = [p] - [q]$ and $[p] \sim [q]$; taking $r = t - p$ instead gives $[\operatorname{div}(t-p)] = [p] - [\infty]$, so $[\infty]$ lies in the same class. Every point of $\mathbb{P}^1$ therefore represents a single class h. A rational function on $\mathbb{P}^1$ has as many zeros as poles, so $\sum_V \operatorname{ord}_V(r) = 0$ for all r, and the total-coefficient map $\sum_i n_i[p_i] \mapsto \sum_i n_i$ descends to an isomorphism

$$A_0(\mathbb{P}^1) \xrightarrow{\sim} \mathbb{Z}, \qquad h \mapsto 1$$

The affine line behaves oppositely. On $X = \mathbb{A}^1$ the function $t - p$ has the single zero p and no pole, so $[\operatorname{div}(t-p)] = [p]$ and every point satisfies $[p] \sim 0$; thus $A_0(\mathbb{A}^1) = 0$. On an affine line a point can be swept away to nothing, whereas on the complete line it cannot, and the surviving invariant of a class is its degree.

The contrast in example 10.1.5 is why completeness recurs throughout the theory: the degree of a zero-cycle is an invariant of its rational equivalence class only on a complete scheme, a point taken

up in section 10.2. The remaining first properties of Chow groups are collected next; each is either immediate or follows from the localization sequence established later in the chapter.

Example 10.1.6: First Properties of Chow Groups
Let X be an algebraic scheme.

1. *Reduction.* Since cycles see only subvarieties, $A_k(X) = A_k(X_{\mathrm{red}})$ for every k.
2. *Disjoint unions.* If $X = X' \sqcup X''$ is a disjoint union of open-and-closed subschemes, then $A_k(X) = A_k(X') \oplus A_k(X'')$, as every subvariety lies in one piece.
3. *Top-dimensional cycles.* If $\dim X = n$, there is no subvariety of dimension $n+1$, so $\mathrm{Rat}_n(X) = 0$ and $A_n(X) = Z_n(X)$ is free on the n-dimensional components of X. In particular the coefficient of such a component in a class $\alpha \in A_n(X)$ is well defined.
4. *Right-exactness.* For closed subschemes $X_1, X_2 \subseteq X$ there is an exact sequence
$$A_k(X_1 \cap X_2) \to A_k(X_1) \oplus A_k(X_2) \to A_k(X_1 \cup X_2) \to 0$$
with no left-exactness in general. This is a consequence of the localization sequence developed later in the chapter.

Exercise 10.1.1

1. Let X be the reduced scheme consisting of two distinct points. Compute $Z_k(X)$ and $A_k(X)$ for all k.
2. Show that $A_0(\mathbb{A}^n) = 0$ for every $n \geq 1$.
3. Prove from the definitions that $Z_k(X) = Z_k(X_{\mathrm{red}})$ and $\mathrm{Rat}_k(X) = \mathrm{Rat}_k(X_{\mathrm{red}})$, and deduce $A_k(X) = A_k(X_{\mathrm{red}})$.
4. Let X have dimension n with n-dimensional irreducible components $X_1, \dots, X_r$. Show that $A_n(X) = \bigoplus_{i=1}^{r} \mathbb{Z}\,[X_i]$.
5. Let C be a smooth projective curve over $\overline{k}$. Show that $A_0(C) \cong \mathrm{Cl}\, C = \mathrm{Pic}\, C$, and that the degree gives a short exact sequence $0 \to \mathrm{Pic}^{\,0} C \to A_0(C) \xrightarrow{\deg} \mathbb{Z} \to 0$.

10.2 Proper Pushforward and the Degree

Cycles and their classes change under morphisms, and the first of these functorialities is covariant: a proper morphism pushes cycles forward, respects rational equivalence, and on a complete scheme produces the degree of a zero-cycle.

A proper morphism $f\colon X \to Y$ carries closed sets to closed sets, so the image of a subvariety $V \subseteq X$ is again a subvariety $W = f(V) \subseteq Y$: the image of an irreducible set is irreducible, and properness (universal closedness) makes it closed. Without properness the image can fail to be closed, as for the projection of example 3.5.26, and pushforward is not defined. The inclusion of function fields $k(W) \hookrightarrow k(V)$ is a finite extension exactly when $\dim V = \dim W$, and its degree counts the points of

V over a general point of W.

Definition 10.2.1: Proper Pushforward

Let $f\colon X \to Y$ be a proper morphism and $V \subseteq X$ a subvariety with image $W = f(V)$. Set

$$\deg(V/W) = \begin{cases} [k(V) : k(W)] & \dim V = \dim W \\ 0 & \dim V > \dim W \end{cases}$$

(the extension $k(W) \hookrightarrow k(V)$ is finite in the first case), and put $f_*[V] = \deg(V/W)\,[W]$. Extending $\mathbb{Z}$-linearly gives the *pushforward* $f_*\colon Z_k(X) \to Z_k(Y)$.

Pushforward is covariant: for composable proper morphisms $(g \circ f)_* = g_* \circ f_*$, since degrees of function-field extensions multiply in towers. When $\dim V = \dim W$ the number $\deg(V/W)$ counts the sheets of the generically finite cover $V \to W$, matching the topological degree over $\mathbb{C}$. That f_* descends to Chow groups is the content of this section, and rests on how it acts on the divisor of a rational function.

Proposition 10.2.2: Pushforward of Divisor

Let $f : X \to Y$ be a proper surjective morphisms between varieties, and let $r \in k(X)^*$. Then:

1. if $\dim(Y) < \dim(X)$, then
$$f_*[\mathrm{div}(r)] = 0$$
2. if $\dim(Y) = \dim(X)$, then
$$f_*[\mathrm{div}(r)] = [\mathrm{div}(N(r))]$$
where $N(r)$ is the *norm* of r (computed as the determinant of the $k(Y)$-linear endomorphism of $k(X)$ given by multiplying by r).

***Proof*:**
The order function and the norm are multiplicative, so both sides of each identity are homomorphisms in r. Both parts reduce to two model computations; write $n = \dim X$.

Step 1: the line over a point. Let $Y = \operatorname{Spec} k$ and $X = \mathbb{P}^1$, with f the structure map. Every closed point of $\mathbb{P}^1$ has residue field $k = \overline{k}$, so $f_*[p] = [Y]$ for each p and $f_*[\mathrm{div}(r)] = \big(\sum_V \operatorname{ord}_V(r)\big)[Y]$. Writing $r = c\prod_j (t - a_j)^{m_j}$ in the affine coordinate t, the order of r at a_j is m_j and its order at ∞ is $-\sum_j m_j$ (in $s = 1/t$ one has $r = s^{-\sum_j m_j} u$ with u a unit at $s = 0$), so $\sum_V \operatorname{ord}_V(r) = 0$ and $f_*[\mathrm{div}(r)] = 0$.

Step 1′: a proper curve over an arbitrary field. The same count, run over irreducible factors rather than linear ones, gives the statement this chapter needs later: on any proper curve C over a field K, a principal divisor has degree zero. For $\mathbb{P}^1_K \to \operatorname{Spec} K$, write $r = c\prod_j p_j^{m_j}$ with the $p_j \in K[t]$ monic irreducible. The closed point V_j cut out by p_j has residue field $K[t]/(p_j)$, so it contributes $m_j[K[t]/(p_j) : K] = m_j \deg p_j$ to $\deg_K \mathrm{div}(r)$, while the order of r at ∞ is $-\sum_j m_j \deg p_j$; the two cancel. For general C, normalize and choose a finite map $\widetilde{C} \to \mathbb{P}^1_K$, then apply Step 2 to that map and the computation just made to $\mathbb{P}^1_K \to \operatorname{Spec} K$.

Step 2: finite morphisms of equal dimension. Suppose f is finite with $\dim Y = \dim X$, so that $K = k(Y) \subseteq L = k(X)$ is a finite extension. Fix a codimension-one subvariety $W \subseteq Y$ and let $A = \mathcal{O}_{Y,W}$, a one-dimensional local domain with fraction field K. Let B be the semilocal ring of X along the codimension-one subvarieties lying over W, that is the localization $(f_*\mathcal{O}_X)_W$. Since f is finite, $f_*\mathcal{O}_X$ is coherent and B is a finite A-module, with $B \otimes_A K = L$; its maximal ideals $\mathfrak{m}_1, \dots, \mathfrak{m}_s$ are exactly the codimension-one subvarieties $V_i \subseteq X$ over W, with $B_{\mathfrak{m}_i} = \mathcal{O}_{X,V_i}$ by construction and residue degree $[k(V_i) : k(W)] = [B/\mathfrak{m}_i : A/\mathfrak{m}]$. Only these V_i contribute to the coefficient of $[W]$ in $f_*[\operatorname{div}(r)]$, which is therefore $\sum_i [k(V_i) : k(W)] \operatorname{ord}_{V_i}(r)$, while the coefficient of $[W]$ in $[\operatorname{div}(N(r))]$ is $\operatorname{ord}_W(N(r))$. For $r \in B$ a nonzerodivisor these agree:

$$\operatorname{ord}_W(N(r)) = \operatorname{length}_A\big(A/N(r)A\big) = \operatorname{length}_A\big(B/rB\big) = \sum_i [k(V_i) : k(W)] \operatorname{ord}_{V_i}(r)$$

the middle equality is the determinant-length formula, since $N(r)$ is the determinant of multiplication by r on $B \otimes_A K = L$, computed through the finite A-module B, which need not be free over the one-dimensional local domain A, and the last is additivity of length across the semilocal decomposition of B, weighted by residue degrees (see [38, Appendix A] for this length bookkeeping). As $L = \operatorname{Frac}(B)$ and both sides are homomorphisms, the identity holds for all $r \in L^*$, which is part (2) for finite f.

Step 3: the general case. A proper surjective f with $\dim Y = \dim X$ is generically finite, and the coefficient of a codimension-one $W \subseteq Y$ in $f_*[\operatorname{div}(r)]$ is computed over the generic point of W, where f becomes finite; Step 2 gives (2). For (1), let $\dim Y < n$. Since $f_*[\operatorname{div}(r)] \in Z_{n-1}(Y)$ vanishes when $\dim Y < n-1$, only $\dim Y = n-1$ remains, and there $f_*[\operatorname{div}(r)] = c\,[Y]$ with c its coefficient over the generic point of Y. Base-changing to $K = k(Y)$ replaces f by a proper curve $C = X_K$ over the field K and r by a function in $k(C)^*$, and $c = \sum_{P \in C} \operatorname{ord}_P(r)\,[k(P) : K]$ is the degree of its principal divisor, which vanishes by Step $1'$. Hence $f_*[\operatorname{div}(r)] = 0$, completing the proof.

Theorem 10.2.3: Pushforward Preserves Rational Equivalence

Let $f\colon X \to Y$ be proper. If $\alpha \in Z_k(X)$ is rationally equivalent to zero, then so is $f_*\alpha$. Consequently f_* descends to a homomorphism

$$f_*\colon A_k(X) \to A_k(Y)$$

and $A_*(-)$ equipped with proper pushforward is a covariant functor.

***Proof*:**
It suffices to push forward a generator $\alpha = [\operatorname{div}(r)]$, where $r \in k(W)^*$ for some $(k+1)$-dimensional subvariety $W \subseteq X$. Replacing X by W and Y by $f(W)$ makes f proper and surjective, and proposition 10.2.2 identifies $f_*[\operatorname{div}(r)]$ with 0 (when $\dim f(W) < \dim W$) or with $[\operatorname{div}(N(r))]$ (when $\dim f(W) = \dim W$). Either value is a principal divisor, hence rationally equivalent to zero, so $f_*\alpha \sim 0$. Functoriality on classes then follows from $(g \circ f)_* = g_* \circ f_*$ on cycles, as we sought to show.

Definition 10.2.4: Degree of a Zero-Cycle

Let X be complete (proper over $\operatorname{Spec} k$), with structure morphism $\pi\colon X \to \operatorname{Spec} k$, and let $\alpha = \sum_P n_P[P]$ be a zero-cycle on X. The *degree* of α is

$$\deg(\alpha) = \int_X \alpha = \sum_P n_P \,[k(P) : k]$$

Since $\operatorname{Spec} k$ is a single point with no lower-dimensional subvarieties, $A_0(\operatorname{Spec} k) = Z_0(\operatorname{Spec} k) = \mathbb{Z}\,[\operatorname{Spec} k] \cong \mathbb{Z}$, and under this identification $\deg(\alpha) = \pi_*\alpha$. When the scheme is clear one writes $\int \alpha$ for $\int_X \alpha$.

By theorem 10.2.3 rationally equivalent zero-cycles have the same degree, so $\deg\colon A_0(X) \to \mathbb{Z}$ is well defined on a complete scheme. Extending by $\int_X \alpha = 0$ for $\alpha \in A_k(X)$ with $k > 0$ and using $\pi_X = \pi_Y \circ f$, any morphism $f\colon X \to Y$ of complete schemes satisfies

$$\int_X \alpha = \int_Y f_*\alpha$$

for every $\alpha \in A_*(X)$, a special case of the functoriality of pushforward.

10.2.5 Assuming Pushforward with subschemes Let $Y_1, \dots, Y_r$ be closed subschemes of a scheme X. Let Y be a closed subscheme of X which contains all the Y_i. Given $\alpha_i \in A_*Y_i$, $i = 1, \dots, r$, and $\beta \in A_*Y$, the notation "$\beta = \sum_{i=1}^r \alpha_i$ in A_*Y" stands in for the precise equation $\beta = \sum_{i=1}^r \varphi_{i*}(\alpha_i)$ where φ_i is the inclusion of Y_i in Y.

Example 10.2.6: Degrees, Bézout, and the Role of Properness

1. *Bézout's theorem.* Two curves $C, D \subseteq \mathbb{P}^2$ of degrees c, d with no common component meet in a zero-cycle $C \cdot D$ of degree cd. Pushing forward to a point, $\int_{\mathbb{P}^2}[C \cdot D] = cd$: the classical intersection number from the chapter opening is the degree of a zero-cycle, and its independence of the choice of C and D in their linear systems is rational equivalence together with theorem 10.2.3.

2. *Properness is necessary.* For the non-proper projection of example 3.5.26 the image of a subvariety can fail to be closed, so f_* is not even defined; and on $\mathbb{A}^1$ every point is rationally equivalent to zero (example 10.1.5), so no degree survives. The degree is an invariant of a rational equivalence class only on a complete scheme.

3. *A finite cover of curves.* A finite morphism $\varphi\colon C \to C'$ of smooth projective curves satisfies $\varphi_*[P] = [k(P) : k(\varphi(P))]\,[\varphi(P)]$. For a point $Q \in C'$ away from the branch locus, $\varphi^{-1}(Q)$ consists of $\deg\varphi = [k(C) : k(C')]$ reduced points, so $\varphi_*\big[\varphi^{-1}(Q)\big] = (\deg\varphi)\,[Q]$; since $\deg(\varphi_*\alpha) = \deg(\alpha)$ on the complete curves, the sheet count is exactly the degree recorded by φ.

Exercise 10.2.1

1. For the finite morphism $\varphi\colon \mathbb{P}^1 \to \mathbb{P}^1$, $[x_0 : x_1] \mapsto [x_0^2 : x_1^2]$ (in characteristic $\neq 2$), compute $\varphi_*[p]$ for a closed point p and $\varphi_*[\varphi^{-1}(q)]$ for a closed point q. Verify that $\deg(\varphi_*\alpha) = \deg(\alpha)$ for every zero-cycle α, and explain where the degree $\deg\varphi = 2$ appears.
2. Let $\alpha = \sum_i n_i[P_i]$ be a zero-cycle on $\mathbb{P}^n$ over $\overline{k}$. Compute $\deg(\alpha)$ and prove it is invariant under rational equivalence.
3. Deduce from proposition 10.2.2 that a nonzero rational function on a smooth projective curve C has principal divisor of degree zero, and show by example that this fails on $\mathbb{A}^1$.
4. For the structure map $\pi\colon \mathbb{P}^1 \to \operatorname{Spec}\overline{k}$ and a rational function $r \in k(\mathbb{P}^1)^*$, verify $\int_{\mathbb{P}^1}[\operatorname{div}(r)] = \int_{\operatorname{Spec}\overline{k}}\pi_*[\operatorname{div}(r)]$, and say which hypothesis of definition 10.2.4 would fail were $\mathbb{P}^1$ replaced by $\mathbb{A}^1$.

10.3 Flat Pullback

Proper pushforward of section 10.2 is covariant: it moves cycles along a morphism in the direction of the arrow, lowering nothing and raising nothing in dimension. The second functoriality of the Chow group runs the other way. A morphism $f\colon X \to Y$ pulls a subvariety $V \subseteq Y$ back to its preimage $f^{-1}(V) \subseteq X$, and one would like to read that preimage as a cycle on X. For an arbitrary f this fails: the preimage can jump in dimension from fiber to fiber, can acquire embedded components, and carries no canonical multiplicities. The hypothesis that repairs every one of these defects at once is flatness. A flat morphism of relative dimension n has equidimensional fibers, so the preimage of a k-dimensional subvariety is pure of dimension $k+n$, and the scheme-theoretic preimage gives the multiplicities with which its components must be counted. The resulting map $f^*\colon Z_k(Y) \to Z_{k+n}(X)$ raises dimension by n, is contravariant, and descends to Chow groups.

This section constructs f^*, records its three structural properties (it is a graded homomorphism, it composes contravariantly, and it commutes with proper pushforward across a fiber square), and proves that it respects rational equivalence. The two guiding examples are the ones every later computation rests on: restriction to an open subscheme, and the projection $X \times \mathbb{A}^n \to X$ of a trivial affine bundle.

Recall that a morphism $f\colon X \to Y$ of algebraic schemes is flat if each local ring $\mathcal{O}_{X,x}$ is flat over $\mathcal{O}_{Y,f(x)}$. Flatness is the algebraic incarnation of the geometric require that the fibers of f vary without collapsing or jumping, and its precise dimensional consequence is what makes pullback of cycles possible.

Definition 10.3.1: Flat Morphism of Relative Dimension n

A morphism $f\colon X \to Y$ of algebraic schemes is *flat of relative dimension n* if f is flat and, for every subvariety $W \subseteq Y$ and every irreducible component Z of $f^{-1}(W)$,

$$\dim Z = \dim W + n$$

Equivalently, f is flat and every nonempty fiber of f has pure dimension n.

The equivalence stated in the definition is the mechanism the whole construction turns on, so it is worth isolating. Flatness forces the fiber dimension to be locally constant, and it forces the preimage of a subvariety to inherit that constant as an additive shift; neither holds without it.

Proposition 10.3.2: Flat Preimages Are Equidimensional

Let $f\colon X \to Y$ be a flat morphism of algebraic schemes with Y a variety, and suppose every nonempty fiber of f has pure dimension n. Then for every subvariety $W \subseteq Y$ each irreducible component of $f^{-1}(W)$ has dimension $\dim W + n$. In particular $f^{-1}(W)$ is either empty or pure of dimension $\dim W + n$.

***Proof*:**

Write $g\colon f^{-1}(W) \to W$ for the restriction of f; it is the base change of f along the closed immersion $W \hookrightarrow Y$, hence flat, and its fibers are fibers of f, so each nonempty fiber of g has pure dimension n. Thus it suffices to prove the statement for $W = Y$: that a flat morphism $g\colon X' \to W$ onto a variety W, with all nonempty fibers of pure dimension n, has $\dim Z = \dim W + n$ for every irreducible component Z of X'.

Let $Z \subseteq X'$ be an irreducible component, with generic point η. Flatness satisfies going-down (the going-down property of flat homomorphisms, [68, §5, Thm. 4]), so the minimal prime η of X' contracts to the minimal prime of W; that is, $g(\eta)$ is the generic point of W, and g restricts to a dominant morphism $g\big|_Z\colon Z \to W$ of varieties. Both are integral of finite type over $\overline{k}$, so their dimensions are transcendence degrees of function fields, and the dimension of a fiber of a dominant morphism of varieties can be read at a closed point.

The fiber-dimension theorem for the dominant morphism $g\big|_Z\colon Z \to W$ of varieties ([50, Exercise II.3.22]) provides a dense open $U \subseteq Z$ such that for every closed point $z \in U$, the fiber $(g\big|_Z)^{-1}(g(z))$ has dimension exactly $\dim Z - \dim W$ at z. The complement in Z of the other irreducible components of X' is also a dense open, so their intersection is nonempty and contains a closed point z; write $w = g(z) \in W$. Since z lies off the other components, X' coincides with Z near z, so the fiber $X'_w = g^{-1}(w)$ coincides with $(g\big|_Z)^{-1}(w)$ near z, and its dimension at z is $\dim Z - \dim W$. By hypothesis X'_w is nonempty of pure dimension n, so this local fiber dimension equals n. Therefore

$$n = \dim Z - \dim W$$

hence $\dim Z = \dim W + n$, as we sought to show.

The proposition is the geometric justification behind the definition of flat pullback. If $V \subseteq Y$ is a k-dimensional subvariety and f is flat of relative dimension n, then $f^{-1}(V)$ is a closed subscheme of X, pure of dimension $k + n$, and one takes its associated cycle, weighting each component by the length that measures the multiplicity with which the scheme carries it. This is exactly the fundamental cycle of definition 10.1.2 applied to the scheme-theoretic preimage.

Definition 10.3.3: Flat Pullback

Let $f\colon X \to Y$ be a flat morphism of relative dimension n and $V \subseteq Y$ a k-dimensional subvariety. The scheme-theoretic preimage $f^{-1}(V) = X \times_Y V$ is a closed subscheme of X, pure of dimension $k+n$, with irreducible components $Z_1, \dots, Z_r$. The *flat pullback* of $[V]$ is the $(k+n)$-cycle

$$f^*[V] = \left[f^{-1}(V)\right] = \sum_{i=1}^{r} \operatorname{length}_{\mathcal{O}_{f^{-1}(V),Z_i}}\left(\mathcal{O}_{f^{-1}(V),Z_i}\right)[Z_i]$$

the length being taken in the local ring of the preimage scheme at the generic point of Z_i. Extending $\mathbb{Z}$-linearly gives the flat pullback

$$f^*\colon Z_k(Y) \to Z_{k+n}(X)$$

The multiplicities are the point of the construction. The preimage as a topological set records only the components Z_i; the scheme structure records how many times f "covers" each one, and it is these lengths that make f^* compatible with divisors and hence with rational equivalence. When f is an open immersion the preimage is reduced and every length is 1, so $f^*[V] = [V \cap X]$; this is the source of the restriction map computed in the next example. The relative dimension n is the amount by which f^* raises the dimension of a cycle, so f^* is graded of degree $+n$.

Example 10.3.4: Open Restriction and the Projection $X \times \mathbb{A}^n \to X$

Two flat morphisms recur throughout the theory, and their pullbacks can be read off the definition.

1. *Open immersion.* Let $j\colon U \hookrightarrow Y$ be the inclusion of an open subscheme. Such j is flat of relative dimension 0: it is a localization at the level of local rings, and its fibers are single reduced points (over $u \in U$) or empty (over $y \notin U$). For a k-dimensional subvariety $V \subseteq Y$ the preimage $j^{-1}(V) = V \cap U$ is the open subscheme of V, which is reduced. If $V \cap U \neq \emptyset$ it is a k-dimensional subvariety of U and $j^*[V] = [V \cap U]$; if $V \subseteq Y \setminus U$ the preimage is empty and $j^*[V] = 0$. Thus flat pullback along an open immersion is the *restriction of cycles* $Z_k(Y) \to Z_k(U)$ that forgets the part of a cycle supported off U, the map at the heart of the localization sequence of section 10.4.

2. *Trivial affine bundle.* Let $p\colon X \times \mathbb{A}^n \to X$ be the projection. It is flat, being a base change of the flat morphism $\mathbb{A}^n_{\overline{k}} \to \operatorname{Spec}\overline{k}$ along $X \to \operatorname{Spec}\overline{k}$, and every fiber is a copy of $\mathbb{A}^n$, pure of dimension n; so p is flat of relative dimension n. For a k-dimensional subvariety $V \subseteq X$ the preimage is $V \times \mathbb{A}^n$, which is integral of dimension $k+n$, so

   $$p^*[V] = [V \times \mathbb{A}^n]$$

   the cylinder over V. No multiplicity appears because $V \times \mathbb{A}^n$ is a variety. This is the computation that will make p^* an isomorphism on Chow groups (theorem 10.4.6).

Both examples exhibit the pattern the general theory generalizes: pullback restricts a cycle to an open part in the first case and thickens it uniformly along the fiber in the second. The structural properties below show that these behaviors are functorial.

The first property collects the ways in which f^* is well behaved as a map of cycle groups. It is a

graded homomorphism raising dimension by the relative dimension, and it composes contravariantly, so that a tower of flat morphisms pulls back through the composite exactly as one expects.

Proposition 10.3.5: Basic Properties of Flat Pullback

Let $f\colon X \to Y$ be flat of relative dimension n.

1. *Homomorphism.* $f^*\colon Z_k(Y) \to Z_{k+n}(X)$ is a homomorphism of abelian groups for each k, and assembles to a graded homomorphism $f^*\colon Z_*(Y) \to Z_*(X)$ of degree n.
2. *Fundamental cycle.* $f^*[Y] = [X]$ for any algebraic scheme Y: flat pullback of the fundamental cycle of the base is the fundamental cycle of the total space.
3. *Composition.* If $g\colon Y \to Y'$ is flat of relative dimension m, then $g \circ f$ is flat of relative dimension $m+n$ and
$$(g \circ f)^* = f^* \circ g^*$$
as maps $Z_k(Y') \to Z_{k+m+n}(X)$.
4. *Identity.* $(\mathrm{id}_X)^* = \mathrm{id}$ on $Z_*(X)$.

***Proof*:**

1. *Homomorphism.* By construction f^* is defined on generators $[V]$ and extended $\mathbb{Z}$-linearly, so it is a homomorphism $Z_k(Y) \to Z_{k+n}(X)$ by fiat; proposition 10.3.2 is what guarantees the target group is $Z_{k+n}(X)$, since $f^{-1}(V)$ is pure of dimension $k+n$. Summing over k gives a degree-n graded homomorphism.
2. *Fundamental cycle.* Write $[Y] = \sum_i m_i[Y_i]$ over the irreducible components of Y, with $m_i = \mathrm{length}_{\mathcal{O}_{Y,Y_i}}(\mathcal{O}_{Y,Y_i})$. If Y is a variety this is the single generator $[Y]$ with multiplicity 1, and $f^{-1}(Y) = X$ gives $f^*[Y] = [X]$ at once.

   In general, $f^*[Y] = \sum_i m_i[f^{-1}(Y_i)]$ by definition of flat pullback, and since $Y = \bigcup_i Y_i$ we have $X = \bigcup_i f^{-1}(Y_i)$. The two sides are cycles, so it is enough to compare the coefficient of each subvariety of X, and the work is in matching up which subvarieties occur. Flatness enters through going-down: $\mathcal{O}_{Y,f(\eta)} \to \mathcal{O}_{X,\eta}$ is a flat local homomorphism for every $\eta \in X$, so every generization of $f(\eta)$ in Y lifts to a generization of η in X.

   Every component of X dominates a component of Y. Let X_j be a component of X, with generic point η_j, and put $y = f(\eta_j)$. A generization of y lifts to a generization of η_j; but η_j is a generic point of X, so its only generization in X is itself, and therefore y has no proper generization in Y. So y is the generic point of some component Y_i, and X_j is a component of $f^{-1}(Y_i)$. That i is unique: for $i' \neq i$ the generic point of Y_i does not lie in $Y_{i'}$, so $\eta_j \notin f^{-1}(Y_{i'})$ and only the i-th term of $\sum_i m_i[f^{-1}(Y_i)]$ contributes to the coefficient of $[X_j]$.

   Conversely, every component of every $f^{-1}(Y_i)$ is a component of X. Let W be one, with generic point η_W. Going-down applied at η_W lifts the generic point of Y_i to a generization of η_W inside $f^{-1}(Y_i)$, and η_W is maximal there, so W dominates Y_i, that is $f(\eta_W)$ is the generic point of Y_i. If W were not a component of X it would lie in some component $X_{j'}$, whose generic point generizes η_W and therefore maps to a generization of the generic point of Y_i; the latter being a generic point of Y, that forces $X_{j'}$ to dominate Y_i as well,

so $\dim X_{j'} = \dim Y_i + n = \dim W$ by proposition 10.3.2, and $W = X_{j'}$. A component Y_i with $f^{-1}(Y_i) = \emptyset$ contributes to neither side.

Multiplicities. It remains to see that the multiplicity of X_j in $[X]$ equals m_i times its multiplicity in $[f^{-1}(Y_i)]$. This is a length computation: $\mathcal{O}_{Y,Y_i} \to \mathcal{O}_{X,X_j}$ is a flat local homomorphism of Noetherian local rings, and [15, Length Along a Flat Local Homomorphism] gives $\operatorname{length}(\mathcal{O}_{X,X_j}) = \operatorname{length}(\mathcal{O}_{Y,Y_i}) \cdot \operatorname{length}\left(\mathcal{O}_{X,X_j}/\mathfrak{m}_{Y_i}\mathcal{O}_{X,X_j}\right)$. Because Y_i is a subvariety and so reduced, $\mathcal{O}_{Y,Y_i}/\mathfrak{m}_{Y_i}$ is the function field of Y_i, whence $\mathcal{O}_{X,X_j}/\mathfrak{m}_{Y_i}\mathcal{O}_{X,X_j}$ is the local ring of $f^{-1}(Y_i)$ at X_j and the second factor is exactly the multiplicity of X_j in $[f^{-1}(Y_i)]$. Summing over i and j gives $f^*[Y] = [X]$, as we sought to show.

3. *Composition.* Composites of flat morphisms are flat, and relative dimensions add because fiber dimensions add along the tower: a fiber of $g \circ f$ over $y' \in Y'$ maps to the fiber $g^{-1}(y')$ of pure dimension m, with fibers of f of pure dimension n, so it has pure dimension $m+n$. Hence $g \circ f$ is flat of relative dimension $m+n$. For the cycle identity it suffices to check on a generator $[V]$ with $V \subseteq Y'$ a k-dimensional subvariety. Both sides are cycles supported on $(g \circ f)^{-1}(V) = f^{-1}(g^{-1}(V))$, so the claim is that the multiplicities match component by component. The scheme-theoretic preimage is computed by iterated fiber product,

$$(g \circ f)^{-1}(V) = X \times_{Y'} V = X \times_Y (Y \times_{Y'} V) = f^{-1}\big(g^{-1}(V)\big)$$

so the underlying scheme of $(g \circ f)^{-1}(V)$ equals the underlying scheme of $f^{-1}(g^{-1}(V))$. It remains to see that the length multiplicities agree, that is, that applying f^* to the cycle $g^*[V] = \sum_i \ell_i [W_i]$ (where W_i are the components of $g^{-1}(V)$ with lengths ℓ_i) reproduces the multiplicities of $(g \circ f)^{-1}(V)$. Fix a component Z of the common preimage, with generic point z lying over the generic point w of some W_i. Flatness of f makes $\mathcal{O}_{X,z}$ flat over $\mathcal{O}_{Y,w}$, and length is additive and multiplies through a flat local homomorphism along the fiber: the length of $\mathcal{O}_{(g\circ f)^{-1}(V),z}$ equals ℓ_i times the length of $\mathcal{O}_{f^{-1}(W_i),z}$. Summing z over the components of $f^{-1}(W_i)$ and i over the components of $g^{-1}(V)$ gives $(g \circ f)^*[V] = f^*(g^*[V])$, as required.

4. *Identity.* The identity map is flat of relative dimension 0 with $(\mathrm{id})^{-1}(V) = V$ reduced, so $(\mathrm{id}_X)^*[V] = [V]$ on generators, completing the proof.

Contravariant functoriality (part 3) is what will let a Chow-group computation be assembled from simpler flat maps, exactly as covariant functoriality of pushforward let degrees be computed in towers. The fundamental-cycle identity (part 2) is the seed of every computation in section 10.5: it identifies the generator of the top Chow group of the total space of a flat family in terms of the base.

The remaining two properties are the interaction of flat pullback with the machinery already built. The first is its compatibility with proper pushforward. Pullback and pushforward move cycles in opposite directions, and they do not commute for a single morphism; but across a fiber square, where one has a flat map and a proper map meeting at right angles, the two operations do commute. This is the cycle-level form of the projection formula, and it is the technical engine behind essentially every later compatibility.

Proposition 10.3.6: Compatibility of Flat Pullback and Proper Pushforward

Consider a fiber square of algebraic schemes

$$\begin{array}{ccc} X' & \xrightarrow{g'} & X \\ \downarrow f' & & \downarrow f \\ Y' & \xrightarrow{g} & Y \end{array}$$

that is Cartesian, $X' = X \times_Y Y'$, with f proper and g flat of relative dimension n. Then f' is proper, g' is flat of relative dimension n, and

$$g^* \circ f_* = f'_* \circ g'^* \colon Z_k(X) \to Z_{k+n}(Y')$$

Consequently the identity holds on Chow groups.

***Proof*:**

Step 1: the maps in the base-changed square. Properness and flatness are stable under base change, so f' is proper and g' is flat; the fibers of g' over a point of X are fibers of g over its image in Y, so g' has the same pure relative dimension n as g. Both composites $g^* \circ f_*$ and $f'_* \circ g'^*$ therefore land in $Z_{k+n}(Y')$, and both are homomorphisms, so it suffices to check the identity on a generator $[V]$ with $V \subseteq X$ a k-dimensional subvariety.

Step 2: reduction to $X = V$. Replacing X by V, Y by $W = f(V)$, and forming the induced fiber squares, the four schemes become V, W, $V' = V \times_W W'$, $W' = W \times_Y Y'$, with $f \colon V \to W$ proper surjective and $g \colon W' \to W$ flat of relative dimension n. It suffices to prove

$$g^*(f_*[V]) = f'_*\big(g'^*[V]\big)$$

where now $f_*[V] = \deg(V/W)[W]$ by definition 10.2.1 and $g'^*[V] = [g'^{-1}(V)] = [V']$ (with its multiplicities).

Step 3: the two dimension regimes. There are two cases according to whether f drops dimension.

If $\dim V > \dim W$, then $\deg(V/W) = 0$, so the left side is $g^*(0) = 0$. On the right, $V' = V \times_W W'$ maps to W' under f' with fibers the fibers of $V \to W$, which are positive dimensional over the generic point; hence $\dim V' > \dim W'$ and every component of V' has image of strictly smaller dimension in W', so $f'_*[V'] = 0$ by the dimension clause of definition 10.2.1. Both sides vanish.

If $\dim V = \dim W$, write $d = \deg(V/W) = [k(V) : k(W)]$. The left side is $g^*(d\,[W]) = d\,[W']$, using $g^*[W] = [W'] = [g^{-1}(W)]$ (the base W is a variety and g is flat, so g^* of its fundamental cycle is the fundamental cycle of W' by proposition 10.3.5(2), which here is the total space $W' = g^{-1}(W)$). For the right side, $[V'] = g'^*[V]$ carries the pullback multiplicities flagged above, and $f'_*[V']$ must account for both those multiplicities and the residue-field degrees; flatness is what makes only the field degree survive. Fix a component W'_j of W', with generic point η_j. Localizing at η_j, the fiber of $f' \colon V' \to W'$ over η_j is Spec of $k(V) \otimes_{k(W)} k(W'_j)$: the generic fiber of $f \colon V \to W$ is $\operatorname{Spec} k(V)$, a $k(W)$-algebra of dimension d since V, W are varieties, and flat base change along $k(W) \hookrightarrow k(W'_j)$ preserves that dimension, so $\dim_{k(W'_j)}\big(k(V) \otimes_{k(W)} k(W'_j)\big) = d$. This dimension is exactly the total multiplicity that $f'_*[V']$ records over W'_j: summing the pullback multiplicity of each component of V' dominating W'_j against its residue degree over $k(W'_j)$ recovers the length d of the fiber algebra, because flatness of g (hence of g') forbids any

length being created or lost in the base change. Thus $f'_*[V'] = \sum_j d\,[W'_j] = d\,[W']$, matching the left side. The two sides agree in both regimes, which establishes $g^* f_* = f'_* g'^*$ on cycles. Since each of g^*, f_*, f'_*, g'^* descends to Chow groups by theorem 10.2.3 and proposition 10.3.7 below, the identity descends as well, completing the proof.

The compatibility should be read as the statement that pushing a cycle forward and then restricting to a flat base change gives the same class as first restricting and then pushing forward within the base change. In the special case where g is an open immersion, it says that pushforward commutes with restriction to an open set, which is the reason the localization sequence of the next section is a sequence of A_*-functorial maps. In the case where f is the projection to a point, it recovers the invariance of the degree of a zero-cycle under a flat base change of the ground scheme.

Everything so far concerns cycles. To obtain a map of Chow groups, flat pullback must carry Rat_k into Rat_{k+n}. The mechanism is that flat pullback commutes with taking the divisor of a rational function, up to the multiplicities that flatness controls, so a cycle that is a sum of divisors pulls back to a sum of divisors.

Proposition 10.3.7: Flat Pullback Preserves Rational Equivalence

Let $f\colon X \to Y$ be flat of relative dimension n. If $\alpha \in Z_k(Y)$ is rationally equivalent to zero, then $f^*\alpha \in Z_{k+n}(X)$ is rationally equivalent to zero. Consequently f^* descends to a homomorphism

$$f^*\colon A_k(Y) \to A_{k+n}(X)$$

and $A_*(-)$ equipped with flat pullback is a contravariant functor on flat morphisms of algebraic schemes, raising dimension by the relative dimension.

***Proof*:**
It suffices to treat a generator of $\mathrm{Rat}_k(Y)$, namely $\alpha = [\mathrm{div}(r)]$ for a $(k+1)$-dimensional subvariety $W \subseteq Y$ and a nonzero $r \in k(W)^*$. The claim is that $f^*[\mathrm{div}(r)]$ is a sum of divisors of rational functions on subvarieties of X.

Step 1: reduction to the total space over W. The cycle $[\mathrm{div}(r)]$ is supported on W, and $f^*[\mathrm{div}(r)]$ is supported on $f^{-1}(W)$. Let $W' = f^{-1}(W) = X \times_Y W$ with its scheme-theoretic (possibly non-reduced) structure, and let $f_W\colon W' \to W$ be the restriction of f, which is flat of relative dimension n by base change. Because the components of $f^{-1}(W)$ are the components of W' and the pullback multiplicities are computed inside W', it is enough to prove that $f_W^*[\mathrm{div}(r)] \sim 0$ in $Z_{k+n}(W')$; the class then remains rationally equivalent to zero in X under the proper (closed immersion) pushforward along $W' \hookrightarrow X$, which preserves rational equivalence by theorem 10.2.3. Thus one may assume $Y = W$ is a variety and $r \in k(Y)^*$.

Step 2: the key identity on components. With Y a variety and $r \in k(Y)^*$, the divisor $[\mathrm{div}(r)] = \sum_V \mathrm{ord}_V(r)[V]$ runs over the codimension-one subvarieties $V \subseteq Y$. The assertion to prove is the flat-pullback divisor formula

$$f^*[\mathrm{div}(r)] = \big[\mathrm{div}(f^{\#}r)\big] \quad \text{on each component of } X \tag{10.1}$$

interpreted componentwise as follows. Let $X_1, \dots, X_s$ be the irreducible components of X, each of dimension $n + \dim Y$ by proposition 10.3.2, with generic points dominating Y (flatness sends generic points to the generic point of the base). On each X_j the pullback $f^{\#}r$ of r is a nonzero

rational function, since $r \neq 0$ and X_j dominates Y. The claim is

$$f^*[\operatorname{div}(r)] = \sum_{j=1}^{s} m_j \, [\operatorname{div}(f^{\#} r\big|_{X_j})]$$

where $m_j = \operatorname{length}_{\mathcal{O}_{X,X_j}}(\mathcal{O}_{X,X_j})$ is the multiplicity of the component X_j in the fundamental cycle $[X]$. Each term on the right is a divisor of a rational function on the subvariety $(X_j)_{\mathrm{red}}$, hence rationally equivalent to zero, so (10.1) gives $f^*[\operatorname{div}(r)] \sim 0$.

Step 3: verifying the identity. Fix a codimension-one subvariety $D \subseteq X_j$, a $(k+n)$-dimensional subvariety of X, and let $V = \overline{f(D)} \subseteq Y$. Two cases arise by the relative-dimension count of proposition 10.3.2 applied to $f\big|_{X_j}$.

If $\dim V = \dim Y$, then $V = Y$ and D dominates Y; the coefficient of $[D]$ in $[\operatorname{div}(f^{\#} r)]$ is $\operatorname{ord}_D(f^{\#} r)$, computed in the discrete-valuation-style local ring $\mathcal{O}_{X_j,D}$, while D does not appear in $f^*[\operatorname{div}(r)]$ because $[\operatorname{div}(r)]$ has no component equal to Y. But $\operatorname{ord}_D(f^{\#} r) = 0$. The point is that D dominates Y: its generic point ξ maps to the generic point of Y, at which r is a nonzero rational function, that is, a unit of $k(Y)$. Since $f^{\#} r$ is the pullback of r along the local homomorphism $\mathcal{O}_{Y,Y} = k(Y) \to \mathcal{O}_{X_j,D}$ induced on stalks at ξ, the image $f^{\#} r$ is a unit of $\mathcal{O}_{X_j,D}$, so $\operatorname{ord}_D(f^{\#} r) = 0$ and no such D contributes to either side. (A nonzero rational function need not be a unit along a codimension-one subvariety in general; here it is one precisely because D dominates the base and so sees r only at the generic point of Y.)

If $\dim V = \dim Y - 1$, then V is one of the codimension-one subvarieties appearing in $[\operatorname{div}(r)]$, and D is a component of $f^{-1}(V)$, lying on one or more of the components X_j. Two kinds of local ring enter the count, and keeping them distinct is the crux. Write

$$A = \mathcal{O}_{Y,V}, \qquad \widetilde{B} = \mathcal{O}_{X,D}$$

Here A is a one-dimensional local domain and $\operatorname{ord}_V(r) = \operatorname{length}_A(A/rA)$; the ring $\widetilde{B}$ is the local ring of the whole (possibly nonreduced) scheme X at the generic point of D, and it is flat over A because f is flat. The minimal primes of the one-dimensional ring $\widetilde{B}$ correspond to the components X_j passing through D; for such a component the quotient $B_j = \widetilde{B}/\mathfrak{p}_j = \mathcal{O}_{X_j,D}$ is the discrete-valuation-style local ring of the reduced component X_j at D, in which $\operatorname{ord}_D(f^{\#} r\big|_{X_j}) = \operatorname{length}_{B_j}(B_j/(f^{\#} r)B_j)$ is computed. When X is irreducible along D there is a single such j, but in general several components may meet along D.
The coefficient of $[D]$ in $f^*[\operatorname{div}(r)]$ is $\operatorname{ord}_V(r) \cdot e_D$, where

$$e_D = \operatorname{length}_{\mathcal{O}_{f^{-1}(V),D}}\big(\mathcal{O}_{f^{-1}(V),D}\big) = \operatorname{length}_{\widetilde{B}}\big(\widetilde{B}/\mathfrak{m}_A\widetilde{B}\big)$$

is the multiplicity of D in the pullback cycle $f^*[V]$, the second equality holding because

$$\mathcal{O}_{f^{-1}(V),D} = \widetilde{B} \otimes_A A/\mathfrak{m}_A = \widetilde{B}/\mathfrak{m}_A\widetilde{B}$$

The coefficient of $[D]$ in $\sum_j m_j[\operatorname{div}(f^{\#} r\big|_{X_j})]$ is $\sum_{j\,:\,D\subseteq X_j} m_j \cdot \operatorname{ord}_D(f^{\#} r\big|_{X_j})$, the sum running over the components X_j that pass through D. That the two coefficients agree is two multiplicative facts chained together. First, flatness of $\widetilde{B}$ over A makes length multiply through the base change: filtering A/rA by its $\operatorname{ord}_V(r)$ composition factors $A/\mathfrak{m}_A$ and applying the exact functor $- \otimes_A \widetilde{B}$ gives

$$\operatorname{length}_{\widetilde{B}}\big(\widetilde{B}/r\widetilde{B}\big) = \operatorname{length}_A(A/rA) \cdot \operatorname{length}_{\widetilde{B}}\big(\widetilde{B}/\mathfrak{m}_A\widetilde{B}\big) = \operatorname{ord}_V(r) \cdot e_D$$

Second, order in the one-dimensional local ring $\widetilde{B}$ distributes over its minimal primes with the generic multiplicities as weights: each minimal prime $\mathfrak{p}_j$ has residue ring $B_j = \mathcal{O}_{X_j,D}$ and localization $\widetilde{B}_{\mathfrak{p}_j} = \mathcal{O}_{X,X_j}$ of length $m_j = \operatorname{length}_{\mathcal{O}_{X,X_j}}(\mathcal{O}_{X,X_j})$, so the additivity of order over the minimal primes of a one-dimensional local ring ([38, Appendix A]) gives, for the nonzerodivisor $f^{\#}r$,

$$\operatorname{length}_{\widetilde{B}}\big(\widetilde{B}/(f^{\#}r)\widetilde{B}\big) = \sum_{j\,:\,D\subseteq X_j} m_j \cdot \operatorname{length}_{B_j}\big(B_j/(f^{\#}r)B_j\big) = \sum_{j\,:\,D\subseteq X_j} m_j \cdot \operatorname{ord}_D\big(f^{\#}r\big|_{X_j}\big)$$

Since $f^{\#}r$ is the image of r in $\widetilde{B}$, the left sides of the two displays coincide, whence $\operatorname{ord}_V(r)\cdot e_D = \sum_{j\,:\,D\subseteq X_j} m_j \cdot \operatorname{ord}_D(f^{\#}r\big|_{X_j})$: the two coefficients of $[D]$ match. When X is irreducible along D the sum has a single term and reduces to $e_D = m_j \cdot e_{D/V}$, where $e_{D/V} = \operatorname{length}_{B_j}(B_j/\mathfrak{m}_A B_j)$ is the ramification-type multiplicity of D over V computed in the reduced component ring B_j; the pullback multiplicity e_D over the full preimage scheme then exceeds it by exactly the factor m_j. Summing over the divisors D and, on the right, over the components X_j reproduces both sides of (10.1) term by term. Hence $f^*[\operatorname{div}(r)] = \sum_j m_j[\operatorname{div}(f^{\#}r\big|_{X_j})]$ is a sum of divisors of rational functions, so $f^*[\operatorname{div}(r)] \sim 0$.

Descent to Chow groups follows: $f^*(\operatorname{Rat}_k(Y)) \subseteq \operatorname{Rat}_{k+n}(X)$, so f^* induces $A_k(Y) \to A_{k+n}(X)$. Functoriality on classes is inherited from proposition 10.3.5(3),(4) on cycles, giving a contravariant functor as claimed, completing the proof.

The proposition completes the package: flat pullback is a well-defined operation on Chow groups, contravariant and dimension-raising, dual to the covariant dimension-preserving pushforward of section 10.2. The pair (f_*, f^*) makes A_* into a functor covariant for proper maps and contravariant for flat maps, with the compatibility of proposition 10.3.6 tying the two together across fiber squares. This is the structure the localization sequence and homotopy invariance of section 10.4 exploit, and it is why the affine-bundle projection $p\colon X \times \mathbb{A}^n \to X$, whose pullback was computed in example 10.3.4, will turn out to induce an isomorphism on Chow groups.

Example 10.3.8: Pullback to a Product and to an Open Set

The two flat morphisms of example 10.3.4 descend to Chow groups explicitly.

1. *Cylinder map.* For $p\colon X \times \mathbb{A}^1 \to X$ the induced map $p^*\colon A_k(X) \to A_{k+1}(X \times \mathbb{A}^1)$ sends the class of a subvariety V to the class of the cylinder $V \times \mathbb{A}^1$. On $X = \operatorname{Spec}\overline{k}$ this reads $A_0(\operatorname{Spec}\overline{k}) = \mathbb{Z} \to A_1(\mathbb{A}^1)$, sending the class of the point to $[\mathbb{A}^1]$, the fundamental class of the affine line, consistent with $p^*[Y] = [X]$ from proposition 10.3.5(2).

2. *Restriction to an open set.* For an open immersion $j\colon U \hookrightarrow Y$ the map $j^*\colon A_k(Y) \to A_k(U)$ restricts a class to U, forgetting components supported on the complement $Y \setminus U$. On $Y = \mathbb{P}^1$ with $U = \mathbb{A}^1$ this is the surjection $A_0(\mathbb{P}^1) = \mathbb{Z} \twoheadrightarrow A_0(\mathbb{A}^1) = 0$ from example 10.1.5: the class of a point on $\mathbb{P}^1$ restricts to a point of $\mathbb{A}^1$, which is rationally trivial. The kernel is generated by the class of the point at infinity, the part of $\mathbb{P}^1$ removed. This surjectivity with the removed piece generating the kernel is the prototype of the localization sequence.

Exercise 10.3.1

1. Let $f\colon X \to Y$ be flat of relative dimension 0 (for instance a finite flat morphism, or an open

immersion). Show directly from definition 10.3.3 that f^* maps $Z_k(Y) \to Z_k(X)$ for every k, preserving dimension, and that $f^*[V] = \sum_i e_i[Z_i]$ where Z_i are the components of $f^{-1}(V)$ and e_i their multiplicities in the fiber over the generic point of V.

2. Let $\pi\colon \mathbb{A}^{n+1} \setminus \{0\} \to \mathbb{P}^n$ be the tautological $\mathbb{G}_m$-bundle. It is flat of relative dimension 1. Compute $\pi^*[\mathbb{P}^k]$ for a linear subspace $\mathbb{P}^k \subseteq \mathbb{P}^n$, identifying its class as a cycle on $\mathbb{A}^{n+1} \setminus \{0\}$.

3. Give an example of a flat morphism f for which $f^*\colon A_*(Y) \to A_*(X)$ is not injective, and one for which it is not surjective. (Hint: the projection $\mathbb{P}^1 \times \mathbb{A}^1 \to \mathbb{A}^1$ and the open immersion $\mathbb{A}^1 \hookrightarrow \mathbb{P}^1$.)

4. Let $q\colon X \times \mathbb{A}^m \times \mathbb{A}^n \to X \times \mathbb{A}^m$ and $p\colon X \times \mathbb{A}^m \to X$ be the projections. Verify the composition law proposition 10.3.5(3) for $p \circ (\mathrm{id} \times \text{-})$ directly on the class of a subvariety $V \subseteq X$, confirming both routes give $[V \times \mathbb{A}^m \times \mathbb{A}^n]$.

5. Let $f\colon X \to Y$ be proper and $j\colon U \hookrightarrow Y$ an open immersion, with fiber square $X_U = f^{-1}(U) \to X$ over j. Using proposition 10.3.6, prove that $(f\big|_{X_U})_*(\alpha\big|_{X_U}) = (f_*\alpha)\big|_U$ in $A_*(U)$ for every $\alpha \in A_*(X)$, that is, proper pushforward commutes with restriction to an open subset.

6. Let $E \to X$ be a vector bundle of rank r over a variety X of dimension d, with projection π flat of relative dimension r. Compute $\pi^*[X]$ and identify the top Chow group $A_{d+r}(E)$, first showing that E is irreducible.

10.4 The Fundamental Sequences

The two functorialities already in hand, proper pushforward (section 10.2) and flat pullback (section 10.3), combine into the two structural results that make Chow groups computable. The first is a long-exact-sequence surrogate: cutting a scheme into a closed piece and its open complement relates the three Chow groups by a right-exact sequence, the algebraic analogue of the excision property of a homology theory. The second is homotopy invariance in its algebraic form: an affine bundle over X, and in particular the trivial bundle $X \times \mathbb{A}^n$, has the same Chow groups as X, shifted in degree by the fibre dimension. Neither result computes a single Chow group in isolation, but together they reduce the computation of $A_*(X)$ for the spaces of the next section to bookkeeping: stratify X by locally closed pieces on which the answer is known, and assemble the pieces through the sequence.

Both proofs rest on a single principle. A cycle on X is a formal combination of subvarieties; a subvariety either meets the open set U or is contained in the closed complement Z, and rational equivalence is generated by divisors of rational functions, which live on subvarieties and so obey the same dichotomy. The localization sequence is the exact translation of this observation into a statement about the three groups, and affine-bundle invariance is its first substantial payoff, extracted by Noetherian induction.

Throughout, $Z \subseteq X$ is a closed subscheme with open complement $U = X \setminus Z$, and

$$i\colon Z \hookrightarrow X, \qquad j\colon U \hookrightarrow X$$

denote the inclusions. The closed immersion i is proper, so it pushes cycles forward by definition 10.2.1: a subvariety $V \subseteq Z$ is also a subvariety of X, and $i_*[V] = [V]$ since $\deg(V/V) = 1$. The open immersion j is flat of relative dimension 0, so it pulls cycles back by definition 10.3.3: for a subvariety

$V \subseteq X$ the restriction is $j^*[V] = [V \cap U]$ when V meets U and $j^*[V] = 0$ when $V \subseteq Z$. These two operations are what the sequence is built from.

Theorem 10.4.1: Localization Sequence

Let X be an algebraic scheme, $Z \subseteq X$ a closed subscheme, and $U = X \setminus Z$ its open complement, with $i\colon Z \hookrightarrow X$ and $j\colon U \hookrightarrow X$ the inclusions. For every k the sequence

$$A_k(Z) \xrightarrow{i_*} A_k(X) \xrightarrow{j^*} A_k(U) \longrightarrow 0$$

is exact: j^* is surjective, and $\ker(j^*) = \operatorname{im}(i_*)$.

***Proof*:**

The map i_* is proper pushforward along the closed immersion (theorem 10.2.3) and j^* is flat pullback along the open immersion (proposition 10.3.7); both are defined on Chow groups, so the sequence is a sequence of homomorphisms. Exactness is checked at the two nonzero spots.

Step 1: surjectivity of j^*. A subvariety $V' \subseteq U$ is a k-dimensional closed integral subscheme of the open set U. Its closure $V = \overline{V'}$ in X is a k-dimensional subvariety of X with $V \cap U = V'$, since closure adds only points lying in the closed set Z and does not raise the dimension. Thus $j^*[V] = [V']$, and every generator of $Z_k(U)$ is hit by a cycle on X. Hence $j^*\colon Z_k(X) \to Z_k(U)$ is already surjective at the level of cycles, and a fortiori $j^*\colon A_k(X) \to A_k(U)$ is surjective.

Step 2: the inclusion $\operatorname{im}(i_*) \subseteq \ker(j^*)$. For a subvariety $V \subseteq Z$ the intersection $V \cap U$ is empty, so $j^* i_*[V] = j^*[V] = 0$. By linearity $j^* \circ i_* = 0$ on $Z_k(Z)$, hence on $A_k(Z)$, which gives $\operatorname{im}(i_*) \subseteq \ker(j^*)$.

Step 3: the inclusion $\ker(j^*) \subseteq \operatorname{im}(i_*)$. This is the substance of the theorem. Let $\alpha \in Z_k(X)$ be a cycle whose class in $A_k(X)$ lies in $\ker(j^*)$, so $j^*\alpha \sim 0$ on U; the goal is to modify α by a cycle rationally equivalent to zero on X until it is supported on Z, that is, until it lies in the image of $i_*\colon Z_k(Z) \to Z_k(X)$.

Split the cycle by whether its components meet U. Group the subvarieties occurring in α as those contained in Z and those meeting U, and write

$$\alpha = \alpha_Z + \beta, \qquad \alpha_Z \in Z_k(Z), \quad \beta = \sum_i n_i [V_i]$$

where each V_i meets U. Since $\alpha_Z = i_* \alpha_Z$ already lies in the image of i_*, it may be discarded, and it suffices to treat β. Applying j^* gives $j^*\alpha = j^*\beta = \sum_i n_i [V_i']$ with $V_i' = V_i \cap U$ the distinct k-dimensional subvarieties of U, and by hypothesis this cycle is rationally equivalent to zero on U:

$$\sum_i n_i [V_i'] = \sum_j [\operatorname{div}(r_j')] \quad \text{in } Z_k(U)$$

for finitely many $(k+1)$-dimensional subvarieties $W_j' \subseteq U$ and rational functions $r_j' \in k(W_j')^*$.

The idea is now to lift each W_j' and r_j' from U to X and compare divisors. Let $W_j = \overline{W_j'} \subseteq X$ be the closure, a $(k+1)$-dimensional subvariety of X with $W_j \cap U = W_j'$. Restriction of functions to the dense open $W_j' \subseteq W_j$ is an isomorphism of function fields $k(W_j) \xrightarrow{\sim} k(W_j')$, since a variety and a dense open subset have the same function field; let $r_j \in k(W_j)^*$ be the function corresponding to r_j'. Form the divisor $[\operatorname{div}(r_j)] \in Z_k(X)$. Its restriction to U is governed by

the flat-pullback compatibility of the divisor construction: for a codimension-one subvariety $V \subseteq W_j$ meeting U, the local ring $\mathcal{O}_{W_j,V} = \mathcal{O}_{W_j',V\cap U}$ is unchanged by passing to the open set, so $\operatorname{ord}_V(r_j) = \operatorname{ord}_{V\cap U}(r_j')$, while a codimension-one subvariety of W_j contained in Z contributes a component of $[\operatorname{div}(r_j)]$ that lies in $Z_k(Z)$. Splitting the sum over these two kinds of V,

$$[\operatorname{div}(r_j)] = [\operatorname{div}(r_j')] + \gamma_j, \qquad \gamma_j \in Z_k(Z) \tag{10.2}$$

where the first term on the right is read inside $Z_k(X)$ via the identification $V \leftrightarrow \overline{V}$ of subvarieties of U with their closures, and γ_j collects the codimension-one subvarieties of W_j that lie in Z.

Step 3, conclusion. Sum (10.2) over j and use $\sum_j [\operatorname{div}(r_j')] = \beta$ as cycles on X under the closure identification (both sides are the cycle $\sum_i n_i[V_i]$, since $V_i = \overline{V_i'}$). This yields

$$\sum_j [\operatorname{div}(r_j)] = \beta + \sum_j \gamma_j$$

so that

$$\beta = \sum_j [\operatorname{div}(r_j)] - \sum_j \gamma_j$$

The first sum is a $\mathbb{Z}$-combination of divisors of rational functions on X, hence lies in $\operatorname{Rat}_k(X)$; the second sum $\gamma := \sum_j \gamma_j$ lies in $Z_k(Z)$. Therefore, in $A_k(X)$,

$$[\beta] = -[\gamma] = i_*(-[\gamma]) \in \operatorname{im}(i_*)$$

Adding back the discarded $\alpha_Z = i_*[\alpha_Z]$ gives $[\alpha] = i_*\big([\alpha_Z] - [\gamma]\big)$, exhibiting the class of α in the image of i_*. This proves $\ker(j^*) \subseteq \operatorname{im}(i_*)$, and with Steps 1 and 2 the sequence is exact, completing the proof.

The mechanism of the proof is worth isolating, because it recurs whenever Chow groups are computed by stratification. Surjectivity on the right is elementary: a subvariety of the open set extends to its closure, so no class on U is unreachable from X. The content is in the middle, and it is entirely a statement about lifting rational equivalences. A relation $j^*\alpha \sim 0$ on U is witnessed by finitely many rational functions on subvarieties of U; each such function extends across Z to a rational function on a subvariety of X (function fields do not see the boundary), and the extended divisor differs from the original only in components supported on Z. The failure of the sequence to be exact on the left, which is left as it stands, measures exactly how much rational equivalence is created by the extra room X provides over Z: a cycle on Z can become rationally equivalent to zero in X without being so in Z, because X contains $(k+1)$-dimensional subvarieties running out of Z into U. The affine line shows this below.

10.4.2 Remark: No Left-Exactness The map $i_*\colon A_k(Z) \to A_k(X)$ need not be injective. Take $X = \mathbb{A}^1$, $Z = \{0\}$, and $k = 0$. Then $A_0(Z) = \mathbb{Z}$, generated by $[0]$, but $[0] \sim 0$ in $A_0(\mathbb{A}^1)$ by example 10.1.5, so $i_*[0] = 0$ and i_* is the zero map on a nonzero group. The kernel of i_* records cycles on Z that bound in X but not in Z, and there is no functorial description of it. This is why the localization sequence is only a three-term right-exact sequence, not a long exact sequence: Bloch's higher Chow groups give the missing terms, but that theory is outside the scope of this book.

The localization sequence is stated for one closed subscheme, but its most frequent use is for a pair. Two closed subschemes X_1, X_2 of an ambient X can be compared through their union and intersection, and the resulting sequence is the Mayer-Vietoris right-exactness that was promised without proof in example 10.1.6. It is a companion to the localization sequence rather than a corollary of it: the derivation below runs directly at the level of cycles, using only that a subvariety of the union lies in one of the two pieces, so no appeal to theorem 10.4.1 is needed.

Corollary 10.4.3: Right-Exactness for Two Closed Subschemes

Let X_1 and X_2 be closed subschemes of an algebraic scheme, and set $X_1 \cup X_2$ and $X_1 \cap X_2$ (with reduced or any fixed scheme structure; Chow groups see only the reduced structure by example 10.1.6). For every k the sequence

$$A_k(X_1 \cap X_2) \xrightarrow{(\iota_{1*},\,-\iota_{2*})} A_k(X_1) \oplus A_k(X_2) \xrightarrow{j_{1*}+j_{2*}} A_k(X_1 \cup X_2) \longrightarrow 0$$

is exact, where $\iota_m \colon X_1 \cap X_2 \hookrightarrow X_m$ and $j_m \colon X_m \hookrightarrow X_1 \cup X_2$ are the inclusions. There is no exactness at $A_k(X_1 \cap X_2)$ in general.

***Proof*:**
Write $Y = X_1 \cup X_2$. The argument is cleanest at the level of cycles, using the one structural fact that an irreducible closed subset of $Y = X_1 \cup X_2$ is contained in X_1 or in X_2. Consequently a subvariety $V \subseteq Y$ lies in X_1 or in X_2 (or in both, in which case $V \subseteq X_1 \cap X_2$), and because $Z_k(Y)$ is free on subvarieties, a cycle expressible both by subvarieties of X_1 and by subvarieties of X_2 has all its components in $X_1 \cap X_2$.

Step 1: surjectivity of $j_{1*} + j_{2*}$. Every subvariety of Y lies in X_1 or X_2, so at the level of cycles $Z_k(Y) = j_{1*}Z_k(X_1) + j_{2*}Z_k(X_2)$; the map $Z_k(X_1) \oplus Z_k(X_2) \to Z_k(Y)$, $(a_1, a_2) \mapsto a_1 + a_2$, is surjective. Passing to classes, $j_{1*} + j_{2*} \colon A_k(X_1) \oplus A_k(X_2) \to A_k(Y)$ is surjective.

Step 2: the composite is zero. For a subvariety $V \subseteq X_1 \cap X_2$ the two pushforwards $j_{1*}\iota_{1*}[V]$ and $j_{2*}\iota_{2*}[V]$ both equal $[V]$ in $Z_k(Y)$, since each inclusion sends $[V]$ to $[V]$. Hence $(j_{1*} + j_{2*}) \circ (\iota_{1*}, -\iota_{2*}) = j_{1*}\iota_{1*} - j_{2*}\iota_{2*} = 0$, giving $\operatorname{im}(\iota_{1*}, -\iota_{2*}) \subseteq \ker(j_{1*} + j_{2*})$.

Step 3: exactness in the middle. Let $(\eta_1, \eta_2) \in A_k(X_1) \oplus A_k(X_2)$ satisfy $j_{1*}\eta_1 + j_{2*}\eta_2 = 0$ in $A_k(Y)$. Represent η_1 and η_2 by cycles $a_1 \in Z_k(X_1)$ and $a_2 \in Z_k(X_2)$. The hypothesis says $a_1 + a_2 \sim 0$ in $Z_k(Y)$, so there are finitely many $(k+1)$-dimensional subvarieties $W_j \subseteq Y$ and $r_j \in k(W_j)^*$ with

$$a_1 + a_2 = \sum_j [\operatorname{div}(r_j)] \quad \text{in } Z_k(Y)$$

Each W_j lies in X_1 or in X_2, and the divisor $[\operatorname{div}(r_j)]$ of a rational function on W_j is a cycle supported on W_j, hence on X_1 or on X_2 accordingly. Collect the terms:

$$b_1 = \sum_{W_j \subseteq X_1} [\operatorname{div}(r_j)] \in \operatorname{Rat}_k(X_1), \qquad b_2 = \sum_{W_j \subseteq X_2,\, W_j \not\subseteq X_1} [\operatorname{div}(r_j)] \in \operatorname{Rat}_k(X_2)$$

where a W_j lying in both is assigned to the first group; then $\sum_j [\operatorname{div}(r_j)] = b_1 + b_2$ and so $a_1 + a_2 = b_1 + b_2$ in $Z_k(Y)$. Rearranging,

$$c := a_1 - b_1 = b_2 - a_2$$

The left expression $a_1 - b_1$ is a cycle supported on X_1, and the right expression $b_2 - a_2$ is a cycle supported on X_2; being the same cycle in the free group $Z_k(Y)$, it is supported on $X_1 \cap X_2$, that is $c \in Z_k(X_1 \cap X_2)$. Now compute classes. In $A_k(X_1)$, $b_1 \in \mathrm{Rat}_k(X_1)$ is zero, so $\eta_1 = [a_1] = [a_1 - b_1] = \iota_{1*}[c]$; in $A_k(X_2)$, $b_2 \in \mathrm{Rat}_k(X_2)$ is zero, so $\eta_2 = [a_2] = [a_2 - b_2] = -\iota_{2*}[c]$. Therefore

$$(\eta_1, \eta_2) = (\iota_{1*}[c], -\iota_{2*}[c]) = (\iota_{1*}, -\iota_{2*})\big([c]\big)$$

lies in the image of $(\iota_{1*}, -\iota_{2*})$. This gives $\ker(j_{1*} + j_{2*}) \subseteq \mathrm{im}(\iota_{1*}, -\iota_{2*})$, and with Step 2 exactness in the middle.

No left-exactness. The map $(\iota_{1*}, -\iota_{2*})$ need not be injective. Take X_1 and X_2 two distinct lines through the origin in $\mathbb{A}^2$, so $X_1 \cap X_2 = \{0\}$, in degree $k = 0$: then $A_0(X_1 \cap X_2) = \mathbb{Z}$ is generated by $[0]$, while $\iota_{1*}[0] = [0] \sim 0$ in $A_0(X_1) = A_0(\mathbb{A}^1)$ and likewise $\iota_{2*}[0] = 0$ in $A_0(X_2)$, so $(\iota_{1*}, -\iota_{2*})[0] = 0$ on a nonzero group. Thus there is no exactness at $A_k(X_1 \cap X_2)$, as we sought to show.

The corollary is the exact sequence recorded, without proof, as item (4) of example 10.1.6; the present derivation discharges that promissory note. Its shape is the Chow-group form of the Mayer-Vietoris sequence familiar from topology, truncated on the left for the same reason the localization sequence is: the intersection $X_1 \cap X_2$ can carry cycles that become rationally equivalent to zero once they are free to move in the larger $X_1 \cup X_2$. Where it is used most is in dévissage arguments, where a scheme is written as a union of simpler closed pieces and its Chow groups are assembled from those of the pieces and their overlaps.

A single application of the localization sequence recovers, from scratch, the computation of $A_0(\mathbb{A}^1)$ recorded in example 10.1.5, this time without touching a rational function by hand. The point is that $\mathbb{A}^1$ is $\mathbb{P}^1$ with a point removed, and the localization sequence turns the known $A_0(\mathbb{P}^1) = \mathbb{Z}$ into the answer for the open complement.

Example 10.4.4: Recomputing $A_0(\mathbb{A}^1)$ by Localization

Take $X = \mathbb{P}^1$, $Z = \{\infty\}$ the point at infinity, and $U = \mathbb{A}^1 = \mathbb{P}^1 \setminus \{\infty\}$. The localization sequence in degree 0 reads

$$A_0(\{\infty\}) \xrightarrow{i_*} A_0(\mathbb{P}^1) \xrightarrow{j^*} A_0(\mathbb{A}^1) \longrightarrow 0$$

The left group is $A_0(\{\infty\}) = \mathbb{Z}$, generated by the class of the single point ∞, and $i_*[\infty] = [\infty] \in A_0(\mathbb{P}^1)$. By example 10.1.5 the group $A_0(\mathbb{P}^1) \cong \mathbb{Z}$ is generated by the class h of any point, and $[\infty] = h$ is a generator, so i_* is surjective. By exactness $\mathrm{im}(i_*) = \ker(j^*)$, and since i_* is onto, $\ker(j^*) = A_0(\mathbb{P}^1)$; the quotient by the whole group is trivial:

$$A_0(\mathbb{A}^1) = A_0(\mathbb{P}^1)/\ker(j^*) \cong \mathrm{coker}(i_*) = \mathbb{Z}/\mathbb{Z} = 0$$

Thus $A_0(\mathbb{A}^1) = 0$, in agreement with the direct computation. The single generator of $A_0(\mathbb{P}^1)$ is killed precisely because the point removed to form $\mathbb{A}^1$ was rationally equivalent to every remaining point; removing it collapses the whole group.

With the localization sequence available, the second structural result of the section follows by Noetherian induction. Homotopy invariance in algebraic geometry takes the form of affine-bundle invariance: pulling a cycle back along the projection of an affine bundle is an isomorphism on Chow groups. The motivating case is the trivial bundle $X \times \mathbb{A}^n \to X$, which asserts that appending an affine factor does not change the Chow group beyond the expected degree shift, the algebraic

counterpart of the fact that $\mathbb{A}^n$ is contractible.

The result is stated for a general affine bundle, of which the trivial bundle is the leading case.

Definition 10.4.5: Affine Bundle of Relative Dimension n

An *affine bundle of relative dimension* n over X is a scheme $p\colon E \to X$ that is locally on X a product with affine space: there is an open cover $\{U_\lambda\}$ of X and isomorphisms $p^{-1}(U_\lambda) \cong U_\lambda \times \mathbb{A}^n$ over U_λ.

A vector bundle of rank n, with its transition maps in GL_n, is such a bundle, as is any torsor under a vector bundle; the trivial example is $X \times \mathbb{A}^n$ itself. In every case p is flat of relative dimension n, so flat pullback $p^*\colon A_k(X) \to A_{k+n}(E)$ is defined by definition 10.3.3.

Theorem 10.4.6: Affine-Bundle Invariance

Let $p\colon E \to X$ be an affine bundle of relative dimension n over an algebraic scheme X. Then the flat pullback

$$p^*\colon A_k(X) \xrightarrow{\sim} A_{k+n}(E)$$

is an isomorphism for every k. In particular, for the trivial bundle, $A_k(X) \xrightarrow{\sim} A_{k+n}(X \times \mathbb{A}^n)$.

***Proof*:**

The proof runs the argument directly at relative dimension n; the fibre dimension enters only through the trivial bundle, where a global tower is available. Note that a global tower of rank-one affine bundles is *not* claimed for a general bundle: the local identification $U \times \mathbb{A}^n = (U \times \mathbb{A}^{n-1}) \times \mathbb{A}^1$ does not glue to a factorization $E \to X$ over X, since a general affine (or vector) bundle carries no global flag of subbundles. The trivial bundle $X \times \mathbb{A}^n$, being a literal product, *is* such a tower, $X \times \mathbb{A}^n = (X \times \mathbb{A}^{n-1}) \times \mathbb{A}^1$; the construction below invokes the tower only there. Fix n and prove that $p^*\colon A_k(X) \to A_{k+n}(E)$ is an isomorphism for all k, by Noetherian induction on the closed subschemes of X. For a closed subscheme $W \subseteq X$ write $E_W = p^{-1}(W)$ and $p_W\colon E_W \to W$ for the restricted bundle, again an affine bundle of relative dimension n.

Step 1: reductions. The scheme X is Noetherian, so its closed subschemes satisfy the descending chain condition and it suffices to prove: if p_W^* is an isomorphism for every proper closed subscheme $W \subsetneq X$, then p^* is an isomorphism for X. Chow groups depend only on the reduced structure (example 10.1.6), so take X reduced. If X is reducible, write $X = X_1 \cup X_2$ with X_1 an irreducible component and X_2 the union of the remaining components, both proper closed subschemes; the pullbacks $p_{X_1}^*, p_{X_2}^*, p_{X_1 \cap X_2}^*$ are isomorphisms by hypothesis. The Mayer-Vietoris sequences of corollary 10.4.3 for $X = X_1 \cup X_2$ and for $E = E_{X_1} \cup E_{X_2}$ (whose intersection is $E_{X_1 \cap X_2}$) form a commutative ladder linked by the vertical pullbacks; a diagram chase using the three outer isomorphisms shows p^* is an isomorphism for X. So assume X is a variety (reduced and irreducible), and let $\eta = \operatorname{Spec} k(X)$ be its generic point, with generic fibre $E_\eta \cong \mathbb{A}^n_{k(X)}$.

Step 2: surjectivity of p^*. It suffices to realize the class of a single $(k+n)$-dimensional subvariety $V \subseteq E$ as a pullback modulo the image of $A_{k+n}(E_Z)$ for some proper closed $Z \subsetneq X$. Let $W = \overline{p(V)} \subseteq X$. If $W \subsetneq X$ is proper, then $V \subseteq E_W$ is supported over $Z = W$, and $[V] \in \operatorname{im}\big(A_{k+n}(E_W) \to A_{k+n}(E)\big)$; by the inductive hypothesis p_W^* is onto, and compatibility of p^* with the closed immersion (the fibre square for p over $W \hookrightarrow X$ gives $p^* i_* = i_* p_W^*$ by proposition 10.3.6) writes $[V]$ as a pullback from X. If instead $W = X$, so V dominates X,

restrict to the generic fibre. There $V_\eta \subseteq \mathbb{A}^n_{k(X)}$ is a closed subvariety, and its class is controlled by the trivial-bundle case of the theorem over the field $K = k(X)$: the projection $\mathbb{A}^n_K \to \operatorname{Spec} K$ has surjective flat pullback. This last fact is elementary and needs no base induction, being the trivial bundle over a point: writing the tower $\mathbb{A}^n_K = (\mathbb{A}^{n-1}_K) \times \mathbb{A}^1$ and inducting on n, the base case $A_*(\mathbb{A}^1_K)$ is generated over $A_*(\operatorname{Spec} K)$ by the pullback (every closed point of $\mathbb{A}^1_K$ is the divisor of its minimal polynomial, so $A_0(\mathbb{A}^1_K) = 0$, exactly as in example 10.1.5 with K in place of $\overline{k}$), and the tower propagates this up the coordinates. Thus $[V_\eta]$ is rationally equivalent on $\mathbb{A}^n_{k(X)}$ to a pullback $p^*_\eta(a_\eta)$ of a class a_η on $\operatorname{Spec} k(X)$. Spreading out the finitely many rational functions that realize this equivalence, together with a_η, to an open $U \subseteq X$ shows $[V]|_{E_U} = p^*_U(\alpha_U)$ for a class $\alpha_U \in A_k(U)$ and hence $[V] - p^*(\alpha_V)$ (with $\alpha_V \in A_k(X)$ lifting α_U via surjectivity of j^*, theorem 10.4.1) restricts to 0 on E_U, so its support lies over the proper closed $Z = X \setminus U$. In every case

$$[V] = p^*(\alpha_V) + \gamma_V \quad \text{in } A_{k+n}(E), \qquad \gamma_V \in \operatorname{im}\big(A_{k+n}(E_Z) \to A_{k+n}(E)\big)$$

for some proper closed $Z \subsetneq X$ and $\alpha_V \in A_k(X)$. By the inductive hypothesis p^*_Z is onto $A_*(E_Z)$, so $\gamma_V = i_* p^*_Z(\delta_V) = p^*(i_*\delta_V)$ for a class δ_V on Z, again by proposition 10.3.6. Hence $[V] = p^*(\alpha_V + i_*\delta_V)$ and p^* is surjective.

Surjectivity of p^* is now in hand for every X; injectivity is the remaining point, and it is not a formal consequence of the localization ladder, since the two rows are only right-exact and provide no left term to chase against. It is proved by exhibiting a left inverse to p^* for the trivial bundle and reducing the general bundle to that case.

Step 3: a left inverse for the trivial bundle. The construction is carried out for a single affine coordinate over an arbitrary base Y; the trivial bundle $X \times \mathbb{A}^n$ is a tower of n such single coordinates, and the rank-n left inverse is the composite of the n single-coordinate left inverses (Step 3c). Take $E = Y \times \mathbb{A}^1$, with coordinate t on the second factor and projection $p\colon Y \times \mathbb{A}^1 \to Y$, and define a homomorphism $\sigma\colon Z_{k+1}(Y \times \mathbb{A}^1) \to Z_k(Y)$ on a generator $[V]$, $V \subseteq Y \times \mathbb{A}^1$ a $(k+1)$-dimensional subvariety, by

$$\sigma[V] = \begin{cases} p_*\big[\operatorname{div}_V(t|_V)\big] & t|_V \in k(V)^* \text{ nonconstant} \\ 0 & t|_V \text{ constant} \end{cases}$$

extended additively; here "$t|_V$ constant" is read to include the degenerate case $t|_V \equiv 0$ (when $V \subseteq Y \times \{0\}$), which likewise contributes 0, since then $t|_V \notin k(V)^*$ and no divisor $\operatorname{div}_V(t|_V)$ is formed. When $t|_V$ is nonconstant, $[\operatorname{div}_V(t|_V)]$ is a $\underline{k\text{-cycle}}$ on V; the pushforward p_* of this particular cycle is well-defined even though $p|_V\colon V \to \overline{p(V)} \subseteq Y$ need not be proper. The point is that t is a regular function on $Y \times \mathbb{A}^1$, so its restriction $t|_V$ is regular on V and $\operatorname{div}_V(t|_V)$ is effective, with support contained in the zero locus $V \cap (Y \times \{0\}) \subseteq Y \times \{0\}$. On $Y \times \{0\}$ the projection p is the closed immersion identifying $Y \times \{0\}$ with Y, in particular proper, so $p_*[\operatorname{div}_V(t|_V)]$ is a well-defined k-cycle on Y by definition 10.2.1, computed component by component over the locus where $t|_V$ vanishes. Geometrically $\sigma[V]$ is the fibre of V over $t = 0$, projected to Y: the specialization of V to the zero section.

Step 3a: $\sigma \circ p^* = \mathrm{id}$. For a k-dimensional subvariety $W \subseteq Y$ the pullback is $p^*[W] = [W \times \mathbb{A}^1]$, and t restricts to the coordinate on $W \times \mathbb{A}^1$, which is nonconstant with $[\operatorname{div}_{W \times \mathbb{A}^1}(t)] = [W \times \{0\}]$ (the coordinate t has its single zero along $W \times \{0\}$ and no pole on $W \times \mathbb{A}^1$). Pushing forward, $p_*[W \times \{0\}] = [W]$, so $\sigma(p^*[W]) = [W]$. By additivity $\sigma \circ p^* = \mathrm{id}$ on $Z_k(Y)$, hence on $A_k(Y)$ once σ is known to descend.

Step 3b: σ respects rational equivalence. A generator of $\mathrm{Rat}_{k+1}(Y \times \mathbb{A}^1)$ is $[\mathrm{div}_S(g)]$ for a $(k+2)$-dimensional subvariety $S \subseteq Y \times \mathbb{A}^1$ and $g \in k(S)^*$, and unwinding the definitions gives $\sigma[\mathrm{div}_S(g)] = p_*\big(\sum_V \mathrm{ord}_V(g)\,[\mathrm{div}_V(t|_V)]\big)$, the outer sum over the codimension-one subvarieties $V \subseteq S$ on which $t|_V$ is nonconstant (a V with $t|_V$ constant, including $V \subseteq Y \times \{0\}$ where $t|_V \equiv 0$, drops out, contributing 0). This iterated divisor is symmetric in the two functions g and $t|_S$ modulo a principal divisor on S:

$$\sum_V \mathrm{ord}_V(g)\,[\mathrm{div}_V(t)] - \sum_V \mathrm{ord}_V(t)\,[\mathrm{div}_V(g)] \in \mathrm{Rat}_k(S) \tag{10.3}$$

The relation (10.3) is the commutativity of two divisor operations on the $(k+2)$-dimensional S, equivalently the well-definedness of intersecting a cycle with a Cartier divisor; its proof requires the divisor-theoretic machinery of the next chapter, and is given there by theorem 11.3.2 (its surface case is exactly (10.3)), so no tool used here depends on it circularly. Granting (10.3), $\sigma[\mathrm{div}_S(g)]$ differs from $p_*\big(\sum_V \mathrm{ord}_V(t)\,[\mathrm{div}_V(g)]\big)$ by the pushforward of a principal divisor, and $\sum_V \mathrm{ord}_V(t)\,[\mathrm{div}_V(g)]$ is itself a $\mathbb{Z}$-combination of principal divisors on the subvarieties V, so its pushforward lies in $\mathrm{Rat}_k(Y)$ by theorem 10.2.3. Either way $\sigma[\mathrm{div}_S(g)] \in \mathrm{Rat}_k(Y)$, so σ descends to

$$\sigma\colon A_{k+1}(Y \times \mathbb{A}^1) \to A_k(Y), \qquad \sigma \circ p^* = \mathrm{id}$$

In particular p^* is injective for the trivial rank-one bundle over any base Y, and being surjective by Step 2, it is an isomorphism there. The left inverse σ commutes with proper pushforward along closed immersions and with flat restriction to opens, since each of p_* and $\mathrm{div}(t)$ does; this compatibility is what carries the trivial-bundle result across the localization sequence in Step 3d.

Step 3c: the trivial rank-n bundle. For $E = X \times \mathbb{A}^n$ with coordinates $t_1, \dots, t_n$, the tower

$$X \times \mathbb{A}^n \xrightarrow{q_n} X \times \mathbb{A}^{n-1} \xrightarrow{q_{n-1}} \cdots \xrightarrow{q_1} X$$

factors $p = q_1 \circ \cdots \circ q_n$ into single-coordinate trivial rank-one bundles $q_m\colon (X \times \mathbb{A}^{m-1}) \times \mathbb{A}^1 \to X \times \mathbb{A}^{m-1}$, so $p^* = q_n^* \circ \cdots \circ q_1^*$ by functoriality of flat pullback (proposition 10.3.5). Applying Step 3b with $Y = X \times \mathbb{A}^{m-1}$ gives a left inverse σ_m to each q_m^*; the composite $\sigma := \sigma_1 \circ \cdots \circ \sigma_n\colon A_{k+n}(X \times \mathbb{A}^n) \to A_k(X)$ satisfies $\sigma \circ p^* = \mathrm{id}$, so p^* is injective, and with Step 2 it is an isomorphism for the trivial bundle. The compatibility of each σ_m with proper pushforward along closed immersions and with flat restriction to opens passes to the composite, so σ has the same compatibility used in the next step.

Step 3d: injectivity for a general bundle. Let $p\colon E \to X$ be an affine bundle of relative dimension n over the variety X and $\alpha \in A_k(X)$ with $p^*\alpha = 0$. Choose a dense open $U \subseteq X$ over which E trivializes, $E_U \cong U \times \mathbb{A}^n$, and set $Z = X \setminus U$, a proper closed subscheme. Flat base change (proposition 10.3.5) gives $p_U^*(j^*\alpha) = j^*(p^*\alpha) = 0$, and p_U^* is injective by Step 3c applied to the trivial bundle over U; hence $j^*\alpha = 0$. By the localization sequence for $Z \subseteq X$ (theorem 10.4.1), $\alpha = i_*\beta$ for some $\beta \in A_k(Z)$. Pushing β into E through the fibre square over $Z \hookrightarrow X$ (proposition 10.3.6) gives $p^*\alpha = p^*i_*\beta = i_*(p_Z^*\beta) = 0$, so $p_Z^*\beta$ lies in the kernel of $i_*\colon A_{k+n}(E_Z) \to A_{k+n}(E)$. Over the total space E the left inverse of Step 3c, restricted to the trivializing locus and extended by $\sigma_Z := (p_Z^*)^{-1}$ over E_Z (the inductive isomorphism), assembles into a retraction $r_E\colon A_{k+n}(E) \to A_k(X)$ of p^*; the compatibility noted at the end of Step 3c makes the square with i_* commute, so that $r_E \circ i_* = i_* \circ \sigma_Z$ on $A_{k+n}(E_Z)$. Evaluating at $p_Z^*\beta$,

$$i_*\beta = i_*\big(\sigma_Z p_Z^*\beta\big) = r_E\big(i_* p_Z^*\beta\big) = r_E(0) = 0$$

so $\alpha = i_*\beta = 0$. Hence p^* is injective.

> Steps 2 and 3 show p^* is an isomorphism for every X and every relative dimension n, completing the Noetherian induction; the tower entered only for the trivial bundle (Step 3c), where it is an actual global factorization, so no global tower was claimed for a general bundle, completing the proof.

The theorem is the algebraic-geometric form of a topological triviality: the projection $X \times \mathbb{A}^n \to X$ is a homotopy equivalence when $\mathbb{A}^n = \mathbb{C}^n$ is given the classical topology, so it induces isomorphisms on singular homology, and Chow groups behave the same way. The degree shift by n is the algebraic bookkeeping for the real dimension shift $2n$ on the topological side, since a k-cycle (complex dimension k) has real dimension $2k$ and A_{k+n} matches $H_{2(k+n)} = H_{2k+2n}$. The proof uses none of this: surjectivity of p^* needs only that every zero-cycle on an affine line over a field is rationally trivial ($A_0(\mathbb{A}^1_K) = 0$), propagated up the base by localization, while injectivity needs a left inverse, the specialization to the zero section. The one step left open, the divisor symmetry (10.3), is exactly the input that makes intersecting with a Cartier divisor well defined on rational equivalence, the payload of the next chapter; the isomorphism here is the first place that well-definedness is needed, and the forward reference is deliberate rather than a gap. It is discharged in theorem 11.3.2. The reason the argument needs Noetherian induction rather than a direct computation is the same reason the localization sequence is not left-exact: one cannot control what rational equivalences a cycle acquires on E without dismantling the base into pieces small enough that the bundle trivializes and the fibrewise vanishing takes over.

Exercise 10.4.1

1. Let $Z \subseteq X$ be closed with complement U. Show directly from theorem 10.4.1 that $A_k(U) \cong A_k(X)/\operatorname{im}\big(A_k(Z) \to A_k(X)\big)$, and use this to prove that if $A_k(Z) = 0$ then $j^*\colon A_k(X) \to A_k(U)$ is an isomorphism.

2. Let $X = \mathbb{A}^2$ and let $Z = \{0\}$ be the origin, so $U = \mathbb{A}^2 \setminus \{0\}$ is the punctured plane. Using the localization sequence together with the values $A_k(\mathbb{A}^2)$ (namely $A_2(\mathbb{A}^2) = \mathbb{Z}$ and $A_k(\mathbb{A}^2) = 0$ for $k < 2$, which you may take from section 10.5), compute $A_k(U)$ for all k.

3. Let X be a variety of dimension n and $U \subseteq X$ a nonempty open subset. Show that $A_n(X) \to A_n(U)$ is an isomorphism, and that both are $\mathbb{Z}$, generated by the fundamental class.

4. Compute $A_*(\mathbb{P}^n \times \mathbb{A}^m)$ in terms of $A_*(\mathbb{P}^n)$, assuming the value $A_k(\mathbb{P}^n) = \mathbb{Z}$ for $0 \le k \le n$ from section 10.5. State the answer as a graded group.

5. Let $p\colon E \to X$ be a vector bundle of rank r over an algebraic scheme X, with zero section $s\colon X \hookrightarrow E$. Affine-bundle invariance makes $p^*\colon A_k(X) \to A_{k+r}(E)$ an isomorphism. Explain why one cannot conclude $A_*(E) \cong A_*(X)$ by inverting p^* with a proper pushforward p_*, identifying the precise obstruction, and describe the degree by which p^* and the closed-immersion pushforward s_* each shift a cycle class.

6. Take X_1 and X_2 to be two distinct lines through the origin in $\mathbb{A}^2$, meeting only at $\{0\}$. Write out the sequence of corollary 10.4.3 in degree 0 and verify its exactness by hand, given that A_0 of a line is 0 and A_0 of a point is $\mathbb{Z}$.

10.5 First Computations

The machinery of the preceding sections is now assembled: cycles, rational equivalence, proper pushforward, flat pullback, and the two fundamental sequences. This section puts it to work on the spaces one meets first. We compute the Chow groups of affine space, of projective space, and of a smooth projective curve, and record the shape the answer takes for a projective bundle. These are the building blocks from which nearly every later computation is assembled, and they already display the two extremes of the theory: affine space, whose cycles almost all sweep away to nothing, and projective space, whose cycles are pinned down by a single integer in each dimension.

The pattern to watch is how the localization sequence and affine-bundle invariance from section 10.4 do the actual work. Affine space is an affine bundle over a point, so its Chow groups collapse; projective space is built from affine space by adding a hyperplane at infinity, so an induction along the localization sequence peels off one $\mathbb{Z}$ per dimension. Every computation below is an instance of one of these two moves.

Affine space is the first computation, and $\mathbb{A}^n$ retracts, in the sense of rational equivalence, all the way down to a point: every subvariety of dimension less than n can be swept off to zero, and only the fundamental class in top dimension survives. This is the higher-dimensional form of the observation $A_0(\mathbb{A}^1) = 0$ from example 10.1.5, and it follows in one line from affine-bundle invariance once one notices that $\mathbb{A}^n$ is an affine bundle over $\operatorname{Spec} \overline{k}$.

Proposition 10.5.1: Chow Groups of Affine Space

For every $n \geq 0$ the Chow groups of affine space are

$$A_k(\mathbb{A}^n) = \begin{cases} \mathbb{Z}\,[\mathbb{A}^n] & k = n \\ 0 & k \neq n \end{cases}$$

the group $A_n(\mathbb{A}^n)$ being free of rank one on the fundamental class $[\mathbb{A}^n]$.

***Proof*:**

The structure morphism $\pi\colon \mathbb{A}^n \to \operatorname{Spec} \overline{k}$ exhibits $\mathbb{A}^n$ as the trivial affine bundle of relative dimension n over a point. Affine-bundle invariance (theorem 10.4.6) states that flat pullback

$$\pi^*\colon A_k(\operatorname{Spec} \overline{k}) \xrightarrow{\sim} A_{k+n}(\mathbb{A}^n)$$

is an isomorphism for every k. The point $\operatorname{Spec} \overline{k}$ has a single subvariety, itself, of dimension 0, so $A_0(\operatorname{Spec} \overline{k}) = Z_0(\operatorname{Spec} \overline{k}) = \mathbb{Z}\,[\operatorname{Spec} \overline{k}]$ and $A_k(\operatorname{Spec} \overline{k}) = 0$ for $k \neq 0$. Transporting these through π^* gives $A_{k+n}(\mathbb{A}^n) = 0$ for $k \neq 0$, that is $A_j(\mathbb{A}^n) = 0$ for $j \neq n$, and $A_n(\mathbb{A}^n) = \pi^*\big(\mathbb{Z}\,[\operatorname{Spec} \overline{k}]\big)$. Flat pullback of the fundamental cycle of the base is the fundamental cycle of the total space (definition 10.3.3), so $\pi^*[\operatorname{Spec} \overline{k}] = [\mathbb{A}^n]$, and $A_n(\mathbb{A}^n) = \mathbb{Z}\,[\mathbb{A}^n]$ is free of rank one, completing the proof.

Affine space thus has no cycles in low dimension worth remembering, a fact that reads two ways. From below it says that any k-dimensional subvariety $V \subseteq \mathbb{A}^n$ with $k < n$ bounds: there is a family of cycles, parametrized by the line, sweeping $[V]$ to zero. From above it isolates the one invariant that does survive, the coefficient of the fundamental class, which for a top cycle records the multiplicity

with which $\mathbb{A}^n$ appears in it. The vanishing in low dimension is what makes affine space so poor a stage for enumerative geometry, and simultaneously what makes it the natural chart in which to localize a computation on a larger space. This second role is exactly how projective space is handled next.

The contrast to keep in mind is the affine line. A single point of $\mathbb{A}^1$ is a 0-cycle in dimension $0 < 1$, so proposition 10.5.1 predicts $A_0(\mathbb{A}^1) = 0$, recovering the computation of example 10.1.5: the coordinate function $t - p$ has $[\mathrm{div}(t-p)] = [p]$, presenting the point as a principal divisor and hence as zero in the Chow group. The proposition is the assertion that this collapse happens in every dimension below the top, uniformly and for the same reason.

Projective space is the opposite. Nothing sweeps to zero for free, because a rational function on a subvariety of $\mathbb{P}^n$ has as many zeros as poles, and the surviving invariant in each dimension is an integer. The computation is an induction that peels $\mathbb{P}^n$ apart along a hyperplane: the closed subscheme $\mathbb{P}^{n-1} \subseteq \mathbb{P}^n$ at infinity, with open complement the affine chart $\mathbb{A}^n$. Affine space contributes nothing below the top by proposition 10.5.1, so the localization sequence forces every class of $\mathbb{P}^n$ in dimension $k < n$ to come from $\mathbb{P}^{n-1}$, and the induction runs.

The motivating principle is that projective space is *cellular*: it is stratified by the chain

$$\mathbb{P}^0 \subset \mathbb{P}^1 \subset \cdots \subset \mathbb{P}^{n-1} \subset \mathbb{P}^n$$

of linear subspaces, each obtained from the previous by adding an affine cell $\mathbb{A}^k = \mathbb{P}^k \setminus \mathbb{P}^{k-1}$. The Chow groups turn out to be free on the classes of these cells, one generator in each dimension. This is the algebraic form of the cell decomposition that computes the singular homology of $\mathbb{C}\mathrm{P}^n$ in [78, CW Homology], where the same chain of linear subspaces yields $H_{2k}(\mathbb{C}\mathrm{P}^n;\mathbb{Z}) = \mathbb{Z}$ and $H_{\mathrm{odd}} = 0$.

Theorem 10.5.2: Chow Groups of Projective Space

For every $n \geq 0$ and every $0 \leq k \leq n$, the Chow group $A_k(\mathbb{P}^n)$ is free abelian of rank one, generated by the class $[\mathbb{P}^k]$ of any linear subspace $\mathbb{P}^k \subseteq \mathbb{P}^n$ of dimension k:

$$A_k(\mathbb{P}^n) = \mathbb{Z}\,[\mathbb{P}^k], \qquad 0 \leq k \leq n$$

and $A_k(\mathbb{P}^n) = 0$ for $k > n$. Any two linear subspaces of the same dimension are rationally equivalent, so the generator does not depend on the choice.

***Proof*:**

The argument is an induction on n, run through projection from a point, which realizes the complement of a point in $\mathbb{P}^n$ as a line bundle over $\mathbb{P}^{n-1}$. Write h_k for the class $[\mathbb{P}^k]$ of a linear k-plane; the claim is that $A_k(\mathbb{P}^n) = \mathbb{Z}\,h_k$ is free of rank one for $0 \leq k \leq n$, and 0 otherwise. Groups $A_k(\mathbb{P}^n)$ with $k > n = \dim \mathbb{P}^n$ vanish because $\mathbb{P}^n$ has no subvariety of that dimension, so only $0 \leq k \leq n$ is at issue.

Step 1: base cases $n = 0$ and $k = 0$. For $n = 0$ the space $\mathbb{P}^0 = \mathrm{Spec}\,\overline{k}$ is a point, with $A_0(\mathbb{P}^0) = \mathbb{Z}\,[\mathbb{P}^0]$ and $A_k(\mathbb{P}^0) = 0$ for $k \neq 0$ by proposition 10.5.1, which is the claim. For general n and $k = 0$, every closed point of $\mathbb{P}^n$ is rationally equivalent to every other: two points p, q both lie on a line $\ell \cong \mathbb{P}^1 \subseteq \mathbb{P}^n$, and on ℓ they are rationally equivalent by example 10.1.5, so $[p] \sim [q]$ in $\mathbb{P}^n$. Thus $A_0(\mathbb{P}^n)$ is cyclic, generated by $h_0 = [p]$. Since $\mathbb{P}^n$ is complete, the degree map $\deg\colon A_0(\mathbb{P}^n) \to \mathbb{Z}$ of definition 10.2.4 is well defined and sends $h_0 = [p] \mapsto [k(p) : \overline{k}] = 1$, so h_0 has infinite order and $A_0(\mathbb{P}^n) = \mathbb{Z}\,h_0$ is free of rank one.

Step 2: projection from a point as a line bundle. Fix $n \geq 1$ and a closed point $P \in \mathbb{P}^n$. Choosing coordinates with $P = [0 : \cdots : 0 : 1]$, linear projection away from P is a morphism

$$q \colon \mathbb{P}^n \setminus \{P\} \to \mathbb{P}^{n-1}, \qquad [x_0 : \cdots : x_n] \mapsto [x_0 : \cdots : x_{n-1}]$$

whose fiber over a point $[a] \in \mathbb{P}^{n-1}$ is the line through P and $[a]$ with P removed, an affine line $\mathbb{A}^1$. This exhibits $\mathbb{P}^n \setminus \{P\}$ as a line bundle over $\mathbb{P}^{n-1}$, the total space of $\mathcal{O}_{\mathbb{P}^{n-1}}(1)$; in particular it is an affine bundle of relative dimension 1. Only the last clause is used below. Affine-bundle invariance (theorem 10.4.6) makes flat pullback

$$q^* \colon A_{k-1}(\mathbb{P}^{n-1}) \xrightarrow{\sim} A_k(\mathbb{P}^n \setminus \{P\}) \tag{10.4}$$

an isomorphism for every k.

Step 3: removing the point via localization. The point $\{P\}$ is a closed subscheme of $\mathbb{P}^n$ with open complement $\mathbb{P}^n \setminus \{P\}$. The localization sequence (theorem 10.4.1) for this pair reads

$$A_k(\{P\}) \xrightarrow{i_*} A_k(\mathbb{P}^n) \xrightarrow{j^*} A_k(\mathbb{P}^n \setminus \{P\}) \to 0 \tag{10.5}$$

exact at $A_k(\mathbb{P}^n)$ and $A_k(\mathbb{P}^n \setminus \{P\})$. The point contributes $A_k(\{P\}) = 0$ for every $k \geq 1$ and $A_0(\{P\}) = \mathbb{Z}\,[P]$. Hence for $k \geq 1$ the left term vanishes and j^* is an isomorphism, which combined with (10.4) gives, for $k \geq 1$,

$$A_k(\mathbb{P}^n) \xrightarrow[j^*]{\sim} A_k(\mathbb{P}^n \setminus \{P\}) \xleftarrow[q^*]{\sim} A_{k-1}(\mathbb{P}^{n-1}) \tag{10.6}$$

so $A_k(\mathbb{P}^n) \cong A_{k-1}(\mathbb{P}^{n-1})$ as abelian groups.

Step 4: the induction. Fix k with $1 \leq k \leq n$. Iterating (10.6) k times descends both indices by k:

$$A_k(\mathbb{P}^n) \cong A_{k-1}(\mathbb{P}^{n-1}) \cong \cdots \cong A_0(\mathbb{P}^{n-k})$$

and $A_0(\mathbb{P}^{n-k}) = \mathbb{Z}$ is free of rank one by Step 1. Together with the case $k = 0$ of Step 1, this proves $A_k(\mathbb{P}^n) \cong \mathbb{Z}$ is free of rank one for every $0 \leq k \leq n$. For $k > n$ the group vanishes as noted at the outset.

Step 5: the generator is the class of a linear subspace. It remains to identify the free generator with $h_k = [\mathbb{P}^k]$. Trace a linear $\mathbb{P}^k \subseteq \mathbb{P}^n$ through (10.6). Choose the point $P \in \mathbb{P}^k$; projection of the linear subspace $\mathbb{P}^k$ from the point $P \in \mathbb{P}^k$ is again linear, of one lower dimension, so $q(\mathbb{P}^k \setminus \{P\})$ is a linear $\mathbb{P}^{k-1} \subseteq \mathbb{P}^{n-1}$. Restricting the bundle $q \colon \mathbb{P}^n \setminus \{P\} \to \mathbb{P}^{n-1}$ of Step 2 over this $\mathbb{P}^{k-1}$ realizes $\mathbb{P}^k \setminus \{P\}$ as the affine bundle over $\mathbb{P}^{k-1}$; concretely $q^{-1}(\mathbb{P}^{k-1}) = \mathbb{P}^k \setminus \{P\}$ as a reduced irreducible subvariety, so flat pullback gives $q^*[\mathbb{P}^{k-1}] = [q^{-1}(\mathbb{P}^{k-1})] = [\mathbb{P}^k \setminus \{P\}]$ with multiplicity 1. Hence by construction of (10.6) the class $h_k = [\mathbb{P}^k]$ satisfies $j^* h_k = [\mathbb{P}^k \setminus \{P\}] = q^*[\mathbb{P}^{k-1}]$, so h_k corresponds to h_{k-1} under the isomorphism $A_k(\mathbb{P}^n) \cong A_{k-1}(\mathbb{P}^{n-1})$. Descending to $A_0(\mathbb{P}^{n-k})$, the class h_k maps to $h_0 = [\mathrm{pt}]$, which is the free generator by Step 1. Thus h_k is a generator of $A_k(\mathbb{P}^n) = \mathbb{Z}$. The top case $k = n$ is consistent with the fundamental-class computation $A_n(\mathbb{P}^n) = Z_n(\mathbb{P}^n) = \mathbb{Z}\,[\mathbb{P}^n]$ of example 10.1.6, since $\mathbb{P}^n$ is irreducible and $h_n = [\mathbb{P}^n]$.

Step 6: independence of the linear subspace. Any two linear k-planes $\Lambda, \Lambda' \subseteq \mathbb{P}^n$ have classes differing by an integer multiple of the generator; the previous step assigns each of them the generator h_0 under the descent to $A_0(\mathbb{P}^{n-k})$, so $[\Lambda] = [\Lambda']$ in $A_k(\mathbb{P}^n)$. Concretely a projective linear transformation carrying Λ to Λ' sweeps out a rational equivalence between them, so the generator h_k is independent of the chosen k-plane, completing the induction and the proof.

The theorem says that the Chow groups of $\mathbb{P}^n$ take the simplest possible form: one copy of $\mathbb{Z}$ in each dimension from 0 to n, with a canonical generator, the class of a linear subspace. Writing the total group additively,

$$A_*(\mathbb{P}^n) = \bigoplus_{k=0}^{n} \mathbb{Z}\, h_k, \qquad h_k = [\mathbb{P}^k]$$

so $A_*(\mathbb{P}^n)$ is free of rank $n+1$. In codimension indexing the generator $h_k = [\mathbb{P}^k]$ has codimension $n-k$, and it is common to write $h = [\mathbb{P}^{n-1}]$ for the hyperplane class and record h_k as the intersection h^{n-k} of $n-k$ hyperplanes; the multiplicative structure that makes this literal is the intersection product developed in a later chapter. For now the additive statement is what matters: on projective space, a k-cycle carries exactly one integer of information, its degree, the coefficient of h_k.

This is the precise sense in which projective space is rigid where affine space is soft. A subvariety $V \subseteq \mathbb{P}^n$ of dimension k and degree d (its degree as a projective variety, the number of points in which it meets a general linear $\mathbb{P}^{n-k}$) has class $[V] = d\, h_k$, and no amount of rational equivalence can change d. The degree is a complete invariant of the class, and rational equivalence on $\mathbb{P}^n$ is, for irreducible cycles, exactly the relation "same dimension and same degree" (and for arbitrary cycles, "same degree in each dimension"). The comparison with singular homology is exact: under the cycle class map to $H_{2k}(\mathbb{C}\mathrm{P}^n)$ studied later, h_k maps to the generator, and the freeness of $A_k(\mathbb{P}^n)$ mirrors the freeness of $H_{2k}(\mathbb{C}\mathrm{P}^n;\mathbb{Z})$ ([78, CW Homology]).

The one-dimensional case deserves its own statement, both because curves are where the theory began and because on a curve the Chow group is an object the reader already knows under another name. On a smooth projective curve C the only cycles are 0-cycles and the fundamental class, and the 0-cycles modulo rational equivalence are precisely the divisor classes. This ties the general construction back to the divisor class group $\operatorname{Cl} C$ and the Picard group $\operatorname{Pic} C$ of section 5.4.

Proposition 10.5.3: Chow Groups of a Smooth Projective Curve

Let C be a smooth projective curve over $\overline{k}$. Then

$$A_1(C) = \mathbb{Z}\,[C], \qquad A_0(C) \cong \operatorname{Cl} C = \operatorname{Pic} C$$

and $A_k(C) = 0$ for $k \neq 0, 1$. Under the second isomorphism the degree of a zero-cycle corresponds to the degree of a divisor, giving a short exact sequence

$$0 \to \operatorname{Pic}^0 C \to A_0(C) \xrightarrow{\deg} \mathbb{Z} \to 0$$

where $\operatorname{Pic}^0 C$ is the group of divisor classes of degree zero.

***Proof*:**

Since $\dim C = 1$, the only nonzero groups are $A_0(C)$ and $A_1(C)$, and $A_k(C) = 0$ for $k \neq 0, 1$. The curve C is irreducible of dimension 1, so by example 10.1.6 its top group is $A_1(C) = Z_1(C) = \mathbb{Z}\,[C]$, free on the fundamental class.

The zero-cycles. A 0-cycle on C is a finite $\mathbb{Z}$-combination of closed points, so $Z_0(C)$ is the group $\operatorname{WDiv} C$ of Weil divisors on C. The subgroup $\operatorname{Rat}_0(C)$ of cycles rationally equivalent to zero is generated by the cycles $[\operatorname{div}(r)]$ for $r \in k(W)^*$ ranging over 1-dimensional subvarieties $W \subseteq C$; the only such W is C itself, so $\operatorname{Rat}_0(C)$ is generated by the principal divisors $[\operatorname{div}(r)]$ with $r \in k(C)^*$. Thus $\operatorname{Rat}_0(C)$ is exactly the group $\operatorname{Prin} C$ of principal divisors in the sense of

definition 5.4.7, and

$$A_0(C) = Z_0(C)/\mathrm{Rat}_0(C) = \mathrm{WDiv}\, C/\operatorname{Prin} C = \mathrm{Cl}\, C$$

is the divisor class group of definition 5.4.8. Because C is smooth, the divisor-to-line-bundle correspondence of section 5.4 identifies $\mathrm{Cl}\, C$ with $\operatorname{Pic} C$.

The degree sequence. On a smooth projective curve linearly equivalent divisors have equal degree: if $D \sim D'$ then $\deg D = \deg D'$, since the Riemann-Roch theorem (theorem 7.2.10) gives $\chi(\mathcal{L}(D)) = \deg D + 1 - g$, a quantity depending only on the class of D, so $\deg D$ is determined by it. Hence deg descends to a homomorphism $\deg\colon A_0(C) \to \mathbb{Z}$, agreeing under the identification $A_0(C) = \mathrm{Cl}\, C$ with the degree of a divisor class. It is surjective because a single closed point has degree $[k(p) : \overline{k}] = 1$, and its kernel is the group $\operatorname{Pic}^0 C$ of degree-zero classes by definition. This gives the stated short exact sequence, completing the proof.

The proposition recovers, in the language of Chow groups, the entire divisor theory of a curve. The degree map splits the class group into a discrete part, the copy of $\mathbb{Z}$ recording degree, and a connected part $\operatorname{Pic}^0 C$, the Jacobian, carrying the continuous moduli of divisor classes of a fixed degree. For $C = \mathbb{P}^1$ the Jacobian is trivial and $A_0(\mathbb{P}^1) = \mathbb{Z}$, in agreement with example 10.1.5 and with the case $n = 1$ of theorem 10.5.2; for a curve of genus $g \geq 1$ the group $\operatorname{Pic}^0 C$ is a g-dimensional abelian variety and $A_0(C)$ is strictly larger than $\mathbb{Z}$, so the degree is no longer a complete invariant of a class. The Chow group of a curve is therefore the first place in the theory where an interesting continuous invariant appears, and it is the model on which the higher-dimensional theory is built.

The Chow group $A_0(C)$ also illustrates the failure of the total-degree map to see everything. On $\mathbb{P}^n$ the degree was a complete invariant of a k-cycle class; on a curve of positive genus it is not, because two points $p, q \in C$ need not be rationally equivalent even though $[p]$ and $[q]$ have the same degree. Their difference $[p] - [q]$ is a nonzero class in $\operatorname{Pic}^0 C$ precisely when p and q are not linearly equivalent, which for $g \geq 1$ is the generic situation. This is the geometric content of the statement that a curve of positive genus admits no nonconstant rational function of degree one.

The last computation of the section is stated but not proved, because its proof needs Segre classes, which are developed later. It generalizes the projective-space computation from the trivial bundle to an arbitrary vector bundle: the Chow groups of a projectivized vector bundle are a free module over the Chow groups of the base, on the powers of the tautological class. This is the projective-bundle formula, and it is the engine that will later define Chern classes.

Given a vector bundle E of rank $r+1$ on a scheme X, write $\mathbb{P}(E) \to X$ for the associated projective bundle, whose fiber over a point x is the projective space $\mathbb{P}(E_x) \cong \mathbb{P}^r$ of one-dimensional subspaces of the fiber E_x. Let $\xi = c_1(\mathcal{O}_{\mathbb{P}(E)}(1)) \in A^1(\mathbb{P}(E))$ be the first Chern class of the Serre-twist line bundle $\mathcal{O}_{\mathbb{P}(E)}(1)$ (the dual of the tautological subbundle, with the "one-dimensional subspaces" convention above), viewed as an operator on cycles. The projective-bundle formula states that the flat pullback π^* together with capping against powers of ξ makes $A_*(\mathbb{P}(E))$ a free module over $A_*(X)$ on the classes $1, \xi, \ldots, \xi^r$:

$$A_*(\mathbb{P}(E)) = \bigoplus_{i=0}^{r} \xi^i \cap \pi^* A_*(X)$$

Concretely, every class on $\mathbb{P}(E)$ is uniquely $\sum_{i=0}^{r} \xi^i \cap \pi^* \alpha_i$ with $\alpha_i \in A_*(X)$. Taking $X = \operatorname{Spec} \overline{k}$ and $E = \overline{k}^{n+1}$ recovers $\mathbb{P}(E) = \mathbb{P}^n$ and the free-module statement collapses to $A_*(\mathbb{P}^n) = \bigoplus_{i=0}^{n} \mathbb{Z}\, \xi^i$ of theorem 10.5.2, with ξ^i the class of a linear subspace of codimension i. The full statement, and the definition of the Chern class operators it rests on, are theorem 12.1.9 in section 12.1; the formula

is recorded here because it is the natural common generalization of the two computations above, and because it is the shape every later Chow-group computation of a bundle takes.

Before the exercises, the three worked instances of the theory are collected side by side, so the common mechanism is visible in one place.

Example 10.5.4: The Chow Groups of $\mathbb{P}^1$, $\mathbb{P}^2$, and a Plane Curve

1. *The projective line.* For $n = 1$, theorem 10.5.2 gives $A_0(\mathbb{P}^1) = \mathbb{Z}\,[\mathrm{pt}]$ and $A_1(\mathbb{P}^1) = \mathbb{Z}\,[\mathbb{P}^1]$, so
$$A_*(\mathbb{P}^1) = \mathbb{Z}\,[\mathbb{P}^1] \oplus \mathbb{Z}\,[\mathrm{pt}]$$
The degree-0 part $A_0(\mathbb{P}^1) = \mathbb{Z}$ agrees with example 10.1.5, and with proposition 10.5.3 for the genus-zero curve $\mathbb{P}^1$, whose Jacobian $\mathrm{Pic}^0\mathbb{P}^1$ is trivial.

2. *The projective plane.* For $n = 2$,
$$A_*(\mathbb{P}^2) = \mathbb{Z}\,[\mathbb{P}^2] \oplus \mathbb{Z}\,[\mathbb{P}^1] \oplus \mathbb{Z}\,[\mathrm{pt}]$$
with $A_2(\mathbb{P}^2) = \mathbb{Z}\,[\mathbb{P}^2]$, $A_1(\mathbb{P}^2) = \mathbb{Z}\,[\mathbb{P}^1]$ generated by the class of a line, and $A_0(\mathbb{P}^2) = \mathbb{Z}\,[\mathrm{pt}]$. A plane curve $D \subseteq \mathbb{P}^2$ of degree d has class $[D] = d\,[\mathbb{P}^1] = d\,h_1$ in $A_1(\mathbb{P}^2)$, since D is cut out by a form of degree d and hence is rationally equivalent to d lines (the pencil spanned by the form and ℓ^d for a linear form ℓ sweeps one to the other). Two plane curves of degrees c and d therefore have classes meeting, after the intersection product is available, in cd points, which is Bézout's theorem ([30, Bézout's Theorem]) read off from $h_1 \cdot h_1 = h_0$.

3. *A plane curve as a curve in its own right.* Let $C \subseteq \mathbb{P}^2$ be a smooth plane curve of degree d, so C is a smooth projective curve of genus $g = \binom{d-1}{2}$. Two computations of its Chow groups coexist. Viewed inside $\mathbb{P}^2$, the class $[C] = d\,h_1 \in A_1(\mathbb{P}^2)$ records only its degree. Viewed intrinsically, proposition 10.5.3 gives $A_0(C) \cong \mathrm{Cl}\,C = \mathrm{Pic}\,C$ with its degree sequence $0 \to \mathrm{Pic}^0 C \to A_0(C) \to \mathbb{Z} \to 0$, and for $d \geq 3$ the genus is positive, so $\mathrm{Pic}^0 C$ is nontrivial and $A_0(C)$ is strictly larger than $\mathbb{Z}$. The pushforward $A_0(C) \to A_0(\mathbb{P}^2) = \mathbb{Z}$ along the inclusion is the degree map, collapsing all of $\mathrm{Pic}^0 C$ to zero: the intrinsic Chow group of the curve sees the moduli that the ambient projective plane cannot.

Exercise 10.5.1

1. Compute $A_*(\mathbb{A}^2 \setminus \{p\})$, the Chow groups of the affine plane with one closed point removed. (Use the localization sequence for the closed point inside $\mathbb{A}^2$ together with proposition 10.5.1.)

2. Let $H \cong \mathbb{P}^{n-1}$ be a hyperplane in $\mathbb{P}^n$ and $U = \mathbb{P}^n \setminus H \cong \mathbb{A}^n$ its complement. Using the localization sequence, show directly that $j^*\colon A_k(\mathbb{P}^n) \to A_k(\mathbb{A}^n)$ is an isomorphism for $k = n$ and the zero map for $k < n$, and reconcile this with theorem 10.5.2.

3. Let $Q \subseteq \mathbb{P}^3$ be a smooth quadric surface. Assuming the isomorphism $Q \cong \mathbb{P}^1 \times \mathbb{P}^1$ and that $A_*(\mathbb{P}^1 \times \mathbb{P}^1)$ is free on the classes of a point, the two rulings, and the fundamental class, determine the rank of each $A_k(Q)$ and describe generators. Compare with $A_*(\mathbb{P}^2)$ and explain why $A_1(Q)$ has rank 2 rather than 1.

4. For $\mathbb{P}^m$ and $\mathbb{P}^n$, use theorem 10.5.2 and the projective-bundle formula (with $\mathbb{P}^m \times \mathbb{P}^n =$

$\mathbb{P}(\mathcal{O}^{\oplus(m+1)})$ over $\mathbb{P}^n$) to show that $A_k(\mathbb{P}^m \times \mathbb{P}^n)$ is free of rank equal to the number of pairs (i, j) with $0 \le i \le m$, $0 \le j \le n$, and $i + j = k$.

5. Let C be a smooth projective curve of genus 1 over $\overline{k}$. Show that $A_0(C)$ is not finitely generated, and identify the classes $[p] - [q]$ of differences of points inside $\operatorname{Pic}^0 C$. Contrast with $A_0(\mathbb{P}^1)$.

6. Let $X \subseteq \mathbb{A}^3$ be the affine cone $x^2 + y^2 = z^2$ over a conic, a surface singular at the origin. Using $A_k(X) = A_k(X_{\mathrm{red}})$ and the vanishing of $A_k(\mathbb{A}^n)$ in low degree as a guide, determine $A_2(X)$ and explain why the singular point does not contribute a class in $A_0(X)$ that survives rational equivalence.

10.6 Summary

Everything later in the book is built from the two functorialities of this chapter, and later chapters cite them singly rather than as a group. They are collected here with the hypothesis each one costs and the effect each has on dimension.

Operation	**Needs**	**Effect on A_k**	**Proved in**
f_*	f proper	$A_k(X) \to A_k(Y)$	theorem 10.2.3
g^*	g flat of relative dimension n	$A_k(X) \to A_{k+n}(X')$	proposition 10.3.7
deg	X complete	$A_0(X) \to \mathbb{Z}$	definition 10.2.4

The two interact on a fibre square, $g^* f_* = f'_* g'^*$ (proposition 10.3.6), and this is the compatibility every later base-change argument runs through; proposition 10.3.5 collects the remaining formal properties of g^*, including that it takes the fundamental cycle of the base to that of the total space.

Two exact tools cut a Chow group into pieces. For a closed $Z \subseteq X$ with open complement U,

$$A_k(Z) \longrightarrow A_k(X) \longrightarrow A_k(U) \longrightarrow 0$$

is exact (theorem 10.4.1), with the two-subscheme form in corollary 10.4.3; and flat pullback along an affine bundle of relative dimension n is an isomorphism $A_k(X) \to A_{k+n}(E)$ (theorem 10.4.6). The computations of section 10.5 are these two applied in turn: $A_*(\mathbb{A}^n)$ in proposition 10.5.1, $A_*(\mathbb{P}^n)$ free on $[\mathbb{P}^k]$ in theorem 10.5.2, and A_0 of a smooth projective curve in proposition 10.5.3, where the genus first obstructs collapse.

One hypothesis recurs and is easy to mislay: f_* requires properness and g^* requires flatness, and neither is available for a general morphism. The Gysin maps of chapter 13 exist to supply pullback where flatness fails.

11

Divisors, Line Bundles, and the First Chern Class

Chapter 10 built the Chow groups and their two functorialities, proper pushforward and flat pullback, but produced no way to multiply cycles: nothing so far intersects a k-cycle with anything to lower its dimension. The first and most basic such operation is intersection with a divisor. A Cartier divisor D on X, equivalently a line bundle together with a rational section, cuts each subvariety V not contained in its support down to a $(k-1)$-cycle $D \cdot [V]$, the divisor of the restricted section. This chapter makes that operation precise, proves it descends to rational equivalence, and establishes its one indispensable property, commutativity: intersecting with D and then with D' agrees with intersecting in the other order.

Commutativity is not a formality. It is the identity whose proof, resting on the vanishing degree of a principal divisor on a complete curve, gives the well-definedness that the affine-bundle-invariance theorem of section 10.4 took on faith. Packaging intersection with a divisor as the *first Chern class* $c_1(L) \cap -$ of the associated line bundle turns these results into the seed of the entire theory of Chern classes, developed for bundles of higher rank in the chapter that follows.

11.1 Cartier Divisors, Line Bundles, and the Class Map

The Chow group of section 10.1 is graded by dimension, and every construction of sections 10.2 to 10.4 either preserves the grading (proper pushforward, flat pullback of the fundamental class) or shifts it by the fixed relative dimension of a flat map. What is still missing is an operation that *lowers* dimension by one, cutting a k-cycle down to a $(k-1)$-cycle by intersecting it with a hypersurface. The classical prototype is Bézout's theorem: a curve of degree d and a curve of degree e in $\mathbb{P}^2$ meet in de points. The intersection is a codimension-one operation, and the object one intersects with is a

divisor. This section sets up the divisor side of that operation. It recalls, from *Algebraic Geometry* [9], the two faces of a divisor (the geometric Weil divisor and the sheaf-theoretic Cartier divisor) and the line bundle that packages the Cartier data, then constructs the first bridge from divisor theory to the Chow group: the class map $\mathrm{Pic}\,(X) \to A_{n-1}(X)$ sending a line bundle to the cycle of its rational sections. The intersection operation itself, and the proof that it is well defined on rational equivalence, occupy section 11.2; here the goal is to fix the input and record how it sits inside the Chow group of a fixed variety.

Throughout, X is an algebraic scheme over $\overline{k}$ and V ranges over subvarieties (closed integral subschemes); a point is a closed point, and $n = \dim X$.

Algebraic Geometry [9] developed two theories of divisors, and the reader who has that material in hand can move quickly here. A *Weil divisor* (definition 5.4.5) on a Noetherian integral separated scheme regular in codimension one is a finite formal integer combination $\sum_i n_i[Y_i]$ of prime divisors, where a prime divisor is a codimension-one subvariety. This is precisely a codimension-one algebraic cycle in the sense of section 10.1: when $\dim X = n$, the group $\mathrm{WDiv}\,X$ of Weil divisors is exactly the cycle group $Z_{n-1}(X)$. A *principal divisor* $\mathrm{div}(f) = \sum_Y \nu_Y(f)[Y]$ (definition 5.4.7) records the zeros and poles of a rational function $f \in K(X)^*$, weighted by the order ν_Y measured in the discrete valuation ring $\mathcal{O}_{X,\eta_Y}$; this is the same order-along-a-subvariety $\mathrm{ord}_Y(f)$ that defines rational equivalence in definition 10.1.1. The divisor class group $\mathrm{Cl}\,X = \mathrm{WDiv}\,X/\mathrm{PDiv}(X)$ of definition 5.4.8 is therefore literally the top Chow group $A_{n-1}(X)$ in the case where the only cycles rationally equivalent to zero come from functions on X itself, that is, on a variety.

A *Cartier divisor* (definition 5.4.24) encodes the same data locally and sheaf-theoretically: it is a global section of $\mathscr{K}_X^*/\mathcal{O}_X^*$, represented by an open cover $\{U_i\}$ with rational functions $f_i \in \Gamma(U_i, \mathscr{K}_X^*)$ whose ratios f_i/f_j are units on overlaps. A Cartier divisor is *principal* when it comes from a single global rational function; two Cartier divisors are linearly equivalent when they differ by a principal one. The gluing data $\{(U_i, f_i)\}$ builds a line bundle $\mathcal{O}_X(D)$, the sub-$\mathcal{O}_X$-module of $\mathscr{K}_X$ generated locally by f_i^{-1}, and this assignment is the heart of the theory: $D \mapsto \mathcal{O}_X(D)$ is a homomorphism $\mathrm{CDiv}\,X \to \mathrm{Pic}\,X$ that carries addition of divisors to tensor product of line bundles, sends $-D$ to the dual, and vanishes exactly on principal divisors. On an integral scheme it induces an isomorphism from the Cartier divisor class group $\mathrm{CaCl}\,X$ of definition 5.4.35 onto the whole Picard group (all of this is developed in section 5.4),

$$\mathrm{CaCl}\,X \xrightarrow{\sim} \mathrm{Pic}\,X$$

so a line bundle is the same thing as a Cartier divisor up to linear equivalence. This is the sense in which the section title lists "Cartier divisors" and "line bundles" as two names for one object.

The reader should keep both faces in view. The Cartier divisor is what one intersects with, because its local equations f_i give the equations to cut against; the line bundle $\mathcal{O}_X(D)$ is the coordinate-free invariant, the thing that survives when the choice of local equations is forgotten. The class map built below is precisely the passage from the line bundle back to a well-defined cycle class.

The two theories agree under a regularity hypothesis, and pinning down that hypothesis is what makes the class map land in the Chow group cleanly. The point is one of local principality: a Weil divisor is Cartier exactly when each of its prime divisors is locally cut out by a single equation. Regularity in codimension one is enough to send a Cartier divisor to a Weil divisor; local factoriality is what makes the map an isomorphism.

Proposition 11.1.1: Weil-Cartier Comparison

Let X be a variety of dimension n over $\overline{k}$.

1. If X is regular in codimension one (for instance X normal), there is a homomorphism
$$\mathrm{CDiv}\, X \longrightarrow \mathrm{WDiv}\, X = Z_{n-1}(X), \qquad D \longmapsto [D]$$
carrying principal Cartier divisors to principal Weil divisors. In local data $D = \{(U_i, f_i)\}$ the associated Weil cycle is $[D] = \sum_Y \nu_Y(f_i)[Y]$, the coefficient of a prime divisor Y being $\nu_Y(f_i)$ for any index i with $\eta_Y \in U_i$.
2. If X is locally factorial (every local ring $\mathcal{O}_{X,x}$ is a unique factorization domain; smooth varieties qualify), this map is an isomorphism $\mathrm{CDiv}\, X \xrightarrow{\sim} \mathrm{WDiv}\, X$ carrying principal divisors to principal divisors, hence an isomorphism of class groups
$$\mathrm{Pic}\, X \;\cong\; \mathrm{CaCl}\, X \;\cong\; \mathrm{Cl}\, X \;=\; A_{n-1}(X)$$

***Proof*:**
Both parts are proved in full in section 5.4 and only recalled here. The homomorphism of part (1) is proposition 5.4.32, and its upgrade to an isomorphism under local factoriality (part (2)) is proposition 5.4.33; the resulting chain of class-group isomorphisms $\mathrm{Pic}\, X \cong \mathrm{CaCl}\, X \cong \mathrm{Cl}\, X$ is corollary 5.4.45. Only the final equality $\mathrm{Cl}\, X = A_{n-1}(X)$ is new to this Part, and it is the identification made in the paragraph below: on a variety the codimension-one cycles modulo rational equivalence are exactly the Weil divisors modulo principal divisors, both quotients of $Z_{n-1}(X)$ by $\mathrm{PDiv}(X)$, as we sought to show.

The equality $\mathrm{Cl}\, X = A_{n-1}(X)$ deserves a moment's reflection, because it is easy to mistake for a definition. Rational equivalence on $Z_{n-1}(X)$ is generated by cycles $[\mathrm{div}(r)]$ where r is a rational function on a subvariety $W \subseteq X$ of dimension n. On a variety X, the only n-dimensional subvariety is X itself, so those generators are exactly the principal Weil divisors $\mathrm{div}(r)$ with $r \in K(X)^*$. Hence $A_{n-1}(X) = Z_{n-1}(X)/\mathrm{Rat}_{n-1}(X)$ and $\mathrm{Cl}\, X = \mathrm{WDiv}\, X/\mathrm{PDiv}(X)$ are the same quotient of the same group. Linear equivalence of divisors *is* rational equivalence of codimension-one cycles. This is what will let the class map below produce Chow classes, not just divisor classes.

Example 11.1.2: The Quadric Cone: Cartier Strictly Inside Weil
The comparison map need not be surjective when factoriality fails. On the affine quadric cone $X = \mathrm{Spec}\, \overline{k}[x, y, z]/(xy - z^2)$, a normal surface singular at the vertex, example 5.4.36 computes that the ruling $Y = V(y, z)$ is a Weil divisor which is not Cartier at the vertex, while its double $2[Y] = \mathrm{div}(y)$ is, so
$$\mathrm{CaCl}\, X = 0 \subsetneq \mathrm{Cl}\, X = \mathbb{Z}/2\mathbb{Z} = A_1(X)$$
the final equality being the identification $\mathrm{Cl}\, X = A_{n-1}(X)$ of proposition 11.1.1. Normality gives part (1), but the vertex obstructs local principality, so part (2) fails; on a smooth variety no such gap exists and Weil, Cartier, Picard, and A_{n-1} all coincide.

On a smooth variety the isomorphism $\mathrm{Pic}\, X \cong A_{n-1}(X)$ of proposition 11.1.1 already provides a bridge from line bundles to Chow classes. To intersect and to compute Chern classes on *arbitrary*

algebraic schemes, one needs this bridge without any regularity hypothesis, and one needs it stated at the level of line bundles rather than Cartier divisors, so that the input is a coordinate-free invariant. The construction is direct: a line bundle L has rational sections, a rational section has a divisor of zeros and poles, and that divisor is a codimension-one cycle whose class in $A_{n-1}(X)$ turns out not to depend on the section chosen.

Fix a variety X of dimension n with function field $K(X)$, and a line bundle L on X. A *rational section* of L is a nonzero section of $L \otimes_{\mathcal{O}_X} K(X)$ over X, equivalently a section of L over some nonempty open subset. Since X is a variety, $L \otimes K(X)$ is a one-dimensional $K(X)$-vector space, so rational sections exist and any two differ by multiplication by an element of $K(X)^*$. On the open set where s is defined and nonvanishing, s trivializes L; along each prime divisor Y one may compare s with a local trivialization of L near η_Y and read off an integer $\operatorname{ord}_Y(s)$, the order of vanishing (or of the pole) of s along Y. Concretely, if t is a local generator of L near η_Y and $s = g \cdot t$ with $g \in K(X)^*$, set $\operatorname{ord}_Y(s) := \nu_Y(g)$; a different generator $t' = ut$ with $u \in \mathcal{O}^*_{X,\eta_Y}$ changes g to $u^{-1}g$ and leaves $\nu_Y(g)$ unchanged, so $\operatorname{ord}_Y(s)$ is well defined. The *divisor of* s is the Weil divisor

$$\operatorname{div}(s) \;=\; \sum_{Y} \operatorname{ord}_Y(s)\,[Y] \;\in\; Z_{n-1}(X)$$

finite because s is a regular nonvanishing section over some nonempty open $U \subseteq X$, where it trivializes L and so $\operatorname{ord}_Y(s) = 0$ for every prime divisor Y meeting U; the only possible contributors are the finitely many prime divisors in the proper closed complement $X \setminus U$. This is the same finiteness that makes the principal divisor $\operatorname{div}(f)$ of definition 5.4.7 a well-defined cycle. If $L = \mathcal{O}_X(D)$ for a Cartier divisor D and s is the canonical rational section (the constant $1 \in \mathscr{K}_X$, which against the local generator f_i^{-1} of $\mathcal{O}_X(D)|_{U_i}$ is written $1 = f_i \cdot f_i^{-1}$, giving $\operatorname{ord}_Y(s) = \nu_Y(f_i)$), then $\operatorname{div}(s)$ is exactly the Weil cycle $[D]$ of proposition 11.1.1.

Proposition 11.1.3: The Class Map

Let X be a variety of dimension n. For a line bundle L on X, choose any nonzero rational section s of L and set

$$c(L) \;:=\; [\operatorname{div}(s)] \;\in\; A_{n-1}(X)$$

Then $c(L)$ is independent of the choice of s, and the resulting assignment

$$c\colon \operatorname{Pic} X \longrightarrow A_{n-1}(X), \qquad L \longmapsto c(L)$$

is a group homomorphism. When X is locally factorial (in particular smooth), c is the isomorphism $\operatorname{Pic} X \cong A_{n-1}(X)$ of proposition 11.1.1; on a general variety c need be neither injective nor surjective.

***Proof*:**

Step 1: independence of the section. Let s, s' be two nonzero rational sections of L. Both lie in the one-dimensional $K(X)$-vector space $L \otimes K(X)$, so $s' = gs$ for a unique $g \in K(X)^*$. Along each prime divisor Y, choose a local generator t of L near η_Y and write $s = at$, $s' = a't$ with $a, a' \in K(X)^*$; then $a' = ga$ and

$$\operatorname{ord}_Y(s') = \nu_Y(a') = \nu_Y(g) + \nu_Y(a) = \nu_Y(g) + \operatorname{ord}_Y(s)$$

because ν_Y is a valuation. Summing over Y gives $\operatorname{div}(s') = \operatorname{div}(g) + \operatorname{div}(s)$ in $Z_{n-1}(X)$, where $\operatorname{div}(g) = \sum_Y \nu_Y(g)[Y]$ is the principal Weil divisor of $g \in K(X)^*$. Since $\operatorname{div}(g)$ is a principal

divisor on the variety X, it is rationally equivalent to zero in $A_{n-1}(X)$ by the identification $\mathrm{Rat}_{n-1}(X) = \mathrm{PDiv}(X)$ recorded after proposition 11.1.1. Hence $[\mathrm{div}(s')] = [\mathrm{div}(s)]$ in $A_{n-1}(X)$, and $c(L)$ is well defined.

Step 2: homomorphism property. Let L, L' be line bundles with rational sections s, s'. Then $s \otimes s'$ is a nonzero rational section of $L \otimes L'$, and along each prime divisor Y, choosing local generators t of L and t' of L' near η_Y and writing $s = at$, $s' = a't'$, the product $s \otimes s' = (aa')(t \otimes t')$ is expressed against the local generator $t \otimes t'$ of $L \otimes L'$. Thus

$$\mathrm{ord}_Y(s \otimes s') = \nu_Y(aa') = \nu_Y(a) + \nu_Y(a') = \mathrm{ord}_Y(s) + \mathrm{ord}_Y(s')$$

so $\mathrm{div}(s \otimes s') = \mathrm{div}(s) + \mathrm{div}(s')$, and passing to classes gives $c(L \otimes L') = c(L) + c(L')$. The trivial bundle $\mathcal{O}_X$ has the rational section 1 with $\mathrm{div}(1) = 0$, so $c(\mathcal{O}_X) = 0$, and $c(L^{-1}) = -c(L)$ follows from $L \otimes L^{-1} = \mathcal{O}_X$. Therefore c is a homomorphism.

Step 3: comparison with the smooth case. When X is locally factorial, every line bundle is $\mathcal{O}_X(D)$ for a Cartier divisor D, and the canonical rational section of $\mathcal{O}_X(D)$ has $\mathrm{div}(s) = [D]$, the Weil cycle of D. Under $\mathrm{Pic}\, X \cong \mathrm{CaCl}\, X$ (section 5.4) and $\mathrm{CaCl}\, X \cong \mathrm{Cl}\, X = A_{n-1}(X)$ (proposition 11.1.1), the assignment $L = \mathcal{O}_X(D) \mapsto [D]$ is exactly that isomorphism, so c is an isomorphism. On a variety where these hypotheses fail, c can lose injectivity or surjectivity, as example 11.1.2 shows for the class-group comparison. This completes the proof.

The class map is the first of the two ways line bundles act on the Chow group. It records *where* a line bundle is, as a codimension-one class $c(L) \in A_{n-1}(X)$, but it does not yet say how L intersects cycles of other dimensions. That is the job of the operator $c_1(L) \cap -$ built in section 11.4, whose value on the fundamental class $[X]$ recovers $c(L)$: writing ahead, $c_1(L) \cap [X] = c(L)$. The class map is thus the top-dimensional case of the full first Chern class, and everything in this chapter can be read as promoting c from a map on line bundles to an operator on all of $A_*(X)$.

The value of stating c at the level of line bundles, rather than resting on the isomorphism $\mathrm{Pic} \cong A_{n-1}$, is that c makes sense with no regularity hypothesis on X: a rational section and its order along a prime divisor require only that X be a variety, and the group $A_{n-1}(X)$ is defined for every algebraic scheme. The intersection theory of section 11.2 is built for arbitrary X, and it needs c in this general form.

Example 11.1.4: The Class Map on Projective Space

Projective space is where every ingredient can be computed by hand. Since $\mathbb{P}^n$ has all local rings unique factorization domains, it is locally factorial, so $\mathrm{Pic}\, \mathbb{P}^n \cong \mathrm{Cl}\, \mathbb{P}^n \cong \mathbb{Z}$, generated by $\mathcal{O}_{\mathbb{P}^n}(1)$, and by theorem 10.5.2 the top Chow group is $A_{n-1}(\mathbb{P}^n) = \mathbb{Z}\,[\mathbb{P}^{n-1}]$, generated by the class of a hyperplane. The class map identifies the two.

A rational section of $\mathcal{O}_{\mathbb{P}^n}(1)$ is a nonzero linear form. Take $s = x_0$, the section whose zero scheme is the hyperplane $H = V_+(x_0)$, whose Cartier data $\{(U_i, x_0/x_i)\}$ was recorded in example 5.4.36. On the standard chart $U_i = D_+(x_i) \cong \mathbb{A}^n$ the sheaf $\mathcal{O}_{\mathbb{P}^n}(1)$ is trivialized by x_i, and $s = x_0 = (x_0/x_i)\, x_i$, so s corresponds to the rational function $x_0/x_i \in K(\mathbb{P}^n)$ against the generator x_i. Along the prime divisor H, the generic point lies in charts U_i with $i \neq 0$, where x_0/x_i is a local equation cutting out H with order one, so $\mathrm{ord}_H(s) = 1$; along every other prime divisor x_0/x_i is a unit near the generic point, contributing zero. Hence

$$\mathrm{div}(x_0) = [H] = [\mathbb{P}^{n-1}], \qquad c\big(\mathcal{O}_{\mathbb{P}^n}(1)\big) = [\mathbb{P}^{n-1}] \in A_{n-1}(\mathbb{P}^n)$$

Choosing instead $s = x_1$ gives the hyperplane $V_+(x_1)$, a different divisor but the same class: $x_1 =$

$(x_1/x_0)\,x_0$ differs from x_0 by the rational function x_1/x_0, and $\operatorname{div}(x_1) - \operatorname{div}(x_0) = \operatorname{div}(x_1/x_0) \sim 0$, confirming the independence of proposition 11.1.3 in this case. More generally, $\mathcal{O}_{\mathbb{P}^n}(d)$ has rational sections given by degree-d forms; the section x_0^d has divisor $d[H]$, so $c(\mathcal{O}_{\mathbb{P}^n}(d)) = d\,[\mathbb{P}^{n-1}]$, and $c\colon \mathbb{Z} \to \mathbb{Z}$ is the identity. The generator $\mathcal{O}(1)$ of Pic maps to the generator [hyperplane] of A_{n-1}, and the class map is the announced isomorphism $\mathbb{Z} \xrightarrow{\sim} \mathbb{Z}$.

There is one further refinement to record before intersecting, and it addresses a bookkeeping problem rather than a new geometric idea. When a Cartier divisor D is intersected with a subvariety V, one wants the resulting cycle to live on $V \cap |D|$, the part of V where D cuts, not just somewhere on V. Localizing the answer to the support is what makes the intersection product refined enough to carry information (for instance, an excess-intersection or a self-intersection formula) and what makes it functorial under the localization sequence of theorem 10.4.1. The device that carries this localized data is the *pseudo-divisor*: a line bundle, a chosen closed support, and a trivialization of the bundle away from that support.

Definition 11.1.5: Pseudo-Divisor

Let X be an algebraic scheme. A *pseudo-divisor* on X is a triple

$$\mathfrak{D} = (L, Z, s)$$

consisting of a line bundle L on X, a closed subset $Z \subseteq X$ (the *support*, written $|\mathfrak{D}|$), and a trivialization $s\colon \mathcal{O}_{X\setminus Z} \xrightarrow{\sim} L|_{X\setminus Z}$ of L over the complement of Z. The line bundle L is denoted $\mathcal{O}_X(\mathfrak{D})$.

A Cartier divisor D on X determines a pseudo-divisor $(\mathcal{O}_X(D),\ |D|,\ s_D)$ whose support is the support $|D|$ of D and whose trivialization s_D is the canonical rational section of $\mathcal{O}_X(D)$, which is a nonvanishing regular section away from $|D|$. Two Cartier divisors D, D' with the same support and the same associated line bundle give the same pseudo-divisor when their canonical sections agree off the support.

The three pieces of data are exactly what a divisor gives for cutting. The line bundle L is the coordinate-free invariant whose class map value is $c(L)$; the support Z pins down where the cutting happens, so the product lands in $A_*(Z)$ rather than $A_*(X)$; and the trivialization s off Z is what lets one measure orders of vanishing, because on the locus where L is trivialized by s there is nothing to cut, and all the divisorial content is concentrated on Z. A Cartier divisor is the special case where $Z = |D|$ is as small as possible, but allowing Z to be larger is what gives the flexibility to restrict, pull back, and add pseudo-divisors while keeping supports under control. Section 11.2 carries this out for Cartier divisors rather than for pseudo-divisors: for a subvariety V not contained in the support it defines $D \cdot [V]$ as a class in $A_{k-1}(V \cap |D|)$, and when $V \subseteq |D|$ the restricted line bundle $\mathcal{O}_X(D)|_V$ gives the answer through its own class map. The pseudo-divisor is recorded here because it is the shape the restricted data take, and corollary 11.4.5 is where that shape does its work.

Example 11.1.6: The Pseudo-Divisor of a Hyperplane

Let $X = \mathbb{P}^n$ and $H = V_+(x_0)$ the hyperplane at $x_0 = 0$. The associated pseudo-divisor is

$$\mathfrak{H} = \big(\mathcal{O}_{\mathbb{P}^n}(1),\ H,\ s\big)$$

with support the hyperplane H and trivialization s given by the section x_0 over the complement $\mathbb{P}^n \setminus H = D_+(x_0) \cong \mathbb{A}^n$, where x_0 is nonvanishing and so trivializes $\mathcal{O}(1)$. The line bundle $\mathcal{O}_{\mathbb{P}^n}(1)$ carries the class $c(\mathcal{O}(1)) = [H] \in A_{n-1}(\mathbb{P}^n)$ computed in example 11.1.4; the support restricts any

intersection against $\mathfrak{H}$ to H; and the trivialization records that off H the hyperplane cuts nothing. Intersecting $\mathfrak{H}$ with a subvariety $V \not\subseteq H$ will, in section 11.2, produce the cycle $[V \cap H]$ with its multiplicities, supported on $V \cap H$, which is the algebraic incarnation of Bézout's degree count.

The class map and the pseudo-divisor together fix the two ways a line bundle enters intersection theory: as a class $c(L) \in A_{n-1}(X)$, which is its total content, and as a localized cutting datum (L, Z, s), which is how it acts. With the input settled, the operation $\mathfrak{D} \cdot -$ can be defined and shown well defined on rational equivalence, which is the subject of section 11.2.

Exercise 11.1.1

1. Let $X = \mathbb{P}^n$ and let $Q = V_+(q)$ be a smooth quadric hypersurface, cut out by a nondegenerate quadratic form q. Compute $c(\mathcal{O}_{\mathbb{P}^n}(Q))$, the class map value of the line bundle of Q, in $A_{n-1}(\mathbb{P}^n) = \mathbb{Z}\,[\mathbb{P}^{n-1}]$, and explain the answer in terms of the degree of Q.

2. Let X be a variety and $r \in K(X)^*$ a nonzero rational function. Show that the line bundle $\mathcal{O}_X(\operatorname{div}(r))$ associated to the principal Cartier divisor $\operatorname{div}(r)$ is trivial, and deduce that $c(\mathcal{O}_X(\operatorname{div}(r))) = 0$ directly from proposition 11.1.3. Which step of the class-map construction is this computing?

3. On the affine quadric cone $X = \operatorname{Spec} \overline{k}[x, y, z]/(xy - z^2)$ of example 11.1.2, the class map $c\colon \operatorname{Pic} X \to A_1(X)$ is a homomorphism $\operatorname{CaCl} X \to \operatorname{Cl} X$. Using the values $\operatorname{CaCl} X = 0$ and $\operatorname{Cl} X = \mathbb{Z}/2\mathbb{Z}$ from that example, describe c explicitly and state whether it is injective, surjective, or neither. What does this say about the necessity of the factoriality hypothesis in proposition 11.1.1(2)?

4. Pseudo-divisors add: given $\mathfrak{D} = (L, Z, s)$ and $\mathfrak{D}' = (L', Z', s')$, define $\mathfrak{D} + \mathfrak{D}' := (L \otimes L',\ Z \cup Z',\ s \otimes s')$. Verify that this is a well-defined pseudo-divisor, that $\mathcal{O}_X(\mathfrak{D} + \mathfrak{D}') = \mathcal{O}_X(\mathfrak{D}) \otimes \mathcal{O}_X(\mathfrak{D}')$, and that on the line-bundle level this addition is compatible with the homomorphism property of the class map in proposition 11.1.3.

5. Let L be a line bundle on a variety X, s a nonzero rational section, and Y a prime divisor. Show that the order $\operatorname{ord}_Y(s) := \nu_Y(a)$, defined by writing $s = a\,t$ against a local generator t of L near η_Y with $a \in K(X)^*$, does not depend on the choice of generator t. Then show that if s is a regular nonvanishing section of L near η_Y, then $\operatorname{ord}_Y(s) = 0$.

11.2 Intersecting with a Divisor

The class map of section 11.1 sends a line bundle to a cycle class in codimension one, but it says nothing about how that cycle meets the other cycles already living on X. This section gives the missing operation. A Cartier divisor D acts on cycles by cutting each subvariety down along the zeros and poles of a rational section, an operation that lowers dimension by one and records where the cut takes place. The construction is the first instance of a general principle of the subject, that a line bundle acts on the Chow group as an operator, and it is the operation whose associativity and commutativity the rest of the chapter is built to establish.

The geometry is the one already met in codimension one. A Cartier divisor is locally the divisor of a single rational function f_i on an open U_i, and the transition ratios f_i/f_j are units, so the zeros and poles of the local equations patch to a well-defined codimension-one cycle on X. To intersect D with

a k-dimensional subvariety V, restrict this local data to V and read off the resulting $(k-1)$-cycle on V. Two features force themselves on the construction. First, the answer is supported on the intersection $V \cap |D|$, since away from the support of D the local equations are units and contribute nothing. Second, the recipe stumbles when V lies inside $|D|$, where the local equations $f_i|_V$ may vanish identically and $\operatorname{div}(f_i|_V)$ is undefined; the trivialization off $|D|$ is exactly what is lost. The definition below treats the two cases separately and unifies them through the restricted line bundle.

Definition 11.2.1: Intersection with a Cartier Divisor

Let D be a Cartier divisor on X with support $|D|$ and associated line bundle $\mathcal{O}_X(D)$, and let $V \subseteq X$ be a k-dimensional subvariety. The *intersection class* $D \cdot [V] \in A_{k-1}(V \cap |D|)$ is defined as follows.

1. If $V \not\subseteq |D|$, then the local equations of D restrict to a nonzero rational function s_V on V: choosing a representative $\{(U_i, f_i)\}$ of D, the ratios $f_i|_V$ agree up to units on overlaps and glue to a rational section s_V of $\mathcal{O}_X(D)|_V$ that is nonzero on the dense open $V \setminus |D|$. Its divisor is a $(k-1)$-cycle supported on $V \cap |D|$, and one sets
$$D \cdot [V] = \big[\operatorname{div}(s_V)\big] \in A_{k-1}(V \cap |D|)$$
2. If $V \subseteq |D|$, then no such nonzero section exists, and one instead uses the restricted line bundle. The class map of proposition 11.1.3 applied to $\mathcal{O}_X(D)|_V$ produces a class in $A_{k-1}(V)$; since $V \subseteq |D|$ gives $V \cap |D| = V$, one sets
$$D \cdot [V] = c\big(\mathcal{O}_X(D)|_V\big) \in A_{k-1}(V) = A_{k-1}(V \cap |D|)$$

Extending $\mathbb{Z}$-linearly over the subvarieties appearing in a cycle $\alpha = \sum_i n_i [V_i]$ gives the *intersection cycle* $D \cdot \alpha = \sum_i n_i \, (D \cdot [V_i])$, a class in $A_{k-1}(|D| \cap \operatorname{Supp} \alpha)$, where $\operatorname{Supp} \alpha = \bigcup_i V_i$.

Two conventions in the definition deserve unpacking, since both recur throughout the theory. The first is that the intersection class is recorded on the intersection $V \cap |D|$, not on all of X. This is a refinement one does not want to discard prematurely: the intersection of a curve with a divisor is a set of points on the curve, and remembering that the points lie in $V \cap |D|$ is exactly what makes localized intersection numbers and excess-intersection formulas possible later. When only the class in $A_{k-1}(X)$ is wanted, push forward along the inclusion $V \cap |D| \hookrightarrow X$, a proper map. The second convention is the treatment of $V \subseteq |D|$. Here the naive recipe fails because the local equations restrict to zero, so there is no rational section to take the divisor of; but $\mathcal{O}_X(D)|_V$ is still a line bundle on V, and its class under the class map $c\colon \operatorname{Pic}(V) \to A_{k-1}(V)$ of proposition 11.1.3 is a $(k-1)$-cycle class. Both clauses are the same construction, taking the class of the restricted bundle $\mathcal{O}_X(D)|_V$. When $V \not\subseteq |D|$ the bundle comes with a preferred rational section s_V and the class is computed as $[\operatorname{div}(s_V)]$; when $V \subseteq |D|$ that section degenerates and only the bundle survives. The packaging of the whole operation as the first Chern class $c_1(\mathcal{O}_X(D)) \cap -$ is the subject of section 11.4.

That the operation lowers dimension by exactly one is built into the definition: the divisor of a rational section on a k-dimensional variety is a codimension-one cycle, hence $(k-1)$-dimensional. Geometrically, $D \cdot [V]$ is the divisor cut out on V by the equation defining D, the higher-dimensional form of substituting a curve into the equation of a hypersurface and reading off the intersection points with multiplicity. The next example shows this in the case a reader already knows from the classical degree of a plane curve.

Example 11.2.2: A Hyperplane Meeting a Plane Curve

Let $X = \mathbb{P}^2$ with homogeneous coordinates $[x_0 : x_1 : x_2]$, let $H = \{x_0 = 0\}$ be the line at infinity, a Cartier divisor with $\mathcal{O}_{\mathbb{P}^2}(H) = \mathcal{O}_{\mathbb{P}^2}(1)$, and let $V \subseteq \mathbb{P}^2$ be a smooth conic, say the closure of $\{x_1^2 = x_0 x_2\}$, a subvariety of dimension 1 not contained in H. The unique intersection point turns out to be $p = [0 : 0 : 1]$, which lies in the chart $U_2 = \{x_2 \neq 0\}$; work there, with affine coordinates $u = x_0/x_2$ and $v = x_1/x_2$. On U_2 the conic is $V = \{u = v^2\}$ (from $x_1^2 = x_0 x_2$), the divisor $H = \{x_0 = 0\}$ is $\{u = 0\}$, and against the local generator x_2 of $\mathcal{O}_{\mathbb{P}^2}(1)$ the section x_0 representing H is the function $x_0/x_2 = u$. Its restriction to V is $s_V = u|_V = v^2$, which vanishes exactly where V meets H: $u = 0$ forces $v = 0$, so p is the only intersection point, and there V is tangent to H. In the local coordinate v on V near p, the function $s_V = v^2$ has a double zero (the conic meets its tangent line to order two), so

$$H \cdot [V] = \big[\operatorname{div}(s_V)\big] = 2\,[p] \in A_0(V \cap H)$$

Pushing forward to $\mathbb{P}^2$ and taking degrees gives $\deg(H \cdot [V]) = 2$, the degree of the conic. The intersection class remembers more than the number 2: it records that both units of intersection are concentrated at the single point p, information the bare degree discards.

The example illustrates the two things the intersection class is meant to capture, the total count and its distribution, and shows how the classical intersection number of two plane curves reappears as the degree of $D \cdot [V]$. For a curve V of degree d and a line H in general position the same computation gives d distinct simple points, and $\deg(H \cdot [V]) = d$ in every case; this is the statement, once the well-definedness below is in hand, that intersecting with a hyperplane computes the degree. Before turning to that, the second worked example records the complementary phenomenon, what happens when V lies inside the support of D, so that the second clause of definition 11.2.1 applies.

Example 11.2.3: A Divisor Restricted to a Component of Its Support

Let $X = \mathbb{P}^2$ again and let $D = L$ be a line, say $L = \{x_0 = 0\}$, so $|D| = L$ and $\mathcal{O}_{\mathbb{P}^2}(L) = \mathcal{O}_{\mathbb{P}^2}(1)$. Take $V = L$ itself, a 1-dimensional subvariety contained in $|D|$. The first clause does not apply, since x_0 restricts to zero on L; the second clause instructs one to compute the class of the restricted line bundle $\mathcal{O}_{\mathbb{P}^2}(1)|_L$. Now $L \cong \mathbb{P}^1$, and $\mathcal{O}_{\mathbb{P}^2}(1)|_L = \mathcal{O}_{\mathbb{P}^1}(1)$ by the adjunction of the hyperplane bundle to a linear subspace. The class map $\operatorname{Pic}(\mathbb{P}^1) = \mathbb{Z} \to A_0(\mathbb{P}^1) = \mathbb{Z}$ of proposition 11.1.3 carries $\mathcal{O}_{\mathbb{P}^1}(1)$ to the class of a single point $[q]$, so

$$L \cdot [L] = c\big(\mathcal{O}_{\mathbb{P}^2}(1)|_L\big) = [q] \in A_0(L)$$

the class of one point on L. This is the self-intersection $L \cdot L = 1$ of a line in the plane, the positive-degree form of the fact that two distinct lines meet in one point: moving L to a nearby line L' and intersecting $L \cdot [L'] = [L \cap L']$ recovers the same class, now visibly one transverse point. The second clause of the definition is what lets self-intersection make sense at all, since a divisor cannot literally be substituted into a variety it defines.

The two examples exhibit the operation on both sides of the containment condition and already hint at the compatibility the operation must have with rational equivalence. In example 11.2.3 the value $L \cdot [L]$ was computed by restricting the bundle, but it was also claimed to agree with $L \cdot [L']$ for a nearby line L', obtained by the first clause. Since $L \sim L'$ as divisors, these two computations must give the same class if the operation is to depend only on the rational-equivalence class of the cycle, and only then does the self-intersection number deserve its name. Establishing that agreement in

general is the content of the section, and it is the property that will let the intersection class be defined on the Chow group rather than on cycles alone.

The stake is higher than notational convenience. Intersection with a divisor is meant to be an operator on $A_*(X)$, so that $D \cdot -$ carries $A_k(X)$ to $A_{k-1}(X)$ and can be iterated; without invariance under rational equivalence the operation lives only on cycles, where iteration is not controlled and no ring structure can form. The following proposition is the foundation of everything downstream, and it is one half of the identity (10.3) that the affine-bundle-invariance theorem of section 10.4 deferred to this chapter, the half asserting that $D \cdot -$ is well defined; the commutativity half is section 11.3.

Proposition 11.2.4: Rational Invariance of Divisor Intersection

Let D be a Cartier divisor on X. If $\alpha \in Z_k(X)$ is rationally equivalent to zero and no component of α lies in $|D|$, then $D \cdot \alpha \sim 0$ in $A_{k-1}(|D|)$. Consequently $D \cdot -$ annihilates every rationally trivial cycle no component of which lies in $|D|$, which makes $D \cdot a$ well defined on any class admitting such a representative. The proof of proposition 11.4.4(3) records that no moving lemma repositions a cycle off a support in this generality; proposition 11.4.6 removes the restriction, and together they give the homomorphism

$$D \cdot -\colon A_k(X) \to A_{k-1}(|D|)$$

independent of all choices.

The proof is the technical heart of the divisor calculus, and it is worth naming the obstacle before entering it. A cycle rationally equivalent to zero is a sum of divisors $[\mathrm{div}(r)]$ of rational functions r on $(k+1)$-dimensional subvarieties W. Intersecting with D replaces each such W-divisor by its trace under the section s_W of $\mathcal{O}_X(D)|_W$, and the claim is that this trace is again a boundary. On the surface W there are now two rational functions in play, the given r and the local equation of D, and the argument turns on the symmetry between them: the order of r measured along the zeros of D matches the order of the equation of D measured along the zeros of r, up to a principal divisor. That symmetry is a statement about a two-dimensional surface, and it is proved by pushing everything down to a complete curve, where a principal divisor has degree zero. Three inputs carry the argument: this degree-zero fact, proposition 10.2.2; the reciprocity lemma on the auxiliary curve that turns it into the two-function symmetry; and the localization sequence theorem 10.4.1 reducing the boundary strata to lower dimension. The degree-zero fact is why the argument could not be given in section 10.4 before the divisor machinery was in place.

***Proof*:**

By linearity it suffices to treat a single generator of $\mathrm{Rat}_k(X)$, so let $W \subseteq X$ be a $(k+1)$-dimensional subvariety and $r \in k(W)^*$, and set $\alpha = [\mathrm{div}(r)]$. The hypothesis that no component of α lies in $|D|$ is used only to make each $D \cdot [V]$ fall under the first clause of definition 11.2.1; the reduction below produces $D \cdot \alpha$ as the divisor of a rational function, and the containment cases are absorbed at the end.

Step 1: Reduction to the surface W. Replacing X by W and D by its restriction $D|_W$ changes neither side: the components V of $[\mathrm{div}(r)]$ are codimension-one subvarieties of W, the section s_V used to form $D \cdot [V]$ is the restriction to V of the section s_W of $\mathcal{O}_X(D)|_W$, and the inclusion $W \hookrightarrow X$ carries $A_{k-1}(|D|_W|) \to A_{k-1}(|D|)$ compatibly. It therefore suffices to prove the statement with $X = W$, so that D is a Cartier divisor on the $(k+1)$-dimensional variety W, $r \in k(W)^*$, and $D \cdot [\mathrm{div}(r)]$ is to be shown rationally equivalent to zero in $A_{k-1}(W)$. Restrict

further to the dense open $W^\circ \subseteq W$ where D is principal, given by a single rational function $g \in k(W)^*$ with $\mathcal{O}_W(D)|_{W^\circ} = \mathcal{O}_{W^\circ} \cdot g^{-1}$; the codimension-one subvarieties of W meeting W° are exactly those on which the computation is nontrivial, and those contained in the complement $W \setminus W^\circ$ contribute to both a principal divisor and the divisor of D and are handled by the localization sequence in Step 4. On W° the section s_V of clause (1) is $g|_V$, so

$$D \cdot [\operatorname{div}(r)] = \sum_V \operatorname{ord}_V(r)\, \big[\operatorname{div}_V(g|_V)\big]$$

the outer sum over the codimension-one subvarieties $V \subseteq W$ with r having a zero or pole along V, and the inner divisor formed on each such V.

Step 2: The two-function symmetry. The right-hand side is not visibly symmetric in r and g, but its symmetrization is the object that vanishes. Consider the two iterated sums

$$\Phi(r,g) = \sum_V \operatorname{ord}_V(r)\, \big[\operatorname{div}_V(g|_V)\big], \qquad \Phi(g,r) = \sum_V \operatorname{ord}_V(g)\, \big[\operatorname{div}_V(r|_V)\big]$$

both $(k-1)$-cycles on W, where in each the outer sum runs over codimension-one subvarieties $V \subseteq W$ and the inner divisor is formed on V of the restricted function. The claim of this step is the tame symmetry

$$\Phi(r,g) - \Phi(g,r) \sim 0 \quad \text{in } A_{k-1}(W)$$

Granting it, the proof is nearly complete: $\Phi(g,r) = \sum_V \operatorname{ord}_V(g)\,[\operatorname{div}_V(r|_V)]$ is a $\mathbb{Z}$-linear combination of divisors of the rational functions $r|_V$ on the k-dimensional subvarieties V, hence lies in $\operatorname{Rat}_{k-1}(W)$ by definition 10.1.3; combined with the symmetry, $\Phi(r,g) = D \cdot [\operatorname{div}(r)]$ is rationally equivalent to $\Phi(g,r) \sim 0$, which is the assertion.

Step 3a: Localizing the symmetry at a codimension-two locus. The symmetry is a statement whose content is concentrated in codimension two on W, so fix a codimension-two subvariety $Z \subseteq W$, a $(k-1)$-dimensional variety, and compare the coefficients of $[Z]$ on the two sides. A codimension-one $V \subseteq W$ contributes to the coefficient of $[Z]$ in $\Phi(r,g)$ only when $Z \subseteq V$, that is when Z is a prime divisor of V; write the coefficient of $[Z]$ in $\Phi(r,g)$ as

$$c_Z(r,g) = \sum_{Z \subseteq V} \operatorname{ord}_V(r)\, \operatorname{ord}_{Z,V}(g|_V)$$

the sum over codimension-one V with $Z \subseteq V \subseteq W$, and $\operatorname{ord}_{Z,V}$ the order along Z computed on V. The task is to show $c_Z(r,g) = c_Z(g,r)$ modulo the coefficient of $[Z]$ in a principal divisor, and this is a computation on the two-dimensional local geometry of W along Z. Passing to the local ring $\mathcal{O}_{W,Z}$, a two-dimensional local domain with fraction field $L = k(W)$ and residue field $K = k(Z)$, the codimension-one V containing Z correspond to the height-one primes $\mathfrak{p} \subseteq \mathcal{O}_{W,Z}$; each carries a discrete valuation $\operatorname{ord}_{\mathfrak{p}} = \operatorname{ord}_V$ on L, and the residue field $k(\mathfrak{p})$ of $\mathfrak{p}$ is the function field $k(V)$ of the divisor V. In these terms

$$c_Z(r,g) = \sum_{\mathfrak{p}} \operatorname{ord}_{\mathfrak{p}}(r)\, \operatorname{ord}_Z(g \bmod \mathfrak{p})$$

where $g \bmod \mathfrak{p}$ is the image of g in $k(\mathfrak{p}) = k(V)^*$ and ord_Z on $k(V)$ is the order along Z regarded as a prime divisor of V. The two factors play asymmetric roles: $\operatorname{ord}_{\mathfrak{p}}(r)$ is the transverse order of r along the entire divisor V, a single integer, while $\operatorname{ord}_Z(g \bmod \mathfrak{p})$ is the order of the residue $g|_V$ along the codimension-one subvariety $Z \subseteq V$. The displayed formula presumes $\operatorname{ord}_{\mathfrak{p}}(g) = 0$,

so that g restricts to a nonzero rational function on V, and the standing hypothesis gives exactly that: the V occurring here are components of $\operatorname{div}(r)$, none of which lies in $|D|$, while on W° the support of D is $|\operatorname{div}(g)|$. So no $\mathfrak{p}$ carries a nonzero order of both r and g, and every term of the sum is defined. Swapping r and g interchanges these two roles rather than permuting equal factors, so $c_Z(r,g) = c_Z(g,r)$ is a genuine reciprocity between a transverse divisorial order and a residual order, not the commutativity of a product.

Step 3b: The exceptional curve and the tame symbol. The two integers in each term of $c_Z(r,g)$, the transverse order $\operatorname{ord}_{\mathfrak{p}}(r)$ and the residual order $\operatorname{ord}_Z(g \bmod \mathfrak{p})$, are the two ends of a single valuation datum, and completeness enters by resolving the two-dimensional geometry of $\mathcal{O}_{W,Z}$ into a curve. Choose a proper birational morphism $\pi\colon S \to \operatorname{Spec}\mathcal{O}_{W,Z}$ with S a regular two-dimensional scheme (a resolution of the localized surface, by normalization and blow-up), and let $E = \pi^{-1}(\mathfrak{m})$ be its exceptional fibre over the closed point, a complete curve over K whose integral components are $E_1, \dots, E_m$, each a complete curve over K with function field $k(E_i)$. The coefficient $c_Z(r,g)$ is invariant under π: since π is proper and birational, The pushforward bookkeeping of proposition 10.2.2, whose Steps $1'$ and 2 are stated over an arbitrary field and apply here with $\operatorname{Spec}\mathcal{O}_{W,Z}$ in place of a variety, identifies the coefficient of $[Z]$ downstairs with the coefficient of the exceptional fibre upstairs, and among the prime divisors of S only the exceptional E_i map onto Z, so the strict transforms of the V contribute to the coefficient of $[Z]$ only through their intersection points with the exceptional fibre, which is where the bookkeeping below records them. Along each exceptional component E_i the function r has a transverse order $a_i = \operatorname{ord}_{E_i}(r)$ and g a transverse order $b_i = \operatorname{ord}_{E_i}(g)$, both single integers, and once these orders are cleared r and g restrict to rational functions on E_i; their zeros and poles on E_i are exactly the points where the strict transforms $\widetilde{V}$ meet E_i. Attach to E_i the *tame symbol* of r and g, the residue element

$$\tau_i(r,g) = (-1)^{a_i b_i} \left(\frac{r^{\,b_i}}{g^{\,a_i}}\right)\Big|_{E_i} \;\in\; k(E_i)^*$$

which is a well-defined nonzero rational function on E_i because r^{b_i}/g^{a_i} has order zero along E_i. Reading off its order at a closed point $P \in E_i$ gives $\operatorname{ord}_P(\tau_i(r,g)) = b_i \operatorname{ord}_P(r|_{E_i}) - a_i \operatorname{ord}_P(g|_{E_i})$. The contribution of (i,P) to $c_Z(r,g)$ is the transverse order of r against the residual order of g, namely $a_i \operatorname{ord}_P(g|_{E_i})$, and its contribution to $c_Z(g,r)$ is $b_i \operatorname{ord}_P(r|_{E_i})$; their difference is thus $-\operatorname{ord}_P(\tau_i(r,g))$. Summing over S and using the π-invariance above, the two coefficients organize as

$$c_Z(r,g) - c_Z(g,r) = -\sum_{i=1}^{m} \sum_{P \in E_i} [k(P) : K] \operatorname{ord}_P\big(\tau_i(r,g)\big)$$

the double sum over the components E_i of the exceptional curve and their closed points P. The pairing is asymmetric: the summand pairs the transverse order of one function along E_i against the residual order of the other at P, and swapping r and g replaces $\tau_i(r,g)$ by $\tau_i(r,g)^{-1}$ up to sign, so the difference is the sum of the point orders of the tame symbols, not a rearrangement of a symmetric product $\operatorname{ord}_P(r)\operatorname{ord}_P(g)$.

Step 3c: Assembling by degree zero. Each tame symbol $\tau_i(r,g)$ is a rational function on the complete curve E_i over K, so its divisor $\operatorname{div}_{E_i}(\tau_i(r,g))$ is a principal divisor on a complete curve. By Step $1'$ of the proof of proposition 10.2.2, applied to the proper curve E_i over K, its degree over K vanishes: $\deg_K \operatorname{div}_{E_i}(\tau_i(r,g)) = \sum_{P \in E_i} [k(P) : K] \operatorname{ord}_P(\tau_i(r,g)) = 0$ for every i. Summing over the finitely many components,

$$c_Z(r,g) - c_Z(g,r) = -\sum_{i=1}^{m} \deg_K \operatorname{div}_{E_i}\big(\tau_i(r,g)\big) = 0$$

so $c_Z(r,g) = c_Z(g,r)$ at every codimension-two Z. This is the reciprocity that a naive term-by-term rearrangement would miss: it pairs the transverse order of one function against the residual order of the other, and its vanishing rests on completeness of each exceptional component E_i through the degree-zero property alone, with no external tame-symbol machinery imported. A $(k-1)$-cycle is determined by its coefficients at the codimension-two subvarieties, so $\Phi(r,g) = \Phi(g,r)$ on the locus where D is principal. Step 2 uses only the weaker $\Phi(r,g) \sim \Phi(g,r)$, which this gives *a fortiori*. The restriction to non-mixed $\mathfrak{p}$ noted in Step 3a is what keeps every term defined; lemma 11.3.1 treats the mixed curves that the hypothesis here excludes, and asserts only rational equivalence.

Step 4: The boundary components. It remains to account for the codimension-one subvarieties $V \subseteq W \setminus W^\circ$, where D was not represented by the single function g. Let $U = W^\circ$ and $Y = W \setminus W^\circ$ be its closed complement, of codimension at least one in W. The localization sequence (theorem 10.4.1) for $Y \subseteq W$,

$$A_{k-1}(Y) \to A_{k-1}(W) \to A_{k-1}(U) \to 0$$

is right exact, and Steps 1 through 3 established $D \cdot [\operatorname{div}(r)] \sim \Phi(g,r) \sim 0$ after restriction to U, that is, the class of $D \cdot [\operatorname{div}(r)]$ dies in $A_{k-1}(U)$. By exactness its class in $A_{k-1}(W)$ comes from $A_{k-1}(Y)$; but Y has dimension at most k, and the restriction $D|_Y$ is again a Cartier divisor, so the boundary class is computed by the same recipe on the lower-dimensional Y. To pin the inductive object down, decompose $Y = \bigcup_j Y_j$ into irreducible components, each of dimension at most k, with inclusions $\iota_j \colon Y_j \hookrightarrow W$. The class in $A_{k-1}(Y)$ produced by the boundary of the localization sequence is represented by $\sum_j (\iota_j)_*\big(D|_{Y_j} \cdot [\operatorname{div}(r_j)]\big)$, where $r_j := r|_{Y_j} \in k(Y_j)^*$ is the restriction of r to the generic point of Y_j, a nonzero rational function since the zero and pole components of r were split off in Steps 1 through 3, and $[\operatorname{div}(r_j)]$ is the principal cycle it cuts on the variety Y_j of dimension at most k. Each summand is thus $D|_{Y_j}$ intersected with a principal cycle on Y_j, the exact object to which the proposition applies one dimension lower. A Noetherian induction on $\dim W$ closes the argument: the base case $\dim W = 0$ is vacuous, and for the inductive step each summand $D|_{Y_j} \cdot [\operatorname{div}(r_j)]$ is rationally trivial on Y_j by the inductive hypothesis applied to the Cartier divisor $D|_{Y_j}$ and the principal cycle $[\operatorname{div}(r_j)]$ on the lower-dimensional Y_j; pushing forward along ι_j preserves rational equivalence, so the whole boundary class in $A_{k-1}(Y)$ vanishes. Hence $D \cdot [\operatorname{div}(r)] \sim 0$ in $A_{k-1}(W)$, and pushing forward along $W \hookrightarrow X$ gives $D \cdot [\operatorname{div}(r)] \sim 0$ in $A_{k-1}(|D|)$.

Step 5: Well-definedness of $D \cdot a$. Fix a class $a \in A_k(X)$. Definition 11.2.1 defines $D \cdot [V]$ for *every* subvariety, its second clause covering the components that lie inside $|D|$, so the operator is defined on all of $Z_k(X)$. What Steps 1 through 4 establish is that it kills those generators of $\operatorname{Rat}_k(X)$ no component of which lies in $|D|$: Step 1 represents D on W° by a single g and takes $s_V = g|_V$, which needs $V \not\subseteq |D|$. Well-definedness on classes admitting such a representative follows; the proof of proposition 11.4.4(3) records that none is available in this generality, and proposition 11.4.6 is what removes the restriction. Let $\alpha \sim \alpha'$ be two such representatives, so their difference lies in $\operatorname{Rat}_k(X)$, a finite $\mathbb{Z}$-combination of generators $[\operatorname{div}(r)]$ with $r \in k(W)^*$ on $(k+1)$-dimensional W. Steps 1 through 4 give $D \cdot [\operatorname{div}(r)] \sim 0$ in $A_{k-1}(|D|)$ for each generator, so summing gives $D \cdot (\alpha - \alpha') \sim 0$, and $D \cdot a := [D \cdot \alpha]$ is independent of the chosen representative. Additivity in a is immediate from additivity of $D \cdot -$ on cycles, so $D \cdot - \colon A_k(X) \to A_{k-1}(|D|)$ is a homomorphism, completing the proof.

The proposition is what permits speaking of $D \cdot a$ for a class a, and with it the intersection with a divisor becomes an operator on the Chow group. Read backward, the argument explains why the

well-definedness was out of reach in section 10.4: the entire content is the tame symmetry of Step 2, and that symmetry rests on the degree-zero property of a principal divisor on a complete curve, a fact about the divisor calculus that section did not yet have. The specialization map used there to invert affine-bundle pullback was built from exactly the operation $\operatorname{div}(t)\cdot -$ for the coordinate t, and its descent to Chow groups is this proposition applied to $D=\{t=0\}$; the forward reference in that proof pointed here.

Two features of the argument recur and are worth isolating. The reduction of Step 1, replacing X by the $(k+1)$-dimensional W on which r lives, is the standard move that turns a statement about intersecting a principal cycle into a statement about a single surface with two functions on it, and it will reappear when commutativity is proved in section 11.3. The symmetry of Step 3, that pairing the zeros of r against g equals pairing the zeros of g against r, is the algebraic form of Weil reciprocity, here proved from the ground up rather than cited: the tame symbol is constructed by hand along each component of the exceptional curve, and its reciprocity is reduced to the vanishing degree of a principal divisor on that complete curve, so no external tame-symbol machinery is imported. The same reciprocity, promoted one dimension higher, is what makes $D\cdot D'=D'\cdot D$, and the two proofs share their engine.

The operator now available, $D\cdot -\colon A_k(X)\to A_{k-1}(|D|)$, invites the computation that motivated the whole construction. Intersecting repeatedly with a hyperplane on projective space should descend through the dimensions and terminate in a point, recovering the degree; the next example carries this out and previews the Chern-class computation of section 11.4.

Example 11.2.5: Iterated Hyperplane Sections on Projective Space

Let $X=\mathbb{P}^n$ and $H=\{x_0=0\}$ a hyperplane, so $\mathcal{O}_{\mathbb{P}^n}(H)=\mathcal{O}_{\mathbb{P}^n}(1)$ and $|H|\cong\mathbb{P}^{n-1}$. By theorem 10.5.2, $A_k(\mathbb{P}^n)=\mathbb{Z}\,h_k$ with h_k the class of a linear subspace $\mathbb{P}^k\subseteq\mathbb{P}^n$. To compute $H\cdot h_k$, represent h_k by a linear $\mathbb{P}^k$ meeting H transversally, that is by an $L\cong\mathbb{P}^k$ not contained in H; then $L\cap H$ is a linear $\mathbb{P}^{k-1}$, and the restricted section x_0/x_j on L has its zero divisor equal to $L\cap H$ with multiplicity one. Hence

$$H\cdot h_k=[L\cap H]=h_{k-1}\in A_{k-1}(\mathbb{P}^{n-1})$$

pushed into $\mathbb{P}^n$, the class of a linear $\mathbb{P}^{k-1}$. Intersecting n times starting from the fundamental class $h_n=[\mathbb{P}^n]$,

$$\underbrace{H\cdot H\cdots H}_{k}\cdot[\mathbb{P}^n]=h_{n-k}$$

and in particular $H^n\cdot[\mathbb{P}^n]=h_0=[\mathrm{pt}]$, a single reduced point of degree one. The iterated intersection walks down the tower of linear subspaces one step at a time, and its terminal value is the class of a point, whose degree 1 is the degree of $\mathbb{P}^n$ under the embedding $\mathcal{O}(1)$. The choice of a transversal representative L at each stage is legitimated precisely by proposition 11.2.4: the answer h_{k-1} does not depend on which $\mathbb{P}^k$ in the class h_k is used, so long as it meets H properly.

The computation is the prototype of every enumerative count the theory produces. Reinterpreted through the first Chern class in section 11.4, it reads $c_1(\mathcal{O}(1))^k\cap[\mathbb{P}^n]=h_{n-k}$, and its terminal instance $c_1(\mathcal{O}(1))^n\cap[\mathbb{P}^n]=[\mathrm{pt}]$ is the statement that the top self- intersection of the hyperplane class on $\mathbb{P}^n$ is one, the algebraic form of the assertion that n general hyperplanes meet in a single point. That the intermediate steps are independent of the representatives chosen is the payoff of this section, and it is what turns a naive count of intersection points into an invariant.

Exercise 11.2.1

1. On $X = \mathbb{P}^2$ let $D = \{x_0x_1 = 0\}$ be the union of two lines, a Cartier divisor with $\mathcal{O}_{\mathbb{P}^2}(D) = \mathcal{O}_{\mathbb{P}^2}(2)$, and let V be the conic $\{x_2^2 = x_0x_1\}$. Compute $D \cdot [V] \in A_0(V \cap |D|)$ explicitly as a sum of points with multiplicities, and verify that its degree equals 4. Explain how the multiplicities distribute among the intersection points.

2. Let $V \subseteq \mathbb{P}^2$ be a smooth curve of degree d and H a line meeting V transversally in d distinct points. Using definition 11.2.1, show that $H \cdot [V]$ is the sum of those d points each with multiplicity one, and deduce $\deg(H \cdot [V]) = d$. Then explain why the value $\deg(H \cdot [V]) = d$ holds for every line H, transversal or not, without recomputing, citing proposition 11.2.4.

3. Let $D = \operatorname{div}(f)$ be a principal Cartier divisor on a variety X, so $\mathcal{O}_X(D) \cong \mathcal{O}_X$ is trivial. Show that $D \cdot a = 0$ in $A_{k-1}(X)$ for every class $a \in A_k(X)$. (Push $D \cdot a$ forward from $|D|$ into X; the point is that a global trivialization of $\mathcal{O}_X(D)$ makes the restricted section extend to all of V.)

4. On $\mathbb{P}^3$ let H be a hyperplane and let V be a smooth cubic surface, regarded through its inclusion as a subvariety, with the induced very ample bundle $\mathcal{O}_V(1) = \mathcal{O}_{\mathbb{P}^3}(1)|_V$. Compute $H \cdot [V]$ as a class in $A_1(V \cap H)$, identify $V \cap H$ geometrically, and compute the degree of the further intersection $H \cdot (H \cdot [V])$.

5. Let $Q = \mathbb{P}^1 \times \mathbb{P}^1$ and let $D = f_1 = \{a\} \times \mathbb{P}^1$ be a ruling of the first kind, with $\mathcal{O}_Q(D) = \operatorname{pr}_1^*\mathcal{O}_{\mathbb{P}^1}(1)$. Compute $D \cdot [f_1]$ and $D \cdot [f_2]$, where $f_2 = \mathbb{P}^1 \times \{b\}$ is a ruling of the second kind, and interpret the results as the self-intersection f_1^2 and the cross-intersection $f_1 \cdot f_2$. Which case uses the second clause of definition 11.2.1?

6. Give an explicit example on $X = \mathbb{P}^1$ of a Cartier divisor D and two rationally equivalent zero-cycles $\alpha \sim \alpha'$ for which the naive formula would assign different answers if one ignored the requirement that components avoid $|D|$, and explain how definition 11.2.1 and proposition 11.2.4 together resolve the apparent discrepancy. (Here $k = 0$, so $D \cdot \alpha$ lands in $A_{-1} = 0$; use this to frame what the proposition is and is not asserting in the lowest dimension.)

11.3 Commutativity and the Projection Formula

Intersection with a divisor, made precise in section 11.2, is an operation $D \cdot -$ that lowers dimension by one and, by proposition 11.2.4, descends to rational equivalence. Nothing so far says these operations may be applied in either order. Given two Cartier divisors D and D' on X and a k-cycle α, one can form $D \cdot (D' \cdot \alpha)$ and $D' \cdot (D \cdot \alpha)$, each a class in $A_{k-2}(X)$; that they agree is the single algebraic fact on which the entire intersection calculus rests. Its proof does not follow from the definitions by formal manipulation, because the two orders of intersection produce different cycles before passing to rational equivalence. The content is that the difference is always a boundary, and the reason it is a boundary is the vanishing of the degree of a principal divisor on a complete curve, established back in proposition 10.2.2.

This is also the point at which a debt from chapter 10 comes due. The proof of affine-bundle invariance (theorem 10.4.6) deferred one identity, the divisor symmetry (10.3), on the grounds that the tools were not yet in place; that identity is exactly the commutativity proved here. This section discharges it in full and then draws the two functorial consequences, compatibility of $D \cdot -$ with proper

pushforward and with flat pullback, that make the operation part of the same covariant/contravariant package as pushforward and pullback themselves.

The obstruction to commutativity lives on a surface, and the mechanism that removes it is a symmetry between two rational functions. Before the theorem, the mechanism deserves to be isolated as a lemma. Let S be a complete variety of dimension two and let $f, g \in k(S)^*$ be nonzero rational functions. Each has a divisor $[\mathrm{div}(f)] = \sum_W \mathrm{ord}_W(f)\,[W]$, the sum over the codimension-one subvarieties (the curves) $W \subseteq S$, and on each such curve W the other function g restricts, wherever it is neither zero nor a pole identically along W, to a rational function $g|_W$ with its own divisor of points. The two-function symmetry lemma compares the two zero-cycles obtained by cutting first with f and then with g, against the same two cuts in the opposite order.

The statement needs the order of one function measured against the divisor of another. For a curve $W \subseteq S$ with $\mathrm{ord}_W(g) = 0$, so that g is a unit at the generic point of W and restricts to a nonzero rational function $g|_W \in k(W)^*$, write $[\mathrm{div}_W(g)] = \sum_{P \in W} \mathrm{ord}_P(g|_W)\,[P]$ for the divisor of that restriction, a zero-cycle on W and hence on S. The lemma is a reciprocity between the iterated cuts $\sum_W \mathrm{ord}_W(f)\,[\mathrm{div}_W(g)]$ and $\sum_W \mathrm{ord}_W(g)\,[\mathrm{div}_W(f)]$.

Lemma 11.3.1: Two-Function Reciprocity on a Surface

Let S be a complete variety of dimension two and let $f, g \in k(S)^*$. Then

$$\sum_W \mathrm{ord}_W(f)\,[\mathrm{div}_W(g)] \;\sim\; \sum_W \mathrm{ord}_W(g)\,[\mathrm{div}_W(f)] \quad \text{in } A_0(S)$$

where each sum runs over the curves $W \subseteq S$ on which the relevant restriction is defined, and the divisors $[\mathrm{div}_W(g)]$, $[\mathrm{div}_W(f)]$ are the zero-cycles of the restricted functions. In fact both sides have the same degree, and their difference is a sum of principal divisors of rational functions on the curves $W \subseteq S$, hence rationally trivial.

The lemma is the two-dimensional heart of commutativity, and its proof is the one place where the degree-zero property of principal divisors on complete curves does the decisive work. The strategy is to reduce the equality of two zero-cycles to an equality of degrees along each curve, and then to recognize each such degree as the value at a point of the *tame symbol*, a bimultiplicative pairing on pairs of rational functions whose reciprocity across a complete curve is precisely the statement that a principal divisor has degree zero.

***Proof*:**
Step 1: the tame symbol at a curve. Fix a curve $W \subseteq S$ and let $A = \mathcal{O}_{S,W}$ be the local ring of S at the generic point of W. Because S is a variety and W has codimension one, A is a one-dimensional local domain with fraction field $k(S)$ and residue field $k(W)$; its normalization is a discrete valuation ring, and after replacing S by its normalization along W (which changes neither side of the asserted identity, both being computed by orders and residues that are birational invariants) one may assume A is itself a discrete valuation ring with valuation $v_W = \mathrm{ord}_W$ and uniformizer π. Define the *tame symbol* of f, g at W to be the residue class

$$\partial_W(f,g) \;=\; (-1)^{v_W(f)\,v_W(g)}\,\frac{f^{\,v_W(g)}}{g^{\,v_W(f)}}\Big|_W \;\in\; k(W)^*$$

the restriction to W of the indicated unit, which lies in A and is a unit there because its valuation

$$v_W\Big((-1)^{v_W(f)v_W(g)}\, f^{v_W(g)} g^{-v_W(f)}\Big) = v_W(g)\, v_W(f) - v_W(f)\, v_W(g) = 0$$

vanishes. The construction is bimultiplicative in f and g and antisymmetric, $\partial_W(g,f) = \partial_W(f,g)^{-1}$, both directly from the formula. The point of the sign is that this antisymmetry holds on the nose, not just up to squares.

Step 2: the tame symbol computes the difference of iterated divisors, pointwise. Fix a closed point $P \in S$ and a curve W through P. When $\operatorname{ord}_W(g) = 0$ the restriction $g|_W$ is a nonzero function on W and the coefficient of $[P]$ in $\operatorname{ord}_W(f)\,[\operatorname{div}_W(g)]$ is $\operatorname{ord}_W(f)\operatorname{ord}_P(g|_W)$; symmetrically for the other cut. Comparing the two iterated cuts at P amounts to comparing, over all curves $W \ni P$,

$$\sum_{W \ni P} \operatorname{ord}_W(f)\operatorname{ord}_P(g|_W) \quad \text{against} \quad \sum_{W \ni P} \operatorname{ord}_W(g)\operatorname{ord}_P(f|_W)$$

The tame symbol reconciles them, but the reconciliation is delicate at the curves where both functions have nonzero order, and getting it right is the whole content of the step. For a single curve W with $\operatorname{ord}_W(f) = a$ and $\operatorname{ord}_W(g) = b$, write $f = \pi^a u$ and $g = \pi^b w$ with u, w units at W. The tame symbol of *Step 1* then simplifies to

$$\partial_W(f,g) = (-1)^{ab}\, \bar{u}^{\,b}\, \bar{w}^{\,-a} \;\in\; k(W)^*$$

the powers of π cancelling, so its order at P is always

$$\operatorname{ord}_P\big(\partial_W(f,g)\big) = b \operatorname{ord}_P(\bar{u}) - a \operatorname{ord}_P(\bar{w}) \tag{11.1}$$

regardless of whether a or b vanishes. The iterated cuts, on the other hand, see only the restricted functions, and $f|_W = \bar{u}$ is defined precisely when $a = 0$ while $g|_W = \bar{w}$ is defined precisely when $b = 0$. Compare the two curve-by-curve.

If $a = 0$ and $b \neq 0$: $\operatorname{ord}_W(g)\,[\operatorname{div}_W(f)]$ contributes $b \operatorname{ord}_P(\bar{u})$ at P while $\operatorname{ord}_W(f)\,[\operatorname{div}_W(g)] = 0$, so the iterated-cut difference is $b \operatorname{ord}_P(\bar{u})$, which is (11.1) since $a = 0$ kills the second term.

If $a \neq 0$ and $b = 0$: symmetrically the difference is $-a \operatorname{ord}_P(\bar{w})$, again (11.1).

If $a = b = 0$: both restrictions are units and both sides vanish.

In all three of these *non-mixed* cases,

$$\Big(\operatorname{ord}_W(g)\operatorname{ord}_P(f|_W) - \operatorname{ord}_W(f)\operatorname{ord}_P(g|_W)\Big) = \operatorname{ord}_P\big(\partial_W(f,g)\big)$$

the left side being the contribution of W to the iterated-cut difference at P, where a term whose restricted function is undefined is read as zero because its coefficient $\operatorname{ord}_W(g)$ or $\operatorname{ord}_W(f)$ then vanishes. The remaining case is the *mixed* one, $a \neq 0$ and $b \neq 0$: here *neither* $f|_W$ nor $g|_W$ is defined, so W contributes nothing to either iterated cut, yet $\partial_W(f,g) = (-1)^{ab}\bar{u}^{\,b}\bar{w}^{\,-a}$ is a genuine nonzero rational function on W whose divisor is generally nonzero. Thus on a mixed curve the iterated-cut difference and $\operatorname{ord}_P(\partial_W)$ do *not* agree; the tame symbol overcounts by exactly the mixed contribution. Summing the non-mixed agreement over the curves through P,

$$\Big(\sum_W \operatorname{ord}_W(g)\,[\operatorname{div}_W(f)] - \sum_W \operatorname{ord}_W(f)\,[\operatorname{div}_W(g)]\Big)_P = \sum_{\substack{W \ni P \\ \text{non-mixed}}} \operatorname{ord}_P\big(\partial_W(f,g)\big) \tag{11.2}$$

the sum on the right running only over curves $W \ni P$ on which at least one of f, g has order zero, and the left side denoting the coefficient of $[P]$ in the difference of the two iterated cuts. The mixed curves are deliberately excluded from the right side; they carry no iterated-cut contribution, and Step 3 will show their tame symbols are individually harmless.

Step 3: reciprocity along each curve kills the total. Fix a curve $W \subseteq S$. The tame symbol $\partial_W(f,g)$ is a nonzero rational function on the complete curve W (it is complete because S is complete and W is closed in S). Its divisor $[\mathrm{div}(\partial_W(f,g))] = \sum_P \mathrm{ord}_P(\partial_W(f,g))\,[P]$ is a principal divisor on W, so by proposition 10.2.2(1) applied to the structure map $W \to \mathrm{Spec}\,\overline{k}$, which is proper surjective with target of strictly smaller dimension, its pushforward vanishes: $\deg[\mathrm{div}(\partial_W(f,g))] = 0$. This holds for *every* curve W, mixed or not. Summing (11.2) over all closed points P and reorganizing the double sum by curves,

$$\deg\Big(\sum_W \mathrm{ord}_W(g)\,[\mathrm{div}_W(f)] - \sum_W \mathrm{ord}_W(f)\,[\mathrm{div}_W(g)]\Big) = \sum_{\text{non-mixed } W} \deg[\mathrm{div}(\partial_W(f,g))] = 0$$

each summand vanishing individually. Thus the difference of the two iterated zero-cycles has degree zero on S.

Step 4: from degree zero to rational equivalence. A zero-cycle of degree zero on the complete variety S need not be rationally equivalent to zero in general, but the difference here is more than a degree-zero cycle: (11.2), summed over all closed points P and reorganized by curves, exhibits it as a sum of principal divisors,

$$\sum_W \mathrm{ord}_W(g)\,[\mathrm{div}_W(f)] - \sum_W \mathrm{ord}_W(f)\,[\mathrm{div}_W(g)] = \sum_{\text{non-mixed } W} [\mathrm{div}(\partial_W(f,g))]$$

the right side running over the curves on which one of f, g has order zero, each term the divisor of the rational function $\partial_W(f,g)$ on the complete curve $W \subseteq S$. Each $[\mathrm{div}(\partial_W(f,g))]$ is by definition rationally equivalent to zero on W, hence on S under the proper pushforward along $W \hookrightarrow S$, which preserves rational equivalence by theorem 10.2.3. Therefore the difference is a finite sum of cycles each ~ 0, so it is itself ~ 0 in $A_0(S)$, which is the asserted reciprocity, as we sought to show.

The lemma is the algebraic incarnation of a classical reciprocity, but the mechanism it uses is elementary: on each curve W the tame symbol $\partial_W(f,g)$ is a single rational function, its divisor on the complete curve W is principal and so rationally trivial, and the difference of the two iterated cuts is a finite sum of such divisors. No appeal to Weil reciprocity or to the point-level tame symbol $\prod_P \partial_P(f,g) = 1$ as an external input is needed, and indeed none is available in this book; the entire force of the lemma comes from the single fact that a rational function on a complete curve has as many zeros as poles, counted with multiplicity and residue degree, applied one curve at a time. That fact is proposition 10.2.2(1), proved in chapter 10 by the model computation on $\mathbb{P}^1$. The reader should notice that the surface S never needed to be smooth; normalizing along each curve reduced every local computation to a discrete valuation ring, which is all the tame symbol requires.

With the reciprocity lemma in hand, commutativity is a matter of reducing the general assertion to the surface case the lemma governs. The reduction is entirely formal, following the pattern used throughout chapter 10: the operation $D \cdot -$ is a homomorphism, so it suffices to check the identity on the class of a single subvariety, and the intersection with D and D' is supported where the two divisors meet the subvariety, so one may replace the ambient scheme by the subvariety itself.

Theorem 11.3.2: Commutativity of Divisor Intersection

Let D and D' be Cartier divisors on an algebraic scheme X, and let $\alpha \in A_k(X)$. Then

$$D \cdot (D' \cdot \alpha) = D' \cdot (D \cdot \alpha) \quad \text{in } A_{k-2}(X)$$

More precisely, both sides are represented by well-defined classes in $A_{k-2}\big(|D| \cap |D'| \cap \operatorname{supp}\alpha\big)$, and they coincide there. This identity is the divisor symmetry (10.3) deferred in the proof of theorem 10.4.6.

***Proof*:**

Step 1: reduction to a variety. Both $D \cdot -$ and $D' \cdot -$ are homomorphisms $A_k \to A_{k-1}$ by definition 11.2.1 and proposition 11.2.4, so both iterated operations are homomorphisms $A_k(X) \to A_{k-2}(X)$. It therefore suffices to verify the identity on a generator $\alpha = [V]$, the class of a k-dimensional subvariety $V \subseteq X$. Restricting the line bundles $\mathcal{O}_X(D)$ and $\mathcal{O}_X(D')$ and their rational sections to V, the entire computation of $D \cdot (D' \cdot [V])$ and $D' \cdot (D \cdot [V])$ takes place on V using the restricted divisors $D|_V$ and $D'|_V$. Replacing X by V, one is reduced to proving

$$D \cdot (D' \cdot [X]) = D' \cdot (D \cdot [X])$$

for X itself a k-dimensional variety and D, D' Cartier divisors on it, with the common value a class in $A_{k-2}(|D| \cap |D'|)$.

Step 2: choosing sections and unwinding the two orders. Let s and s' be the rational sections of $\mathcal{O}_X(D)$ and $\mathcal{O}_X(D')$ cutting out D and D', so that on the variety X,

$$D \cdot [X] = [\operatorname{div}(s)] = \sum_W \operatorname{ord}_W(s)\,[W], \qquad D' \cdot [X] = [\operatorname{div}(s')] = \sum_{W'} \operatorname{ord}_{W'}(s')\,[W']$$

the sums over the codimension-one subvarieties $W, W' \subseteq X$. To compute the double intersection one then intersects each $[W']$ with D and each $[W]$ with D'. On a codimension-one subvariety W not contained in $|D'|$, the section s' restricts to a rational section $s'|_W$ of $\mathcal{O}_X(D')|_W$, whose divisor is $[\operatorname{div}_W(s')]$, and by definition 11.2.1,

$$D' \cdot (D \cdot [X]) = \sum_W \operatorname{ord}_W(s)\,[\operatorname{div}_W(s')], \qquad D \cdot (D' \cdot [X]) = \sum_{W'} \operatorname{ord}_{W'}(s')\,[\operatorname{div}_{W'}(s)]$$

as cycles supported on $|D| \cap |D'|$. The two expressions are the two iterated cuts of the reciprocity lemma, with the roles of the two divisors interchanged.

Step 3: the difference as a sum of tame symbols. The difference

$$\Delta \;=\; \sum_{W'} \operatorname{ord}_{W'}(s')\,[\operatorname{div}_{W'}(s)] \;-\; \sum_W \operatorname{ord}_W(s)\,[\operatorname{div}_W(s')]$$

is a $(k-2)$-cycle supported on $|D| \cap |D'|$, and the claim is $\Delta \sim 0$ in $A_{k-2}(|D| \cap |D'|)$. The strategy is to write Δ as a $\mathbb{Z}$-combination of divisors of rational functions on $(k-1)$-dimensional subvarieties of X, using the tame symbol of lemma 11.3.1. For a $(k-1)$-dimensional subvariety $W \subseteq X$ on which one of the two sections has nonzero order, choose a common local trivialization of $\mathcal{O}_X(D)$ and $\mathcal{O}_X(D')$ near the generic point of W (a line bundle is locally trivial, and one open

set trivializes both), turning s, s' into rational functions in the local ring $\mathcal{O}_{X,W}$, a two-dimensional local domain. The tame symbol

$$\partial_W(s,s') = (-1)^{\operatorname{ord}_W(s)\operatorname{ord}_W(s')} \frac{s^{\operatorname{ord}_W(s')}}{s'^{\operatorname{ord}_W(s)}}\Big|_W \in k(W)^*$$

is then a nonzero rational function on the $(k-1)$-dimensional variety W, defined exactly as in the lemma. Localizing X along W removes the trivialization ambiguity: two trivializations differ by a unit, which does not change $\partial_W(s,s')$ up to a rational function that is regular and nonvanishing at the generic point of W, so its divisor on W is well defined.

Step 4: applying reciprocity, one codimension-two point at a time. Fix a $(k-2)$-dimensional subvariety $Z \subseteq |D| \cap |D'|$ and compute the coefficient of $[Z]$ on both sides of the asserted identity $\Delta = \sum_{\text{non-mixed } W} [\operatorname{div}(\partial_W(s,s'))]$, the sum running over $(k-1)$-dimensional W on which one of s, s' has order zero. That coefficient is determined at the generic point ζ of Z, where $\mathcal{O}_{X,\zeta}$ has dimension two; the two-dimensional local situation there is governed by lemma 11.3.1, whose (11.2) reads, at ζ,

$$\Big(\sum_W \operatorname{ord}_W(s')\,[\operatorname{div}_W(s)] - \sum_W \operatorname{ord}_W(s)\,[\operatorname{div}_W(s')]\Big)_\zeta = \sum_{\substack{W \ni \zeta \\ \text{non-mixed}}} \operatorname{ord}_\zeta\big(\partial_W(s,s')\big)$$

the right sum over the $(k-1)$-dimensional subvarieties W through ζ on which one of s, s' has order zero, exactly as in the lemma; the mixed W, on which both sections have nonzero order, are excluded because they contribute to neither iterated cut. This is the coefficient of $[Z]$ in Δ set equal to the coefficient of $[Z]$ in $\sum_{\text{non-mixed } W} [\operatorname{div}(\partial_W(s,s'))]$. Since the two sides agree at every such Z, they agree as cycles:

$$\Delta = \sum_{\text{non-mixed } W} [\operatorname{div}(\partial_W(s,s'))]$$

Each term $[\operatorname{div}(\partial_W(s,s'))]$ is the divisor of a rational function on the $(k-1)$-dimensional subvariety W, hence rationally equivalent to zero on W, and its proper pushforward to $|D| \cap |D'|$ along $W \hookrightarrow |D| \cap |D'|$ preserves that equivalence by theorem 10.2.3. As a finite sum of cycles each ~ 0, therefore $\Delta \sim 0$, so

$$D \cdot (D' \cdot [X]) = D' \cdot (D \cdot [X]) \quad \text{in } A_{k-2}(|D| \cap |D'|)$$

Pushing forward to X along the inclusion, the identity holds in $A_{k-2}(X)$ for $\alpha = [X]$, and by Step 1 for every $\alpha \in A_k(X)$. The surface case $X = S$, in which the difference of the two orders is exhibited as a sum of principal cycles, is precisely the deferred divisor symmetry (10.3), with the two rational functions $s|_S$ and $s'|_S$ here playing the roles of g and the coordinate t there, completing the proof.

Commutativity is the property that makes the phrase "intersection number" unambiguous. Without it, the number attached to a chain of divisors would depend on the order in which they are imposed, and no well-defined product on cycles could exist. With it, one may write $D_1 \cdot D_2 \cdots D_r \cdot \alpha$ for an iterated intersection and speak of it without specifying an order, and the class of a complete intersection $D_1 \cap \cdots \cap D_r$ in A_* is symmetric in the defining divisors. The proof also settles the debt from chapter 10: the identity (10.3) that theorem 10.4.6 took on faith is the surface case here, so affine-bundle invariance is now unconditional. The tame symbol was the only tool required beyond

the definitions, and its reciprocity was nothing more than the degree-zero property of principal divisors, propagated from curves to surfaces.

A first reading of the theorem should note what it does *not* require. The divisors need not be effective, the sections need not be regular, and X need not be smooth or even normal; the entire argument localizes to one-dimensional local rings, where a divisor is controlled by a single valuation. This is why intersection with a Cartier divisor is available on every algebraic scheme, in contrast to the intersection product of arbitrary cycles, which will require the deformation-to-the-normal-cone machinery of a later chapter and works cleanly only on smooth varieties.

The second half of the section records how $D \cdot -$ interacts with the two functorialities of the Chow group. Both statements are what one would guess from the topological analogy, in which cap product with a cohomology class is natural for maps: pushforward absorbs the pullback of a divisor, and flat pullback commutes with intersection outright. The proofs run through the same reduction to a single subvariety and the same input, the pushforward of a principal divisor, that powered commutativity.

For a proper morphism $f\colon X \to Y$ and a Cartier divisor D on Y, the pullback f^*D is defined whenever no component of X maps into $|D|$, by pulling back the line bundle $\mathcal{O}_Y(D)$ and its rational section; it is the Cartier divisor $\operatorname{div}(f^{\#}s)$ of the pulled-back section. The projection formula compares intersecting upstairs and pushing down against pushing down and intersecting downstairs.

Proposition 11.3.3: Projection Formula for Divisors

Let D be a Cartier divisor on Y.

1. *Proper pushforward.* If $f\colon X \to Y$ is proper and $\alpha \in A_k(X)$ is a cycle no component of whose support maps into $|D|$, so that $f^*D \cdot \alpha$ is defined, then

$$f_*\big(f^*D \cdot \alpha\big) = D \cdot f_*\alpha \quad \text{in } A_{k-1}(Y)$$

   and, more precisely, both sides are classes in $A_{k-1}\big(|D| \cap f(\operatorname{supp}\alpha)\big)$ and agree there, f being proper so that it carries $f^{-1}(|D|) \cap \operatorname{supp}\alpha$ onto $|D| \cap f(\operatorname{supp}\alpha)$.

2. *Flat pullback.* If $g\colon X' \to Y$ is flat of relative dimension n and $\beta \in A_k(Y)$, then

$$g^*\big(D \cdot \beta\big) = g^*D \cdot g^*\beta \quad \text{in } A_{k+n-1}(X')$$

   where g^*D is the pullback Cartier divisor $\operatorname{div}(g^{\#}s)$; more precisely both sides are classes in $A_{k+n-1}\big(g^{-1}(|D| \cap \operatorname{supp}\beta)\big)$ and agree there.

***Proof*:**
Both statements are linear in α and β, so it suffices to verify each on the class of a subvariety, and both reduce, by the argument that opened the commutativity proof, to a computation with the divisor of a rational function that is settled by proposition 10.2.2 and proposition 10.3.6. The refined statements come for free: definition 11.2.1 records $D \cdot [V]$ on $V \cap |D|$ to begin with, and each identity below is an equality of cycles supported there, so no step passes to the ambient group. This refinement is what chapter 13 uses.

1. *Proper pushforward.* Take $\alpha = [V]$ for a k-dimensional subvariety $V \subseteq X$, and set $W = f(V) \subseteq Y$, so $f_*[V] = \deg(V/W)\,[W]$ if $\dim W = k$ and $f_*[V] = 0$ if $\dim W < k$, by definition 10.2.1. Restricting to V and W, one may assume $X = V$, $Y = W$, and

$f\colon V \to W$ proper surjective with V a variety. Let s be the rational section of $\mathcal{O}_Y(D)$ cutting out D; its pullback $f^{\#}s$ is a rational section of $f^{*}\mathcal{O}_Y(D)$ cutting out $f^{*}D$, and $f^{*}D \cdot [V] = [\operatorname{div}(f^{\#}s)]$ while $D \cdot [W] = [\operatorname{div}(s)]$, both by definition 11.2.1. There are two cases.

If $\dim W < k$, then $f_{*}[V] = 0$, so the right side $D \cdot f_{*}[V]$ vanishes. On the left, $[\operatorname{div}(f^{\#}s)]$ is a $(k-1)$-cycle on V, and f pushes it into Y; but $f(V) = W$ has dimension $< k$, so $f_{*}[\operatorname{div}(f^{\#}s)]$ is a cycle of dimension $k-1$ supported on the $(<k)$-dimensional W, and proposition 10.2.2(1) applied to $f\colon V \to W$ (proper surjective, target of strictly smaller dimension) gives $f_{*}[\operatorname{div}(f^{\#}s)] = 0$. Both sides vanish.

If $\dim W = k$, then $f\colon V \to W$ is proper surjective of equal dimension, generically finite of degree $d = \deg(V/W) = [k(V) : k(W)]$. Now $f^{\#}s$ is a rational section whose local expression, in a trivialization of $\mathcal{O}_Y(D)$ near a curve of W, is a rational function $r \in k(V)^{*}$ pulled back from $k(W)$, and proposition 10.2.2(2) gives $f_{*}[\operatorname{div}(f^{\#}s)] = [\operatorname{div}(N(f^{\#}s))]$ with N the norm along $k(V)/k(W)$. Because $f^{\#}s$ is pulled back from s, its norm is $N(f^{\#}s) = s^{\,d}$ up to the local trivialization, so $[\operatorname{div}(N(f^{\#}s))] = d\,[\operatorname{div}(s)] = d\,(D \cdot [W])$. Hence

$$f_{*}\big(f^{*}D \cdot [V]\big) = f_{*}[\operatorname{div}(f^{\#}s)] = d\,(D \cdot [W]) = D \cdot (d\,[W]) = D \cdot f_{*}[V]$$

as required.

2. *Flat pullback.* Take $\beta = [V]$ for a k-dimensional subvariety $V \subseteq Y$. Both sides are supported over $V \cap |D|$, so restricting to V one may assume $Y = V$ is a variety and D a Cartier divisor on it with cutting section s, so $D \cdot [V] = [\operatorname{div}(s)]$. Then $g^{*}(D \cdot [V]) = g^{*}[\operatorname{div}(s)]$, and by the flat-pullback divisor formula established in proposition 10.3.7, flat pullback commutes with taking the divisor of a rational function: $g^{*}[\operatorname{div}(s)] = [\operatorname{div}(g^{\#}s)]$ componentwise, with the multiplicities of the components of $g^{-1}(V)$ accounted by flatness. On the other side, $g^{*}D$ is the Cartier divisor $\operatorname{div}(g^{\#}s)$ on X' by definition, and $g^{*}[V] = [g^{-1}(V)] = \sum_j m_j [X'_j]$ over the components X'_j of the preimage with their flat multiplicities m_j by proposition 10.3.5. Intersecting,

$$g^{*}D \cdot g^{*}[V] = g^{*}D \cdot \sum_j m_j [X'_j] = \sum_j m_j \,[\operatorname{div}((g^{\#}s)|_{X'_j})] = [\operatorname{div}(g^{\#}s)] = g^{*}(D \cdot [V])$$

the middle equality being definition 11.2.1 applied on each component and the last the same componentwise divisor formula. This is the claim; the compatibility of these classes with the base change is proposition 10.3.6, which guarantees the two routes land in the same class of $A_{k+n-1}(X')$. This establishes both parts, completing the proof.

The projection formula is the mechanism by which a computation on a resolved or covering space transfers to the base. In its pushforward form, intersecting the pullback of D upstairs and pushing the answer down is the same as pushing the cycle down and intersecting with D there, which is exactly what one does when computing an intersection number on Y by passing to a modification $X \to Y$ where the geometry is transparent. The scalar $d = \deg(V/W)$ in the equal-dimensional case is the reason degrees multiply under finite covers, and it is the algebraic source of formulas like $\deg(f^{*}D) = (\deg f)(\deg D)$ for a finite map of curves. In its flat form, the formula says intersection with a divisor is a local construction, insensitive to flat base change: pulling back the divisor and pulling back the cycle and then intersecting reproduces the pullback of the intersection. Together the

two halves make $D \cdot -$ compatible with the covariant/contravariant package (f_*, g^*) of chapter 10, the bimodule structure that all of intersection theory is built to respect.

The abstractions above are best seen at work on the projective plane, where every class is a known multiple of a linear space and the intersection numbers can be read off by hand. The following example verifies commutativity concretely and recovers the intersection number of two lines.

Example 11.3.4: Two Lines on the Projective Plane

Let $X = \mathbb{P}^2$ over $\overline{k}$, with homogeneous coordinates $[x_0 : x_1 : x_2]$. By theorem 10.5.2, $A_2(\mathbb{P}^2) = \mathbb{Z}\,[\mathbb{P}^2]$, $A_1(\mathbb{P}^2) = \mathbb{Z}\,[L]$ generated by the class of a line L, and $A_0(\mathbb{P}^2) = \mathbb{Z}\,[P]$ generated by the class of a point. Take the two Cartier divisors $D = \{x_0 = 0\}$ and $D' = \{x_1 = 0\}$, each a line, with $\mathcal{O}_{\mathbb{P}^2}(D) \cong \mathcal{O}_{\mathbb{P}^2}(D') \cong \mathcal{O}(1)$ and cutting sections $s = x_0$, $s' = x_1$ (rational sections of $\mathcal{O}(1)$ in the trivialization on the chart $U_2 = \{x_2 \neq 0\}$, where the affine coordinates are $u = x_0/x_2$, $v = x_1/x_2$).

First order. Intersecting $[\mathbb{P}^2]$ with D gives $D \cdot [\mathbb{P}^2] = [\mathrm{div}(s)] = [D] = [L]$, the line $\{x_0 = 0\}$. Now intersect with D'. Since $D = \{x_0 = 0\}$ is not contained in $|D'| = \{x_1 = 0\}$, the section $s'|_D = x_1|_D$ is a rational section of $\mathcal{O}(1)|_D$; on the line $D \cong \mathbb{P}^1$ with coordinate $[x_1 : x_2]$ it vanishes to order one at the single point $x_1 = 0$, namely $[0 : 0 : 1]$. Thus

$$D' \cdot (D \cdot [\mathbb{P}^2]) = D' \cdot [L] = [\mathrm{div}_D(s')] = \big[\,[0 : 0 : 1]\,\big]$$

the class of the point where the two lines meet.

Reverse order. Intersecting $[\mathbb{P}^2]$ with D' first gives $D' \cdot [\mathbb{P}^2] = [\mathrm{div}(s')] = [D'] = [L]$, the line $\{x_1 = 0\}$. Intersecting with D, the section $s|_{D'} = x_0|_{D'}$ on $D' \cong \mathbb{P}^1$ with coordinate $[x_0 : x_2]$ vanishes to order one at $x_0 = 0$, again $[0 : 0 : 1]$, so

$$D \cdot (D' \cdot [\mathbb{P}^2]) = D \cdot [L] = [\mathrm{div}_{D'}(s)] = \big[\,[0 : 0 : 1]\,\big]$$

The two orders produce the same zero-cycle, the reduced point $[0 : 0 : 1]$, on the nose, which is theorem 11.3.2 made visible: here no rational equivalence was even needed, because the two lines are transverse and the tame symbol $\partial_W(x_0, x_1)$ has no zeros or poles. Taking degrees on the complete $\mathbb{P}^2$,

$$\deg\big(D \cdot D' \cdot [\mathbb{P}^2]\big) = 1$$

the intersection number of two distinct lines: they meet in exactly one point. This is the case $c = d = 1$ of Bézout's theorem ([30, Bézout's Theorem]), recovered from the divisor calculus.

Where reciprocity would enter. Replacing D' by D itself, one must intersect $[L]$ with the same line, which requires moving D within its linear system: since $\mathcal{O}(1)$ has many sections, choose instead $s'' = x_1$, whose divisor $\{x_1 = 0\}$ is linearly equivalent to $\{x_0 = 0\}$, and the previous computation gives $D \cdot D \cdot [\mathbb{P}^2] = [\,[0 : 0 : 1]\,]$ of degree 1, so the self-intersection $L^2 = 1$ on $\mathbb{P}^2$. The passage from $s = x_0$ to the linearly equivalent $s'' = x_1$ changes the cutting section by the rational function x_1/x_0, and that the answer is unchanged is precisely proposition 11.2.4, the well-definedness whose commutativity companion is proved in this section.

The example is the enumerative payoff in miniature. The number 1 is the degree of a zero-cycle, the two lines meet where their defining sections simultaneously vanish, and the independence of the answer from the order of intersection and from the choice of representative in each linear system is exactly what theorem 11.3.2 and proposition 11.2.4 guarantee. Iterating, r general hyperplanes in $\mathbb{P}^n$ intersect in $c_1(\mathcal{O}(1))^r \cap [\mathbb{P}^n] = [\mathbb{P}^{n-r}]$, and taking $r = n$ recovers a single reduced point of degree one, the statement that n general hyperplanes meet in one point. This is the computation the next

section packages as the first Chern class.

Exercise 11.3.1

1. On $\mathbb{P}^2$, let $D = \{x_0x_1 = 0\}$ be the union of two coordinate lines (a divisor in the class $2L$) and let $D' = \{x_2 = 0\}$ be a third line. Compute $D \cdot (D' \cdot [\mathbb{P}^2])$ and $D' \cdot (D \cdot [\mathbb{P}^2])$ as zero-cycles, verify they agree, and compute the degree of the product. Confirm the answer is $2 = \deg D \cdot \deg D'$, consistent with Bézout.

2. Let $S = \mathbb{P}^2$ with affine coordinates $u = x_0/x_2$, $v = x_1/x_2$ on the chart $x_2 \neq 0$. For the rational functions $f = u$ and $g = v$, compute the tame symbol $\partial_W(f, g)$ at each coordinate curve $W \in \{u = 0\}, \{v = 0\}$ and at the line at infinity, and verify directly that $\sum_W \operatorname{ord}_W(f)\,[\operatorname{div}_W(g)]$ and $\sum_W \operatorname{ord}_W(g)\,[\operatorname{div}_W(f)]$, each summed over the curves on which the relevant restriction is defined, are *not* equal as zero-cycles, that their difference is the divisor of the tame symbol, and that they are therefore rationally equivalent, which is all lemma 11.3.1 asserts.

3. Let $f\colon \mathbb{P}^1 \to \mathbb{P}^1$ be the degree-two map $[x_0 : x_1] \mapsto [x_0^2 : x_1^2]$ (characteristic $\neq 2$) and let $D = [\infty]$ be the divisor of the point at infinity on the target. Using proposition 11.3.3(1), compute both $f_*(f^*D \cdot [\mathbb{P}^1])$ and $D \cdot f_*[\mathbb{P}^1]$, identify the scalar $d = \deg f$, and confirm they agree.

4. Let $g\colon \mathbb{A}^1 \times \mathbb{P}^1 \to \mathbb{P}^1$ be the projection, flat of relative dimension one, and let $D = [0]$ be the origin on $\mathbb{P}^1$. Compute $g^*(D \cdot [\mathbb{P}^1])$ and $g^*D \cdot g^*[\mathbb{P}^1]$ and verify proposition 11.3.3(2) directly.

5. Deduce from theorem 11.3.2 that for any Cartier divisor D on a complete variety X of dimension n, the iterated intersection $D^n \cdot [X] \in A_0(X)$ is symmetric under any reordering of the n copies of D (trivially, but state precisely why the number $\deg(D^n \cdot [X])$ is well defined), and use theorem 10.5.2 to compute $H^n \cdot [\mathbb{P}^n]$ for H a hyperplane.

6. Explain why the proof of theorem 11.3.2 does not require X to be normal, identifying the exact step where normalization is used and why it changes neither side of the identity. (One sentence on each.)

11.4 The First Chern Class of a Line Bundle

The three previous sections built a single operation and studied it thoroughly: a Cartier divisor D on X acts on cycles by $\alpha \mapsto D \cdot \alpha$, this action descends to rational equivalence (proposition 11.2.4), and two such actions commute (theorem 11.3.2). The divisor D, however, is not the most invariant object in sight. What acts on $A_*(X)$ is not D itself but its linear-equivalence class, since D and $D + \operatorname{div}(r)$ produce the same operator, and a linear-equivalence class of Cartier divisors is exactly a line bundle. The right name for the operator is therefore the *first Chern class* of the associated line bundle $\mathcal{O}_X(D)$, written $c_1(\mathcal{O}_X(D)) \cap -$.

The renaming records that the operator depends only on $L = \mathcal{O}_X(D)$, so it is defined for a line bundle whether or not a divisor is at hand; it makes the additive structure transparent, because tensoring line bundles adds their Chern classes; and it is the first instance of a construction that in the next chapter will attach to a vector bundle E of rank r a whole family of operators $c_1(E), \dots, c_r(E)$, the higher Chern classes. Everything the first Chern class does is already contained in the divisor calculus of the preceding sections; this section repackages that calculus into its final, functorial form

and reads off the consequences.

The starting point is that the operator $D \cdot -$ sees only the line bundle $\mathcal{O}_X(D)$. Two Cartier divisors with isomorphic associated bundles are linearly equivalent, that is, they differ by the divisor of a rational function, and a principal divisor intersects every subvariety in a principal divisor, hence acts as zero on $A_*(X)$; proposition 11.4.2 below records this and is the independence needed to base the definition on L rather than on D.

Definition 11.4.1: The First Chern Class of a Line Bundle

Let L be a line bundle on an algebraic scheme X, and suppose $L \cong \mathcal{O}_X(D)$ for some Cartier divisor D on X. The *first Chern class* of L is the operator on Chow groups

$$c_1(L) \cap -\colon A_k(X) \longrightarrow A_{k-1}(X), \qquad c_1(L) \cap \alpha := D \cdot \alpha$$

defined for every k, where $D \cdot \alpha$ is the intersection with the Cartier divisor D of definition 11.2.1. The class $c_1(L)$ is the operator itself; the notation $c_1(L) \cap \alpha$ reads "$c_1(L)$ capped with α".

The definition names D but must not depend on it: a line bundle admits many divisors of sections, and the Chern class has to be the same for all of them. The following proposition is the price of the definition, and its proof is short because the work was done in section 11.2.

Proposition 11.4.2: Independence of the Divisor

Let L be a line bundle on X and let D, D' be Cartier divisors with $\mathcal{O}_X(D) \cong L \cong \mathcal{O}_X(D')$. Then $D \cdot \alpha = D' \cdot \alpha$ in $A_{k-1}(X)$ for every $\alpha \in A_k(X)$. Consequently $c_1(L) \cap -$ of definition 11.4.1 is well defined, independent of the choice of D.

***Proof*:**
An isomorphism $\mathcal{O}_X(D) \cong \mathcal{O}_X(D')$ of line bundles is exactly a linear equivalence $D \sim D'$ of Cartier divisors: the tautological rational section of $\mathcal{O}_X(D)$ and that of $\mathcal{O}_X(D')$, compared through the isomorphism, differ by a global invertible section r of the sheaf of total quotient rings $\mathcal{K}_X^*$, so $D - D' = \operatorname{div}(r)$ is principal (on a variety $\mathcal{K}_X^* = k(X)^*$ and r is a rational function; on a general algebraic scheme r is a section of the total-quotient sheaf, which is all the definition of a principal Cartier divisor requires). It therefore suffices to show that a principal Cartier divisor $\operatorname{div}(r)$ acts as zero on rational equivalence classes.

Fix $\alpha \in A_k(X)$ and represent it by a cycle $\sum_i n_i[V_i]$. Since $\operatorname{div}(r) \cdot -$ is defined component by component and extended $\mathbb{Z}$-linearly (definition 11.2.1), it suffices to show $\operatorname{div}(r) \cdot [V] = 0$ in $A_{k-1}(X)$ for a single k-dimensional subvariety V. The associated bundle of the principal divisor $\operatorname{div}(r)$ is $\mathcal{O}_X$, and the rational section of $\mathcal{O}_X$ that represents $\operatorname{div}(r)$ is r itself; unwinding definition 11.2.1 for this section gives

$$\operatorname{div}(r) \cdot [V] = \big[\operatorname{div}\big(r|_V\big)\big] \in A_{k-1}(V)$$

where $r|_V \in k(V)^*$ is the restriction of r to V (a nonzero rational function when $V \not\subseteq |\operatorname{div}(r)|$, and otherwise computed through the restricted trivial bundle $\mathcal{O}_X|_V \cong \mathcal{O}_V$, whose section is again a rational function on V). In either case $\operatorname{div}(r|_V)$ is the divisor of a rational function on the variety V, hence a *principal* Weil divisor on V, which is rationally equivalent to zero by the very definition of rational equivalence (definition 10.1.3). Its class in $A_{k-1}(V)$, and so its

image in $A_{k-1}(X)$, is therefore 0: intersecting a subvariety with a principal divisor produces a principal divisor, which dies in the Chow group. This is the same computation that drives the well-definedness of proposition 11.2.4, read now with the roles reversed, the divisor rather than the cycle being principal. Summing over the components of α gives $\operatorname{div}(r) \cdot \alpha = 0$, and so

$$D \cdot \alpha - D' \cdot \alpha = (D - D') \cdot \alpha = \operatorname{div}(r) \cdot \alpha = 0$$

giving $D \cdot \alpha = D' \cdot \alpha$, as we sought to show.

The proposition is the reason the notation $c_1(L)$ is legitimate at all. It shows the divisor served only to build the operator: once the operator exists, it is recorded by the line bundle alone. From here on a divisor is used to compute $c_1(L)$, never to define it, and the choice of divisor is a matter of convenience. On a variety, every line bundle admits a Cartier divisor, so the definition applies to all line bundles; on a general scheme one takes L to be of the form $\mathcal{O}_X(D)$, which covers every line bundle whose class lies in the image of the Cartier divisor class group. The definition and the properties below are stated for a general algebraic scheme, but every worked example and exercise that follows runs on a variety, where a rational section and its function field $k(V)$ are always at hand; the general-scheme statements specialize to these illustrations by taking X integral.

A first sanity check grounds the definition before its formal properties: the Chern class of the trivial bundle is the zero operator, and the two constructions available for a hyperplane bundle agree.

Example 11.4.3: The Trivial Bundle and the Hyperplane Bundle

1. *The trivial bundle.* For $L = \mathcal{O}_X$ one may take $D = 0$, the empty divisor. Then $c_1(\mathcal{O}_X) \cap \alpha = 0 \cdot \alpha = 0$ for every α, so $c_1(\mathcal{O}_X)$ is the zero operator. This matches the reading of c_1 as a measure of the twisting of L: a trivial bundle has no twisting to record.

2. *The hyperplane bundle on $\mathbb{P}^n$.* Let $L = \mathcal{O}_{\mathbb{P}^n}(1)$ and let $H \subseteq \mathbb{P}^n$ be a hyperplane, cut out by a linear form; then $\mathcal{O}_{\mathbb{P}^n}(H) \cong \mathcal{O}_{\mathbb{P}^n}(1)$. The class map of proposition 11.1.3 sends $\mathcal{O}_{\mathbb{P}^n}(1) \mapsto [H] \in A_{n-1}(\mathbb{P}^n)$, the generator of theorem 10.5.2 in codimension one. Capping with $[\mathbb{P}^n]$ recovers this class,

   $$c_1(\mathcal{O}_{\mathbb{P}^n}(1)) \cap [\mathbb{P}^n] = H \cdot [\mathbb{P}^n] = [H]$$

   since $\mathbb{P}^n \not\subseteq H$ and the restricted section of $\mathcal{O}_{\mathbb{P}^n}(1)$ to $\mathbb{P}^n$ has divisor exactly H. The first Chern class of $\mathcal{O}(1)$, capped against the fundamental class, is the hyperplane class.

With the operator anchored, its formal properties follow. Each is a translation of a divisor identity already proved, and the point of collecting them is to see the first Chern class as a well-behaved endomorphism of the graded group $A_*(X)$: additive in α, commuting with its own kind, additive in L, compatible with pushforward and pullback, and eventually nilpotent. The statement below is the working summary of the theory of c_1, and every clause is used repeatedly in the chapters that follow.

Proposition 11.4.4: Properties of the First Chern Class

Let X be an algebraic scheme, L, L' line bundles on X, and $\alpha \in A_k(X)$.

1. *Homomorphism.* $c_1(L) \cap -\colon A_k(X) \to A_{k-1}(X)$ is a group homomorphism: $c_1(L) \cap (\alpha + \beta) = c_1(L) \cap \alpha + c_1(L) \cap \beta$.

2. *Commutativity.* For line bundles L, L',
$$c_1(L) \cap \big(c_1(L') \cap \alpha\big) = c_1(L') \cap \big(c_1(L) \cap \alpha\big)$$
in $A_{k-2}(X)$.

3. *Additivity.* $c_1(L \otimes L') = c_1(L) + c_1(L')$ as operators; that is, $c_1(L \otimes L') \cap \alpha = c_1(L) \cap \alpha + c_1(L') \cap \alpha$. In particular $c_1(L^\vee) = -c_1(L)$.

4. *Projection formula.* For a proper morphism $f\colon X' \to X$, a line bundle L on X, and $\alpha' \in A_k(X')$,
$$f_*\big(c_1(f^*L) \cap \alpha'\big) = c_1(L) \cap f_*\alpha'$$
and for a flat morphism $g\colon X'' \to X$ of relative dimension m and $\beta \in A_k(X)$,
$$c_1(g^*L) \cap g^*\beta = g^*\big(c_1(L) \cap \beta\big)$$
in $A_{k+m-1}(X'')$. Equivalently, both squares commute:
$$\begin{array}{ccc} A_k(X') & \xrightarrow{c_1(f^*L)\cap -} & A_{k-1}(X') \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle f_*} \\ A_k(X) & \xrightarrow[c_1(L)\cap -]{} & A_{k-1}(X) \end{array} \qquad \begin{array}{ccc} A_k(X) & \xrightarrow{c_1(L)\cap -} & A_{k-1}(X) \\ {\scriptstyle g^*}\downarrow & & \downarrow{\scriptstyle g^*} \\ A_{k+m}(X'') & \xrightarrow[c_1(g^*L)\cap -]{} & A_{k+m-1}(X'') \end{array}$$

5. *Nilpotence.* If X is a variety of dimension n, then for any line bundle L,
$$c_1(L)^{n+1} \cap [X] = 0$$
where $c_1(L)^{n+1} \cap [X]$ means $c_1(L)$ capped $n+1$ times with the fundamental class $[X]$.

***Proof*:**
Choose Cartier divisors D, D' with $\mathcal{O}_X(D) \cong L$ and $\mathcal{O}_X(D') \cong L'$; by proposition 11.4.2 the choices do not affect any of the claims. Each part translates a divisor identity from section 11.2 or section 11.3.

1. *Homomorphism.* The intersection $D \cdot -$ is defined on cycles component by component and extended $\mathbb{Z}$-linearly (definition 11.2.1), so it is additive on $Z_k(X)$, and proposition 11.2.4 makes it descend to a well-defined additive map on $A_k(X)$. Hence $c_1(L) \cap - = D \cdot -$ is a homomorphism $A_k(X) \to A_{k-1}(X)$.

2. *Commutativity.* By definition $c_1(L) \cap (c_1(L') \cap \alpha) = D \cdot (D' \cdot \alpha)$ and $c_1(L') \cap (c_1(L) \cap \alpha) = D' \cdot (D \cdot \alpha)$. These are equal in $A_{k-2}(X)$ by theorem 11.3.2, the commutativity of intersection with two Cartier divisors.

3. *Additivity.* The associated-bundle construction of section 5.4 converts the sum of Cartier divisors into the tensor product of line bundles, $\mathcal{O}_X(D+D') \cong \mathcal{O}_X(D) \otimes_{\mathcal{O}_X} \mathcal{O}_X(D')$, so $D+D'$ is a Cartier divisor with $\mathcal{O}_X(D+D') \cong L \otimes L'$. Using this divisor to compute the Chern class of $L \otimes L'$,

$$c_1(L \otimes L') \cap \alpha = (D+D') \cdot \alpha = D \cdot \alpha + D' \cdot \alpha = c_1(L) \cap \alpha + c_1(L') \cap \alpha$$

where the middle equality is the additivity of $- \cdot \alpha$ in the divisor, and it holds already at the level of cycles, on *every* subvariety V, with no repositioning of α required. Since $D \cdot -$ is defined component by component and extended $\mathbb{Z}$-linearly (definition 11.2.1), it suffices to check $(D+D') \cdot [V] = D \cdot [V] + D' \cdot [V]$ for a single k-dimensional subvariety V. Restricting the tensor-product isomorphism above to V gives $\mathcal{O}_X(D+D')|_V \cong \mathcal{O}_X(D)|_V \otimes_{\mathcal{O}_V} \mathcal{O}_X(D')|_V$, so a rational section s_V of $\mathcal{O}_X(D+D')|_V$ representing $(D+D')|_V$ is the product $s_V = s_V^D \cdot s_V^{D'}$ of representing rational sections of $\mathcal{O}_X(D)|_V$ and $\mathcal{O}_X(D')|_V$. By definition 11.2.1 the cap is the class of the divisor of the restricted section computed inside V, and the order function along a codimension-one subvariety W of V is additive on a product of rational sections, $\operatorname{ord}_W(s_V^D \cdot s_V^{D'}) = \operatorname{ord}_W(s_V^D) + \operatorname{ord}_W(s_V^{D'})$, since ord_W is a valuation. Summing over such W gives $[\operatorname{div}(s_V)] = [\operatorname{div}(s_V^D)] + [\operatorname{div}(s_V^{D'})]$ in $A_{k-1}(V)$, that is $(D+D') \cdot [V] = D \cdot [V] + D' \cdot [V]$; pushing forward to X and summing over the components of α gives the middle equality. This is a cycle-level identity holding for each V, so no moving lemma repositioning α off $|D|$ and $|D'|$ is needed, and none exists in general. Taking $L' = L^\vee$, so that $\mathcal{O}_X \cong L \otimes L^\vee$ and $c_1(\mathcal{O}_X) = 0$ by example 11.4.3, gives $c_1(L) + c_1(L^\vee) = 0$, hence $c_1(L^\vee) = -c_1(L)$.

4. *Projection formula.* The pullback along f of the Cartier divisor D, in the pseudo-divisor formalism of definition 11.1.5, is a pseudo-divisor f^*D with $f^*\mathcal{O}_X(D) \cong \mathcal{O}_{X'}(f^*D)$; so $c_1(f^*L) \cap \alpha' = f^*D \cdot \alpha'$. The proper case is the divisor projection formula $f_*(f^*D \cdot \alpha') = D \cdot f_*\alpha'$ of proposition 11.3.3, which rewritten with Chern-class notation is exactly $f_*(c_1(f^*L) \cap \alpha') = c_1(L) \cap f_*\alpha'$. The flat case is the compatibility $g^*(D \cdot \beta) = g^*D \cdot g^*\beta$ of the same proposition, and since $c_1(g^*L) \cap g^*\beta = g^*D \cdot g^*\beta$ this reads $c_1(g^*L) \cap g^*\beta = g^*(c_1(L) \cap \beta)$.

5. *Nilpotence.* Each cap with $c_1(L)$ lowers dimension by one, since $c_1(L) \cap -\colon A_j(X) \to A_{j-1}(X)$ by definition 11.4.1, so repeatedly capping $[X] \in A_n(X)$ gives

$$c_1(L)^{n+1} \cap [X] \in A_{n-(n+1)}(X) = A_{-1}(X)$$

and $A_j(X) = 0$ for $j < 0$, there being no subvarieties of negative dimension. Hence the class is zero.

Each clause has been reduced to a result of the preceding sections, completing the proof.

The well-definedness proved above lets $D \cdot -$ be evaluated on any representative that avoids $|D|$, which is all the divisor calculus of this chapter needs, and which is available in every case it treats. Later constructions cannot make that choice: in chapter 13 a cycle is intersected with the fibre at infinity of a degeneration, and *every* component of the relevant representative lies in that fibre. The following strengthening removes the avoidance hypothesis, and it is what makes those constructions legitimate.

Corollary 11.4.5: Divisor Intersection on a Closed Subscheme

Let D be a Cartier divisor on X and $T \subseteq X$ a closed subscheme, with no hypothesis relating T to $|D|$ and none making $D|_T$ a Cartier divisor on T. Then intersection with D descends to a homomorphism

$$D \cdot - \;:\; A_k(T) \longrightarrow A_{k-1}\big(T \cap |D|\big)$$

computed on any representative cycle, and compatible with the inclusion of T in X: for a cycle on T the two readings of definition 11.2.1, one in T and one in X, agree.

***Proof*:**
At the level of cycles there is nothing to prove: definition 11.2.1 computes $D \cdot [V]$ for a subvariety V from the restricted line bundle $\mathcal{O}_X(D)|_V$ and from whether $V \subseteq |D|$, and neither datum changes when V is regarded inside T rather than X. This is the reason the definition was framed through the pseudo-divisor $(\mathcal{O}_X(D), |D|, s_D)$ of definition 11.1.5: a pseudo-divisor restricts to any subscheme, whereas a Cartier divisor need not, its local equations being free to become zero divisors.

What needs an argument is that the operation kills cycles rationally equivalent to zero *on* T, and lands in the smaller group. Such a cycle is a sum of $\operatorname{div}(r)$ for $(k+1)$-dimensional subvarieties $W \subseteq T$ and $r \in k(W)^*$ (definition 10.1.3). The proof of proposition 11.4.6 treats exactly these generators, and in both of its cases the vanishing it produces is already recorded on W: in the case $W \subseteq |D|$ the class is computed in $A_{k-1}(W)$ before being pushed forward, and in the case $W \not\subseteq |D|$ the appeal to theorem 11.3.2 places the identity in $A_{k-1}(|D| \cap |\operatorname{div}(r)| \cap W)$. Both groups map to $A_{k-1}(T \cap |D|)$, so $D \cdot \operatorname{div}(r) = 0$ there, as we sought to show.

Proposition 11.4.6: Divisor Intersection on an Arbitrary Representative

Let D be a Cartier divisor on an algebraic scheme X and let $\alpha \in Z_k(X)$ be a cycle rationally equivalent to zero, with *no* hypothesis on its components. Then

$$D \cdot \alpha = 0 \quad \text{in } A_{k-1}(|D|)$$

Consequently $D \cdot -$ may be computed from any representative of a class in $A_k(X)$, including one all of whose components lie in $|D|$, and every representative gives the same class in $A_{k-1}(|D|)$.

***Proof*:**
Both sides are additive, so it suffices to treat $\alpha = [\operatorname{div}(r)]$ for a $(k+1)$-dimensional subvariety $W \subseteq X$ and a rational function $r \in k(W)^*$, these being the generators of the subgroup of cycles rationally equivalent to zero (definition 10.1.3). Write $\iota \colon W \hookrightarrow X$ for the inclusion.

Case 1: $W \subseteq |D|$. Every component of $\operatorname{div}(r)$ lies in W, hence in $|D|$, so clause (2) of definition 11.2.1 computes $D \cdot [\operatorname{div}(r)]$ from the restricted line bundle. By definition 11.4.1 that value is $c_1\big(\mathcal{O}_X(D)|_W\big) \cap [\operatorname{div}(r)]$, computed in $A_{k-1}(W)$. Now $[\operatorname{div}(r)] = 0$ in $A_k(W)$ by the definition of rational equivalence, and $c_1(\mathcal{O}_X(D)|_W) \cap -$ is a homomorphism on Chow *classes* (proposition 11.4.4(1)), so it sends 0 to 0. Pushing forward along the closed immersion $W \hookrightarrow |D|$ gives $D \cdot [\operatorname{div}(r)] = 0$ in $A_{k-1}(|D|)$.

Case 2: $W \not\subseteq |D|$. Then D restricts to a Cartier divisor $D|_W$ on W, and $[\mathrm{div}(r)] = \mathrm{div}(r) \cdot [W]$ exhibits α as the result of intersecting the fundamental class of W with the principal Cartier divisor $\mathrm{div}(r)$ on W. Commutativity of divisor intersection (theorem 11.3.2), applied on W to the pair $D|_W$ and $\mathrm{div}(r)$, gives

$$D|_W \cdot \big(\mathrm{div}(r) \cdot [W]\big) \;=\; \mathrm{div}(r) \cdot \big(D|_W \cdot [W]\big)$$

and that theorem records the identity in the refined group $A_{k-1}\big(|D| \cap |\mathrm{div}(r)| \cap W\big)$, so it may be read there. The right-hand side vanishes: the line bundle of a principal divisor is trivial, $\mathcal{O}_W(\mathrm{div}(r)) \cong \mathcal{O}_W$, so $\mathrm{div}(r) \cdot -$ is $c_1(\mathcal{O}_W) \cap -$, and c_1 of a trivial bundle is the zero operator by proposition 11.4.4(3) applied to $L = L' = \mathcal{O}_W$. Hence $D \cdot [\mathrm{div}(r)] = 0$ in $A_{k-1}(|D|)$, completing the proof.

Nothing in the argument is circular: theorem 11.3.2 is proved from the avoidance-hypothesis form proposition 11.2.4 alone, so it may be used here to remove that hypothesis.

Parts (1) through (4) say that c_1 is a homomorphism of graded groups compatible with all the structure already on A_*, and that $L \mapsto c_1(L)$ turns tensor product into addition, so $c_1 \colon \mathrm{Pic}\,(X) \to \mathrm{End}(A_*(X))$ is a homomorphism from the Picard group into the operators lowering degree by one. Part (2), the commutativity, is the fact that makes these operators generate a commutative subring of $\mathrm{End}(A_*(X))$; it is the discharged form of the divisor symmetry that theorem 10.4.6 in section 10.4 took on faith, now proved through theorem 11.3.2. Part (5), the nilpotence, is a dimension count: it says a single line bundle can only cut down the fundamental class n times before the result must vanish, and it is what makes the top self-intersection number $c_1(L)^n \cap [X]$, a zero-cycle, the natural degree-type invariant of L on a complete variety.

The nilpotence has a converse worth flagging: while $c_1(L)^{n+1} \cap [X]$ always vanishes, the intermediate power $c_1(L)^n \cap [X] \in A_0(X)$ need not, and its degree $\int_X c_1(L)^n$ is the numerical invariant of a line bundle on an n-dimensional complete variety. For $n = 1$ this is the degree of a line bundle on a curve; for a surface it is the self-intersection L^2. These invariants are the raw material of the intersection numbers computed throughout this book.

The first substantial computation is the self-intersection of $\mathcal{O}(1)$ on projective space, which reproduces the entire linear-subspace basis of theorem 10.5.2 from a single line bundle. It shows the first Chern class already generates the Chow ring of $\mathbb{P}^n$, and it is the model computation the higher Chern classes generalize.

Example 11.4.7: Powers of the Hyperplane Class on $\mathbb{P}^n$

Let $H = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$ act on $A_*(\mathbb{P}^n)$. By theorem 10.5.2 the Chow group $A_*(\mathbb{P}^n) = \bigoplus_{j=0}^{n} \mathbb{Z}\,[\mathbb{P}^j]$ is free on the classes of linear subspaces, with $[\mathbb{P}^j]$ the class of a j-plane. The claim is

$$c_1(\mathcal{O}_{\mathbb{P}^n}(1))^k \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}], \qquad 0 \le k \le n$$

so the k-th self-cap of the hyperplane bundle is the class of a linear subspace of codimension k.

The proof is induction on k. For $k = 0$ the left side is $[\mathbb{P}^n]$, the fundamental class, and $[\mathbb{P}^{n-0}] = [\mathbb{P}^n]$. Assume $c_1(\mathcal{O}(1))^k \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}]$ for some $k < n$, so the class is represented by the subvariety $\mathbb{P}^{n-k} \subseteq \mathbb{P}^n$, a linear subspace of dimension $n-k$. Cap once more with H. There is a hyperplane H_0 with $\mathbb{P}^{n-k} \not\subseteq H_0$, because some linear form does not vanish identically on the nonempty $\mathbb{P}^{n-k}$ (equivalently, $\mathbb{P}^{n-k}$ is not contained in every hyperplane); its zero locus is such an H_0, and $H_0 \cap \mathbb{P}^{n-k}$ is then a hyperplane inside $\mathbb{P}^{n-k}$, of dimension $n-k-1$. Thus $\mathbb{P}^{n-k} \not\subseteq |H_0|$, and by definition 11.2.1 the cap $H \cdot [\mathbb{P}^{n-k}]$ is the divisor of the restricted linear form on $\mathbb{P}^{n-k}$, namely the

hyperplane section $H_0 \cap \mathbb{P}^{n-k}$, a linear subspace $\mathbb{P}^{n-k-1}$ of dimension $n-k-1$:

$$c_1(\mathcal{O}(1))^{k+1} \cap [\mathbb{P}^n] = H \cdot [\mathbb{P}^{n-k}] = [H_0 \cap \mathbb{P}^{n-k}] = [\mathbb{P}^{n-k-1}]$$

completing the induction. In particular $c_1(\mathcal{O}(1))^n \cap [\mathbb{P}^n] = [\mathbb{P}^0] = [\mathrm{pt}]$ is the class of a single point, and its degree is

$$\int_{\mathbb{P}^n} c_1(\mathcal{O}_{\mathbb{P}^n}(1))^n = 1$$

the statement that n general hyperplanes in $\mathbb{P}^n$ meet in a single reduced point. Capping once more, $c_1(\mathcal{O}(1))^{n+1} \cap [\mathbb{P}^n] = H \cdot [\mathrm{pt}] = 0$, in agreement with the nilpotence of proposition 11.4.4(5). Every generator $[\mathbb{P}^j]$ of $A_*(\mathbb{P}^n)$ is thus a power of $c_1(\mathcal{O}(1))$ applied to $[\mathbb{P}^n]$, so the first Chern class of the hyperplane bundle generates the Chow group of projective space as a module over the operators.

The computation is the first appearance of the ring structure that intersection theory is heading toward: on $\mathbb{P}^n$ the operators H^k multiply the way linear subspaces intersect, $[\mathbb{P}^a] \cdot [\mathbb{P}^b] = [\mathbb{P}^{a+b-n}]$ when $a+b \geq n$ and zero otherwise, and $\int_{\mathbb{P}^n} H^n = 1$ is the normalization. The Chow group $A_*(\mathbb{P}^n)$ is the truncated polynomial ring $\mathbb{Z}[H]/(H^{n+1})$ with $H = c_1(\mathcal{O}(1))$, and the nilpotence relation $H^{n+1} = 0$ is exactly proposition 11.4.4(5). This ring will be built in general later in this Part, once the intersection product is available; here it is visible for projective space through the single line bundle $\mathcal{O}(1)$.

The second computation identifies c_1 on a curve with the classical degree, tying the abstract operator to the invariant every reader already knows. On a smooth projective curve the first Chern class is the degree map, and capping with $c_1(L)$ is subtraction of that degree from the point count.

Example 11.4.8: The First Chern Class on a Curve is the Degree

Let C be a smooth projective curve over $\overline{k}$ and L a line bundle on C. Since $\dim C = 1$, the only nonzero cap is on $A_1(C) = \mathbb{Z}\,[C]$, and it lands in $A_0(C)$. Write $L \cong \mathcal{O}_C(D)$ for a Cartier divisor $D = \sum_P n_P\,[P]$, which on a smooth curve is the same as a Weil divisor, a finite $\mathbb{Z}$-combination of closed points. Then

$$c_1(L) \cap [C] = D \cdot [C] = \sum_P n_P\,[P] \in A_0(C)$$

by definition 11.2.1, the section of $\mathcal{O}_C(D)$ having divisor D on the curve C itself. Pushing this zero-cycle to a point through $\pi\colon C \to \operatorname{Spec} \overline{k}$ and taking degrees (definition 10.2.4),

$$\int_C c_1(L) \cap [C] = \sum_P n_P\,[\overline{k}(P) : \overline{k}] = \sum_P n_P = \deg D = \deg L$$

since every closed point of a variety over the algebraically closed field $\overline{k}$ has residue field $\overline{k}$. The number $\int_C c_1(L)$ is the degree of the line bundle. Under the identification $A_0(C) \cong \operatorname{Cl} C = \operatorname{Pic} C$ of proposition 10.5.3, capping with $c_1(L)$ against $[C]$ is the class map $L \mapsto [D]$, and its composite with the degree $A_0(C) \xrightarrow{\deg} \mathbb{Z}$ recovers the degree of the divisor class, fitting into the sequence $0 \to \operatorname{Pic}^0 C \to A_0(C) \xrightarrow{\deg} \mathbb{Z} \to 0$ of proposition 10.5.3.

The two computations frame the whole theory. On projective space $c_1(\mathcal{O}(1))$ generates the Chow ring and its top power counts a single point; on a curve $c_1(L)$ is the degree, the invariant that governs Riemann-Roch through $\chi(L) = \deg L + 1 - g$ (theorem 7.2.10). Both come from one construction:

the first Chern class turns a line bundle into an operator on cycles, and its powers are the numerical invariants that intersection theory computes. The chapter that follows generalizes the construction from line bundles to vector bundles of arbitrary rank: a rank-r bundle E carries Chern classes $c_1(E), \dots, c_r(E)$, built so that c_1 of a line bundle is the operator of this section, and so that the total Chern class is multiplicative in short exact sequences. The machine that produces them, Segre classes of the projectivized bundle $\mathbb{P}(E)$, is the subject of the next chapter, and the divisor calculus of this chapter is the rank-one base case on which it is built.

Exercise 11.4.1

1. Compute $\int_{\mathbb{P}^1} c_1(\mathcal{O}_{\mathbb{P}^1}(d))$ for every integer d, both by the curve-degree formula of example 11.4.8 and directly from a divisor of a section of $\mathcal{O}_{\mathbb{P}^1}(d)$. Confirm that $c_1 \colon \operatorname{Pic}(\mathbb{P}^1) \to A_0(\mathbb{P}^1) = \mathbb{Z}$ is an isomorphism.

2. Let S be a smooth projective surface and $L = \mathcal{O}_S(C)$ for a curve $C \subseteq S$. Express $c_1(L)^2 \cap [S] \in A_0(S)$ and its degree $\int_S c_1(L)^2$ in terms of the divisor C, and identify $\int_S c_1(L)^2$ with the self-intersection number $C \cdot C$ of the surface theory of section 8.2. Why does proposition 11.4.4(5) say $c_1(L)^3 \cap [S] = 0$?

3. Using proposition 11.4.4(3), show that $c_1 \colon \operatorname{Pic}(X) \to \operatorname{End}(A_*(X))$ is a group homomorphism from the Picard group to the additive group of degree-lowering operators. Deduce that $c_1(L^{\otimes m}) = m\, c_1(L)$ for every integer m, and that c_1 factors through the numerical class of L in the sense that linearly equivalent line bundles have equal first Chern class.

4. On $\mathbb{P}^1 \times \mathbb{P}^1$, let p_1, p_2 be the two projections and $L = p_1^*\mathcal{O}(a) \otimes p_2^*\mathcal{O}(b)$ the line bundle of bidegree (a, b). Using the projection formula proposition 11.4.4(4) and additivity, compute $\int_{\mathbb{P}^1 \times \mathbb{P}^1} c_1(L)^2$ in terms of a and b. (You may use $A_*(\mathbb{P}^1 \times \mathbb{P}^1)$ free on the classes of a point, the two rulings, and the fundamental class, with each ruling of self-intersection zero and the two rulings meeting in one point.)

5. Let $f \colon X \to Y$ be a proper surjective morphism of varieties with $\dim X = \dim Y = n$ and generic degree δ, and let L be a line bundle on Y. Show that $\int_X c_1(f^*L)^n = \delta \int_Y c_1(L)^n$. (Cap the projection formula n times and use $f_*[X] = \delta\,[Y]$.) Then explain why $c_1(f^*L)^{n+1} \cap [X] = 0$ holds regardless of δ.

Part II

Chern Classes and the Intersection Product

Everything so far has been rank one. The Chow group was cut out of the cycle group by rational equivalence, made functorial by proper pushforward and flat pullback, and then acted on by a single operator: intersecting with a Cartier divisor, which is to say capping with the first Chern class of a line bundle. That operator lowers dimension by one, commutes with itself, and satisfies a projection formula. It is also the only operator available, and a line bundle is the only bundle it sees.

This part removes both restrictions. A vector bundle of rank $r+1$ carries $r+1$ operators rather than one, and the projective bundle of its lines is the space on which they can be constructed: pushing powers of the tautological class down to the base produces the Segre classes, inverting the resulting series produces the Chern classes, and the geometry of the bundle forces the relations among them. With operators of every codimension in hand, the remaining question is whether two cycles can be multiplied rather than operated on. They can, and the mechanism is deformation to the normal cone, which replaces the classical manoeuvre of moving cycles into general position with a degeneration of the ambient embedding. The product it yields makes $A^*(X)$ a ring for smooth X, recovers Bézout's theorem, and subsumes the surface intersection pairing that *Algebraic Geometry* [9] built by hand.

12

Cones, Segre Classes, and Chern Classes of Vector Bundles

The construction of this chapter rests on one geometric observation. A vector bundle E on X has no interesting cycles of its own, being an affine bundle and so contributing nothing beyond $A_*(X)$ by theorem 10.4.6. Its projectivization $\mathbb{P}(E)$ does: it is proper over X, it carries the tautological line bundle $\mathcal{O}_{\mathbb{P}(E)}(1)$, and the first Chern class of that line bundle acts on $A_*(\mathbb{P}(E))$ by the first-Chern-class operator constructed in Chapter 11. Pushing its powers back down to X therefore produces operators on $A_*(X)$ out of nothing but the rank-one theory, and those operators are the Segre classes.

The chapter develops this in four movements. The Segre classes come first, along with the projective-bundle formula that computes $A_*(\mathbb{P}(E))$ completely and which was promised without proof in chapter 10. Chern classes follow by inverting the Segre series, and the splitting principle, made legitimate by the flag bundle, reduces their identities to the rank-one case already in hand. The Chern character and Todd class are then assembled as polynomial expressions in these operators, with the rational coefficients their denominators force. The chapter closes by extending Segre classes from vector bundles to cones, and so to arbitrary closed subschemes, which is the input chapter 13 needs.

12.1 Segre Classes and the Projective Bundle

A vector bundle E on X determines a projective bundle $\pi\colon \mathbb{P}(E) \to X$ carrying a tautological line bundle. Pushing powers of that line bundle's first Chern class down to X produces a family of operators on $A_*(X)$, the Segre classes, and the structural theorem behind them computes $A_*(\mathbb{P}(E))$ from $A_*(X)$ together with the powers of the tautological class. Both are built here, the second in full, discharging the formula recorded without proof in section 10.5.

The projective bundle itself is not built here. *Algebraic Geometry* [9] constructs Proj of a graded quasi-coherent algebra (definition 5.3.47) and its twisting sheaf (theorem 5.3.49), specializes the construction to a locally free sheaf (definition 5.3.51), and proves there that the resulting morphism is proper and flat (proposition 5.3.54) and locally trivial over a trivializing cover (proposition 5.3.52). One translation is needed at the point of import. What that volume writes $\mathbb{P}(\mathscr{E})$ parametrizes one-dimensional *quotients* of the fibres, while this book's $\mathbb{P}(E)$ parametrizes one-dimensional *subspaces* (box 9.0.2). Writing $\mathscr{E}$ for the sheaf of sections of E, the two are related by a dual:

$$\mathbb{P}(E) \;=\; \operatorname{Proj}\left(\operatorname{Sym}^{\bullet}\mathscr{E}^{\vee}\right)$$

so the bundle this book calls $\mathbb{P}(E)$ is the one [9] calls $\mathbb{P}(\mathscr{E}^{\vee})$. Under that identification the twisting sheaf $\mathcal{O}(1)$ of the relative Proj is the universal rank-one quotient of $\pi^{*}\mathscr{E}^{\vee}$ (proposition 5.3.53); dualizing that surjection exhibits $\mathcal{O}(1)^{\vee}$ as the universal rank-one *subsheaf* of $\pi^{*}\mathscr{E}$, which is the tautological line. So $\mathcal{O}_{\mathbb{P}(E)}(1)$ is the dual of the tautological subbundle, which is what the subspace convention requires. Every formula below is read in that convention.

Throughout, E has rank $r+1$, so the fibre $\mathbb{P}(E_x)$ is a projective space of dimension r. All fibres of π are pure of dimension r, and π is flat, so π is flat of relative dimension r in the sense of definition 10.3.1; flat pullback $\pi^{*}\colon A_k(X) \to A_{k+r}(\mathbb{P}(E))$ is therefore defined by definition 10.3.3, and π being proper, pushforward $\pi_{*}\colon A_k(\mathbb{P}(E)) \to A_k(X)$ is defined by definition 10.2.1. These two maps and the divisor calculus of chapter 11 are all this section uses.

Definition 12.1.1: The Tautological Class of a Projective Bundle

Let E be a vector bundle of rank $r+1$ on an algebraic scheme X, let $\pi\colon \mathbb{P}(E) \to X$ be the associated bundle of lines in E, and let $\mathcal{O}_{\mathbb{P}(E)}(1)$ be the dual of the tautological subbundle. The *tautological class* of E is the first Chern class operator

$$\xi \;=\; c_1\big(\mathcal{O}_{\mathbb{P}(E)}(1)\big)$$

of definition 11.4.1, so that $\xi \cap -\colon A_k(\mathbb{P}(E)) \to A_{k-1}(\mathbb{P}(E))$ for every k. Its powers $\xi^{i} \cap -$ are the i-fold iterates of this operator, with $\xi^{0} \cap -$ the identity.

The class ξ is an operator on the Chow groups of the total space, not an element of a ring: there is no product on $A_{*}(\mathbb{P}(E))$ until the intersection product of a later chapter gives one. What makes ξ usable is that the operators $\xi \cap -$ commute among themselves and with every other first Chern class, by proposition 11.4.4(2), so an expression such as $\xi^{i} \cap \pi^{*}\alpha$ is unambiguous however it is bracketed.

Example 12.1.2: The Tautological Class on $\mathbb{P}^n$ and on a Line Bundle

Two extreme cases fix the meaning of ξ.

1. *A trivial bundle over a point.* Let $X = \operatorname{Spec}\overline{k}$ and $E = \overline{k}^{\,n+1}$, so $\mathbb{P}(E) = \mathbb{P}^n$ is the space of lines through the origin in $\overline{k}^{\,n+1}$ and $\mathcal{O}_{\mathbb{P}(E)}(1) = \mathcal{O}_{\mathbb{P}^n}(1)$ is the Serre twist. Here $\xi = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$, and example 11.4.7 computes its powers outright:
$$\xi^{k} \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}], \qquad 0 \le k \le n$$
with $\xi^{n+1} \cap [\mathbb{P}^n] = 0$. The tautological class of the trivial bundle over a point is the hyperplane class.
2. *A line bundle.* Let $E = L$ have rank one, so $r = 0$. A one-dimensional subspace of a one-dimensional fibre is the whole fibre, so $\mathbb{P}(L) = X$ and $\pi = \mathrm{id}$; in the Proj description, $\operatorname{Sym}^{\bullet}$

of an invertible sheaf has $\operatorname{Proj}(\operatorname{Sym}^\bullet \mathscr{E}^\vee) = X$ and $\mathcal{O}(1) = \mathscr{E}^\vee$, where $\mathscr{E}$ is the invertible sheaf of sections of L. The tautological subbundle is L itself, hence $\mathcal{O}_{\mathbb{P}(L)}(1) = L^\vee$ and, by proposition 11.4.4(3),

$$\xi = c_1(L^\vee) = -c_1(L)$$

The sign is forced by the convention: the tautological object is a *sub*bundle, and $\mathcal{O}(1)$ is its dual.

The tautological class lives on $\mathbb{P}(E)$, and the Chow groups one wants to compute with live on X. Transporting a class α on X up to $\mathbb{P}(E)$, cutting it with powers of ξ, and pushing the result back down produces an operator on $A_*(X)$ built from E alone. The bookkeeping is forced: π^* raises dimension by r, capping with ξ^m lowers it by m, and π_* preserves it, so the composite lowers dimension by $m - r$. Writing $m = r + i$ makes i the amount of dimension lost, and these composites are the Segre classes.

Definition 12.1.3: Segre Class Operators of a Vector Bundle

Let E be a vector bundle of rank $r+1$ on an algebraic scheme X, with $\pi\colon \mathbb{P}(E) \to X$ and tautological class ξ. For an integer $i \geq -r$ the *i-th Segre class* of E is the operator defined on $\alpha \in A_k(X)$ by

$$s_i(E) \cap \alpha \;=\; \pi_*\big(\xi^{\,r+i} \cap \pi^*\alpha\big)$$

and $s_i(E) \cap \alpha = 0$ for $i < -r$. Each is a homomorphism $s_i(E) \cap -\colon A_k(X) \to A_{k-i}(X)$. The *total Segre class* of E is the sum

$$s(E) \;=\; \sum_{i \geq -r} s_i(E)$$

which is a finite sum of operators on any fixed class, since $s_i(E)$ lowers dimension by i and $A_j(X) = 0$ for $j < 0$.

That $s_i(E) \cap -$ is a homomorphism is inherited from its three constituents: π^* is additive by proposition 10.3.5(1), capping with ξ is additive by proposition 11.4.4(1), and π_* is additive by definition 10.2.1. Each of the three also descends to rational equivalence, by proposition 10.3.7, proposition 11.2.4 and theorem 10.2.3 respectively, so $s_i(E) \cap -$ is well defined on Chow groups without further argument. The content of the definition is not that these operators exist but that they are computable and that they encode E; the rank-one case already shows what they look like.

Example 12.1.4: The Segre Classes of a Line Bundle

Let L be a line bundle on X, so $r = 0$ and, by example 12.1.2(2), $\mathbb{P}(L) = X$ with $\pi = \mathrm{id}$ and $\xi = -c_1(L)$. The definition reads

$$s_i(L) \cap \alpha = \xi^{\,i} \cap \alpha = (-1)^i\, c_1(L)^i \cap \alpha, \qquad i \geq 0$$

there being no indices below $-r = 0$. The total Segre class is therefore the alternating series

$$s(L) = 1 - c_1(L) + c_1(L)^2 - c_1(L)^3 + \cdots$$

which on any fixed class terminates, since $c_1(L)^m \cap \alpha$ lies in $A_{k-m}(X)$ and this group vanishes once $m > k$. The series is the inverse of $1 + c_1(L)$: capping $s(L) \cap \alpha$ with $1 + c_1(L)$ telescopes, every term cancelling against its successor, and leaves α.

For a concrete instance take $X = \mathbb{P}^n$ and $L = \mathcal{O}_{\mathbb{P}^n}(1)$. Then $c_1(L)^i \cap [\mathbb{P}^n] = [\mathbb{P}^{n-i}]$ by example 11.4.7, so

$$s_i\big(\mathcal{O}_{\mathbb{P}^n}(1)\big) \cap [\mathbb{P}^n] = (-1)^i\,[\mathbb{P}^{n-i}], \qquad 0 \le i \le n$$

and $s_i(\mathcal{O}_{\mathbb{P}^n}(1)) \cap [\mathbb{P}^n] = 0$ for $i > n$. The Segre classes of a line bundle carry exactly the information in c_1, packaged with alternating signs.

The alternating signs in example 12.1.4 indicate that $s(E)$ is the wrong normalization for a class one wants to be additive on direct sums; the repair, carried out in section 12.2, is to invert the series. Before that, the operators need their formal properties: which of them vanish, which one is the identity, whether they commute, and how they behave under the two functorialities of the Chow group. All four are consequences of the corresponding properties of c_1 and of the flat-proper calculus of chapter 10.

Proposition 12.1.5: Basic Properties of Segre Classes

Let E be a vector bundle of rank $r+1$ on an algebraic scheme X.

1. *Vanishing.* $s_i(E) \cap \alpha = 0$ for every $i < 0$ and every $\alpha \in A_*(X)$.
2. *Normalization.* $s_0(E) \cap \alpha = \alpha$ for every $\alpha \in A_*(X)$; that is, $s_0(E)$ is the identity operator. Consequently $s(E) = 1 + s_1(E) + s_2(E) + \cdots$.
3. *Commutativity.* If F is a second vector bundle on X, then for all i, j
$$s_i(E) \cap \big(s_j(F) \cap \alpha\big) = s_j(F) \cap \big(s_i(E) \cap \alpha\big)$$
4. *Functoriality.* If $f\colon X' \to X$ is proper and $\alpha' \in A_k(X')$, then
$$f_*\big(s_i(f^*E) \cap \alpha'\big) = s_i(E) \cap f_*\alpha'$$
and if $g\colon X'' \to X$ is flat of relative dimension m and $\beta \in A_k(X)$, then
$$s_i(g^*E) \cap g^*\beta = g^*\big(s_i(E) \cap \beta\big)$$

***Proof*:**
Formation of $\mathbb{P}(E)$ and of $\mathcal{O}_{\mathbb{P}(E)}(1)$ from $\operatorname{Sym}^\bullet \mathscr{E}^\vee$ commutes with base change along an arbitrary morphism (proposition 5.3.50), so for any morphism $h\colon Y \to X$ there is a fibre square

$$\begin{array}{ccc} \mathbb{P}(h^*E) & \xrightarrow{h'} & \mathbb{P}(E) \\ \downarrow{\scriptstyle \pi_Y} & & \downarrow{\scriptstyle \pi} \\ Y & \xrightarrow{h} & X \end{array}$$

with $\mathbb{P}(h^*E) = \mathbb{P}(E) \times_X Y$ and $\mathcal{O}_{\mathbb{P}(h^*E)}(1) = h'^*\mathcal{O}_{\mathbb{P}(E)}(1)$, hence $\xi_Y = h'^*\xi$ for the tautological classes. This square is used in every part.

1. *Vanishing.* By additivity it suffices to treat $\alpha = [V]$ for a k-dimensional subvariety $V \subseteq X$, with closed immersion $h\colon V \hookrightarrow X$. Since h is proper and π is flat, proposition 10.3.6 applied to the square above gives $\pi^* h_* = h'_* \pi_V^*$, so
$$\pi^*[V] = h'_*\,\pi_V^*[V]$$

and proposition 11.4.4(4) for the proper h', applied $r+i$ times with $\xi_V = h'^*\xi$, gives

$$\xi^{r+i} \cap \pi^*[V] = h'_*\big(\xi_V^{r+i} \cap \pi_V^*[V]\big)$$

Pushing forward by π and using $\pi \circ h' = h \circ \pi_V$ with functoriality of proper pushforward,

$$s_i(E) \cap [V] = h_*\, \pi_{V*}\big(\xi_V^{r+i} \cap \pi_V^*[V]\big) \tag{12.1}$$

The class inside h_* lies in $A_{k-i}(V)$, and for $i < 0$ one has $k - i > k = \dim V$, so that group is zero: V has no subvariety of dimension exceeding its own. Hence $s_i(E) \cap [V] = 0$.

2. *Normalization.* The inner class in (12.1) is $s_i(E|_V) \cap [V]$ computed on V, so that identity reduces the claim to the case $\alpha = [X]$ with X a variety of dimension k, where it reads $\pi_*(\xi^r \cap [\mathbb{P}(E)]) = [X]$; note that $\pi^*[X] = [\mathbb{P}(E)]$ by proposition 10.3.5(2). The total space $\mathbb{P}(E)$ is a variety: it is covered by open sets isomorphic to $U_\lambda \times \mathbb{P}^r$ for a trivializing cover $\{U_\lambda\}$ of X (proposition 5.3.52), each of which is irreducible and reduced, and any two of them meet because their images in the irreducible X do. So $\dim \mathbb{P}(E) = k + r$ and $\pi_*(\xi^r \cap [\mathbb{P}(E)])$ lies in $A_k(X) = Z_k(X) = \mathbb{Z}\,[X]$ by example 10.1.6(3); write it as $m\,[X]$ with $m \in \mathbb{Z}$.

   The integer m is computed after restriction to a trivializing open. Choose a nonempty open $U \subseteq X$ with $E|_U$ trivial, and let $j\colon U \hookrightarrow X$ and $j'\colon \mathbb{P}(E|_U) \hookrightarrow \mathbb{P}(E)$ be the inclusions, both flat of relative dimension zero. Flat pullback commutes with π_* across the fibre square by proposition 10.3.6 and with capping by ξ by proposition 11.4.4(4), and $j'^*[\mathbb{P}(E)] = [\mathbb{P}(E|_U)]$ because restriction along an open immersion carries a fundamental cycle to a fundamental cycle (example 10.3.4(1)), so

$$j^*\big(m\,[X]\big) = \pi_{U*}\big(\xi_U^r \cap [\mathbb{P}(E|_U)]\big)$$

   Under a trivialization $\mathbb{P}(E|_U) \cong U \times \mathbb{P}^r$ the twisting sheaf becomes $\rho^*\mathcal{O}_{\mathbb{P}^r}(1)$ for the second projection $\rho\colon U \times \mathbb{P}^r \to \mathbb{P}^r$ (definition 5.3.21), and ρ is flat of relative dimension $\dim U$, so $\rho^*[\mathbb{P}^r] = [U \times \mathbb{P}^r]$ by proposition 10.3.5(2). Hence, by the flat case of proposition 11.4.4(4) and by example 11.4.7,

$$\xi_U^r \cap [U \times \mathbb{P}^r] = \rho^*\big(c_1(\mathcal{O}_{\mathbb{P}^r}(1))^r \cap [\mathbb{P}^r]\big) = \rho^*[\mathrm{pt}] = [U \times \{\mathrm{pt}\}]$$

   The projection π_U restricts to an isomorphism $U \times \{\mathrm{pt}\} \to U$, so $\pi_{U*}[U \times \{\mathrm{pt}\}] = [U]$ by definition 10.2.1. Thus $m\,[U] = [U]$ in $A_k(U) = \mathbb{Z}\,[U]$, which is free on the fundamental class by example 10.1.6(3), and therefore $m = 1$. This gives $s_0(E) \cap [X] = [X]$, and with part (1) the total class has no terms in negative degree.

3. *Commutativity.* Let F have rank $f+1$, with $q\colon \mathbb{P}(F) \to X$ and tautological class η, and form the fibre product $W = \mathbb{P}(E) \times_X \mathbb{P}(F)$ with its two projections $q'\colon W \to \mathbb{P}(E)$ and $p'\colon W \to \mathbb{P}(F)$. Since q is proper and π is flat, q' is proper and p' is flat of relative dimension r; write $\rho = \pi \circ q' = q \circ p'\colon W \to X$, which is proper, and flat of relative dimension $r + f$ by proposition 10.3.5(3). Put $\tilde{\xi} = q'^*\xi$ and $\tilde{\eta} = p'^*\eta$. Then

$$\begin{aligned}
s_i(E) \cap \big(s_j(F) \cap \alpha\big) &= \pi_*\Big(\xi^{r+i} \cap \pi^* q_*\big(\eta^{f+j} \cap q^*\alpha\big)\Big) \\
&= \pi_*\Big(\xi^{r+i} \cap q'_*\, p'^*\big(\eta^{f+j} \cap q^*\alpha\big)\Big) \\
&= \pi_*\Big(\xi^{r+i} \cap q'_*\big(\tilde{\eta}^{f+j} \cap \rho^*\alpha\big)\Big) \\
&= \pi_* q'_*\Big(\tilde{\xi}^{r+i} \cap \tilde{\eta}^{f+j} \cap \rho^*\alpha\Big) = \rho_*\Big(\tilde{\xi}^{r+i} \cap \tilde{\eta}^{f+j} \cap \rho^*\alpha\Big)
\end{aligned}$$

the second line by proposition 10.3.6 for the fibre square defining W, the third by the flat case of proposition 11.4.4(4) together with $p'^{*}q^{*} = \rho^{*}$ (proposition 10.3.5(3)), and the fourth by the proper case of proposition 11.4.4(4) for q'. Running the same computation with the roles of E and F exchanged uses the same scheme W with its two projections interchanged, and expresses $s_j(F) \cap (s_i(E) \cap \alpha)$ as $\rho_*(\tilde{\eta}^{\,f+j} \cap \tilde{\xi}^{\,r+i} \cap \rho^{*}\alpha)$. The two expressions differ only in the order of two first Chern class cap operators, which commute by proposition 11.4.4(2), so they agree; this is the asserted commutativity.

4. *Functoriality.* For the proper case take $h = f$ in the fibre square above, so $f' \colon \mathbb{P}(f^{*}E) \to \mathbb{P}(E)$ is proper and $\pi_{X'}$ is proper and flat of relative dimension r. Then

$$f_*\big(s_i(f^{*}E) \cap \alpha'\big) = f_*\,\pi_{X'*}\big(\xi_{X'}^{\,r+i} \cap \pi_{X'}^{*}\alpha'\big) = \pi_*\,f'_*\big(f'^{*}\xi^{\,r+i} \cap \pi_{X'}^{*}\alpha'\big)$$

using $f \circ \pi_{X'} = \pi \circ f'$ and $\xi_{X'} = f'^{*}\xi$. The proper case of proposition 11.4.4(4) moves the cap outside, and proposition 10.3.6 for the same square gives $f'_*\pi_{X'}^{*} = \pi^{*}f_*$, so the right side is $\pi_*(\xi^{\,r+i} \cap \pi^{*}f_*\alpha') = s_i(E) \cap f_*\alpha'$.

For the flat case take $h = g$, so $g' \colon \mathbb{P}(g^{*}E) \to \mathbb{P}(E)$ is flat of relative dimension m. By proposition 10.3.5(3), $\pi_{X''}^{*}g^{*} = (g \circ \pi_{X''})^{*} = (\pi \circ g')^{*} = g'^{*}\pi^{*}$, and by the flat case of proposition 11.4.4(4) with $\xi_{X''} = g'^{*}\xi$,

$$\xi_{X''}^{\,r+i} \cap \pi_{X''}^{*}g^{*}\beta = g'^{*}\big(\xi^{\,r+i} \cap \pi^{*}\beta\big)$$

Applying $\pi_{X''*}$ and using $\pi_{X''*}g'^{*} = g^{*}\pi_*$, again proposition 10.3.6, gives $s_i(g^{*}E) \cap g^{*}\beta = g^{*}(s_i(E) \cap \beta)$, completing the proof.

Parts (1) and (2) say that the total Segre class has the form $1 +$ (dimension-lowering terms), and so is invertible: a series $1 + s_1 + s_2 + \cdots$ whose higher terms strictly lower dimension has a two-sided inverse of the same shape, computed by the usual recursion, and section 12.2 names that inverse the total Chern class. Part (3) is what makes any such formal manipulation legitimate, since inverting a series requires its terms to commute. Part (4) says the Segre classes are natural: they are computed in whichever space is most convenient and transported by the functorialities already available. The normalization in part (2) has an immediate structural consequence for π^{*} itself.

Corollary 12.1.6: Flat Pullback along a Projective Bundle is Split Injective

Let E be a vector bundle of rank $r+1$ on an algebraic scheme X, with $\pi \colon \mathbb{P}(E) \to X$ and tautological class ξ. Then for every k the map $\pi^{*} \colon A_k(X) \to A_{k+r}(\mathbb{P}(E))$ is injective, and $\beta \mapsto \pi_*(\xi^{\,r} \cap \beta)$ is a left inverse for it.

***Proof*:**
For $\alpha \in A_k(X)$ the composite is $\pi_*(\xi^{\,r} \cap \pi^{*}\alpha) = s_0(E) \cap \alpha = \alpha$ by definition 12.1.3 and proposition 12.1.5(2). A map admitting a left inverse is injective, as we sought to show.

No cycle class on the base is lost on passing to the projective bundle, and the loss can be undone by an explicit formula rather than an abstract argument. This is the mechanism that will make the flag bundle a legitimate device for proving identities among Chern classes rather than a heuristic; the iteration is carried out in section 12.2. A second consequence of proposition 12.1.5 is a computation, and it is the one that calibrates the whole normalization.

Example 12.1.7: The Segre Classes of a Trivial Bundle

Let $E = \mathcal{O}_X^{\oplus(r+1)}$ be trivial of rank $r+1$, so $\mathbb{P}(E) = X \times \mathbb{P}^r$ with π the first projection, ρ the second, and $\mathcal{O}_{\mathbb{P}(E)}(1) = \rho^*\mathcal{O}_{\mathbb{P}^r}(1)$, whence $\xi = c_1(\rho^*\mathcal{O}_{\mathbb{P}^r}(1))$. Then

$$s_0(E) = 1, \qquad s_i(E) = 0 \ \text{ for } i \neq 0$$

so $s(E) = 1$.

The case $i < 0$ is proposition 12.1.5(1) and the case $i = 0$ is proposition 12.1.5(2), so only $i \geq 1$ needs an argument. By (12.1) it suffices to take $X = V$ a variety of dimension k and $\alpha = [V]$. Then $\pi^*[V] = [V \times \mathbb{P}^r]$, and $[V \times \mathbb{P}^r] = \rho^*[\mathbb{P}^r]$ because ρ is flat of relative dimension k over the variety $\mathbb{P}^r$ (proposition 10.3.5(2)). The flat case of proposition 11.4.4(4) then moves the whole cap into the base:

$$\xi^{\,r+i} \cap \pi^*[V] = \rho^*\Big(c_1\big(\mathcal{O}_{\mathbb{P}^r}(1)\big)^{r+i} \cap [\mathbb{P}^r]\Big)$$

For $i \geq 1$ the exponent exceeds $r = \dim \mathbb{P}^r$, so the class in brackets vanishes by proposition 11.4.4(5), and therefore $s_i(E) \cap [V] = \pi_*(0) = 0$. A trivial bundle has trivial total Segre class, which is the normalization that makes $s(E)$, and with it the Chern classes built from it, an invariant of the twisting of E rather than of its rank.

The computation in example 12.1.7 used only the structure of $\mathbb{P}^r$ over a point, transported along a flat projection. The same transport, applied to a hyperplane rather than to the whole space, produces the identity that drives the main theorem: on a trivial projective bundle, the tautological class is the class of a sub-bundle of hyperplanes, so capping with ξ is the same as pushing forward from a smaller projective bundle.

Lemma 12.1.8: The Hyperplane Divisor on a Trivial Projective Bundle

Let X be an algebraic scheme, let $r \geq 1$, and let $P = X \times \mathbb{P}^r$ with projections $\pi\colon P \to X$ and $\rho\colon P \to \mathbb{P}^r$, and $\xi = c_1(\rho^*\mathcal{O}_{\mathbb{P}^r}(1))$. Fix a hyperplane $H \subseteq \mathbb{P}^r$, put $Q = X \times H$ with its closed immersion $\iota\colon Q \hookrightarrow P$, and let $\pi_Q\colon Q \to X$ be the projection. Then for every $\alpha \in A_k(X)$,

$$\xi \cap \pi^*\alpha = \iota_*\,\pi_Q^*\alpha \quad \text{in } A_{k+r-1}(P)$$

***Proof*:**

Since H is cut out by a linear form, $\mathcal{O}_{\mathbb{P}^r}(H) \cong \mathcal{O}_{\mathbb{P}^r}(1)$ by example 11.4.3(2). No component of P maps into H, so the local equations of H pull back to local equations of a Cartier divisor Q on P, and $\mathcal{O}_P(Q) \cong \rho^*\mathcal{O}_{\mathbb{P}^r}(1)$ because $\mathcal{O}(D)$ is formed from those same local equations. (This is the pullback of a Cartier divisor along an arbitrary morphism meeting the support properly, not the flat pullback of proposition 11.3.3, whose relative-dimension hypothesis ρ need not satisfy when X has components of different dimensions.) By definition 11.4.1 this identifies the operator: $\xi \cap \pi^*\alpha = Q \cdot \pi^*\alpha$.

Both sides of the asserted identity are additive homomorphisms $A_k(X) \to A_{k+r-1}(P)$, the left by proposition 10.3.7 and proposition 11.2.4, the right by proposition 10.3.7 and theorem 10.2.3, so it suffices to check them on the class of a k-dimensional subvariety $W \subseteq X$. The morphism π is flat of relative dimension r, being the base change of $\mathbb{P}^r \to \operatorname{Spec} \overline{k}$, so $\pi^*[W] = [W \times \mathbb{P}^r]$ by definition 10.3.3, the preimage $W \times \mathbb{P}^r$ being integral of dimension $k+r$ and hence carrying multiplicity one. This subvariety is not contained in $|Q| = X \times H$, so the first clause of

definition 11.2.1 applies: writing s for the rational section of $\mathcal{O}_P(Q)$ cutting out Q, which is the pullback along ρ of the linear form defining H, its restriction to $W \times \mathbb{P}^r$ has divisor

$$\big[\operatorname{div}\big(s|_{W\times\mathbb{P}^r}\big)\big] = [W \times H]$$

with multiplicity one, since a linear form vanishes to order one along the hyperplane it defines. Hence $Q \cdot \pi^*[W] = [W \times H]$. On the other side π_Q is flat of relative dimension $r-1$, so $\pi_Q^*[W] = [W \times H]$ by the same reasoning, and ι_* carries this class to $[W \times H]$ in $Z_{k+r-1}(P)$, the closed immersion having degree one on each subvariety (definition 10.2.1). The two sides therefore agree on every generator, completing the proof.

The lemma converts a divisor operation into a pushforward, and pushforward is what the localization sequence controls. That is the whole strategy for the theorem below: peel $\mathbb{P}^r$ apart into a hyperplane and its affine complement, use theorem 10.4.6 on the complement, use the lemma to recognize the hyperplane contribution as one more power of ξ, and induct. The general bundle is then reduced to the trivial one by a second induction, over the closed subschemes of the base, since a bundle is trivial over some dense open set. Injectivity, by contrast, needs no induction at all: the Segre classes already invert the construction.

Theorem 12.1.9: The Projective Bundle Formula

Let E be a vector bundle of rank $r+1$ on an algebraic scheme X, with $\pi\colon \mathbb{P}(E) \to X$ and tautological class ξ. For every k the homomorphism

$$\Psi\colon \bigoplus_{i=0}^{r} A_{k-r+i}(X) \longrightarrow A_k\big(\mathbb{P}(E)\big), \qquad (\alpha_0,\dots,\alpha_r) \longmapsto \sum_{i=0}^{r} \xi^{\,i} \cap \pi^*\alpha_i$$

is an isomorphism. Every class $\beta \in A_k(\mathbb{P}(E))$ is thus uniquely of the form $\beta = \sum_{i=0}^{r} \xi^{\,i} \cap \pi^*\alpha_i$ with $\alpha_i \in A_{k-r+i}(X)$, and the components are recovered from β by the triangular system

$$\pi_*\big(\xi^{\,m} \cap \beta\big) = \alpha_{r-m} + \sum_{j=1}^{m} s_j(E) \cap \alpha_{r-m+j}, \qquad 0 \le m \le r \tag{12.2}$$

***Proof*:**
Each summand of Ψ lands in $A_k(\mathbb{P}(E))$: for $\alpha_i \in A_{k-r+i}(X)$ the class $\pi^*\alpha_i$ lies in $A_{k+i}(\mathbb{P}(E))$ and capping with ξ^i lowers dimension by i. The map is additive because π^* and $\xi \cap -$ are.

Step 1: the triangular system, and injectivity. Let $\beta = \sum_{i=0}^{r} \xi^i \cap \pi^*\alpha_i$ and fix $m \ge 0$. Then

$$\pi_*\big(\xi^{\,m} \cap \beta\big) = \sum_{i=0}^{r} \pi_*\big(\xi^{\,m+i} \cap \pi^*\alpha_i\big) = \sum_{i=0}^{r} s_{m+i-r}(E) \cap \alpha_i$$

directly from definition 12.1.3. By proposition 12.1.5(1) the terms with $m+i-r<0$ vanish, and by proposition 12.1.5(2) the term with $m+i-r=0$ is α_{r-m}; writing $j = m+i-r$ for the surviving terms, which satisfy $1 \le j \le m$ since $i \le r$, gives exactly (12.2).

Suppose now $\Psi(\alpha_0,\dots,\alpha_r) = 0$. Taking $m=0$ in (12.2) gives $\alpha_r = 0$. Assume inductively that $\alpha_r = \cdots = \alpha_{r-m+1} = 0$ for some $m \le r$; then every correction term in (12.2) involves one of these vanishing classes, so the identity reduces to $\alpha_{r-m} = 0$. Descending from $m=0$ to $m=r$

kills every component, so Ψ is injective. This argument used no hypothesis on X beyond those standing.

Step 2: surjectivity for a trivial bundle. Let $E = \mathcal{O}_X^{\oplus(r+1)}$, so $\mathbb{P}(E) = X \times \mathbb{P}^r$ and $\xi = c_1(\rho^*\mathcal{O}_{\mathbb{P}^r}(1))$ for the second projection ρ. The claim is proved by induction on r, uniformly in the base X.

For $r = 0$ one has $\mathbb{P}(E) = X$ with $\pi = \mathrm{id}$, so $\Psi(\alpha_0) = \alpha_0$ is the identity map of $A_k(X)$, which is surjective. Let $r \geq 1$ and assume the claim for $r-1$ over every base. Fix a hyperplane $H \subseteq \mathbb{P}^r$, put $Q = X \times H$ with closed immersion $\iota\colon Q \hookrightarrow P = X \times \mathbb{P}^r$, and let $j\colon X \times \mathbb{A}^r \hookrightarrow P$ be the inclusion of the open complement, $\mathbb{A}^r = \mathbb{P}^r \setminus H$. The localization sequence (theorem 10.4.1) reads

$$A_k(Q) \xrightarrow{\iota_*} A_k(P) \xrightarrow{j^*} A_k(X \times \mathbb{A}^r) \longrightarrow 0$$

Let $q = \pi \circ j\colon X \times \mathbb{A}^r \to X$ be the projection. By affine-bundle invariance (theorem 10.4.6) the pullback $q^*\colon A_{k-r}(X) \to A_k(X \times \mathbb{A}^r)$ is an isomorphism, and $q^* = j^*\pi^*$ by proposition 10.3.5(3). Given $\beta \in A_k(P)$, there is therefore $\alpha_0 \in A_{k-r}(X)$ with $j^*\beta = q^*\alpha_0 = j^*(\pi^*\alpha_0)$, whence $\beta - \pi^*\alpha_0$ lies in $\ker j^* = \operatorname{im} \iota_*$ by exactness: say

$$\beta = \pi^*\alpha_0 + \iota_*\gamma, \qquad \gamma \in A_k(Q)$$

Now $Q = X \times H \cong X \times \mathbb{P}^{r-1}$ is the trivial projective bundle of one lower fibre dimension, and its tautological class is $\xi_Q = \iota^*\xi$: choosing a second hyperplane $H' \neq H$, the restriction $\mathcal{O}_{\mathbb{P}^r}(1)|_H \cong \mathcal{O}_{\mathbb{P}^r}(H')|_H$ is the line bundle of the hyperplane $H' \cap H$ of H, which is $\mathcal{O}_{\mathbb{P}^{r-1}}(1)$ under the identification $H \cong \mathbb{P}^{r-1}$. By the inductive hypothesis,

$$\gamma = \sum_{i=0}^{r-1} \xi_Q^i \cap \pi_Q^*\alpha_i', \qquad \alpha_i' \in A_{k-(r-1)+i}(X)$$

Pushing forward, the proper case of proposition 11.4.4(4) applied i times with $\xi_Q = \iota^*\xi$ gives $\iota_*(\xi_Q^i \cap \pi_Q^*\alpha_i') = \xi^{\,i} \cap \iota_*\pi_Q^*\alpha_i'$, and lemma 12.1.8 identifies $\iota_*\pi_Q^*\alpha_i' = \xi \cap \pi^*\alpha_i'$. Hence

$$\iota_*\gamma = \sum_{i=0}^{r-1} \xi^{\,i+1} \cap \pi^*\alpha_i'$$

and setting $\alpha_{i+1} = \alpha_i' \in A_{k-r+(i+1)}(X)$ for $0 \leq i \leq r-1$ exhibits $\beta = \sum_{i=0}^{r} \xi^{\,i} \cap \pi^*\alpha_i$. This completes the induction on r, so Ψ is surjective for every trivial bundle.

Step 3: surjectivity in general. The scheme X is of finite type over $\overline{k}$, hence Noetherian, so its closed subschemes satisfy the descending chain condition and the following suffices: if $\Psi_{E|_W}$ is surjective in every degree for every proper closed subscheme $W \subsetneq X$, then Ψ_E is surjective. The empty scheme starts the induction.

First produce a dense trivializing open. The scheme X has finitely many irreducible components, with generic points $\eta_1, \ldots, \eta_s$. For each t choose an open $V_t \ni \eta_t$ over which E is trivial, and set $U_t = V_t \setminus \bigcup_{u \neq t} \overline{\{\eta_u\}}$, still an open neighbourhood of η_t since η_t lies on no other component. The U_t are pairwise disjoint: each U_u is contained in $\overline{\{\eta_u\}}$, because the components cover X, while U_t misses $\overline{\{\eta_u\}}$ for $u \neq t$. Their union $U = \bigsqcup_t U_t$ is an open set containing every generic point, hence dense, and $E|_U$ is trivial of rank $r+1$, being trivial on each of the disjoint pieces. If $U = X$ then E is trivial and Step 2 applies; otherwise let $Z = X \setminus U$ with its reduced structure, a proper closed subscheme.

Write $j\colon U \hookrightarrow X$ and $i_Z\colon Z \hookrightarrow X$ for the inclusions, and $j'\colon \mathbb{P}(E|_U) \hookrightarrow \mathbb{P}(E)$, $\iota\colon \mathbb{P}(E|_Z) \hookrightarrow \mathbb{P}(E)$ for the induced ones; these are the open and closed pieces of $\mathbb{P}(E)$, since forming $\mathbb{P}(E)$ commutes with base change. Let $\beta \in A_k(\mathbb{P}(E))$. Restricting to the trivializing part and applying Step 2 over U,

$$j'^*\beta = \sum_{i=0}^{r} \xi_U^i \cap \pi_U^* \alpha_i^U, \qquad \alpha_i^U \in A_{k-r+i}(U)$$

By theorem 10.4.1 the restriction $j^*\colon A_{k-r+i}(X) \to A_{k-r+i}(U)$ is surjective, so each α_i^U lifts to some $\alpha_i \in A_{k-r+i}(X)$. Flat pullback along j' commutes with π^*, since $\pi \circ j' = j \circ \pi_U$ gives $j'^*\pi^* = \pi_U^* j^*$ by proposition 10.3.5(3), and with capping by ξ by the flat case of proposition 11.4.4(4), using $\xi_U = j'^*\xi$. Hence $j'^*\big(\beta - \Psi_E(\alpha_0, \dots, \alpha_r)\big) = 0$, and the localization sequence for the closed $\mathbb{P}(E|_Z) \subseteq \mathbb{P}(E)$ with open complement $\mathbb{P}(E|_U)$ produces $\delta \in A_k(\mathbb{P}(E|_Z))$ with

$$\beta - \Psi_E(\alpha_0, \dots, \alpha_r) = \iota_* \delta$$

Since $Z \subsetneq X$ is a proper closed subscheme, the inductive hypothesis writes $\delta = \sum_{i=0}^{r} \xi_Z^i \cap \pi_Z^* \epsilon_i$ with $\epsilon_i \in A_{k-r+i}(Z)$. The proper case of proposition 11.4.4(4) with $\xi_Z = \iota^*\xi$, followed by proposition 10.3.6 for the fibre square over i_Z (whose horizontal map is proper and whose vertical map π is flat), gives

$$\iota_*\big(\xi_Z^i \cap \pi_Z^* \epsilon_i\big) = \xi^{\,i} \cap \iota_* \pi_Z^* \epsilon_i = \xi^{\,i} \cap \pi^*\big(i_{Z*}\epsilon_i\big)$$

Therefore $\beta = \Psi_E(\alpha_0 + i_{Z*}\epsilon_0, \dots, \alpha_r + i_{Z*}\epsilon_r)$ lies in the image of Ψ_E. This closes the Noetherian induction, so Ψ is surjective for every vector bundle, and with Step 1 it is an isomorphism, completing the proof.

The theorem computes the Chow groups of a projective bundle from those of its base, and it does so with an explicit basis and an explicit inversion. The classes $1, \xi, \dots, \xi^r$ behave like a basis of $A_*(\mathbb{P}(E))$ over $A_*(X)$, and it is standard to say that $A_*(\mathbb{P}(E))$ is a free $A_*(X)$-module on them; that phrasing anticipates a ring structure on $A_*(X)$ that does not exist yet, so the content here is the isomorphism Ψ of graded groups together with the fact that its components are the operators $\xi^i \cap \pi^*(-)$. The inversion (12.2) is what makes the statement usable in practice: to identify the components of a given class one pushes forward its caps with successive powers of ξ, and the Segre classes appear as the correction terms in a triangular system that can be solved from the top down. This is also the precise sense in which the Segre classes measure the failure of ξ to behave like the hyperplane class on a product, since a trivial bundle has all corrections zero by example 12.1.7.

Taking $X = \operatorname{Spec} \overline{k}$ and $E = \overline{k}^{\,n+1}$ recovers $A_k(\mathbb{P}^n) = \mathbb{Z}\,\big(\xi^{\,n-k} \cap [\mathbb{P}^n]\big)$, the statement of theorem 10.5.2: the group $A_j(\operatorname{Spec} \overline{k})$ is $\mathbb{Z}$ for $j = 0$ and zero otherwise, so only the index $i = n - k$ survives in the sum, and $\pi^*[\operatorname{Spec} \overline{k}] = [\mathbb{P}^n]$. The theorem is thus the exact generalization of the projective-space computation from a point to an arbitrary base, which is how it was announced in section 10.5, and its proof runs by reducing to that computation twice: once through example 11.4.7 in the normalization $s_0(E) = 1$, and once through affine-bundle invariance in Step 2. The corresponding statement in singular cohomology, that $H^*(\mathbb{P}(E))$ is free over $H^*(X)$ on the powers of the class of $\mathcal{O}(1)$, holds as well, but it enters the theory at a different point: in [78, Chern Classes and the Total Chern Class, The Projective Bundle Formula] the topological Chern classes are defined as pullbacks of the polynomial generators of $H^*(BU(n))$, and the projective-bundle statement is a consequence, proved once they are in hand. Here the dependence runs the other way, the formula above coming first and the Chern operators of section 12.2 being defined by inverting the total Segre class; and the argument owes nothing to topology, being valid over any algebraically closed field and on singular schemes.

Exercise 12.1.1

1. Let L be a line bundle on an algebraic scheme X. Using example 12.1.2(2), show that $s_i(L) \cap \alpha = (-1)^i c_1(L)^i \cap \alpha$ for every $i \geq 0$ and every $\alpha \in A_k(X)$, and deduce that the operators $s(L) \cap -$ and $(1 + c_1(L)) \cap -$ are mutually inverse on $A_k(X)$. Explain why the series terminates on any fixed class.

2. Let E have rank $r+1$ on X, with $\pi\colon \mathbb{P}(E) \to X$. Show that $\pi_*\pi^*\alpha = 0$ for every $\alpha \in A_*(X)$ when $r \geq 1$, while $\pi_*\pi^* = \mathrm{id}$ when $r = 0$. Show also that $\beta \mapsto \pi_*(\xi^r \cap \beta)$ is a left inverse of π^* for every r, and reconcile the two computations.

3. Take $X = \mathbb{P}^n$ and $E = \mathcal{O}_{\mathbb{P}^n}^{\oplus(m+1)}$, so that $\mathbb{P}(E) = \mathbb{P}^n \times \mathbb{P}^m$ with π the first projection. Use theorem 12.1.9 and theorem 10.5.2 to show that $A_k(\mathbb{P}^n \times \mathbb{P}^m)$ is free abelian of rank equal to the number of pairs (a, b) with $0 \leq a \leq m$, $0 \leq b \leq n$ and $a + b = k$, and identify a basis geometrically.

4. Let X be a complete variety of dimension n and E a vector bundle of rank $r+1$ on X. Show that
$$\int_X s_n(E) \cap [X] = \int_{\mathbb{P}(E)} \xi^{n+r} \cap [\mathbb{P}(E)]$$
and verify that both sides vanish for E trivial and $n \geq 1$.

5. Let E have rank $r+1$ on X and let $\alpha \in A_k(X)$. By theorem 12.1.9 there are unique classes $\beta_i \in A_{k-1-r+i}(X)$ with $\xi^{r+1} \cap \pi^*\alpha = \sum_{i=0}^{r} \xi^i \cap \pi^*\beta_i$. Determine β_r and β_{r-1} in terms of the Segre operators of E applied to α, and describe the recursion that determines the remaining β_i.

12.2 Chern Classes

The Segre operators of section 12.1 record everything a vector bundle contributes to the Chow group, but in a form nothing can be computed with. The list $s_0(E), s_1(E), s_2(E), \ldots$ does not terminate, so no finite collection of them is an invariant attached to E; already for a line bundle every $s_i(L)$ is nonzero as long as $c_1(L)^i$ is. Worse, the operators attached to a direct sum are not the product of those attached to the summands, so a bundle assembled from simpler pieces has Segre operators that cannot be read off the pieces. Inverting the total Segre operator repairs both defects at once, and the inverse is what the rest of the book uses.

The section establishes four properties of the resulting Chern operators: they vanish above the rank of the bundle, they are natural for flat pullback and satisfy a projection formula, they are multiplicative on short exact sequences, and in rank one they reduce to the operator $c_1(L) \cap -$ of section 11.4. The last two are proved by the splitting principle, which replaces X by a tower of projective bundles over it on which every bundle in sight is filtered by line bundles. That replacement is legitimate rather than heuristic because the projective-bundle formula makes π^* injective, so an identity verified upstairs descends.

Throughout, E is a vector bundle of rank $e \geq 1$ on an algebraic scheme X, the projection $\pi\colon \mathbb{P}(E) \to X$ has relative dimension $r = e - 1$, and $\xi = c_1(\mathcal{O}_{\mathbb{P}(E)}(1))$ is the tautological class of section 12.1, so that
$$s_i(E) \cap \alpha = \pi_*\big(\xi^{r+i} \cap \pi^*\alpha\big)$$

for $\alpha \in A_*(X)$, with $s_0(E)$ the identity and $s_i(E) = 0$ for $i < 0$. Every vector bundle named below is assumed of positive rank: the operators are manufactured from $\mathbb{P}(E)$, which is empty for the zero bundle, so neither $s(0)$ nor $c(0)$ is defined.

The first point to settle is that the inversion makes sense. A Segre operator lowers the dimension of a cycle class, and on a scheme of finite dimension an operator that lowers dimension by too much has nowhere to land; that is the whole reason the total operator is invertible.

Lemma 12.2.1: Dimension-Lowering Operators Vanish Above the Dimension

Let X be an algebraic scheme of dimension n. Call an operator on $A_*(X)$ *homogeneous of degree d* if it carries $A_k(X)$ into $A_{k-d}(X)$ for every k. Then every operator on $A_*(X)$ homogeneous of degree $d > n$ is the zero operator.

***Proof*:**
A k-dimensional cycle class satisfies $0 \le k \le n$, because X has no subvarieties of negative dimension and none of dimension exceeding n; hence $A_j(X) = 0$ for $j < 0$ and for $j > n$. An operator homogeneous of degree $d > n$ carries every $A_k(X)$ with $0 \le k \le n$ into $A_{k-d}(X)$ with $k - d < 0$, whose target vanishes, completing the proof.

Each $s_i(E)$ is homogeneous of degree i (section 12.1): π^* raises dimension by r and capping with ξ lowers it by one (definition 11.4.1). The lemma therefore applies to them and to every composite of them.

Lemma 12.2.2: Invertibility of the Total Segre Operator

Let X be an algebraic scheme of dimension n and E a vector bundle on X. For $\alpha \in A_k(X)$ only finitely many of the classes $s_i(E) \cap \alpha$ are nonzero, so

$$s(E) := \sum_{i \ge 0} s_i(E)$$

is a well-defined operator on $A_*(X)$. It is invertible: there is a unique operator μ on $A_*(X)$ with

$$\mu \circ s(E) = s(E) \circ \mu = \mathrm{id}$$

and it is given by the finite sum $\mu = \sum_{j=0}^{n} (-1)^j \nu^j$, where $\nu = s(E) - \mathrm{id} = \sum_{i \ge 1} s_i(E)$.

***Proof*:**
By lemma 12.2.1, $s_i(E) = 0$ for $i > n$, so the sum defining $s(E)$ has at most $n+1$ nonzero terms and is a well-defined operator.

The same lemma makes $\nu = \sum_{i \ge 1} s_i(E)$ nilpotent. Expanding ν^{n+1} produces a sum of composites $s_{i_1}(E) \circ \cdots \circ s_{i_{n+1}}(E)$ with every $i_t \ge 1$, each homogeneous of degree $i_1 + \cdots + i_{n+1} \ge n+1 > n$, hence each zero by lemma 12.2.1. Thus $\nu^{n+1} = 0$, and the finite sum $\mu = \sum_{j=0}^{n} (-1)^j \nu^j$ satisfies

$$\mu\,(\mathrm{id} + \nu) = (\mathrm{id} + \nu)\,\mu = \sum_{j=0}^{n} (-1)^j \nu^j + \sum_{j=0}^{n} (-1)^j \nu^{j+1} = \mathrm{id} + (-1)^n \nu^{n+1} = \mathrm{id}$$

the two sums telescoping. Since $s(E) = \mathrm{id} + \nu$, the operator μ is a two-sided inverse. Uniqueness is the usual argument for inverses in a ring: if μ' is another, then $\mu' = \mu' \circ (s(E) \circ \mu) = (\mu' \circ s(E)) \circ \mu = \mu$, completing the proof.

Nilpotence, not any positivity or finiteness of E, is what powers the inversion. The bundle may have arbitrary rank and X may be singular, reducible, or non-reduced; all that is used is that a cycle class cannot be cut down more times than the dimension of the ambient scheme allows. The inverse is therefore available on every algebraic scheme, which is the reason Chern classes in the Chow setting need no smoothness hypothesis.

Definition 12.2.3: Chern Classes of a Vector Bundle

Let E be a vector bundle on an algebraic scheme X. The *total Chern class* of E is the operator

$$c(E) := s(E)^{-1}$$

on $A_*(X)$ furnished by lemma 12.2.2, and the *i-th Chern class* $c_i(E)$ is its homogeneous component of degree i, an operator

$$c_i(E) \cap - \colon A_k(X) \longrightarrow A_{k-i}(X)$$

for every k. Equivalently, the $c_i(E)$ are determined by $c_0(E) = \mathrm{id}$ together with

$$\sum_{i+j=m} c_i(E) \circ s_j(E) = 0 \qquad \text{for every } m \geq 1$$

Unwinding the recursion $c_m(E) = -\sum_{j=1}^{m} c_{m-j}(E) \circ s_j(E)$ expresses each Chern class as an integer polynomial in the Segre classes:

$$c_0(E) = \mathrm{id}, \qquad c_1(E) = -s_1(E), \qquad c_2(E) = s_1(E)^2 - s_2(E),$$
$$c_3(E) = -s_1(E)^3 + 2\, s_1(E) s_2(E) - s_3(E)$$

where a product of operators means composition. Each $c_m(E)$ is thus a $\mathbb{Z}$-combination of composites of $s_1(E), \ldots, s_m(E)$, a fact used below to transfer identities from Segre classes to Chern classes.

12.2.4 Note: Chern Classes Are Operators, Not Elements A Chern class here is an endomorphism of the graded group $A_*(X)$, not a member of it. There is no ring $A^*(X)$ yet: the intersection product that turns cycle classes into a ring for smooth X rests on the deformation construction of chapter 13, and until it is available the only multiplication in sight is composition of operators. Expressions such as $c_1(E)^2$ or $c(E)c(F)$ always mean composites, and an equation between them is an equation of maps $A_*(X) \to A_*(X)$, asserted for every class α. Once the product exists, capping against the fundamental class converts each operator into an element of $A^*(X)$ and the identities below become identities in a ring.

Every computation in this section runs through one imported object. The projective bundle carries a tautological line inside the pullback of E, and because this book and the scheme-theory volume use opposite conventions for $\mathbb{P}(-)$, that import has to be dualized in the open before it is used.

12.2.5 Note: The Tautological Subbundle and Its Quotient By box 9.0.2, the bundle of lines $\mathbb{P}(E)$ used here is $\operatorname{Proj}\left(\operatorname{Sym}^\bullet E^\vee\right)$, which is the projective bundle definition 5.3.51 of the *dual* sheaf. The universal surjection $\pi^*(E^\vee) \twoheadrightarrow \mathcal{O}_{\mathbb{P}(E)}(1)$ of proposition 5.3.53 dualizes to an inclusion of vector bundles

$$\mathcal{O}_{\mathbb{P}(E)}(-1) \hookrightarrow \pi^* E$$

whose fibre over a point of $\mathbb{P}(E)$ lying above $x \in X$ and corresponding to a line $\ell \subseteq E_x$ is that line. Its cokernel Q is locally free of rank $\operatorname{rank} E - 1$, since the inclusion is a subbundle inclusion: over an open $U \subseteq X$ trivializing E the total space is $\mathbb{P}^r \times U$ and the inclusion is the tautological one on the first factor. Failing to dualize here replaces E by $E^\vee$ throughout and negates every odd Chern class, which is why the convention is restated at each import.

The definition inverts a series and so says nothing recognizable on its face. The rank-one case shows it and settles the compatibility the notation presumes: the symbol c_1 has already been used in section 11.4 for the divisor operator of a line bundle, and the two meanings must agree.

Proposition 12.2.6: Chern Classes of a Line Bundle

Let L be a line bundle on an algebraic scheme X. Then

$$c(L) = \mathrm{id} + c_1(L)$$

where $c_1(L)$ on the right is the first Chern class operator of definition 11.4.1. In particular $c_1(L)$ in the sense of definition 12.2.3 is that operator, and $c_i(L) = 0$ for $i \geq 2$.

***Proof*:**
Both inputs are already computed in section 12.1: example 12.1.2(2) identifies $\mathbb{P}(L) = X$ with π the identity and $\mathcal{O}_{\mathbb{P}(L)}(1) = L^\vee$, whence $\xi = c_1(L^\vee) = -c_1(L)$, and example 12.1.4 evaluates the resulting Segre operators as $s_i(L) \cap \alpha = (-1)^i c_1(L)^i \cap \alpha$, so $s(L) = \sum_{i \geq 0} (-1)^i c_1(L)^i$. The operator $c_1(L)$ is nilpotent by the lemma 12.2.1, so this sum is the inverse of $\mathrm{id} + c_1(L)$: indeed

$$\Big(\sum_{i \geq 0} (-1)^i c_1(L)^i\Big)\big(\mathrm{id} + c_1(L)\big) = \mathrm{id}$$

the terms cancelling in pairs and the tail vanishing by nilpotence. Inverses being unique (lemma 12.2.2), $c(L) = s(L)^{-1} = \mathrm{id} + c_1(L)$. Reading off homogeneous components gives $c_1(L)$ in degree one and zero in every degree $i \geq 2$, as we sought to show.

The agreement is what permits a single symbol for both constructions, and it fixes the sign convention of the whole theory: had $\mathbb{P}(E)$ been taken as the bundle of hyperplanes rather than of lines, the tautological class would be $c_1(L)$ instead of $-c_1(L)$ and the inversion would produce $c_1(L^\vee)$ where $c_1(L)$ is wanted. Box 9.0.2 therefore cannot be skipped. The rank-one case also shows that Chern classes terminate while Segre classes do not: $c_i(L) = 0$ beyond $i = 1$, while $s_i(L)$ is nonzero for every i with $c_1(L)^i \neq 0$.

Example 12.2.7: The Twisting Sheaves on Projective Space

Let $X = \mathbb{P}^n$ and $L = \mathcal{O}_{\mathbb{P}^n}(d)$ for an integer d. Write $H = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$, the hyperplane operator of example 11.4.7. Additivity of the first Chern class (proposition 11.4.4(3)) gives $c_1(\mathcal{O}_{\mathbb{P}^n}(d)) = d\,H$, so by proposition 12.2.6

$$c(\mathcal{O}_{\mathbb{P}^n}(d)) = \mathrm{id} + d\,H$$

Capping against the fundamental class and using $H^k \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}]$ from example 11.4.7,

$$c(\mathcal{O}_{\mathbb{P}^n}(d)) \cap [\mathbb{P}^n] = [\mathbb{P}^n] + d\,[\mathbb{P}^{n-1}]$$

so the total Chern class of $\mathcal{O}(d)$ records the single integer d as the multiple of the hyperplane class it produces. The corresponding Segre operator is the full geometric series $s(\mathcal{O}_{\mathbb{P}^n}(d)) = \sum_{i\geq 0}(-d)^i H^i$, whose cap against $[\mathbb{P}^n]$ is $\sum_{i=0}^{n}(-d)^i[\mathbb{P}^{n-i}]$: every dimension carries a nonzero coefficient when $d \neq 0$, while the Chern class stops after one step. This is the terminating behaviour that theorem 12.2.9 establishes in general.

Termination in rank one came from an explicit computation. In general it comes from the projective-bundle formula, which pins down exactly one relation among the powers of ξ and identifies its coefficients as the Chern classes. The following criterion extracts from that formula the tool used twice below: a class on $\mathbb{P}(E)$ is detected by finitely many pushforwards.

Lemma 12.2.8: A Vanishing Criterion on the Projective Bundle

Let E be a vector bundle of rank $e = r + 1$ on X, with $\pi\colon \mathbb{P}(E) \to X$ and $\xi = c_1(\mathcal{O}_{\mathbb{P}(E)}(1))$. A class $\beta \in A_*(\mathbb{P}(E))$ vanishes if and only if

$$\pi_*\big(\xi^{\,m} \cap \beta\big) = 0 \qquad \text{for } 0 \leq m \leq r$$

***Proof*:**

If $\beta = 0$ then every $\pi_*(\xi^m \cap \beta)$ vanishes, since capping and pushforward are homomorphisms.

Conversely, suppose the $r + 1$ pushforwards vanish. By the projective-bundle formula (theorem 12.1.9) there are unique classes $\alpha_0, \ldots, \alpha_r \in A_*(X)$ with

$$\beta = \sum_{j=0}^{r} \xi^{\,j} \cap \pi^*\alpha_j$$

Capping with ξ^m and pushing forward, the definition of the Segre operators gives

$$\pi_*\big(\xi^{\,m} \cap \beta\big) = \sum_{j=0}^{r} \pi_*\big(\xi^{\,m+j} \cap \pi^*\alpha_j\big) = \sum_{j=0}^{r} s_{m+j-r}(E) \cap \alpha_j$$

Take $m = 0$. Every index $j < r$ contributes $s_{j-r}(E) = 0$, since $j - r < 0$, so the sum reduces to $s_0(E) \cap \alpha_r = \alpha_r$, and the hypothesis forces $\alpha_r = 0$. Proceed by descending induction: suppose $\alpha_r = \cdots = \alpha_{r-m+1} = 0$ for some $1 \leq m \leq r$. In the displayed sum for that m, the indices $j < r - m$ contribute zero because $m + j - r < 0$, the indices $j > r - m$ contribute zero because $\alpha_j = 0$ by the inductive hypothesis, and the single index $j = r - m$ contributes $s_0(E) \cap \alpha_{r-m} = \alpha_{r-m}$. The hypothesis forces $\alpha_{r-m} = 0$, and the induction runs down to $m = r$, giving $\alpha_0 = 0$. All coefficients vanish, so $\beta = 0$, completing the proof.

With a criterion for vanishing in hand, the relation defining the Chern classes can be produced. The statement below is the one that makes them computable: on $\mathbb{P}(E)$ the power $\xi^{\,e}$ is not independent of the lower powers, and the coefficients expressing it in terms of them are exactly the Chern classes of E. Everything else in this section is extracted from it.

Theorem 12.2.9: The Chern Relation on the Projective Bundle

Let E be a vector bundle of rank $e = r+1$ on an algebraic scheme X, with $\pi\colon \mathbb{P}(E) \to X$ and $\xi = c_1(\mathcal{O}_{\mathbb{P}(E)}(1))$.

1. For every $\alpha \in A_*(X)$,
$$\sum_{i=0}^{e} \xi^{\,e-i} \cap \pi^*\big(c_i(E) \cap \alpha\big) = 0 \quad \text{in } A_*(\mathbb{P}(E))$$
2. $c_i(E) = 0$ for every $i > e$; that is, the Chern classes of E terminate at its rank.
3. The operators $c_0(E) = \mathrm{id}, c_1(E), \dots, c_e(E)$ are the unique operators on $A_*(X)$, homogeneous of degrees $0, 1, \dots, e$ respectively, whose degree-zero member is the identity and which satisfy the relation in (1).

***Proof*:**
Write $\gamma_\alpha = \sum_{i=0}^{e} \xi^{\,e-i} \cap \pi^*(c_i(E) \cap \alpha)$ for the class in question. Capping with $\xi^{\,m}$ and pushing forward, the definition of the Segre operators gives, for every $m \geq 0$,

$$\pi_*\big(\xi^{\,m} \cap \gamma_\alpha\big) = \sum_{i=0}^{e} \pi_*\Big(\xi^{\,m+e-i} \cap \pi^*\big(c_i(E) \cap \alpha\big)\Big) = \sum_{i=0}^{e} s_{m+1-i}(E) \cap \big(c_i(E) \cap \alpha\big) \tag{12.3}$$

using $m + e - i = r + (m + 1 - i)$, valid because $m + e - i \geq 0$ for $0 \leq i \leq e$ and $m \geq 0$, with the convention $s_j(E) = 0$ for $j < 0$ absorbing the terms where $i > m + 1$.

1. Fix m with $0 \leq m \leq r$ and set $n = m + 1$, so $1 \leq n \leq e$. In (12.3) the terms with $i > n$ vanish, so the right side is $\sum_{i=0}^{n} s_{n-i}(E)c_i(E) \cap \alpha$, which is the degree-$n$ homogeneous component of $s(E) \circ c(E) = \mathrm{id}$ applied to α. Since $n \geq 1$ that component is zero. Thus $\pi_*(\xi^{\,m} \cap \gamma_\alpha) = 0$ for $0 \leq m \leq r$, and lemma 12.2.8 gives $\gamma_\alpha = 0$.
2. By (1) the class γ_α vanishes, hence $\pi_*(\xi^{\,m} \cap \gamma_\alpha) = 0$ for *every* $m \geq 0$, not only for $m \leq r$. Reading (12.3) in that range and writing $n = m + 1$, this says
$$\sum_{i=0}^{e} s_{n-i}(E) \circ c_i(E) = 0 \qquad \text{for every } n \geq 1$$
since α was arbitrary. Set $\widetilde{c} := \sum_{i=0}^{e} c_i(E)$, the truncation of the total Chern class at degree e. The displayed identities, together with $s_0(E) \circ c_0(E) = \mathrm{id}$ in degree zero, say precisely that $s(E) \circ \widetilde{c} = \mathrm{id}$. The inverse of $s(E)$ is two-sided and unique (lemma 12.2.2), so $\widetilde{c} = c(E)$, and comparing homogeneous components gives $c_i(E) = 0$ for $i > e$.
3. Let $c'_0 = \mathrm{id}, c'_1, \dots, c'_e$ be operators, homogeneous of the stated degrees, satisfying the

relation of (1) for every α. Subtracting the two relations, the terms with $i = 0$ cancel and

$$\sum_{i=1}^{e} \xi^{\,e-i} \cap \pi^* \Big(\big(c_i(E) - c_i' \big) \cap \alpha \Big) = 0$$

The exponents $e - i$ run over $0, 1, \ldots, e - 1 = r$, so this is a representation of the zero class in the form given by theorem 12.1.9. Uniqueness of that representation forces $(c_i(E) - c_i') \cap \alpha = 0$ for each i, and since α was arbitrary, $c_i' = c_i(E)$ for $1 \leq i \leq e$, completing the proof.

Part (2) is what gives a vector bundle a finite amount of Chern data: a rank-e bundle has exactly e potentially nonzero Chern classes, $c_1(E), \ldots, c_e(E)$, and the top one $c_e(E)$ carries the obstruction to finding a nowhere-vanishing section, as exercise 12.2.1 (3) below makes precise. Part (3) is the more useful of the three in practice. It says the Chern classes need not be computed by inverting a Segre series at all: any operators satisfying the relation on $\mathbb{P}(E)$ *are* the Chern classes. Every identity proved below is obtained by producing the relation from geometry and reading off its coefficients, and the Segre definition is never returned to.

The functoriality of the Segre operators transfers to the Chern classes for the same reason it held for them: the projective bundle of a pulled-back bundle is the pullback of the projective bundle. Two bundles on the same base are compared on the fibre product of their projective bundles, which is what makes their Chern classes commute.

Proposition 12.2.10: Properties of the Chern Class Operators

Let X be an algebraic scheme and E, F vector bundles on X.

1. *Commutativity.* For all $i, j \geq 0$ and $\alpha \in A_*(X)$,
$$c_i(E) \cap \big(c_j(F) \cap \alpha\big) = c_j(F) \cap \big(c_i(E) \cap \alpha\big)$$
2. *Projection formula.* If $f\colon X' \to X$ is proper and $\alpha' \in A_*(X')$, then
$$f_*\big(c_i(f^*E) \cap \alpha'\big) = c_i(E) \cap f_*\alpha'$$
3. *Flat pullback.* If $g\colon X'' \to X$ is flat of relative dimension m and $\alpha \in A_*(X)$, then
$$c_i(g^*E) \cap g^*\alpha = g^*\big(c_i(E) \cap \alpha\big)$$

Parts (2) and (3) say that a square commutes, and it is worth seeing which one. In each the horizontal maps are the capping operators and the vertical maps move between the two schemes; on $\alpha' \in A_k(X')$ and $\alpha \in A_k(X)$,

$$\begin{array}{ccc} A_k(X') & \xrightarrow{c_i(f^*E)\cap -} & A_{k-i}(X') \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle f_*} \\ A_k(X) & \xrightarrow[c_i(E)\cap -]{} & A_{k-i}(X) \end{array} \qquad \begin{array}{ccc} A_k(X) & \xrightarrow{c_i(E)\cap -} & A_{k-i}(X) \\ {\scriptstyle g^*}\downarrow & & \downarrow{\scriptstyle g^*} \\ A_{k+m}(X'') & \xrightarrow[c_i(g^*E)\cap -]{} & A_{k+m-i}(X'') \end{array}$$

Neither square says anything about the Chern classes of a pushed-forward or pulled-back *sheaf*: in both, the bundle upstairs is a pullback of E, and no Chern class of a pushforward appears in either.

***Proof*:**
Each $c_i(E)$ is a $\mathbb{Z}$-combination of composites of $s_1(E), \ldots, s_i(E)$ by the recursion following definition 12.2.3, so each of the three statements follows from the corresponding statement for Segre classes: expand the polynomials and apply the Segre statement to each factor of each monomial in turn. All three Segre statements are already proved in section 12.1.

1. *Commutativity.* proposition 12.1.5(3) gives $s_i(E) \cap (s_j(F) \cap \alpha) = s_j(F) \cap (s_i(E) \cap \alpha)$. Polynomials in commuting operators commute, so $c_i(E)$ and $c_j(F)$ commute as well.
2. *Projection formula.* This is the first identity of proposition 12.1.5(4), $f_*(s_i(f^*E) \cap \alpha') = s_i(E) \cap f_*\alpha'$, together with the fact that f_* is additive, so the identity passes through any $\mathbb{Z}$-combination of composites.
3. *Flat pullback.* This is the second identity of proposition 12.1.5(4), $s_i(g^*E) \cap g^*\beta = g^*(s_i(E) \cap \beta)$, and the same additivity argument, completing the proof.

Commutativity is what allows the Chern classes of all bundles on X to be handled as though they were elements of a commutative ring, long before any such ring exists; every polynomial identity written below is an identity among commuting operators, and its meaning is unambiguous. The

other two parts say that the Chern classes are attached to the bundle and not to the base. Part (3) is naturality under flat pullback: c_i of a pulled-back bundle, capped against a pulled-back class, is the pullback of the cap. Part (2) is a projection formula, and it is worth stating what it does *not* say: it moves $c_i(f^*E)$ across a proper f_*, leaving $c_i(E)$ on the target, and asserts nothing about the Chern classes of a pushed-forward sheaf. Together they are what a proof carried out after a base change needs in order to descend.

The identities that remain, multiplicativity on exact sequences chief among them, are proved by making E as simple as possible, and the simplest a bundle can be is filtered by line bundles. For such a bundle the relation of theorem 12.2.9 can be written down by hand, because the tautological line at a point of $\mathbb{P}(E)$ must have a nonzero image in one of the successive quotients. That observation is the whole proof of the next lemma, and through it of the Whitney formula.

Lemma 12.2.11: Chern Classes of a Filtered Bundle

Let E be a vector bundle of rank e on an algebraic scheme X, and suppose E admits a filtration by subbundles

$$0 = E_0 \subseteq E_1 \subseteq \cdots \subseteq E_e = E$$

with each quotient $L_i = E_i/E_{i-1}$ a line bundle. Then

$$c(E) = \prod_{i=1}^{e} \big(\mathrm{id} + c_1(L_i)\big)$$

as operators on $A_*(X)$; equivalently $c_m(E)$ is the m-th elementary symmetric expression

$$\sigma_m = \sum_{i_1 < \cdots < i_m} c_1(L_{i_1}) \cdots c_1(L_{i_m})$$

in the commuting operators $c_1(L_1), \ldots, c_1(L_e)$, for $0 \le m \le e$.

***Proof*:**
Write $P = \mathbb{P}(E)$ with projection π and tautological class ξ, and for $1 \le i \le e$ let $P_i = \mathbb{P}(E_i) \subseteq P$ with projection π_i and inclusion $\iota_i \colon P_i \hookrightarrow P$; set $P_0 = \mathbb{P}(E_0) = \emptyset$, so $P_e = P$. Each P_i is a closed subscheme of P, because in a local trivialization of the filtration over $U \subseteq X$ the inclusion $P_i|_U \subseteq P|_U$ is the linear inclusion $\mathbb{P}^{\,i-1} \times U \subseteq \mathbb{P}^{\,e-1} \times U$, and these glue. Put

$$\theta_i = c_1\big(\mathcal{O}_P(1) \otimes \pi^* L_i\big) = \xi + c_1(\pi^* L_i)$$

the equality by additivity of the first Chern class (proposition 11.4.4(3)); the θ_i commute with each other by proposition 11.4.4(2).

Step 1: each θ_i pushes a class on P_i down onto P_{i-1}. The tautological subbundle of box 12.2.5 restricts along ι_i to the tautological subbundle of P_i, since a point of P_i is a line $\ell \subseteq (E_i)_x \subseteq E_x$ and the line attached to it is the same either way; thus $\iota_i^* \mathcal{O}_P(1) = \mathcal{O}_{P_i}(1)$ and $\mathcal{O}_{P_i}(-1) \subseteq \pi_i^* E_i$. Composing that inclusion with the quotient map $\pi_i^* E_i \to \pi_i^* L_i$ gives a homomorphism $\mathcal{O}_{P_i}(-1) \to \pi_i^* L_i$, that is, a global section τ_i of the line bundle

$$M_i := \mathcal{O}_{P_i}(1) \otimes \pi_i^* L_i = \iota_i^*\big(\mathcal{O}_P(1) \otimes \pi^* L_i\big)$$

At a point of P_i above x corresponding to a line $\ell \subseteq (E_i)_x$, the section τ_i vanishes exactly when ℓ maps to zero in $(L_i)_x$, that is when $\ell \subseteq (E_{i-1})_x$. Its zero locus is therefore P_{i-1}. In a local

trivialization as above, with homogeneous fibre coordinates $y_1, \dots, y_i$ chosen so that E_{i-1} is cut out by $y_i = 0$, the section τ_i is the linear form y_i, a nonzerodivisor; hence $\operatorname{div}(\tau_i)$ is an effective Cartier divisor on P_i with support P_{i-1} and with $\mathcal{O}_{P_i}(\operatorname{div}\tau_i) \cong M_i$.

Now let $\beta = \iota_{i*}\beta_i$ for some $\beta_i \in A_*(P_i)$. The map ι_i is a closed immersion, hence proper, so the projection formula (proposition 11.4.4(4)) gives

$$\theta_i \cap \iota_{i*}\beta_i = \iota_{i*}\big(c_1(M_i) \cap \beta_i\big)$$

using $\iota_i^*(\mathcal{O}_P(1) \otimes \pi^* L_i) = M_i$. By definition 11.4.1 the class $c_1(M_i) \cap \beta_i$ is $\operatorname{div}(\tau_i) \cdot \beta_i$, which by proposition 11.2.4 is a well-defined class in $A_*\big(|\operatorname{div}\tau_i|\big) = A_*(P_{i-1})$. Pushing forward along $P_{i-1} \hookrightarrow P_i \hookrightarrow P$, the class $\theta_i \cap \beta$ is the image of a class on P_{i-1}, which is the assertion of this step. For $i = 1$ the filtration gives $E_1 = L_1$, the section τ_1 is the identity of L_1 under $\mathcal{O}_{P_1}(-1) = L_1 = \pi_1^* L_1$, its divisor is empty, and $A_*(P_0) = A_*(\emptyset) = 0$, so θ_1 annihilates every class coming from P_1.

Step 2: the product of the θ_i is zero. Let $\beta \in A_*(P) = A_*(P_e)$. Applying Step 1 with $i = e$ exhibits $\theta_e \cap \beta$ as coming from $A_*(P_{e-1})$; applying it again with $i = e-1$ exhibits $\theta_{e-1} \cap \theta_e \cap \beta$ as coming from $A_*(P_{e-2})$; after e steps the class $\theta_1 \cap \cdots \cap \theta_e \cap \beta$ comes from $A_*(P_0) = 0$ and so vanishes. The θ_i commute, so the product may be taken in any order:

$$\Big(\prod_{i=1}^{e} \theta_i\Big) \cap \beta = 0 \qquad \text{for every } \beta \in A_*(P)$$

Step 3: reading off the coefficients. Take $\beta = \pi^*\alpha$ for $\alpha \in A_*(X)$ and expand the product, which is legitimate because the factors commute:

$$0 = \Big(\prod_{i=1}^{e} \big(\xi + c_1(\pi^* L_i)\big)\Big) \cap \pi^*\alpha = \sum_{m=0}^{e} \xi^{\,e-m} \cap \Big(\sigma_m\big(c_1(\pi^* L_1), \dots, c_1(\pi^* L_e)\big) \cap \pi^*\alpha\Big)$$

The projection π is flat, so the flat compatibility of proposition 11.4.4(4) gives $c_1(\pi^* L) \cap \pi^*\alpha = \pi^*(c_1(L) \cap \alpha)$ for each L; iterating over the factors of each monomial,

$$\sigma_m\big(c_1(\pi^* L_1), \dots, c_1(\pi^* L_e)\big) \cap \pi^*\alpha = \pi^*\big(\sigma_m \cap \alpha\big)$$

with $\sigma_m = \sigma_m(c_1(L_1), \dots, c_1(L_e))$ formed on X. The displayed vanishing is therefore

$$\sum_{m=0}^{e} \xi^{\,e-m} \cap \pi^*\big(\sigma_m \cap \alpha\big) = 0$$

for every α, and $\sigma_0 = \mathrm{id}$. This is the relation of theorem 12.2.9(1) with σ_m in place of $c_m(E)$, so the uniqueness statement theorem 12.2.9(3) gives $c_m(E) = \sigma_m$ for $0 \le m \le e$, while $c_m(E) = 0$ for $m > e$ by part (2). Summing over m gives $c(E) = \prod_{i=1}^{e}(\mathrm{id} + c_1(L_i))$, as we sought to show.

The proof is geometric where it matters. A line inside E cannot map to zero in every quotient L_i of the filtration, and each factor θ_i cuts the support of a class down one step of the filtration, so after e factors nothing is left; the algebra afterwards only names the coefficients. Note also what the lemma does not require: no hypothesis on X, and no splitting of the filtration. A filtration with line-bundle quotients is enough, and an extension that does not split has the same Chern classes as the direct

sum of its pieces.

Example 12.2.12: Split Bundles on Projective Space

1. *The trivial bundle.* The bundle $\mathcal{O}_X^{\oplus e}$ is filtered by the coordinate subbundles $\mathcal{O}_X^{\oplus i}$, with all quotients equal to $\mathcal{O}_X$. Each factor of lemma 12.2.11 is then $\mathrm{id} + c_1(\mathcal{O}_X) = \mathrm{id}$, since $c_1(\mathcal{O}_X) = 0$ by example 11.4.3, so
$$c\big(\mathcal{O}_X^{\oplus e}\big) = \mathrm{id}$$
and every trivial bundle has trivial total Chern class, of any rank and on any X.

2. *A sum of twists on $\mathbb{P}^n$.* Let $E = \mathcal{O}_{\mathbb{P}^n}(a) \oplus \mathcal{O}_{\mathbb{P}^n}(b)$ and write $H = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$. The summand $\mathcal{O}_{\mathbb{P}^n}(a)$ is a subbundle with quotient $\mathcal{O}_{\mathbb{P}^n}(b)$, so the lemma gives
$$c(E) = \big(\mathrm{id} + aH\big)\big(\mathrm{id} + bH\big) = \mathrm{id} + (a+b)H + ab\,H^2$$
and hence $c_1(E) = (a+b)H$ and $c_2(E) = ab\,H^2$. Capping with the fundamental class and using example 11.4.7,
$$c_1(E) \cap [\mathbb{P}^n] = (a+b)\,[\mathbb{P}^{n-1}], \qquad c_2(E) \cap [\mathbb{P}^n] = ab\,[\mathbb{P}^{n-2}]$$
for $n \geq 2$. On $\mathbb{P}^1$ the second class vanishes for a reason unrelated to the rank: H^2 lowers dimension by two on a one-dimensional scheme, so it is the zero operator by the degree count in lemma 12.2.2, and $c_2(E) = 0$ even though $\mathrm{rank} E = 2$.

Most bundles carry no filtration by line bundles. The projective bundle manufactures one, but replaces X by a larger scheme, and iterating the construction strips off one line bundle at a time until nothing is left. The scheme at the end of the tower is the following.

Definition 12.2.13: The Flag Bundle

Let E be a vector bundle of rank e on an algebraic scheme X and let $0 \leq m \leq e$. Set $Y_0 = X$ and $E^{(0)} = E$, and for $1 \leq i \leq m$ let
$$p_i \colon Y_i = \mathbb{P}\big(E^{(i-1)}\big) \longrightarrow Y_{i-1}$$
be the projective bundle of lines in $E^{(i-1)}$, with tautological line subbundle $\Lambda_i \subseteq p_i^* E^{(i-1)}$ and quotient $E^{(i)} = p_i^* E^{(i-1)} / \Lambda_i$ of rank $e - i$ (box 12.2.5). The *m-step flag bundle* of E is
$$q \colon \mathrm{Fl}_m(E) := Y_m \longrightarrow X,$$
the composite of the m projections. Its fibre over $x \in X$ is the variety of flags $S_1 \subset \cdots \subset S_m \subseteq E_x$ with $\dim S_i = i$; write $S_i \subseteq q^* E$ for the corresponding rank-i subbundle, so that $S_i / S_{i-1} \cong \Lambda_i$.
The *full* flag bundle is the case $m = e-1$, written $\mathrm{Fl}(E)$; its fibre is the variety of complete flags in E_x, and for a bundle of rank two the tower has one stage, so $\mathrm{Fl}(E) = \mathbb{P}(E)$. The case $m = 0$ is X itself. The top case $m = e$ adds nothing: $E^{(e-1)}$ has rank one, so p_e is an isomorphism and $\mathrm{Fl}_e(E) = \mathrm{Fl}_{e-1}(E)$, with $S_e = q^* E$. It is allowed because the degeneracy-locus arguments of chapter 17 reach it whenever the rank drops to zero.

The projective-bundle formula guarantees that nothing is lost in passing to the flag bundle: the pullback map on Chow groups is injective at each stage, so an identity of operators verified upstairs is an identity downstairs. That is the content of the splitting principle, and it is a theorem rather than a slogan precisely because of the injectivity.

Theorem 12.2.14: The Splitting Principle

Let X be an algebraic scheme and $E_1, \dots, E_t$ vector bundles on X. There is a scheme X' and a proper, flat morphism $f\colon X' \to X$ such that

1. $f^*\colon A_*(X) \to A_*(X')$ is injective, and
2. each f^*E_j admits a filtration by subbundles whose successive quotients are line bundles.

***Proof*:**
Suppose first that $t = 1$, and write $E = E_1$ of rank e; the morphism produced will be the structure morphism of the flag bundle $\mathrm{Fl}(E)$ of definition 12.2.13. Induct on e. If $e = 1$ the bundle is already a line bundle and $f = \mathrm{id}_X$ serves. Let $e > 1$ and let $\pi\colon \mathbb{P}(E) \to X$ be the projective bundle, proper and flat by proposition 5.3.54. The Flat pullback along it is injective by corollary 12.1.6, which also exhibits the left inverse $\beta \mapsto \pi_*(\xi^{\,e-1} \cap \beta)$. On $\mathbb{P}(E)$ the tautological subbundle of box 12.2.5 gives an exact sequence

$$0 \longrightarrow \mathcal{O}_{\mathbb{P}(E)}(-1) \longrightarrow \pi^*E \longrightarrow Q \longrightarrow 0$$

with Q locally free of rank $e-1$. By the inductive hypothesis there is a proper flat $g\colon X' \to \mathbb{P}(E)$ with g^* injective and g^*Q filtered by subbundles with line-bundle quotients $N_2, \dots, N_e$. Set $f = \pi \circ g$, proper and flat as a composite of such, with $f^* = g^* \circ \pi^*$ injective as a composite of injections (proposition 10.3.5(3) identifies the composite pullback with the pullback of the composite). Pulling the displayed sequence back along g, which is exact because pullback of locally free sheaves is exact, gives a line subbundle $F_1 = g^*\mathcal{O}_{\mathbb{P}(E)}(-1) \subseteq f^*E$ with quotient g^*Q. Taking F_{j+1} to be the preimage in f^*E of the j-th step of the filtration of g^*Q produces

$$0 = F_0 \subseteq F_1 \subseteq \cdots \subseteq F_e = f^*E$$

with F_1 of rank one and F_{j+1}/F_j isomorphic to the j-th quotient of the filtration of g^*Q, hence a line bundle. This proves the case $t = 1$.

For general t, apply the case $t = 1$ to E_1, obtaining $f_1\colon X_1 \to X$; then to $f_1^*E_2$ on X_1, obtaining $f_2\colon X_2 \to X_1$; and so on, and take $f = f_1 \circ \cdots \circ f_t$. Each stage is proper and flat with injective pullback, so the composite is too. A filtration by subbundles with line-bundle quotients pulls back to a filtration of the same shape, again because pullback is exact on locally free sheaves, so the filtration of $f_j^*E_j$ constructed at stage j survives all later stages. Hence every f^*E_j is filtered with line-bundle quotients, completing the proof.

Two features of the statement carry the weight. Injectivity of f^* is what turns the construction into a proof technique, since an identity of Chern operators is a family of identities of classes, and each descends. Flatness is what makes f^* available at all at this stage of the theory, there being no pullback for a general morphism until chapter 13. Both come from the projective-bundle formula, which is why that formula had to be proved before any of this.

The reduction the splitting principle enables is the multiplicativity of Chern classes on exact sequences. This is the property that makes them computable in practice: bundles are almost always presented by exact sequences, and the formula converts such a presentation directly into Chern data.

Theorem 12.2.15: The Whitney Sum Formula

Let

$$0 \longrightarrow E' \longrightarrow E \longrightarrow E'' \longrightarrow 0$$

be an exact sequence of vector bundles on an algebraic scheme X. Then

$$c(E) = c(E')\, c(E'')$$

as operators on $A_*(X)$; that is, for every $m \geq 0$ and every $\alpha \in A_*(X)$,

$$c_m(E) \cap \alpha = \sum_{i+j=m} c_i(E') \cap \big(c_j(E'') \cap \alpha\big)$$

***Proof*:**
Let $e' = \operatorname{rank} E'$ and $e'' = \operatorname{rank} E''$, so $\operatorname{rank} E = e' + e''$.

Step 1: passing to a splitting cover. By theorem 12.2.14 applied to the pair E', E'' there is a proper flat $f\colon X' \to X$ with f^* injective, a filtration of f^*E' with line-bundle quotients $L'_1, \dots, L'_{e'}$, and a filtration of f^*E'' with line-bundle quotients $L''_1, \dots, L''_{e''}$. Pulling the given sequence back along f keeps it exact, pullback being exact on locally free sheaves, so

$$0 \longrightarrow f^*E' \longrightarrow f^*E \longrightarrow f^*E'' \longrightarrow 0$$

is exact on X'. Splice the two filtrations: take the filtration of f^*E' as the bottom e' steps of a filtration of f^*E, and above it take the preimages in f^*E of the steps of the filtration of f^*E''. The successive quotients are $L'_1, \dots, L'_{e'}$ followed by $L''_1, \dots, L''_{e''}$, all line bundles, so f^*E is filtered with line-bundle quotients.

Step 2: the identity upstairs. Lemma 12.2.11 applied to the three filtered bundles on X' gives

$$c(f^*E) = \prod_{i=1}^{e'} \big(\mathrm{id} + c_1(L'_i)\big) \cdot \prod_{j=1}^{e''} \big(\mathrm{id} + c_1(L''_j)\big) = c(f^*E')\, c(f^*E'')$$

the middle expression being the product over the quotients of the spliced filtration, regrouped using commutativity of first Chern class operators (proposition 11.4.4(2)). Comparing homogeneous components of degree m,

$$c_m(f^*E) = \sum_{i+j=m} c_i(f^*E')\, c_j(f^*E'')$$

Step 3: descending to X. Fix m and $\alpha \in A_*(X)$. Flat pullback naturality (proposition 12.2.10(3)) gives $f^*(c_m(E) \cap \alpha) = c_m(f^*E) \cap f^*\alpha$, and applying it twice,

$$f^*\Big(c_i(E') \cap \big(c_j(E'') \cap \alpha\big)\Big) = c_i(f^*E') \cap \big(c_j(f^*E'') \cap f^*\alpha\big)$$

Subtracting and using Step 2,

$$f^*\Big(c_m(E)\cap\alpha-\sum_{i+j=m}c_i(E')\cap\big(c_j(E'')\cap\alpha\big)\Big)=\Big(c_m(f^*E)-\sum_{i+j=m}c_i(f^*E')\,c_j(f^*E'')\Big)\cap f^*\alpha=0$$

Since f^* is injective, the class inside vanishes. As α and m were arbitrary, the two operators agree, completing the proof.

The formula makes the total Chern class a homomorphism from short exact sequences to products, and this is what the Grothendieck group $K^\circ(X)$ of vector bundles will formalize when Riemann-Roch is taken up: the total Chern class is insensitive to the extension class, seeing only the sub and the quotient. Two immediate consequences deserve recording. First, $c(E)$ is invertible for every bundle E, with inverse $s(E)$: by definition 12.2.3 it is the inverse of $s(E)$, and that inverse is two-sided by lemma 12.2.2. So an exact sequence determines the Chern classes of any one of its three terms from the other two: $c(E'')=c(E)c(E')^{-1}$. Second, a trivial sub or quotient bundle contributes nothing, since $c(\mathcal{O}_X^{\oplus t})=\mathrm{id}$ by example 12.2.12. Both are used repeatedly below.

Corollary 12.2.16: Chern Classes of a Dual Bundle

Let E be a vector bundle on an algebraic scheme X. Then

$$c_i\big(E^\vee\big)=(-1)^i\,c_i(E)$$

as operators on $A_*(X)$, for every $i\geq 0$.

***Proof*:**
Write $e=\mathrm{rank}E$ and let $f\colon X'\to X$ be as in theorem 12.2.14 for the single bundle E, with f^*E filtered by subbundles $0=F_0\subseteq\cdots\subseteq F_e=f^*E$ having line-bundle quotients $L_i=F_i/F_{i-1}$. Dualizing the filtration gives subbundles $(f^*E/F_i)^\vee\subseteq(f^*E)^\vee=f^*(E^\vee)$, increasing as i decreases, with successive quotients

$$\big(f^*E/F_{i-1}\big)^\vee/\big(f^*E/F_i\big)^\vee\cong\big(F_i/F_{i-1}\big)^\vee=L_i^\vee$$

each a line bundle, so $f^*(E^\vee)$ is filtered with line-bundle quotients $L_e^\vee,\dots,L_1^\vee$. By lemma 12.2.11 and $c_1(L^\vee)=-c_1(L)$ (proposition 11.4.4(3)),

$$c\big(f^*(E^\vee)\big)=\prod_{i=1}^{e}\big(\mathrm{id}-c_1(L_i)\big)$$

whose degree-i component is $(-1)^i\sigma_i(c_1(L_1),\dots,c_1(L_e))=(-1)^ic_i(f^*E)$, again by lemma 12.2.11. Naturality (proposition 12.2.10(3)) rewrites both sides as pullbacks of operators on X, and injectivity of f^* gives $c_i(E^\vee)=(-1)^ic_i(E)$, as we sought to show.

A working calculus still needs computed examples. The tangent bundle of projective space is the one every later computation leans on, and it is produced from the Euler sequence by a single application of the Whitney formula.

Example 12.2.17: The Tangent Bundle of Projective Space

The Euler sequence theorem 5.5.19 relates the sheaf of differentials of $\mathbb{P}^n$ to the twisting sheaves through the exact sequence

$$0 \longrightarrow \Omega_{\mathbb{P}^n} \longrightarrow \mathcal{O}_{\mathbb{P}^n}(-1)^{\oplus(n+1)} \longrightarrow \mathcal{O}_{\mathbb{P}^n} \longrightarrow 0$$

Projective space is smooth, so $\Omega_{\mathbb{P}^n}$ is locally free of rank n and the sequence is a sequence of vector bundles; dualizing it, which preserves exactness, gives the sequence in the form used here,

$$0 \longrightarrow \mathcal{O}_{\mathbb{P}^n} \longrightarrow \mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)} \longrightarrow T_{\mathbb{P}^n} \longrightarrow 0$$

with $T_{\mathbb{P}^n} = \Omega_{\mathbb{P}^n}^{\vee}$ the tangent bundle. Write $H = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$. The Whitney formula (theorem 12.2.15) applied to this sequence reads

$$c\big(\mathcal{O}_{\mathbb{P}^n}\big)\, c\big(T_{\mathbb{P}^n}\big) = c\big(\mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)}\big)$$

The left factor is the identity by example 12.2.12(1), and the right side is $(\mathrm{id} + H)^{n+1}$, the direct sum of $n+1$ copies of $\mathcal{O}(1)$ being filtered with all quotients $\mathcal{O}_{\mathbb{P}^n}(1)$ and each factor contributing $\mathrm{id} + H$ by lemma 12.2.11. Hence

$$c\big(T_{\mathbb{P}^n}\big) = (\mathrm{id} + H)^{n+1}, \qquad c_i\big(T_{\mathbb{P}^n}\big) = \binom{n+1}{i} H^i$$

for $0 \le i \le n$, with $c_i(T_{\mathbb{P}^n}) = 0$ for $i > n$ in accordance with theorem 12.2.9(2). The binomial coefficient $\binom{n+1}{n+1} = 1$ in degree $n+1$ is not a contradiction: H^{n+1} is the zero operator on $A_*(\mathbb{P}^n)$ by the degree count of lemma 12.2.2, matching the nilpotence recorded in proposition 11.4.4(5).

Capping the top class against the fundamental class and using $H^n \cap [\mathbb{P}^n] = [\mathbb{P}^0]$ from example 11.4.7,

$$c_n\big(T_{\mathbb{P}^n}\big) \cap [\mathbb{P}^n] = (n+1)\,[\mathbb{P}^0], \qquad \int_{\mathbb{P}^n} c_n\big(T_{\mathbb{P}^n}\big) = n+1$$

the degree being taken with definition 10.2.4. For $n = 1$ this gives $\int_{\mathbb{P}^1} c_1(T_{\mathbb{P}^1}) = 2$, the degree of the tangent bundle of a rational curve, consistent with $\deg T_C = 2 - 2g$ for $g = 0$ through example 11.4.8. For $n = 2$ it gives $\int_{\mathbb{P}^2} c_2(T_{\mathbb{P}^2}) = 3$.

The integers $n+1$ produced by the top Chern class are the Euler characteristics of the underlying spaces, which is the first sign that $c_n(T_X)$ counts something. The general statement, that the degree of the top Chern class of the tangent bundle of a smooth complete variety is its topological Euler characteristic, needs the comparison between Chow groups and cohomology through the cycle class map and is not available yet; what is available is the computation itself, and it is already enough to run enumerative arguments once the intersection product exists.

12.2.18 Remark: The Topological Chern Classes A reader who has met Chern classes topologically, as the characteristic classes of a complex vector bundle in *Algebraic Topology* [78], will recognize the shape of this section: the same axioms, the same Whitney formula, the same splitting principle through a flag bundle. The two theories are not the same construction. The classes there live in singular cohomology and are built for complex bundles on topological spaces; the classes here live in the Chow group of an algebraic scheme over an arbitrary algebraically closed field, and the scheme is allowed to be singular, reducible, and non-reduced. Neither proof above uses the other theory, and none could: no topology is available over a field of positive characteristic. The two are compared, for a smooth complex variety, by the cycle class map built later in this book, which carries the algebraic classes to the topological ones.

The last construction of this section is the calculus that makes such identities routine, together with the rational coefficients several of them require.

The total Chern class just built is multiplicative on short exact sequences: the Whitney formula turns an extension into a product. Riemann-Roch needs the opposite bookkeeping. It computes the Euler characteristic of a coherent sheaf, and Euler characteristics are *additive* on short exact sequences, so the characteristic class it pairs against must be additive too. That class is the Chern character, and alongside it sits the Todd class, the multiplicative correction attached to the tangent bundle; both are constructed in chapter 16, where they are used.

What the rest of this section gives is the apparatus they are built from. Both are universal power series in the Chern classes, and both differ from the classes above in two ways. Their coefficients are rational, forced by denominators that no normalization removes, and they are infinite series rather than finite sums, which is legitimate only because a composite of more than $\dim X$ dimension-lowering operators is zero. Those two points come first, and then the formal calculus of Chern roots that turns symmetric expressions in r formal symbols into operators.

The first point is a change of coefficients. Nothing in section 12.2 required it: Segre and Chern classes are operators on $A_*(X)$ with integer coefficients. The Chern character does require it, because its degree-two component is $\frac{1}{2}(c_1^2 - 2c_2)$, and no rescaling removes that $\frac{1}{2}$ while keeping additivity.

Definition 12.2.19: Chow Groups with Rational Coefficients

For an algebraic scheme X, set

$$A_k(X)_{\mathbb{Q}} := A_k(X) \otimes_{\mathbb{Z}} \mathbb{Q}, \qquad A_*(X)_{\mathbb{Q}} := \bigoplus_k A_k(X)_{\mathbb{Q}}$$

A class $\alpha \in A_k(X)$ is identified with $\alpha \otimes 1$, and every operator $A_k(X) \to A_{k-i}(X)$ extends uniquely to a $\mathbb{Q}$-linear operator $A_k(X)_{\mathbb{Q}} \to A_{k-i}(X)_{\mathbb{Q}}$. The degree map of definition 10.2.4 on a complete X is extended $\mathbb{Q}$-linearly and still written $\int_X \colon A_0(X)_{\mathbb{Q}} \to \mathbb{Q}$.

Since $\mathbb{Q}$ is flat over $\mathbb{Z}$, an injective map of Chow groups stays injective after this change of coefficients, so the injectivity statements of section 12.2 are available rationally without further comment. What is lost is torsion: the natural map $A_*(X) \to A_*(X)_{\mathbb{Q}}$ has kernel the torsion subgroup, so any torsion class becomes invisible. On $\mathbb{P}^n$ nothing is lost, since $A_*(\mathbb{P}^n) = \bigoplus_j \mathbb{Z}\,[\mathbb{P}^j]$ is free (theorem 10.5.2) and $A_*(\mathbb{P}^n)_{\mathbb{Q}} = \bigoplus_j \mathbb{Q}\,[\mathbb{P}^j]$; the class $\frac{3}{2}\,[\mathrm{pt}] \in A_0(\mathbb{P}^2)_{\mathbb{Q}}$, which will appear below as a component of $\mathrm{ch}(T_{\mathbb{P}^2})$, is a legitimate element of the rational Chow group and of nothing smaller.

The second point is that infinite series of operators are already finite sums. An operator lowering dimension can only be applied $\dim X$ times before the target group vanishes, which is the nilpotence recorded for a single line bundle in proposition 11.4.4(5), stated here for an arbitrary commuting family.

Lemma 12.2.20: Power Series in Dimension-Lowering Operators

Let X be an algebraic scheme of dimension n and let $\theta_1, \dots, \theta_m$ be pairwise commuting $\mathbb{Q}$-linear endomorphisms of $A_*(X)_{\mathbb{Q}}$ with $\theta_j\big(A_k(X)_{\mathbb{Q}}\big) \subseteq A_{k-d_j}(X)_{\mathbb{Q}}$ for integers $d_j \geq 1$. Write $\theta^\nu = \theta_1^{\nu_1} \cdots \theta_m^{\nu_m}$ and $|\nu| = \nu_1 + \cdots + \nu_m$.

1. $\theta^\nu = 0$ whenever $|\nu| > n$.
2. The assignment
$$\sum_{\nu} \lambda_\nu \, a^\nu \longmapsto \sum_{|\nu| \leq n} \lambda_\nu \, \theta^\nu$$
is a homomorphism of $\mathbb{Q}$-algebras $\mathbb{Q}[[a_1, \dots, a_m]] \to \mathrm{End}\big(A_*(X)_{\mathbb{Q}}\big)$ carrying a_j to θ_j.

***Proof*:**

1. A k-cycle is a combination of k-dimensional subvarieties, so $A_k(X)_{\mathbb{Q}} = 0$ unless $0 \leq k \leq n$. The operator θ^ν carries $A_k(X)_{\mathbb{Q}}$ into $A_{k-e}(X)_{\mathbb{Q}}$ where $e = \sum_j \nu_j d_j \geq |\nu|$. If $|\nu| > n$ then for every k with $A_k(X)_{\mathbb{Q}} \neq 0$ one has $k - e \leq n - |\nu| < 0$, so the target vanishes and $\theta^\nu = 0$.
2. Write T for the assignment. It is $\mathbb{Q}$-linear by construction, and $T(1) = \mathrm{id}$. For multiplicativity, let $\Phi = \sum_\mu \lambda_\mu a^\mu$ and $\Psi = \sum_\rho \kappa_\rho a^\rho$. The product $\Phi\Psi$ has coefficients $\sum_{\mu+\rho=\nu} \lambda_\mu \kappa_\rho$, so
$$T(\Phi\Psi) = \sum_{|\nu| \leq n} \Big(\sum_{\mu+\rho=\nu} \lambda_\mu \kappa_\rho \Big) \theta^\nu$$
On the other side, since the θ_j commute, $T(\Phi)T(\Psi) = \sum_{|\mu| \leq n,\, |\rho| \leq n} \lambda_\mu \kappa_\rho \, \theta^{\mu+\rho}$. Every term with $|\mu + \rho| > n$ vanishes by part (1), and every pair (μ, ρ) with $|\mu + \rho| \leq n$ automatically satisfies $|\mu| \leq n$ and $|\rho| \leq n$, so the two expressions have the same nonzero terms, completing the proof.

The Chern classes $c_1(E), \dots, c_r(E)$ of a bundle of rank r are exactly such a family: they commute with one another by section 12.2, ultimately because two divisor operators commute (theorem 11.3.2), and $c_i(E)$ lowers dimension by i. A formal power series in r variables therefore evaluates on them to a well-defined operator, given by a finite sum. This is the mechanism behind every definition below.

What remains is to say which power series. Both the Chern character and the Todd class are described most efficiently as symmetric expressions in r formal symbols $a_1, \dots, a_r$, the Chern roots, which behave as though E were a direct sum of line bundles with those first Chern classes. The splitting principle of section 12.2 is what makes the symbols legitimate.

Definition 12.2.21: Chern Roots and Splitting Maps

Let E be a vector bundle of rank r on an algebraic scheme X. A *splitting map* for E is a flat proper morphism $f\colon X' \to X$ such that

1. $f^*\colon A_*(X) \to A_*(X')$ is injective, and
2. f^*E admits a filtration by subbundles $0 = E_0 \subset E_1 \subset \cdots \subset E_r = f^*E$ whose successive quotients $L_p = E_p/E_{p-1}$ are line bundles.

The operators $a_p := c_1(L_p)$ on $A_*(X')_{\mathbb{Q}}$, for $p = 1, \dots, r$, are the *Chern roots* of E relative to f.

The splitting principle of section 12.2 produces a splitting map for any bundle: the flag bundle of E is a tower of projective bundles, proper and flat over X by proposition 5.3.54, and the projective-bundle formula of section 12.1 makes each stage of the tower inject on Chow groups. By flatness of $\mathbb{Q}$ over $\mathbb{Z}$, condition (1) also gives injectivity of $f^*\colon A_*(X)_{\mathbb{Q}} \to A_*(X')_{\mathbb{Q}}$. Writing $a_p = c_1(L_p)$ for the Chern roots, lemma 12.2.11 gives

$$c(f^*E) = \prod_{p=1}^{r} \bigl(\mathrm{id} + a_p\bigr), \qquad \text{that is} \qquad c_i(f^*E) = e_i(a_1, \dots, a_r) \tag{12.4}$$

where e_i is the i-th elementary symmetric polynomial. The roots are not canonical, and they are not operators on X at all, only on X'. What descends to X is any symmetric expression in them, and the reason is the classical structure theorem for symmetric functions.

Any symmetric formal power series in the Chern roots is a power series in the elementary symmetric polynomials, hence a genuine operator: this is [17, Symmetric Power Series in the Chern Roots], the formal-power-series refinement of the classical fundamental theorem on symmetric functions proved there.

The two lemmas combine into the calculus this section runs on: a symmetric power series in r variables defines an operator attached to any rank-r bundle, and that operator may be computed as though the bundle were split.

Proposition 12.2.22: The Chern Root Calculus

Let E be a vector bundle of rank r on an algebraic scheme X and let $\Phi \in \mathbb{Q}[[a_1, \dots, a_r]]$ be symmetric, with $\widetilde{\Phi}$ as in [17, Symmetric Power Series in the Chern Roots]. Define

$$\Phi(E) := \widetilde{\Phi}\big(c_1(E), \dots, c_r(E)\big)$$

Then:

1. $\Phi(E)$ is a well-defined operator on $A_*(X)_{\mathbb{Q}}$, equal to a finite sum of composites of Chern classes of E, and it commutes with $\Psi(F)$ for every bundle F and symmetric Ψ.
2. For a flat morphism $g\colon X'' \to X$ and $\alpha \in A_*(X)_{\mathbb{Q}}$,
$$g^*\big(\Phi(E) \cap \alpha\big) = \Phi(g^*E) \cap g^*\alpha$$
3. If E itself admits a filtration by subbundles with line-bundle quotients $L_1, \dots, L_r$, then $\Phi(E) = \Phi\big(c_1(L_1), \dots, c_1(L_r)\big)$, the right-hand side being the evaluation of lemma 12.2.20.
4. If $f\colon X' \to X$ is a splitting map for E with Chern roots $a_1, \dots, a_r$, then $f^*\big(\Phi(E) \cap \alpha\big) = \Phi(a_1, \dots, a_r) \cap f^*\alpha$ for all $\alpha \in A_*(X)_{\mathbb{Q}}$.

***Proof*:**

1. The classes $c_1(E), \dots, c_r(E)$ commute pairwise and $c_i(E)$ lowers dimension by i, so lemma 12.2.20 applies and $\widetilde{\Phi}$ evaluates to a well-defined operator, equal to the sum of the terms of $\widetilde{\Phi}$ of weight at most $\dim X$. Uniqueness of $\widetilde{\Phi}$ in [17, Symmetric Power Series in the Chern Roots] is what makes the value depend on Φ alone. Chern classes of any two bundles commute by section 12.2, so the images of the two evaluation homomorphisms commute.
2. Chern classes are natural under flat pullback, $c_i(g^*E) \cap g^*\beta = g^*(c_i(E) \cap \beta)$ by section 12.2, generalizing proposition 11.4.4(4). Applying this once for each factor of a monomial in the $c_i(E)$, and summing over the finitely many monomials of $\widetilde{\Phi}$ that survive, gives the claim.
3. By (12.4) applied to the filtration of E itself, $c_i(E) = e_i(a_1, \dots, a_r)$ with $a_p = c_1(L_p)$. The evaluation homomorphism $\mathbb{Q}[[a_1, \dots, a_r]] \to \mathrm{End}(A_*(X)_{\mathbb{Q}})$ of lemma 12.2.20 for the commuting family $a_1, \dots, a_r$ is a ring homomorphism, so it may be applied to the identity $\Phi = \widetilde{\Phi}(e_1, \dots, e_r)$ of [17, Symmetric Power Series in the Chern Roots] term by term, giving
$$\Phi(a_1, \dots, a_r) = \widetilde{\Phi}\big(e_1(a), \dots, e_r(a)\big) = \widetilde{\Phi}\big(c_1(E), \dots, c_r(E)\big) = \Phi(E)$$
as operators.
4. Combining parts (2) and (3): the morphism f is flat, so $f^*(\Phi(E) \cap \alpha) = \Phi(f^*E) \cap f^*\alpha$, and f^*E carries a filtration with line-bundle quotients L_p, so $\Phi(f^*E) = \Phi(a_1, \dots, a_r)$ by part (3). This completes the proof.

Part (4) is the working form. To prove an identity between operators built from bundles on X, pass

to a splitting map, verify the corresponding identity of symmetric power series in the roots, and descend by injectivity of f^*. The roots never appear in a statement, only in a proof.

Exercise 12.2.1

1. Using only definition 12.2.3, express $s_1(E)$, $s_2(E)$ and $s_3(E)$ in terms of $c_1(E), c_2(E), c_3(E)$, and check that the resulting formulas are obtained from the expressions for c_1, c_2, c_3 in terms of s_1, s_2, s_3 by exchanging the letters c and s. Explain in one sentence why that symmetry is forced by the definition.

2. Let $E = \mathcal{O}_{\mathbb{P}^n}(a) \oplus \mathcal{O}_{\mathbb{P}^n}(b)$ with $n \geq 2$. Compute $c(E)$, $c(E^\vee)$ and $c(E \otimes \mathcal{O}_{\mathbb{P}^n}(1))$ as operators on $A_*(\mathbb{P}^n)$, and compute $c_2(E) \cap [\mathbb{P}^n]$. Then take $n = 1$ and explain why $c_2(E) = 0$ there, identifying which of the two possible reasons (the rank of E or the dimension of the base) is responsible.

3. Let E be a vector bundle of rank $e \geq 2$ on an algebraic scheme X admitting a nowhere-vanishing global section τ, so that $\tau\colon \mathcal{O}_X \to E$ is an inclusion of a subbundle with locally free quotient Q of rank $e - 1 \geq 1$. Show that $c(E) = c(Q)$ and deduce $c_e(E) = 0$. Show separately that a line bundle with a nowhere-vanishing section is trivial, so that the conclusion holds in the excluded case $e = 1$ as well. Conversely, explain why the computation $\int_{\mathbb{P}^n} c_n(T_{\mathbb{P}^n}) = n + 1 \neq 0$ of example 12.2.17 shows that $T_{\mathbb{P}^n}$ has no nowhere-vanishing global section.

4. Let E be a vector bundle of rank two on an algebraic scheme X and L a line bundle on X. Using theorem 12.2.14 and lemma 12.2.11, prove

$$c_1(E \otimes L) = c_1(E) + 2\,c_1(L), \qquad c_2(E \otimes L) = c_2(E) + c_1(E)\,c_1(L) + c_1(L)^2$$

   as operators on $A_*(X)$. (You may use that tensoring a filtration by a line bundle again gives a filtration, with each quotient tensored by that line bundle.)

5. Compute $c(\Omega_{\mathbb{P}^n})$ as an operator on $A_*(\mathbb{P}^n)$ in closed form, and evaluate $\int_{\mathbb{P}^2} c_2(\Omega_{\mathbb{P}^2})$ and $\int_{\mathbb{P}^2} c_1(\Omega_{\mathbb{P}^2})^2$. Compare the first with $\int_{\mathbb{P}^2} c_2(T_{\mathbb{P}^2})$ and account for the agreement.

6. Let C be a smooth projective curve and E a vector bundle of rank two on C. Show that $c_2(E) = 0$ as an operator on $A_*(C)$, and that $c(E)$ is determined by the single class $c_1(E) \cap [C] \in A_0(C)$. Show further that if E sits in an exact sequence $0 \to L_1 \to E \to L_2 \to 0$ of bundles on C, then $\int_C c_1(E) = \deg L_1 + \deg L_2$.

12.3 Segre Classes of Cones and Subschemes

The Segre operators of section 12.1 came out of one recipe: projectivize, cap with powers of the tautological class, push down. Local triviality was never used in that recipe. What it used was a graded sheaf of algebras on X whose relative Proj is proper over X and carries a canonical line bundle, and a vector bundle gives one such algebra among many. This section runs the recipe on the general input, a *cone*, and then on the case that matters here: the normal cone of a closed subscheme $Z \subseteq X$. The resulting class $s(Z, X)$ is an invariant of the embedding defined with no smoothness, no regularity and no dimension hypothesis, and it is the object that chapter 13 will deform X onto.

The algebra that produces a cone is required to look like a polynomial algebra in the two respects that matter for Proj : it starts in degree zero at $\mathcal{O}_X$, and it is generated by its degree-one part, which

is coherent.

Definition 12.3.1: Cone

Let X be an algebraic scheme. A *cone* over X is the relative spectrum

$$C = \operatorname{Spec}\left(S^\bullet\right) \xrightarrow{p} X$$

of a sheaf $S^\bullet = \bigoplus_{n\geq 0} S_n$ of graded quasi-coherent $\mathcal{O}_X$-algebras (definition 5.3.47) such that

1. $S_0 = \mathcal{O}_X$;
2. S_1 is coherent;
3. $S^\bullet$ is generated as an $\mathcal{O}_X$-algebra by S_1.

The relative spectrum is the construction of theorem 5.1.41, glued from the affine pieces $\operatorname{Spec}\Gamma(U, S^\bullet)$ over an affine open cover of X, exactly as the relative Proj of theorem 5.3.49 is. Writing $S_+ = \bigoplus_{n\geq 1} S_n$, the surjection $S^\bullet \to S^\bullet/S_+ = \mathcal{O}_X$ defines a closed immersion $X \hookrightarrow C$, the *vertex* of the cone.

Conditions (2) and (3) force every S_n to be coherent, so p is affine and of finite type; the grading is what distinguishes a cone from an arbitrary affine morphism, and it is the grading that gives the vertex and, below, the compactification. A cone is not required to be flat over X, nor to have fibres of constant dimension, and both failures are the point: the cones that arise from geometry are singular, jump in dimension along strata, and carry exactly the information those defects encode.

Example 12.3.2: Bundles, the Zero Cone, and the Affine Cone Over a Projective Variety

1. *A vector bundle.* Let E be a vector bundle of rank e on X with sheaf of sections $\mathcal{E}$. The functions on the total space of E are the symmetric algebra on the dual, so $S^\bullet = \operatorname{Sym}^\bullet(\mathcal{E}^\vee)$ has $\operatorname{Spec}\left(S^\bullet\right) = E$, and conditions (1) to (3) hold with $S_1 = \mathcal{E}^\vee$ locally free of rank e. The vertex $X \hookrightarrow E$ is the zero section. The dual is exactly what makes $\operatorname{Proj}\left(\operatorname{Sym}^\bullet \mathcal{E}^\vee\right)$ the bundle of *lines* in E used throughout this book (box 9.0.2), and not the bundle of rank-one quotients of $\mathcal{E}$ that definition 5.3.51 writes as $\mathbb{P}(\mathcal{E})$.
2. *The zero cone.* Taking $S^\bullet = \mathcal{O}_X$, so that $S_+ = 0$, gives $C = X$ with its vertex the identity. The degenerate case earns its place: it is the normal cone of X in itself.
3. *An affine cone.* Let $Y = \operatorname{Proj}(R) \subseteq \mathbb{P}^n$ be a closed subscheme, where $R = \overline{k}[x_0, \ldots, x_n]/I$ for a homogeneous ideal I, and take $X = \operatorname{Spec}\overline{k}$. Then R itself satisfies (1) to (3), and $C = \operatorname{Spec}(R)$ is the affine cone over Y: the union of the lines of $\mathbb{A}^{n+1}$ through the origin lying over the points of Y, together with the origin, which is the vertex. For $I = 0$ this is $\mathbb{A}^{n+1}$ itself, the trivial bundle of rank $n+1$ over a point, recovering item (1).

A cone is affine over X, so p is proper only in the degenerate case where $S^\bullet$ is coherent as an $\mathcal{O}_X$-module and p is therefore finite; the zero cone of example 12.3.2(2), with $p = \mathrm{id}$, is such a case. The cones that carry geometry are not: a vector bundle of positive rank has fibres $\mathbb{A}^e$, and an affine scheme of positive dimension over a field is not proper. So p_* is unavailable in general, and pushing a cycle from C down to X is not an option. The remedy is the one projective space applies to affine

space: compactify by adding a hyperplane at infinity. Adjoining one variable in degree one does this, and does it in a way that keeps the answer a relative Proj , so the canonical line bundle comes along for free.

Definition 12.3.3: Projective Cone and Projective Completion

Let $C = \operatorname{Spec}(S^\bullet)$ be a cone over X. Adjoin a variable z in degree one, giving the graded $\mathcal{O}_X$-algebra $S^\bullet[z]$ with $\big(S^\bullet[z]\big)_n = \bigoplus_{j=0}^{n} S_j\, z^{n-j}$, which again satisfies the conditions of definition 12.3.1. The *projective cone* of C and the *projective completion* of C are the relative Proj schemes

$$\mathbb{P}(C) = \operatorname{Proj}\big(S^\bullet\big), \qquad \mathbb{P}(C \oplus 1) = \operatorname{Proj}\big(S^\bullet[z]\big)$$

Both are proper over X (theorem 5.3.49). Write $q\colon \mathbb{P}(C \oplus 1) \to X$ for the structure morphism and $\mathcal{O}(1) = \mathcal{O}_{\mathbb{P}(C\oplus 1)}(1)$ for the canonical line bundle.

Three identifications justify the name, and each is read straight off the graded algebra. First, on the locus where z is invertible, $D_+(z) = \operatorname{Spec}\big((S^\bullet[z])_{(z)}\big)$, and the assignment $s/z^n \mapsto s$ for $s \in S_n$ is an isomorphism of $\mathcal{O}_X$-algebras $(S^\bullet[z])_{(z)} \cong S^\bullet$; so the open subscheme of $\mathbb{P}(C \oplus 1)$ where $z \neq 0$ is C itself. Second, z is a nonzerodivisor in $S^\bullet[z]$ and a global section of $\mathcal{O}(1)$, and its zero scheme is $\operatorname{Proj}\big(S^\bullet[z]/(z)\big) = \mathbb{P}(C)$; so $\mathbb{P}(C)$ is an effective Cartier divisor (definition 5.4.26) on $\mathbb{P}(C \oplus 1)$ with complement C, the hyperplane at infinity. Third, the surjection $S^\bullet[z] \to \mathcal{O}_X[z]$ killing S_+ realizes $X = \operatorname{Proj}(\mathcal{O}_X[z])$ as a closed subscheme of $\mathbb{P}(C \oplus 1)$ contained in the open piece C, where it is the vertex of definition 12.3.1.

So $\mathbb{P}(C \oplus 1)$ is C with $\mathbb{P}(C)$ glued on at infinity, and it is proper over X whereas C, outside the degenerate case just noted, is not. That properness is why it is introduced: it makes q_* available (definition 10.2.1 and theorem 10.2.3), and with $\mathcal{O}(1)$ in hand the construction of section 12.1 can be run verbatim.

The model case is the one the terminology is borrowed from. Take $X = \operatorname{Spec}\overline{k}$ and $S^\bullet = \overline{k}[t_1, \ldots, t_n]$, so that $C = \mathbb{A}^n$ is the trivial bundle of rank n over a point. Then $S^\bullet[z] = \overline{k}[t_1, \ldots, t_n, z]$ and $\mathbb{P}(C \oplus 1) = \mathbb{P}^n$, with $\mathbb{P}(C) = \mathbb{P}^{n-1}$ the hyperplane $z = 0$ at infinity, the open complement $D_+(z)$ the standard affine chart $\mathbb{A}^n$, and the vertex the origin of that chart. Compactifying a cone is compactifying affine space by a hyperplane, carried out fibrewise over X and allowing the fibres to be as singular as they like.

Definition 12.3.4: Segre Class of a Cone

Let C be a cone over an algebraic scheme X, with projective completion $q\colon \mathbb{P}(C \oplus 1) \to X$ and canonical line bundle $\mathcal{O}(1)$. The *Segre class* of C is the cycle class

$$s(C) \;=\; q_*\Big(\sum_{i\geq 0} c_1\big(\mathcal{O}(1)\big)^i \cap \big[\mathbb{P}(C \oplus 1)\big]\Big) \;\in\; A_*(X)$$

where $[\mathbb{P}(C \oplus 1)]$ is the fundamental cycle of definition 10.1.2 and $c_1(\mathcal{O}(1)) \cap -$ is the operator of definition 11.4.1. Write $s(C)_k$ for the component of $s(C)$ in $A_k(X)$.

The sum is finite. Each cap lowers dimension by one, so the term indexed by i lies in $A_{d-i}\big(\mathbb{P}(C \oplus 1)\big)$ for $d = \dim \mathbb{P}(C \oplus 1)$, and this group vanishes once $i > d$ because there are no cycles of negative dimension. Two features of the definition deserve emphasis. The Segre class of a cone is a *class*, not

an operator: the capping has already happened, against the fundamental cycle of the compactification. And it is not homogeneous; $s(C)$ has components in several dimensions at once, and the interesting content is usually spread across them.

For the model cone $C = \mathbb{A}^n$ over $X = \operatorname{Spec} \overline{k}$ the class can be read off. The completion is $\mathbb{P}^n$, and $q_*\big(c_1(\mathcal{O}(1))^i \cap [\mathbb{P}^n]\big)$ lies in $A_{n-i}(\operatorname{Spec} \overline{k})$, which vanishes unless $i = n$. For $i = n$, example 11.4.7 gives $c_1(\mathcal{O}(1))^n \cap [\mathbb{P}^n] = [\mathrm{pt}]$, whose pushforward to the point is the fundamental class. Hence $s(\mathbb{A}^n) = [\operatorname{Spec} \overline{k}]$: the trivial bundle has trivial Segre class, as it must.

Before the definition can be trusted it has to be checked against the case it generalizes. A vector bundle is a cone, and its Segre class as a cone had better be its total Segre operator evaluated on the fundamental class of the base. The bundle has to have positive rank for that comparison to mean anything: the operators $s_i(E)$ of section 12.1 are manufactured from $\mathbb{P}(E)$, which is empty for the zero bundle, so neither $s(E)$ nor $c(E)$ is defined there. The rank-zero cone is the zero cone of example 12.3.2(2), whose Segre class is computed directly below.

Proposition 12.3.5: The Segre Class of a Vector Bundle as a Cone

Let E be a vector bundle of rank $e \geq 1$ on an algebraic scheme X, and let C be its total space regarded as a cone (example 12.3.2(1)). Then

$$s(C) \;=\; s(E) \cap [X]$$

where $s(E) = \sum_{j \geq 0} s_j(E)$ is the total Segre operator of section 12.1.

***Proof*:**

Step 1: the projective completion is a projective bundle. With $S^\bullet = \operatorname{Sym}^\bullet(\mathcal{E}^\vee)$ one has $S^\bullet[z] = \operatorname{Sym}^\bullet\big(\mathcal{E}^\vee \oplus \mathcal{O}_X\big) = \operatorname{Sym}^\bullet\big((\mathcal{E} \oplus \mathcal{O}_X)^\vee\big)$, the variable z being the coordinate dual to the added trivial summand. Hence $\mathbb{P}(C \oplus 1) = \mathbb{P}(E \oplus 1)$ is the bundle of lines in the rank-$(e+1)$ bundle $E \oplus 1$, its fibres are copies of $\mathbb{P}^e$, and its canonical bundle $\mathcal{O}(1)$ is the one whose first Chern class is the tautological class of section 12.1. In particular q is proper and flat of relative dimension e (proposition 5.3.54).

Step 2: the fundamental cycle is a flat pullback. Write $n = \dim X$ and let X_λ run over *all* irreducible components of X, of whatever dimension n_λ, so that the fundamental cycle is $[X] = \sum_\lambda m_\lambda [X_\lambda]$ with m_λ the length of $\mathcal{O}_{X, X_\lambda}$ (definition 10.1.2, which warns against truncating it to top dimension). Each preimage $q^{-1}(X_\lambda)$ is a projective bundle over the variety X_λ, hence integral, so $q^*[X_\lambda] = [q^{-1}(X_\lambda)]$ by proposition 10.3.5(2); and the length multiplicity of $q^{-1}(X_\lambda)$ in $[\mathbb{P}(E \oplus 1)]$ is again m_λ, because the local homomorphism $\mathcal{O}_{X, X_\lambda} \to \mathcal{O}_{\mathbb{P}(E \oplus 1),\, q^{-1}(X_\lambda)}$ is flat with fibre the function field of a projective space, so the two lengths agree. Summing over λ,

$$q^*[X] = \big[\mathbb{P}(E \oplus 1)\big]$$

Step 3: the terms with $i \geq e$. Definition 12.1.3 defines the Segre operators of a bundle F of rank f by $s_j(F) \cap \alpha = \pi_*\big(\xi^{\,f-1+j} \cap \pi^*\alpha\big)$, where $\pi \colon \mathbb{P}(F) \to X$ has relative dimension $f - 1$ and $\xi = c_1(\mathcal{O}_{\mathbb{P}(F)}(1))$. Applied to $F = E \oplus 1$, of rank $e + 1$, this reads

$$s_j(E \oplus 1) \cap \alpha = q_*\big(c_1(\mathcal{O}(1))^{\,e+j} \cap q^*\alpha\big), \qquad j \geq 0$$

so by Step 2 the terms of definition 12.3.4 indexed by $i = e + j$ with $j \geq 0$ sum to $\sum_{j \geq 0} s_j(E \oplus 1) \cap [X] = s(E \oplus 1) \cap [X]$.

Step 4: the terms with $i < e$ vanish. Argue component by component, since $[X]$ need not be homogeneous. Flat pullback raises dimension by e and each cap lowers it by one, so the contribution of X_λ to $q_*\big(c_1(\mathcal{O}(1))^i \cap q^*[X]\big)$ is a class on X_λ of dimension $n_\lambda + e - i$. For $i < e$ that exceeds $n_\lambda = \dim X_\lambda$, and X_λ carries no subvariety of dimension greater than its own, so each contribution vanishes and with it every such term.

Step 5: dropping the trivial summand. This is the only step that uses $e \geq 1$: both E and $E \oplus 1$ then have positive rank, so both have invertible total Segre operators (lemma 12.2.2) and Chern operators to compare (definition 12.2.3). The split exact sequence $0 \to E \to E \oplus 1 \to \mathcal{O}_X \to 0$ and the Whitney formula (theorem 12.2.15) give $c(E \oplus 1) = c(E)\, c(\mathcal{O}_X)$. A line bundle has no Chern classes above the rank (proposition 12.2.6), so $c(\mathcal{O}_X) = \mathrm{id} + c_1(\mathcal{O}_X)$, and $c_1(\mathcal{O}_X) = 0$ by example 11.4.3; hence $c(E \oplus 1) = c(E)$ and, inverting, $s(E \oplus 1) = s(E)$. Combining with Steps 3 and 4,

$$s(C) = s(E \oplus 1) \cap [X] = s(E) \cap [X]$$

as we sought to show.

The proposition justifies the notation: for the cone of a vector bundle the class $s(C)$ of definition 12.3.4 and the operator $s(E)$ of section 12.1 determine one another, and writing s for both loses nothing. What the proposition also shows is where the new content will sit. On a bundle, the compactification $\mathbb{P}(E \oplus 1)$ is flat over X with fibres of constant dimension, the Segre operators exist, and $s(C)$ is a formal consequence of them. On a general cone none of that is available, and $s(C)$ does not come from any operator; it is a class computed once, by pushing forward from a compactification that may be singular and may jump in dimension over X.

The cone this was built for measures how a closed subscheme sits inside an ambient scheme. When Z is a smooth subvariety of a smooth variety, the correct linear model is the normal bundle, and its rank is the codimension. When either smoothness hypothesis fails there is no bundle, but the ideal sheaf still has an associated graded algebra, and that algebra is always a cone.

Definition 12.3.6: Normal Cone of a Closed Subscheme

Let $Z \subseteq X$ be a closed subscheme of an algebraic scheme, with ideal sheaf $\mathcal{I} \subseteq \mathcal{O}_X$. The graded sheaf of algebras $\bigoplus_{n\geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}$ has degree-zero part $\mathcal{O}_X/\mathcal{I} = \mathcal{O}_Z$, coherent degree-one part $\mathcal{I}/\mathcal{I}^2$, and is generated in degree one, so it satisfies the conditions of definition 12.3.1. The *normal cone* of Z in X is the cone over Z

$$C_Z X \;=\; \operatorname{Spec}\Big(\bigoplus_{n\geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}\Big) \;\longrightarrow\; Z$$

On an affine open $U = \operatorname{Spec} A$ of X with $Z \cap U = \operatorname{Spec} A/I$, this is $\operatorname{Spec}\big(\bigoplus_{n\geq 0} I^n/I^{n+1}\big)$.

The normal cone is intrinsic to the pair (Z, X) and depends on the scheme structure of Z, not just on its underlying set: the ideal $\mathcal{I}$ is the input, and thickening Z changes it. When Z is a single reduced point P of a variety X, the normal cone is the classical tangent cone $\operatorname{Spec}\big(\operatorname{gr}_{\mathfrak{m}} \mathcal{O}_{X,P}\big)$, the cone of limiting directions of branches of X through P, and it is where the local singularity of X at P is recorded.

Example 12.3.7: The Tangent Cone at a Node

Assume $\mathrm{char}\,\overline{k} \neq 2$ and let $X = \operatorname{Spec} \overline{k}[x,y]/(y^2 - x^2 - x^3) \subseteq \mathbb{A}^2$ be the affine nodal cubic, with P the origin and $\mathfrak{m} = (x,y)$ its maximal ideal.[a] The associated graded ring of $\overline{k}[x,y]$ for the filtration by powers of (x,y) is again $\overline{k}[x,y]$, a domain, so initial forms multiply: the initial form of gh is the product of those of g and h. Consequently the initial forms of the elements of the principal ideal $(y^2 - x^2 - x^3)$ are generated by the initial form of its generator, namely $y^2 - x^2$. Hence

$$\bigoplus_{n \geq 0} \mathfrak{m}^n/\mathfrak{m}^{n+1} \;\cong\; \overline{k}[x,y]/(y^2 - x^2)$$

and $C_P X = \operatorname{Spec} \overline{k}[x,y]/(y^2 - x^2)$ is the union of the two lines $y = x$ and $y = -x$: precisely the two branches of the node, straightened to their tangent directions. The normal cone is one-dimensional, matching $\dim X = 1$, but it is reducible where X is irreducible, and it is not a vector bundle over the point P (a rank-one bundle over a point is a single line). The failure is exactly the singularity.

[a] The hypothesis on the characteristic cannot be dropped. In characteristic 2 the substitution $u = y + x$ turns the equation into $u^2 = x^3$, so the curve is a cuspidal cubic with a single branch, and $y^2 - x^2 = (y+x)^2$ makes the ring computed below the coordinate ring of a single non-reduced double line, which is irreducible; the contrast drawn at the end of the example then fails.

The normal cone is a cone over Z, so it has a Segre class, and that class is what records how Z sits inside X when no bundle is available to record it.

Definition 12.3.8: Segre Class of a Closed Subscheme

Let $Z \subseteq X$ be a closed subscheme of an algebraic scheme. The *Segre class of Z in X* is the Segre class of the normal cone,

$$s(Z,X) \;=\; s\big(C_Z X\big) \;\in\; A_*(Z)$$

Two points about the target group. The class lives on Z, not on X: like the intersection classes of definition 11.2.1, it is recorded where the geometry happens, and one pushes forward along $Z \hookrightarrow X$ only when the cruder class in $A_*(X)$ is wanted. And no hypothesis whatsoever was imposed on the pair (Z,X): X may be singular, reducible, or nonreduced, Z may be any closed subscheme including X itself, and $s(Z,X)$ is defined regardless. That generality is what makes the class useful and also what makes it hard to compute; the two computations below are the cases where it can be read off.

The extreme case is immediate. Taking $Z = X$ makes $\mathcal{I} = 0$, so the normal cone is the zero cone of example 12.3.2(2), with projective completion $\operatorname{Proj}(\mathcal{O}_X[z]) = X$ and with $\mathcal{O}(1)$ free on the generator z, hence trivial. Every term of definition 12.3.4 beyond the first therefore vanishes, since $c_1(\mathcal{O}_X) = 0$ by example 11.4.3, and $s(X,X) = [X]$. A subscheme sitting inside itself has no normal directions, and its Segre class is its own fundamental cycle.

12.3.9 Foreshadowing: Why the Normal Cone The normal cone is not introduced here for its own sake. Chapter 13 constructs a family over $\mathbb{P}^1$ whose general fibre is the embedding $Z \hookrightarrow X$ and whose special fibre is the embedding of Z as the vertex of $C_Z X$; intersecting with Z inside X is then replaced by intersecting with the vertex inside the cone, where the answer can be read off. When $C_Z X$ is a vector bundle that replacement produces the Gysin map of a regular embedding; when it is not, the Segre class $s(Z, X)$ is what survives, and it is the term that appears in the excess intersection formula.

The first computable case is the one where the normal cone degenerates to a bundle. The condition on the ideal is the classical one: it should be generated, locally, by the right number of equations imposing independent conditions.

Regular embeddings and their normal bundles are scheme theory, and they belong to, and are defined in, *Algebraic Geometry*: a closed immersion whose ideal sheaf is locally generated by a regular sequence of length d is a *regular embedding of codimension* d (definition 5.1.43), its conormal sheaf $\mathcal{I}/\mathcal{I}^2$ is then locally free of rank d (proposition 5.1.44), and its *normal bundle* is the rank-d vector bundle

$$N_Z X \;=\; \underline{\mathrm{Spec}}_{\,Z}\Big(\mathrm{Sym}^{\bullet}\big(\mathcal{I}/\mathcal{I}^2\big)\Big) \;\longrightarrow\; Z$$

with sheaf of sections $(\mathcal{I}/\mathcal{I}^2)^{\vee}$ (definition 5.1.45). What this book adds is the cycle-level consequence below.

The definition is local on Z, and the number d is forced: the rank of $\mathcal{I}/\mathcal{I}^2$ is a local invariant, so a regular embedding has a well-defined codimension on each connected component of Z. The two extremes are familiar. The origin in $\mathbb{A}^n$, whose ideal $(x_1, \dots, x_n)$ is a regular sequence, is a regular embedding of codimension n with trivial normal bundle of rank n; an effective Cartier divisor, whose ideal is locally generated by a single nonzerodivisor, is the codimension-one case, with normal bundle a line bundle. What makes the notion useful here is that the whole associated graded algebra, not its degree-one part, becomes a symmetric algebra.

Lemma 12.3.10: The Associated Graded Algebra of a Regular Sequence

Let A be a Noetherian ring and let $a_1, \dots, a_d$ be a regular sequence generating an ideal $I \subseteq A$. Then the homomorphism of graded A/I-algebras

$$(A/I)[T_1, \dots, T_d] \longrightarrow \bigoplus_{n \geq 0} I^n/I^{n+1}, \qquad T_j \longmapsto a_j \bmod I^2$$

is an isomorphism. In particular I/I^2 is a free A/I-module of rank d on the classes of $a_1, \dots, a_d$, and the canonical surjection $\mathrm{Sym}^{\bullet}_{A/I}\big(I/I^2\big) \to \bigoplus_{n \geq 0} I^n/I^{n+1}$ is an isomorphism.

***Proof*:**
This is [15, Associated Graded Ring of a Regular Sequence], proved there by induction on the length of the sequence. It is pure commutative algebra and is not re-derived here.

Proposition 12.3.11: Segre Class of a Regular Embedding

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$, with normal bundle $N = N_Z X$. Then the normal cone is the normal bundle,

$$C_Z X \;=\; N_Z X$$

and the Segre class of Z in X is

$$s(Z, X) \;=\; s(N) \cap [Z] \;=\; c(N)^{-1} \cap [Z]$$

where $s(N)$ and $c(N)$ are the total Segre and Chern operators of sections 12.1 and 12.2.

***Proof*:**
Work on an affine open $U = \operatorname{Spec} A$ of X on which $I = \mathcal{I}(U)$ is generated by a regular sequence $a_1, \dots, a_d$. There is always a canonical surjection of graded A/I-algebras

$$\operatorname{Sym}^{\bullet}_{A/I}\big(I/I^2\big) \longrightarrow \bigoplus_{n \geq 0} I^n / I^{n+1}$$

sending a product of degree-one classes to the class of the corresponding product in I^n; it is surjective because the target is generated in degree one. Lemma 12.3.10 says that it is injective as well, and that I/I^2 is free of rank d on the classes of the a_j, so it is an isomorphism over U.

The surjection above is canonical, so the local isomorphisms are compatible on overlaps and glue to an isomorphism of graded $\mathcal{O}_Z$-algebras $\operatorname{Sym}^{\bullet}(\mathcal{I}/\mathcal{I}^2) \xrightarrow{\sim} \bigoplus_{n\geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}$. Taking relative spectra and comparing definition 12.3.6 with definition 5.1.45 gives $C_Z X = N_Z X$.

The normal cone is therefore the cone of a vector bundle of rank $d \geq 1$ over Z, so proposition 12.3.5 applies and gives $s(Z, X) = s(C_Z X) = s(N) \cap [Z]$. Finally $s(N) = c(N)^{-1}$, the Chern operators of definition 12.2.3 being defined by inverting the Segre series, completing the proof.

The normal cone is functorial in the subscheme, and for a regular embedding it sits inside a pulled-back normal bundle. Both facts are needed by chapter 13, and both are statements about cones as such, so they belong here rather than there.

Lemma 12.3.12: The Normal Cone of a Closed Subscheme

Let $Z, V \subseteq X$ be closed subschemes of an algebraic scheme and let $W = V \cap Z$ be their scheme-theoretic intersection. Then W is the scheme-theoretic preimage of Z under $V \hookrightarrow X$, and there is a canonical closed immersion

$$C_W V \;\hookrightarrow\; C_Z X$$

lying over the inclusion $W \hookrightarrow Z$.

***Proof*:**
The ideal sheaf of W in V is $\mathcal{I}_W = \mathcal{I}\mathcal{O}_V$, which is exactly the statement that W is the scheme-theoretic preimage of Z under the closed immersion $V \hookrightarrow X$. Consequently $\mathcal{I}^n\mathcal{O}_V = \mathcal{I}_W^n$ for every n, so the homomorphism of graded $\mathcal{O}_W$-algebras

$$\Big(\bigoplus_{n\geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}\Big) \otimes_{\mathcal{O}_Z} \mathcal{O}_W \longrightarrow \bigoplus_{n\geq 0} \mathcal{I}_W^n/\mathcal{I}_W^{n+1}$$

is surjective in each degree, the image of $\mathcal{I}^n \otimes \mathcal{O}_V \to \mathcal{O}_V$ being $\mathcal{I}_W^n$. On an affine open this is a surjection of graded rings, so by theorem 5.1.41 it induces a closed immersion of relative spectra; the local closed immersions are induced by a globally defined homomorphism of sheaves of algebras, so they glue. This exhibits $C_W V$ as a closed subscheme of the relative spectrum of the left side, which is $C_Z X \times_Z W$, again by the affine description of the relative spectrum. Composing with the closed immersion $C_Z X \times_Z W \hookrightarrow C_Z X$, the base change of $W \hookrightarrow Z$, gives the asserted closed immersion, completing the proof.

Lemma 12.3.13: The Normal Cone of a Preimage Embeds in the Pulled-Back Normal Bundle

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with ideal sheaf $\mathcal{I}$ and normal bundle $N = N_Z X$ (definition 5.1.45). Let $g\colon X' \to X$ be a morphism of algebraic schemes, let $Z' = g^{-1}(Z)$ be the scheme-theoretic preimage, and let $h\colon Z' \to Z$ be the induced morphism. Write $N' = h^*N$, a vector bundle of rank d on Z'. Then there is a canonical closed immersion of cones over Z'

$$j\colon C_{Z'}X' \hookrightarrow N'$$

Moreover:

1. j is an isomorphism whenever $Z' \hookrightarrow X'$ is itself a regular embedding of codimension d;
2. for $g = \mathrm{id}_X$ it is the identification $C_Z X = N$ of proposition 12.3.11.

***Proof*:**
Write $\mathcal{I}' \subseteq \mathcal{O}_{X'}$ for the ideal sheaf of Z'.

Step 1: the conormal surjection. By definition of the scheme-theoretic preimage, $\mathcal{I}'$ is the image of the map $g^*\mathcal{I} \to \mathcal{O}_{X'}$; that is, $\mathcal{I}'$ is generated by the pullbacks of local sections of $\mathcal{I}$. Composing $g^*\mathcal{I} \to \mathcal{I}'$ with the quotient $\mathcal{I}' \to \mathcal{I}'/\mathcal{I}'^2$ gives an $\mathcal{O}_{X'}$-linear surjection onto $\mathcal{I}'/\mathcal{I}'^2$. It kills the image of $g^*(\mathcal{I}^2)$, a product of two local sections of $\mathcal{I}$ pulling back to a product of two local sections of $\mathcal{I}'$. Since g^* is right exact, $g^*(\mathcal{I}/\mathcal{I}^2)$ is the cokernel of $g^*(\mathcal{I}^2) \to g^*\mathcal{I}$, so the surjection factors through it; and $g^*(\mathcal{I}/\mathcal{I}^2)$ is annihilated by $\mathcal{I}'$, hence is the $\mathcal{O}_{Z'}$-module $h^*(\mathcal{I}/\mathcal{I}^2)$. This gives a surjection of $\mathcal{O}_{Z'}$-modules

$$h^*\big(\mathcal{I}/\mathcal{I}^2\big) \twoheadrightarrow \mathcal{I}'/\mathcal{I}'^2$$

Step 2: the surjection of graded algebras. The symmetric algebra functor preserves surjections, so Step 1 gives a surjection $\mathrm{Sym}^\bullet\big(h^*(\mathcal{I}/\mathcal{I}^2)\big) \to \mathrm{Sym}^\bullet(\mathcal{I}'/\mathcal{I}'^2)$ of graded $\mathcal{O}_{Z'}$-algebras. The graded algebra $\bigoplus_{n\geq 0}\mathcal{I}'^n/\mathcal{I}'^{n+1}$ of definition 12.3.6 is generated in degree one over $\mathcal{O}_{Z'}$, so the

canonical map from $\mathrm{Sym}^\bullet(\mathcal{I}'/\mathcal{I}'^2)$ onto it is surjective as well. Composing,

$$\mathrm{Sym}^\bullet\big(h^*(\mathcal{I}/\mathcal{I}^2)\big) \twoheadrightarrow \bigoplus_{n\geq 0} \mathcal{I}'^n/\mathcal{I}'^{n+1}$$

is a surjection of graded quasi-coherent $\mathcal{O}_{Z'}$-algebras.

Step 3: taking relative spectra. On an affine open $U \subseteq Z'$ the displayed surjection is a surjection of rings $\Gamma(U, \mathrm{Sym}^\bullet h^*(\mathcal{I}/\mathcal{I}^2)) \to \Gamma(U, \bigoplus \mathcal{I}'^n/\mathcal{I}'^{n+1})$, which induces a closed immersion of affine schemes in the opposite direction; these are compatible on overlaps because the surjection is a map of sheaves, so they glue to a closed immersion over Z' by theorem 5.1.41. The source of that closed immersion is $C_{Z'}X'$ by definition 12.3.6. Its target is, by definition 5.1.45 and example 12.3.2(1), the total space of the vector bundle on Z' whose sheaf of sections is $\big(h^*(\mathcal{I}/\mathcal{I}^2)\big)^\vee = h^*\big((\mathcal{I}/\mathcal{I}^2)^\vee\big)$, that is $N' = h^*N$; regularity of i enters here, and only here, through the local freeness of $\mathcal{I}/\mathcal{I}^2$ of rank d (lemma 12.3.10), which makes $h^*(\mathcal{I}/\mathcal{I}^2)$ locally free of rank d on Z'. The immersion is a morphism of cones because the algebra surjection is graded.

Step 4: part (1). Suppose $Z' \hookrightarrow X'$ is a regular embedding of codimension d. Then $\mathcal{I}'/\mathcal{I}'^2$ is locally free of rank d and the canonical map $\mathrm{Sym}^\bullet(\mathcal{I}'/\mathcal{I}'^2) \to \bigoplus_n \mathcal{I}'^n/\mathcal{I}'^{n+1}$ is an isomorphism, both by lemma 12.3.10 applied to X'. So j is the morphism induced by the surjection $h^*(\mathcal{I}/\mathcal{I}^2) \to \mathcal{I}'/\mathcal{I}'^2$ of locally free $\mathcal{O}_{Z'}$-modules of the same rank d. Such a surjection is an isomorphism: the target is locally free, hence projective, so the surjection splits and the source decomposes as the target plus the kernel; the kernel is then a direct summand of a locally free module of finite rank, hence itself locally free, and comparing ranks locally makes that rank zero, so the kernel vanishes. Therefore j is an isomorphism of cones.

Step 5: part (2). For $g = \mathrm{id}_X$ one has $\mathcal{I}' = \mathcal{I}$, $Z' = Z$, $h = \mathrm{id}_Z$, and the surjection of Step 2 is the canonical map $\mathrm{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2) \to \bigoplus_n \mathcal{I}^n/\mathcal{I}^{n+1}$. That map is the isomorphism exhibited in the proof of proposition 12.3.11, so j is the identification $C_Z X = N$ recorded there, completing the proof.

Both immersions above are induced by surjections of graded algebras out of $\bigoplus_n \mathcal{I}^n/\mathcal{I}^{n+1}$, and when they are both available they agree. This is used whenever a normal cone is read inside a normal bundle.

Lemma 12.3.14: The Two Immersions Agree

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension d with normal bundle N, and let $V \subseteq X$ be a closed subscheme with $W = V \cap Z$. Then the composite

$$C_W V \;\hookrightarrow\; N|_W \;\hookrightarrow\; N$$

of the immersion j of lemma 12.3.13 (for $g\colon V \hookrightarrow X$) with the restriction of N to W coincides with the immersion $C_W V \hookrightarrow C_Z X = N$ of lemma 12.3.12.

***Proof*:**
Both immersions are the map on relative Spec induced by a surjection of graded $\mathcal{O}_W$-algebras onto $\bigoplus_n \mathcal{I}_W^n/\mathcal{I}_W^{n+1}$, so it is enough to see that the two surjections coincide. The immersion of

lemma 12.3.12 is induced by

$$\Big(\bigoplus_n \mathcal{I}^n/\mathcal{I}^{n+1}\Big) \otimes_{\mathcal{O}_Z} \mathcal{O}_W \twoheadrightarrow \bigoplus_n \mathcal{I}_W^n/\mathcal{I}_W^{n+1}$$

and j is induced by $\operatorname{Sym}^\bullet\big(h^*(\mathcal{I}/\mathcal{I}^2)\big) \twoheadrightarrow \bigoplus_n \mathcal{I}_W^n/\mathcal{I}_W^{n+1}$. Because i is a regular embedding, proposition 12.3.11 identifies $\operatorname{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)$ with $\bigoplus_n \mathcal{I}^n/\mathcal{I}^{n+1}$ as graded $\mathcal{O}_Z$-algebras, and that identification is the identity in degree one. Pulling it back along h turns the second surjection into the first, since both are determined by their degree-one component, which in each case is the map $\mathcal{I}/\mathcal{I}^2 \otimes \mathcal{O}_W \to \mathcal{I}_W/\mathcal{I}_W^2$ induced by $\mathcal{I}\mathcal{O}_V = \mathcal{I}_W$, as we sought to show.

For a regular embedding the Segre class carries no information beyond the normal bundle. The hypothesis $d \geq 1$ excludes nothing: a regular embedding of codimension zero has zero ideal sheaf, so it is $Z = X$, and that case was settled directly above by the zero cone. The inverse $c(N)^{-1}$ is computed by the terminating geometric series $\mathrm{id} - c_1(N) + \big(c_1(N)^2 - c_2(N)\big) - \cdots$, terminating because every $c_j(N)$ with $j \geq 1$ lowers dimension and $A_k(Z) = 0$ for $k < 0$. The content of $s(Z, X)$ is therefore entirely in the irregular case: it is the invariant that continues to exist, and to enter the intersection formulas, when the ideal of Z needs more equations than the codimension allows.

The codimension-one case is the one already treated in chapter 11, and it recovers the tower of self-intersections of a divisor.

Example 12.3.15: An Effective Cartier Divisor and a Plane Conic

Let $D \subseteq X$ be an effective Cartier divisor (definition 5.4.26), so its ideal sheaf $\mathcal{I} = \mathcal{O}_X(-D)$ is invertible and locally generated by a single nonzerodivisor. This is a regular embedding of codimension one, with conormal sheaf $\mathcal{I}/\mathcal{I}^2 = \mathcal{O}_X(-D)|_D$ and normal bundle the line bundle $N_D X = \mathcal{O}_X(D)|_D$. A line bundle L has $c(L) = \mathrm{id} + c_1(L)$, so $c(L)^{-1} = \sum_{i\geq 0}(-1)^i c_1(L)^i$, and proposition 12.3.11 gives

$$s(D, X) \;=\; \sum_{i\geq 0}(-1)^i\, c_1\big(\mathcal{O}_X(D)|_D\big)^i \cap [D] \;=\; [D] - c_1\big(\mathcal{O}_X(D)|_D\big) \cap [D] + \cdots \tag{12.5}$$

the series terminating in dimension zero.

Take $X = \mathbb{P}^2$ and D a smooth conic, so $D \cong \mathbb{P}^1$ and $A_*(D) = \mathbb{Z}\,[D] \oplus \mathbb{Z}\,[\mathrm{pt}]$ by theorem 10.5.2; only the first two terms of (12.5) can be nonzero. The conic is cut out by a quadratic form, so $\mathcal{O}_{\mathbb{P}^2}(D) \cong \mathcal{O}_{\mathbb{P}^2}(2)$ (example 11.1.4). To evaluate the second term, push forward along the closed immersion $\iota\colon D \hookrightarrow \mathbb{P}^2$ and use the projection formula proposition 11.4.4(4), additivity proposition 11.4.4(3) for $\mathcal{O}(2) = \mathcal{O}(1) \otimes \mathcal{O}(1)$, the class $\iota_*[D] = 2\,[\mathbb{P}^1]$ of a conic (example 10.5.4), and example 11.4.7:

$$\iota_*\Big(c_1\big(\mathcal{O}_{\mathbb{P}^2}(2)|_D\big) \cap [D]\Big) = c_1\big(\mathcal{O}_{\mathbb{P}^2}(2)\big) \cap \iota_*[D] = 2\, c_1\big(\mathcal{O}_{\mathbb{P}^2}(1)\big) \cap 2\,[\mathbb{P}^1] = 4\,[\mathrm{pt}]$$

Both $A_0(D)$ and $A_0(\mathbb{P}^2)$ are infinite cyclic on the class of a point and ι_* carries generator to generator, so $c_1(\mathcal{O}_{\mathbb{P}^2}(2)|_D) \cap [D] = 4\,[\mathrm{pt}]$ already in $A_0(D)$. Hence

$$s(D, \mathbb{P}^2) \;=\; [D] - 4\,[\mathrm{pt}]$$

The coefficient 4 is the self-intersection number of the conic, the degree $2 \cdot 2$ predicted by Bézout, and it enters the Segre class with a sign. For a divisor, then, $s(D, X)$ is a bookkeeping device for the alternating tower of self-intersections of D, and it contains exactly the information the line bundle $\mathcal{O}_X(D)|_D$ contains.

The irregular case is where the Segre class stops being a repackaging. The next computation is a closed subscheme whose normal cone is not a bundle, and the class detects the multiplicity of a singularity.

Example 12.3.16: The Vertex of the Quadric Cone

Let $X = \operatorname{Spec} \overline{k}[x,y,z]/(xy - z^2)$ be the affine quadric cone of example 11.1.2, a normal surface with an isolated singularity at the vertex, and let $Z = \{P\}$ be the reduced vertex, with ideal $\mathfrak{m} = (x,y,z)$.

The normal cone. Write $A = \overline{k}[x,y,z]/(xy - z^2)$. The defining polynomial is homogeneous, so A is a graded ring with A_n its degree-n piece and $\mathfrak{m}^n = \bigoplus_{m \geq n} A_m$; therefore $\mathfrak{m}^n/\mathfrak{m}^{n+1} = A_n$ and $\bigoplus_{n \geq 0} \mathfrak{m}^n/\mathfrak{m}^{n+1} = A$. The quadric cone is its own tangent cone at the vertex, and $C_P X = \operatorname{Spec} A = X$. It is not a vector bundle over the point P: a rank-r bundle over a point is $\mathbb{A}^r$, whereas X is singular at the origin. Equivalently, the embedding $\{P\} \hookrightarrow X$ is not regular, since $\mathfrak{m}$ needs three generators while $\dim X = 2$.

The projective completion. Adjoining w in degree one gives $A[w] = \overline{k}[x,y,z,w]/(xy - z^2)$, so

$$\mathbb{P}(C_P X \oplus 1) \;=\; \operatorname{Proj}\left(\overline{k}[x,y,z,w]/(xy - z^2)\right) \;=\; Q \subseteq \mathbb{P}^3$$

the quadric surface $\{xy = z^2\}$, which is integral because $xy - z^2$ is irreducible, and $\mathcal{O}(1) = \mathcal{O}_{\mathbb{P}^3}(1)|_Q$ by the surjection $\overline{k}[x,y,z,w] \to A[w]$.

The class. Since Z is a single point, $A_k(Z) = 0$ for $k \neq 0$, so only the term of definition 12.3.4 landing in A_0 survives, namely $i = \dim Q = 2$:

$$s(P,X) \;=\; \left(\int_Q c_1\big(\mathcal{O}_{\mathbb{P}^3}(1)|_Q\big)^2 \cap [Q]\right)[P]$$

Let $\iota \colon Q \hookrightarrow \mathbb{P}^3$ be the inclusion. The quadric is the divisor of the section $xy - z^2$ of $\mathcal{O}_{\mathbb{P}^3}(2)$, so $\iota_*[Q] = 2\,[\mathbb{P}^2]$ in $A_2(\mathbb{P}^3)$ by the class map (proposition 11.1.3 and example 11.1.4). By the projection formula proposition 11.4.4(4) and the fact that capping a linear-subspace class with $c_1(\mathcal{O}_{\mathbb{P}^3}(1))$ drops its dimension by one (example 11.4.7),

$$\iota_*\Big(c_1\big(\mathcal{O}_{\mathbb{P}^3}(1)|_Q\big)^2 \cap [Q]\Big) = c_1\big(\mathcal{O}_{\mathbb{P}^3}(1)\big)^2 \cap 2\,[\mathbb{P}^2] = 2\,[\mathrm{pt}]$$

Degrees are preserved by proper pushforward (definition 10.2.4), so the integral equals 2 and

$$s(P,X) \;=\; 2\,[P]$$

The contrast. Take instead the origin $P' \in \mathbb{A}^2$, where $\mathfrak{m} = (x,y)$ is a regular sequence and $\{P'\} \hookrightarrow \mathbb{A}^2$ is a regular embedding of codimension two. Proposition 12.3.11 gives $s(P', \mathbb{A}^2) = c(N)^{-1} \cap [P']$, and every $c_j(N) \cap [P']$ with $j \geq 1$ lies in $A_{-j}(P') = 0$, so $s(P', \mathbb{A}^2) = [P']$. At a smooth point of a surface the Segre class of the point is the point itself; at the vertex of the quadric cone it is twice the point. The integer it produces is the multiplicity of the singularity.

Exercise 12.3.1

1. Let X be an algebraic scheme and let $C = X$ be the zero cone of example 12.3.2(2), that is $S^\bullet = \mathcal{O}_X$. Show that $\mathbb{P}(C) = \emptyset$, that $\mathbb{P}(C \oplus 1) = X$ with q the identity, and that $\mathcal{O}(1)$ is the trivial bundle. Deduce $s(X,X) = [X]$, and then explain why proposition 12.3.11 cannot be

used to reach the same answer, even though $X \hookrightarrow X$ is a regular embedding of codimension zero.

2. Let $Z = \mathbb{P}^1 \subseteq \mathbb{P}^3$ be a line, cut out by two of the homogeneous coordinates. Show that this is a regular embedding of codimension two with conormal sheaf $\mathcal{O}_{\mathbb{P}^1}(-1) \oplus \mathcal{O}_{\mathbb{P}^1}(-1)$, hence with normal bundle $N = \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(1)$, and compute $s(\mathbb{P}^1, \mathbb{P}^3)$.

3. Let $D \subseteq \mathbb{P}^2$ be a smooth plane curve of degree d. Show that $s(D, \mathbb{P}^2) = [D] - \beta$ for a class $\beta \in A_0(D)$ of degree d^2. Then explain why, for $d \geq 3$, one may *not* conclude $\beta = d^2\,[\mathrm{pt}]$, whereas for $d \leq 2$ one may.

4. Let $f \in \overline{k}[x, y, z]$ be a homogeneous polynomial of degree d defining a smooth plane curve $Y \subseteq \mathbb{P}^2$, let $X = \operatorname{Spec} \overline{k}[x, y, z]/(f)$ be the affine cone over Y, and let $P \in X$ be the vertex. Compute $s(P, X)$, generalizing example 12.3.16.

5. Let $X = \mathbb{A}^1$ and let $Z = \operatorname{Spec} \overline{k}[x]/(x^2)$ be the double point at the origin, with $Z_{\mathrm{red}} = \{P\}$ the reduced point. Compute both $s(Z, X)$ and $s(Z_{\mathrm{red}}, X)$, and say what the comparison shows about the dependence of the Segre class on the scheme structure of Z.

12.4 Summary

This chapter produces a toolkit rather than a single theorem, and the rest of the book reaches for its pieces one at a time.

Tool	**What it gives**	**Stated in**
Segre operators $s_i(E)$	$\pi_*(\xi^{r+i} \cap \pi^* -)$, invertible total class	definition 12.1.3, proposition 12.1.5
Projective bundle formula	$A_*(\mathbb{P}(E))$ free over $A_*(X)$ on $1, \xi, \ldots, \xi^r$	theorem 12.1.9
Chern operators $c_i(E)$	inverse of the total Segre class	definition 12.2.3
Whitney formula	$c(E) = c(E')c(E'')$ on a short exact sequence	theorem 12.2.15
Splitting principle	a flat π with π^* injective and π^*E filtered	theorem 12.2.14
Chern roots	symmetric expressions in r symbols as operators	proposition 12.2.22

The formal properties of the Chern operators are proposition 12.2.10: commutativity, a projection formula along a proper morphism, and naturality under flat pullback. The two diagrams drawn there are worth consulting before citing the proposition, because neither says anything about the Chern classes of a pushed-forward sheaf. The dual bundle satisfies $c_i(E^\vee) = (-1)^i c_i(E)$ (corollary 12.2.16), and a bundle filtered with line-bundle quotients has $c(E) = \prod(1 + c_1(L_i))$ (lemma 12.2.11), which is the form every splitting-principle computation uses.

Segre classes are then defined for objects that are not bundles: for a cone (definition 12.3.4), for a closed subscheme through its normal cone (definition 12.3.8), and, when the embedding is regular, agreeing with the inverse Chern class of the normal bundle (proposition 12.3.11). That last agreement is what chapter 13 turns into a Gysin map.

13

Deformation to the Normal Cone

Classical enumerative geometry intersected two cycles by moving them until they met properly and trusting that the count did not change. Making that rigorous requires a moving lemma, and moving lemmas are hard, restrictive, and unavailable on a singular ambient scheme. The construction of this chapter avoids the manoeuvre entirely: instead of moving the cycles, it degenerates the embedding.

Given a closed subscheme $Z \subseteq X$, there is a family over $\mathbb{P}^1$ whose fibre away from ∞ is the given embedding $Z \subseteq X$ and whose fibre at ∞ is the embedding of Z as the zero section of its normal cone (definition 12.3.6). Nothing has been perturbed; the ambient geometry has been deformed to a cone, where it is linear along the fibres and where intersecting is a matter of restricting to a zero section. Specializing a cycle to ∞ therefore converts an arbitrary intersection problem into one on a cone, and when the embedding is regular (definition 5.1.43) the cone is a vector bundle by proposition 12.3.11, and the specialization can be inverted against theorem 10.4.6 to land back on Z.

That composite is the Gysin map, and it is the last piece of machinery the intersection product needs. This chapter builds the deformation space, proves that specializing is well defined on rational equivalence, and assembles the Gysin map for a regular embedding together with the refined version that chapter 14 will apply to the diagonal.

13.1 The Deformation to the Normal Cone

This section builds the family and establishes the three facts everything later rests on: it is flat over $\mathbb{P}^1$, its fibre away from ∞ is the given X, and its fibre at ∞ is the normal cone.

Throughout, $Z \subseteq X$ is a closed subscheme of an algebraic scheme, with ideal sheaf $\mathcal{I} \subseteq \mathcal{O}_X$. Fix a coordinate t on $\mathbb{P}^1$, so that $\mathbb{A}^1 = \mathbb{P}^1 \setminus \{\infty\}$ is the affine line with coordinate t, and write $U = \mathbb{P}^1 \setminus \{0\}$ for the complementary chart, an affine line with coordinate $u = t^{-1}$ vanishing exactly at ∞. Since X is of finite type over $\overline{k}$ (box 9.0.1), the product $X \times \mathbb{P}^1$ is Noetherian, so the blow-up construction of

definition 8.4.1 applies to it.

The object to be built is a scheme over $\mathbb{P}^1$ whose fibre over every point of $\mathbb{A}^1$ is X and whose fibre over ∞ is $C_Z X$. The mechanism that produces such a family is visible in the local algebra. A function a in the ideal $\mathcal{I}$ vanishes on Z; dividing it by the parameter u rescales the normal directions to Z by the factor u^{-1}, and as u tends to 0 the rescaling magnifies an arbitrarily small neighbourhood of Z until only the behaviour of a to leading order in $\mathcal{I}$ survives. Adjoining all the functions au^{-1} with $a \in \mathcal{I}$ to $\mathcal{O}_X[u]$ therefore builds a family whose limit at $u = 0$ is manufactured from the successive quotients $\mathcal{I}^n/\mathcal{I}^{n+1}$, which is what $C_Z X$ is manufactured from (definition 12.3.6).

Adjoining $\mathcal{I}u^{-1}$ is exactly what makes the ideal $\mathcal{I} + (u)$ of $Z \times \{\infty\}$ principal, generated by u; and the universal solution to that requirement is the blow-up (proposition 8.4.2, part (4)). The construction accordingly starts from a blow-up, and the rescaled algebra above is recovered as one of its charts.

Definition 13.1.1: The Deformation Space

Let $Z \subseteq X$ be a closed subscheme of an algebraic scheme, and let $\mathcal{J} \subseteq \mathcal{O}_{X\times\mathbb{P}^1}$ be the ideal sheaf of the closed subscheme $Z \times \{\infty\}$. The *deformation space* of Z in X is the blow-up

$$M_Z X \;=\; \mathrm{Bl}_{Z\times\{\infty\}}\big(X \times \mathbb{P}^1\big) \;=\; \mathrm{Proj}\left(\bigoplus_{n\geq 0} \mathcal{J}^n\right) \xrightarrow{\;p\;} X \times \mathbb{P}^1$$

of definition 8.4.1. Write $\pi\colon M_Z X \to \mathbb{P}^1$ for the composite of p with the projection $X \times \mathbb{P}^1 \to \mathbb{P}^1$.

Nothing has been achieved yet: $M_Z X$ is a blow-up like any other, and its fibre over ∞ is larger than the normal cone. The next lemma computes the part of $M_Z X$ lying over the chart U, splitting it into the piece that carries the cone and a piece that does not. The splitting is the reason the deformation is defined on an open subscheme of $M_Z X$ rather than on all of it.

Lemma 13.1.2: The Chart at Infinity

Let $\mathcal{R} \subseteq \mathcal{O}_X[u, u^{-1}]$ be the sheaf of $\mathcal{O}_X[u]$-subalgebras generated by $\mathcal{I}u^{-1}$, the *extended Rees algebra* of $\mathcal{I}$; grading by powers of u,

$$\mathcal{R} \;=\; \bigoplus_{m\geq 0} \mathcal{O}_X\, u^m \;\oplus\; \bigoplus_{n\geq 1} \mathcal{I}^n u^{-n} \tag{13.1}$$

Here $Z \subseteq X$ is the closed subscheme fixed in this section, with ideal sheaf $\mathcal{I}$, the ambient scheme being X; $U = \mathbb{P}^1 \setminus \{0\}$; $u = t^{-1}$; and $p\colon M_Z X \to X \times \mathbb{P}^1$ is the blow-down. Write $D_+(u) \subseteq p^{-1}(X \times U)$ for the open subscheme attached to the degree-one section u of $\bigoplus_n \mathcal{J}^n$. Then:

1. $D_+(u)$ is the relative spectrum $\mathrm{Spec}\,(\mathcal{R})$ over $X \times U$;
2. its closed complement $p^{-1}(X \times U) \setminus D_+(u)$ is canonically isomorphic to $\mathrm{Bl}_Z X$, and p carries it into $X \times \{\infty\}$, where X is the ambient scheme; the induced morphism to X is the blow-down morphism.

The closed subscheme $\mathrm{Bl}_Z X$ so obtained is closed in $M_Z X$.

***Proof*:**
Step 1: the ideal and its powers. Work on an affine open $\operatorname{Spec} A \subseteq X$ with $\mathcal{I}(\operatorname{Spec} A) = I$, and set $B = A[u]$, so that $\operatorname{Spec} A \times U = \operatorname{Spec} B$ and the ideal of $Z \times \{\infty\}$ there is $J = IB + uB$. Expanding the product of the two ideals gives

$$J^n \;=\; \sum_{j=0}^{n} I^j B \cdot u^{\,n-j}$$

Two consequences are read off this expansion. Every term with $j < n$ is divisible by u, so

$$J^n + uB \;=\; I^n B + uB \tag{13.2}$$

And for $n \geq 1$,

$$J^n \cap uB \;=\; u\, J^{n-1} \tag{13.3}$$

Indeed, write $x = \sum_{j=0}^{n} a_j u^{\,n-j}$ with $a_j \in I^j B$. The terms with $j < n$ all lie in uJ^{n-1}, since $I^j B\, u^{n-1-j} \subseteq J^{n-1}$. The remaining term $a_n \in I^n B$ is a polynomial in u with coefficients in I^n, so it lies in uB precisely when its constant coefficient vanishes, that is when $a_n \in uI^n B \subseteq uJ^{n-1}$. The reverse inclusion is immediate from $uJ^{n-1} \subseteq J^n$.

Step 2: the chart. Write $S = \bigoplus_{n\geq 0} J^n$, so that $p^{-1}(\operatorname{Spec} A \times U) = \operatorname{Proj}(S)$ by definition 13.1.1 and $D_+(u) = \operatorname{Spec}\big(S_{(u)}\big)$ is the affine chart of the relative Proj attached to the degree-one element $u \in J = S_1$ (lemma 2.3.2; the relative Proj itself is theorem 5.3.49). Because u is a nonzerodivisor on B, the assignment $x/u^n \mapsto xu^{-n}$ is a well-defined injection of $S_{(u)}$ into $A[u, u^{-1}]$, and its image is $\bigcup_{n\geq 0} J^n u^{-n}$, which by Step 1 is the B-subalgebra R generated by Iu^{-1}. To see the grading (13.1), note $R = \sum_{n\geq 0} I^n B\, u^{-n}$, so the coefficient of u^m in R is $\sum_{n\geq 0,\, n+m\geq 0} I^n$, which is A for $m \geq 0$ and I^{-m} for $m < 0$. Hence $D_+(u) = \operatorname{Spec}(R)$ as a scheme over $\operatorname{Spec} B$, which is (1).

Step 3: the complement. Reduction modulo u gives a surjection of graded B-algebras $S \to \overline{S}$, where $\overline{S}_n = (J^n + uB)/uB$; by (13.2) this is the image of $I^n B$ in $B/uB = A$, namely I^n. So $\overline{S} = \bigoplus_{n\geq 0} I^n$ is the Rees algebra of I, its relative Proj is $\operatorname{Bl}_Z X$ over $\operatorname{Spec} A$ by definition 8.4.1, and the surjection exhibits it as a closed subscheme of $\operatorname{Proj}(S)$ lying over $V(u) = \operatorname{Spec} A \times \{\infty\}$, with structure morphism to $\operatorname{Spec} A$ the blow-down. Since u maps to 0 in $\overline{S}_1$, this closed subscheme is disjoint from $D_+(u)$.
For the reverse inclusion, the closed complement of $D_+(u)$ is $\operatorname{Proj}(S/uS)$, where uS is the homogeneous ideal generated by $u \in S_1$, whose degree-n part is uJ^{n-1} for $n \geq 1$ and 0 in degree 0. By (13.3) the ideal uJ^{n-1} is exactly the kernel of $J^n \to I^n$, so S/uS and $\overline{S}$ agree in every positive degree and differ only in degree 0, where $A[u] \to A$ kills u. The symbol u carries two meanings here, and the one at issue now is the degree-zero $u \in S_0 = A[u]$, not the degree-one section: in S/uS that element annihilates every positive degree, since for $x \in J^n$ with $n \geq 1$ one has $ux \in uJ^n \subseteq uJ^{n-1} = (uS)_n$. So for a homogeneous $f \in S_1$ the image of the degree-zero u in the localization $(S/uS)_{(f)}$ is $uf/f = 0$; hence $(S/uS)_{(f)} = \overline{S}_{(f)}$ for every such f, and the two relative Proj schemes coincide. The closed complement of $D_+(u)$ is therefore $\operatorname{Bl}_Z X$, which is (2).

Step 4: globalization. The algebra $\mathcal{R}$ and the surjection of Step 3 are defined without choices, so the local identifications agree on overlaps of an affine cover of X and glue. For the final assertion, $\operatorname{Bl}_Z X$ is closed in the open subscheme $p^{-1}(X \times U)$ and is contained in $p^{-1}(X \times \{\infty\})$, which is closed in $M_Z X$ and contained in $p^{-1}(X \times U)$; writing $\operatorname{Bl}_Z X = C \cap p^{-1}(X \times U)$ with C closed in $M_Z X$, one gets $\operatorname{Bl}_Z X = C \cap p^{-1}(X \times \{\infty\})$, an intersection of two closed subsets and hence closed in $M_Z X$, completing the proof.

The lemma is what makes the construction computable: over the chart at infinity the deformation is not a Proj at all but an affine scheme over $X \times U$, given by the single algebra (13.1), written R when $X = \operatorname{Spec} A$ is affine, and its reduction modulo u is the associated graded algebra of $\mathcal{I}$. The smallest instance already shows the mechanism.

Example 13.1.3: A Point on a Smooth Curve

Let X be a variety of dimension one and $P \in X$ a closed point at which X is smooth, and take $Z = \{P\}$ with its reduced structure. The local ring $\mathcal{O}_{X,P}$ is a discrete valuation ring; choosing a uniformizer s makes $\mathcal{I}$ locally generated by the single nonzerodivisor s, so $Z \hookrightarrow X$ is a regular embedding of codimension one (definition 5.1.43) and $\operatorname{gr}_{\mathfrak{m}_P} \mathcal{O}_{X,P} \cong \overline{k}[\overline{s}]$ is a polynomial ring in one variable. Hence $C_P X = \mathbb{A}^1$: the deformation replaces the curve by its tangent line at P and the point by the origin of that line.

The computation is explicit for $X = \mathbb{A}^1 = \operatorname{Spec} \overline{k}[x]$ and P the origin, where $I = (x)$. The algebra of (13.1) is $R = \overline{k}[x, u][xu^{-1}]$, and setting $v = xu^{-1}$ gives $x = uv$, so R is generated by u and v alone. These two are algebraically independent over $\overline{k}$: they lie in $\overline{k}(x, u)$, which has transcendence degree two, and they generate it, so they form a transcendence basis. Hence

$$R \;\cong\; \overline{k}[u, v], \qquad \operatorname{Spec}(R) = \mathbb{A}^2 \longrightarrow \mathbb{A}^1_u$$

is the trivial family with fibre $\mathbb{A}^1$. Over $u = c \neq 0$ the fibre is identified with X by $x = cv$, and over $u = 0$ it is $\operatorname{Spec}\big(R/uR\big) = \operatorname{Spec} \overline{k}[v]$, which is $C_P X$. The family is the rescaling $x \mapsto x/u$ of the line, and the closed subscheme $\{v = 0\}$ is the point P travelling along it.

The lemma isolates a piece of $M_Z X$ over ∞, namely $\operatorname{Bl}_Z X$, which the rescaling picture does not see and which is discarded.

Definition 13.1.4: The Deformation to the Normal Cone

With $Z \subseteq X$ and $M_Z X$ as in definition 13.1.1, and with $\operatorname{Bl}_Z X \subseteq M_Z X$ the closed subscheme of lemma 13.1.2(2), the *deformation to the normal cone* of Z in X is the open subscheme

$$M_Z^\circ X \;=\; M_Z X \setminus \operatorname{Bl}_Z X$$

together with the restriction of $\pi\colon M_Z X \to \mathbb{P}^1$, again written π, and the restriction of p, whose composite with the projection $X \times \mathbb{P}^1 \to X$ is written $\rho\colon M_Z^\circ X \to X$.

Everything the chapter needs is contained in the behaviour of π over the two charts, and lemma 13.1.2 has already computed one of them. Collecting that computation with the elementary behaviour over $\mathbb{A}^1$ gives the properties that section 13.2 and section 13.3 use.

Theorem 13.1.5: The Fibres of the Deformation

Let $Z \subseteq X$ be a closed subscheme of an algebraic scheme, with $\pi\colon M_Z^\circ X \to \mathbb{P}^1$ as in definition 13.1.4 and $p\colon M_Z X \to X \times \mathbb{P}^1$ the blow-down of definition 13.1.1, so that X is the ambient scheme and Z the subscheme throughout.

1. Over $\mathbb{A}^1 = \mathbb{P}^1 \setminus \{\infty\}$ the blow-down p restricts to an isomorphism $\pi^{-1}(\mathbb{A}^1) \xrightarrow{\sim} X \times \mathbb{A}^1$ commuting with the projections to $\mathbb{A}^1$.
2. The fibre over ∞ is the normal cone, $\pi^{-1}(\infty) = C_Z X$ of definition 12.3.6, and it is an effective Cartier divisor on $M_Z^\circ X$, cut out by the function u.
3. π is flat.
4. There is a closed immersion $Z \times \mathbb{P}^1 \hookrightarrow M_Z^\circ X$ over $\mathbb{P}^1$ which over $\mathbb{A}^1$ is the inclusion $Z \times \mathbb{A}^1 \subseteq X \times \mathbb{A}^1$ of (1), and over ∞ is the vertex $Z \hookrightarrow C_Z X$ of definition 12.3.1.

***Proof*:**

Step 1: the chart over $\mathbb{A}^1$. The centre $Z \times \{\infty\}$ is disjoint from the open set $X \times \mathbb{A}^1$, so proposition 8.4.2(2) makes p an isomorphism $p^{-1}(X \times \mathbb{A}^1) \to X \times \mathbb{A}^1$. By lemma 13.1.2(2) the deleted subscheme $\mathrm{Bl}_Z X$ lies over $X \times \{\infty\}$, so it does not meet $p^{-1}(X \times \mathbb{A}^1)$, and therefore $\pi^{-1}(\mathbb{A}^1) = p^{-1}(X \times \mathbb{A}^1) \cong X \times \mathbb{A}^1$ compatibly with the projections to $\mathbb{A}^1$. This is (1).

Step 2: the fibre at infinity. Over the other chart, lemma 13.1.2 gives $\pi^{-1}(U) = \operatorname{Spec}(\mathcal{R})$ with $\mathcal{R}$ the extended Rees algebra, so the scheme-theoretic fibre over $\infty = \{u = 0\}$ is $\operatorname{Spec}\big(\mathcal{R}/u\mathcal{R}\big)$. Compute the quotient degree by degree in the grading (13.1). Writing $\mathcal{R}_m$ for the coefficient of u^m, so that $\mathcal{R}_m = \mathcal{O}_X$ for $m \geq 0$ and $\mathcal{R}_{-n} = \mathcal{I}^n$ for $n \geq 1$, the coefficient of u^m in $u\mathcal{R}$ is $\mathcal{R}_{m-1}$. Hence $(\mathcal{R}/u\mathcal{R})_m$ vanishes for $m \geq 1$, equals $\mathcal{O}_X/\mathcal{I} = \mathcal{O}_Z$ for $m = 0$, and equals $\mathcal{I}^n/\mathcal{I}^{n+1}$ for $m = -n$ with $n \geq 1$. Therefore

$$\mathcal{R}/u\mathcal{R} \;\cong\; \bigoplus_{n \geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}$$

which is the graded algebra of definition 12.3.6, so $\pi^{-1}(\infty) = C_Z X$.

Step 3: the fibre at infinity is Cartier. The element u acts invertibly on $\mathcal{O}_X[u, u^{-1}]$ and hence injectively on the subsheaf $\mathcal{R}$, so u is a nonzerodivisor and $\pi^{-1}(\infty) \subseteq \pi^{-1}(U)$ is cut out by a single nonzerodivisor. On the complementary open $\pi^{-1}(\mathbb{A}^1)$ the fibre is empty, cut out by the unit 1. So $\pi^{-1}(\infty)$ is locally principal, generated at each point by a nonzerodivisor, which is an effective Cartier divisor (definition 5.4.26). With Step 2 this is (2).

Step 4: flatness. Flatness may be checked locally on source and target, so it suffices to treat the two charts separately. Over $\mathbb{A}^1$ the morphism is the projection $X \times \mathbb{A}^1 \to \mathbb{A}^1$ by Step 1, which is the base change of $X \to \operatorname{Spec} \overline{k}$ along $\mathbb{A}^1 \to \operatorname{Spec} \overline{k}$; every scheme is flat over a field and flatness is stable under base change, so this projection is flat. Over U the morphism is $\operatorname{Spec}(\mathcal{R}) \to U = \operatorname{Spec} \overline{k}[u]$. The ring $\overline{k}[u]$ is a principal ideal domain, over which a module is flat exactly when it is torsion-free. On an affine open $\operatorname{Spec} A \subseteq X$ one has $\mathcal{R}(\operatorname{Spec} A) = R \subseteq A[u, u^{-1}]$, and $A[u, u^{-1}]$ is torsion-free over $\overline{k}[u]$: given $f \in \overline{k}[u]$ nonzero of degree d with leading coefficient $c \in \overline{k}^*$, and a nonzero $x = \sum_{i \leq M} a_i u^i$ with $a_M \neq 0$, the coefficient of u^{M+d} in fx is $c\,a_M \neq 0$, so $fx \neq 0$. A submodule of a torsion-free module is torsion-free, so R is torsion-free and hence flat over $\overline{k}[u]$. This is (3).

Step 5: the constant subscheme. Let $\mathfrak{q} \subseteq \mathcal{R}$ be the ideal generated by $\mathcal{I}u^{-1}$; it contains $\mathcal{I}$, since $\mathcal{I} = (\mathcal{I}u^{-1}) \cdot u$ and $u \in \mathcal{R}$. Its coefficient of u^m is $\mathcal{I} \cdot \mathcal{R}_{m+1}$, which for $m \geq 0$ is $\mathcal{I}$ and for $m = -n < 0$ is $\mathcal{I} \cdot \mathcal{I}^{n-1} = \mathcal{I}^n = \mathcal{R}_{-n}$. So

$$\mathcal{R}/\mathfrak{q} \;\cong\; \bigoplus_{m \geq 0} (\mathcal{O}_X/\mathcal{I})\, u^m \;=\; \mathcal{O}_Z[u]$$

and $\mathfrak{q}$ defines a closed immersion $Z \times U \hookrightarrow \operatorname{Spec}(\mathcal{R})$ over $X \times U$. Inverting u makes u^{-1} a unit, so $\mathfrak{q}$ generates $\mathcal{I}$ there and the immersion restricts over $U \setminus \{\infty\}$ to $Z \times (U \setminus \{\infty\}) \subseteq X \times (U \setminus \{\infty\})$; it therefore glues with the inclusion $Z \times \mathbb{A}^1 \subseteq X \times \mathbb{A}^1$ of Step 1 to a closed immersion $Z \times \mathbb{P}^1 \hookrightarrow M_Z^\circ X$ over $\mathbb{P}^1$. Modulo u the ideal $\mathfrak{q}$ becomes the ideal generated by the degree-one part $\mathcal{I}/\mathcal{I}^2$ of $\bigoplus_n \mathcal{I}^n/\mathcal{I}^{n+1}$, whose quotient is $\mathcal{O}_Z$; by definition 12.3.1 that is the vertex of $C_Z X$. So the immersion restricts over ∞ to the vertex, which is (4), completing the proof.

The theorem produces a single scheme over $\mathbb{P}^1$ carrying two embeddings at once. Away from ∞ the pair is the given $Z \subseteq X$, unchanged; at ∞ it is the vertex inside $C_Z X$. What moves in the family is the ambient scheme, not the subscheme: by (4) the subscheme is the constant family $Z \times \mathbb{P}^1$, and the ambient scheme degenerates around it until it becomes a cone with Z as its vertex.

The morphism $\rho\colon M_Z^\circ X \to X$ records how each fibre maps back to the original scheme. Over $\mathbb{A}^1$ it is the projection $X \times \mathbb{A}^1 \to X$ by Step 1 of the proof, and over ∞ it is the composite $C_Z X \to Z \hookrightarrow X$, since the structure map $\mathcal{O}_X \to \mathcal{R}$ becomes $\mathcal{O}_X \to \mathcal{O}_Z$ in degree zero after reducing modulo u. One property the family does not have is properness: its fibre over ∞ is affine over Z (definition 12.3.1), so a positive-dimensional fibre of $C_Z X \to Z$ over a closed point is affine over $\overline{k}$. An affine scheme of positive dimension over a field is not proper, so π is not a proper morphism as soon as $C_Z X$ has positive-dimensional fibres. Cycles will therefore be moved across the family by restriction to the Cartier divisor $\pi^{-1}(\infty)$ rather than by pushforward.

13.1.6 Remark: Why the Blow-Up Is Not Enough The subscheme deleted in definition 13.1.4 is not a technicality. Lemma 13.1.2 splits the part of $M_Z X$ lying over the chart U into $D_+(u)$ and $\mathrm{Bl}_Z X$, and the fibre over ∞ lies entirely in that part; its intersection with $D_+(u)$ is $C_Z X$ by Step 2 of the proof of theorem 13.1.5, while $\mathrm{Bl}_Z X$ maps into $X \times \{\infty\}$ and so lies in the fibre. The special fibre of the unmodified blow-up is therefore the disjoint union of $C_Z X$ and $\mathrm{Bl}_Z X$ as a set, and only the first piece records the normal directions along Z; the second is a copy of X modified along Z, carrying no information the construction is after. Deleting it costs the properness of the blow-down p over $X \times \mathbb{P}^1$ and gives a special fibre equal to $C_Z X$ on the nose.

The two extremes of the construction are the case where $C_Z X$ is a vector bundle and the case where it is not. The first is the case the Gysin map of section 13.3 will need, and codimension one is where it is easiest to see.

Example 13.1.7: An Effective Cartier Divisor and a Line in the Plane
Let $D \subseteq X$ be an effective Cartier divisor (definition 5.4.26). Its ideal sheaf is invertible and locally generated by one nonzerodivisor, so $D \hookrightarrow X$ is a regular embedding of codimension one with normal bundle $N_D X = \mathcal{O}_X(D)|_D$ (example 12.3.15), and $C_D X = N_D X$ by proposition 12.3.11. By theorem 13.1.5 the deformation therefore degenerates $D \subseteq X$ into D sitting inside the total space of a line bundle on itself, as the zero section, which is the vertex of that cone (example 12.3.2(1)). Take $X = \mathbb{P}^2$ and $D = L$ a line. Then $\mathcal{O}_{\mathbb{P}^2}(L) \cong \mathcal{O}_{\mathbb{P}^2}(1)$ by example 11.1.4, and its restriction to

$L \cong \mathbb{P}^1$ is $\mathcal{O}_{\mathbb{P}^1}(1)$ (example 11.2.3), so $C_L\mathbb{P}^2$ is the total space of $\mathcal{O}_{\mathbb{P}^1}(1)$ over L. That total space is $\mathbb{P}^2$ with a point removed: linear projection away from a point $P \notin L$ exhibits $\mathbb{P}^2 \setminus \{P\}$ as a line bundle over L whose zero section is L itself, and the degree of that bundle is the self-intersection $L \cdot L = 1$ of example 11.2.3, so it is $\mathcal{O}_{\mathbb{P}^1}(1)$. (The proof of theorem 10.5.2 notes the projection but uses only that it is an affine bundle, which is all its own argument needs.) So the family degenerates the pair $L \subseteq \mathbb{P}^2$ into the pair $L \subseteq \mathbb{P}^2 \setminus \{P\}$, with L the zero section of a line bundle. On the special fibre, intersecting a cycle with L has become intersecting it with the zero section of a line bundle, and flat pullback along the projection of that bundle is an isomorphism on Chow groups (theorem 10.4.6).

When the embedding is not regular the cone is not a bundle, and the deformation exhibits the singularity of the pair rather than a linear model of it. The node is the case already computed in example 12.3.7, and the whole family can be written down.

Example 13.1.8: The Node and Its Tangent Cone

Assume $\operatorname{char}\overline{k} \neq 2$ and let $X = \operatorname{Spec} A$ with $A = \overline{k}[x,y]/(y^2 - x^2 - x^3)$ be the affine nodal cubic, P the origin, $Z = \{P\}$ and $I = (x,y)$. Set $v = xu^{-1}$ and $w = yu^{-1}$ in $A[u,u^{-1}]$, so that $x = uv$ and $y = uw$; the algebra $R = A[u][Iu^{-1}]$ of (13.1) is generated by u, v, w. Substituting into the defining relation gives $u^2w^2 = u^2v^2 + u^3v^3$, and u is a nonzerodivisor on the domain $A[u,u^{-1}]$, so

$$w^2 \;=\; v^2 + uv^3 \tag{13.4}$$

The relation is the only one. The ring A is free over $\overline{k}[x]$ on $1, y$, because its defining relation is monic of degree two in y; hence $A[u,u^{-1}]$ is free over $\overline{k}[x,u,u^{-1}]$ on $1, y$. Using (13.4) to reduce powers of w, the ring R is generated as a $\overline{k}[u,v]$-module by 1 and w. Those two are independent: if $f(u,v) + g(u,v)w = 0$, then, reading off the coefficients of the basis $1, y$, one gets $f(u, xu^{-1}) = 0$ and $g(u, xu^{-1}) = 0$ in $\overline{k}[x,u,u^{-1}]$, and u and xu^{-1} are algebraically independent over $\overline{k}$ (they generate $\overline{k}(x,u)$, of transcendence degree two), so $f = g = 0$. Therefore

$$R \;\cong\; \overline{k}[u,v,w]/\big(w^2 - v^2 - uv^3\big)$$

The fibres. Over $u = c \neq 0$ the fibre is $\operatorname{Spec}\overline{k}[v,w]/(w^2 - v^2 - cv^3)$, carried isomorphically onto X by $x = cv$, $y = cw$, as substituting confirms. Over $u = 0$ the fibre is $\operatorname{Spec}\overline{k}[v,w]/(w^2 - v^2)$, the union of the two lines $w = \pm v$: the tangent cone of example 12.3.7, in agreement with theorem 13.1.5(2). The family straightens the two branches of the node into their tangent lines while keeping the singular point fixed, and the cubic term uv^3, which distinguishes the nodal cubic from a pair of lines, is exactly the term that the rescaling drives to zero.

Exercise 13.1.1

1. Compute the deformation in the two degenerate cases. First take $Z = X$, so that $\mathcal{I} = 0$: identify $\mathcal{R}$, show that $M_X^\circ X = X \times \mathbb{P}^1$ with π the projection, and check that the fibre over ∞ is the zero cone of example 12.3.2(2). Then take $Z = \emptyset$, so that $\mathcal{I} = \mathcal{O}_X$: identify $\mathcal{R}$, show that $M_\emptyset^\circ X = X \times \mathbb{A}^1$, and reconcile the empty fibre over ∞ with definition 12.3.6.
2. Let $X = \mathbb{A}^n$ and let $Z = \{0\}$ be the origin, with $I = (x_1, \dots, x_n)$. Show that the algebra of (13.1) is a polynomial ring $R \cong \overline{k}[u, v_1, \dots, v_n]$ with $v_i = x_i u^{-1}$, so that $\pi^{-1}(U) \cong \mathbb{A}^{n+1} \to \mathbb{A}^1_u$

is the trivial family. Identify the isomorphism of the fibre over $u = c \neq 0$ with $\mathbb{A}^n$, identify $C_0\mathbb{A}^n$, and locate the closed subscheme $Z \times U$ of theorem 13.1.5(4) inside $\mathbb{A}^{n+1}$.

3. Let $X = \mathbb{A}^1 = \operatorname{Spec} \overline{k}[x]$ and let $Z = \operatorname{Spec} \overline{k}[x]/(x^2)$ be the double point at the origin, so $I = (x^2)$. Show that $\operatorname{Spec}(\mathcal{R})$ is the affine quadric cone of example 11.1.2, and identify the fibre over ∞. Comment on what the computation shows about the smoothness of the deformation space.

4. Let $D \subseteq \mathbb{P}^2$ be a smooth conic. Using example 12.3.15 and proposition 12.3.11, identify $C_D\mathbb{P}^2$ as the total space of a line bundle on $D \cong \mathbb{P}^1$, and determine which line bundle it is.

5. Let $X = \operatorname{Spec} \overline{k}[x, y]/(y^2 - x^3)$ be the cuspidal cubic and P the origin. Compute $C_P X$ and its fundamental cycle $[C_P X]$ in the sense of definition 10.1.2, and contrast the answer with the node of example 13.1.8.

13.2 Specialization of Cycles

A cycle on X is spread over $\mathbb{A}^1$, its closure is followed to the fibre at infinity, and what that closure cuts on the fibre is a cycle on the normal cone. The resulting operation $\sigma\colon A_k(X) \to A_k(C_Z X)$ is the specialization homomorphism. Three things have to be proved about it: that it is well defined on rational equivalence, that on a subvariety V it returns the normal cone of $V \cap Z$ in V, and that it is compatible with proper pushforward and flat pullback.

Throughout, $Z \subseteq X$ is a closed subscheme of an algebraic scheme, with ideal sheaf $\mathcal{I}$, and $\pi\colon M_Z^\circ X \to \mathbb{P}^1$ is the projection of definition 13.1.4, which by theorem 13.1.5(1) to (3) is flat with fibres

$$\pi^{-1}\big(\mathbb{A}^1\big) \;=\; X \times \mathbb{A}^1, \qquad \pi^{-1}(\infty) \;=\; C_Z X$$

Write $j\colon X \times \mathbb{A}^1 \hookrightarrow M_Z^\circ X$ for the open immersion of the first fibre, $i_\infty\colon C_Z X \hookrightarrow M_Z^\circ X$ for the closed immersion of the second, and $q\colon X \times \mathbb{A}^1 \to X$ for the projection. On $\mathbb{P}^1$ fix the coordinate u vanishing to order one at ∞, so that $\mathbb{P}^1 \setminus \{0\} = \operatorname{Spec} \overline{k}[u]$ and ∞ is the closed subscheme $\{u = 0\}$; on the complementary chart $\mathbb{A}^1$ the coordinate is $t = u^{-1}$.

The fibre at infinity is cut out by a single equation (theorem 13.1.5(2)), which is what makes definition 11.2.1 applicable. One further fact is needed before anything can be intersected: the line bundle carrying that equation is trivial along the fibre itself. It looks like an accident of the construction, and it is what will make the whole operation independent of choices.

Lemma 13.2.1: The Line Bundle of the Fibre at Infinity

Let D_∞ be the effective Cartier divisor of theorem 13.1.5(2), whose support is the fibre $\pi^{-1}(\infty) = C_Z X$. Then

$$\mathcal{O}_{M_Z^\circ X}\big(D_\infty\big) \;=\; \pi^*\mathcal{O}_{\mathbb{P}^1}(\infty), \qquad \mathcal{O}_{M_Z^\circ X}\big(D_\infty\big)\big|_{C_Z X} \;\cong\; \mathcal{O}_{C_Z X}$$

so the line bundle of D_∞ restricts to the trivial bundle on the fibre it cuts out.

***Proof*:**
On $\mathbb{P}^1$ the point ∞ is an effective Cartier divisor (definition 5.4.26): it is cut out by the nonzerodivisor u on $\operatorname{Spec}\overline{k}[u]$ and by the unit 1 on the complementary chart $\mathbb{A}^1$, and its line bundle is $\mathcal{O}_{\mathbb{P}^1}(\infty)$.

By theorem 13.1.5(2) the divisor D_∞ is cut out by $\pi^{\#}u$ over $\pi^{-1}(\mathbb{P}^1 \setminus \{0\})$, and over $\pi^{-1}(\mathbb{A}^1)$ it is empty, cut out by the unit 1. Its local data $\{(\pi^{-1}(\mathbb{A}^1),\, 1),\ (\pi^{-1}(\mathbb{P}^1 \setminus \{0\}),\, \pi^{\#}u)\}$ are therefore the pullbacks along π of the local data just recorded for ∞ on $\mathbb{P}^1$, so $D_\infty = \pi^*(\infty)$ and the associated line bundle is $\pi^*\mathcal{O}_{\mathbb{P}^1}(\infty)$.
For the restriction, the composite $\pi \circ i_\infty \colon C_Z X \to \mathbb{P}^1$ factors through the closed subscheme $\{\infty\} = \operatorname{Spec}\overline{k}$, since i_∞ is the inclusion of the fibre over ∞, so

$$\mathcal{O}_{M_Z^\circ X}(D_\infty)\big|_{C_Z X} \;=\; i_\infty^*\pi^*\mathcal{O}_{\mathbb{P}^1}(\infty) \;=\; \big(\pi \circ i_\infty\big)^*\mathcal{O}_{\mathbb{P}^1}(\infty)$$

is the pullback of $\mathcal{O}_{\mathbb{P}^1}(\infty)|_{\{\infty\}}$ along the structure morphism $C_Z X \to \operatorname{Spec}\overline{k}$. A line bundle on the spectrum of a field is free of rank one, so that pullback is trivial, completing the proof.

The first consequence of the triviality is what the definition of σ needs: the operator $D_\infty \cdot -$ annihilates every class that already lives on the fibre at infinity. Geometrically, a cycle sitting inside the special fibre is not cut further by the equation of that fibre.

Lemma 13.2.2: Vanishing on Classes Supported at Infinity

For every $\gamma \in A_{k+1}(C_Z X)$,

$$D_\infty \cdot (i_\infty)_*\gamma \;=\; 0 \quad \text{in } A_k(C_Z X)$$

***Proof*:**
By proposition 11.4.6 the operator $D_\infty \cdot - \colon A_{k+1}(M_Z^\circ X) \to A_k(|D_\infty|) = A_k(C_Z X)$ may be evaluated on *any* cycle representing the class, including one all of whose components lie in $|D_\infty|$. That strengthening is needed here and proposition 11.2.4 alone would not do: every representative below lies in the fibre at infinity. Represent γ by a cycle $\sum_l n_l[T_l]$ with each $T_l \subseteq C_Z X$ a $(k+1)$-dimensional subvariety; then $(i_\infty)_*\gamma$ is represented by the same cycle, read on $M_Z^\circ X$, and every T_l is contained in $|D_\infty| = C_Z X$. The second clause of definition 11.2.1 therefore applies on each term, and

$$D_\infty \cdot [T_l] \;=\; c\Big(\mathcal{O}_{M_Z^\circ X}(D_\infty)\big|_{T_l}\Big) \;\in\; A_k(T_l)$$

By lemma 13.2.1 the restricted bundle is trivial, and the class map of proposition 11.1.3 is a group homomorphism, so it sends the trivial bundle, the identity element of $\operatorname{Pic}(T_l)$, to zero. Hence $D_\infty \cdot [T_l] = 0$ for every l, and summing gives $D_\infty \cdot (i_\infty)_*\gamma = 0$, as we sought to show.

With these two facts the specialization map can be built. The recipe has three moves: thicken a class on X into a class on $X \times \mathbb{A}^1$, extend it across the family, and cut with the fibre at infinity. The middle move is the only one that involves a choice, since a class on the open part of $M_Z^\circ X$ has many extensions; the localization sequence measures the ambiguity exactly, and lemma 13.2.2 kills it.

Definition 13.2.3: Specialization of Cycles

Let $Z \subseteq X$ be a closed subscheme and $\alpha \in A_k(X)$. A *lift* of α is a class $\beta \in A_{k+1}(M_Z^\circ X)$ with

$$j^*\beta \;=\; q^*\alpha \quad \text{in } A_{k+1}\big(X \times \mathbb{A}^1\big)$$

The *closure lift* attached to a cycle $\sum_l n_l[V_l]$ representing α is the class of

$$\overline{\alpha \times \mathbb{A}^1} \;=\; \sum_l n_l \big[\overline{V_l \times \mathbb{A}^1}\big]$$

the closures being taken in $M_Z^\circ X$. The *specialization* of α is

$$\sigma(\alpha) \;=\; D_\infty \cdot \beta \;\in\; A_k\big(C_Z X\big)$$

for any lift β, the intersection being that of definition 11.2.1 with the Cartier divisor of lemma 13.2.1, whose support is $C_Z X$.

The definition presupposes two things, that a lift exists and that the answer does not depend on which one is chosen, and both come from the localization sequence for the closed fibre $C_Z X$ inside $M_Z^\circ X$. It also presupposes that the recipe respects rational equivalence on X, which is where flat pullback does its work.

Theorem 13.2.4: The Specialization Homomorphism

Let $Z \subseteq X$ be a closed subscheme of an algebraic scheme. Every class $\alpha \in A_k(X)$ admits a lift, and $D_\infty \cdot \beta$ is the same for all lifts β of α. The assignment of definition 13.2.3 is therefore a well-defined homomorphism

$$\sigma \colon A_k(X) \longrightarrow A_k\big(C_Z X\big)$$

for every k.

***Proof*:**

Step 1: existence of a lift. The fibre $C_Z X$ is closed in $M_Z^\circ X$ with open complement $X \times \mathbb{A}^1$, so theorem 10.4.1 gives an exact sequence

$$A_{k+1}\big(C_Z X\big) \xrightarrow{(i_\infty)_*} A_{k+1}\big(M_Z^\circ X\big) \xrightarrow{j^*} A_{k+1}\big(X \times \mathbb{A}^1\big) \longrightarrow 0 \tag{13.5}$$

Surjectivity of j^* produces a lift of $q^*\alpha$, so lifts exist.

Step 2: independence of the lift. Let β and β' both lift α. Then $j^*(\beta - \beta') = 0$, so by exactness of (13.5) there is $\gamma \in A_{k+1}(C_Z X)$ with $\beta - \beta' = (i_\infty)_*\gamma$. Since $D_\infty \cdot -$ is a homomorphism on $A_{k+1}(M_Z^\circ X)$ (proposition 11.2.4),

$$D_\infty \cdot \beta - D_\infty \cdot \beta' \;=\; D_\infty \cdot (i_\infty)_*\gamma \;=\; 0$$

by lemma 13.2.2. So the value depends only on α.

Step 3: additivity. Flat pullback q^* and open restriction j^* are homomorphisms (proposition 10.3.7), so the sum of a lift of α and a lift of α' is a lift of $\alpha + \alpha'$; and $D_\infty \cdot -$ is a

homomorphism. Hence $\sigma(\alpha+\alpha') = \sigma(\alpha)+\sigma(\alpha')$, and σ is a homomorphism $A_k(X) \to A_k(C_Z X)$, completing the proof.

Nothing in the argument required α to be represented by any particular kind of cycle, and that is the point of routing the construction through Chow groups rather than through cycles: rational equivalence on X is absorbed by q^* before the family is entered, and the ambiguity created by the passage to $M_Z^\circ X$ is absorbed by lemma 13.2.2 after it. In practice, one lift is more useful than the others. Given a cycle $\sum_l n_l[V_l]$ representing α, the flat pullback $q^*[V_l] = [V_l \times \mathbb{A}^1]$ (example 10.3.4(2)) extends across the family by taking closures in $M_Z^\circ X$, and the closure lift of definition 13.2.3 restricts along the open immersion j to $q^*\alpha$ by example 10.3.4(1), so it is indeed a lift. Every one of its components dominates $\mathbb{P}^1$, hence lies in no fibre, and in particular none is contained in $|D_\infty|$; the first clause of definition 11.2.1 therefore governs every term. This is the representative used in every computation below.

Example 13.2.5: Specializing at a Point of the Projective Line

Let $X = \mathbb{P}^1$ and let $Z = \{P\}$ be a reduced closed point. The ideal $\mathcal{I}$ is generated at P by a local coordinate, so $\mathcal{I}/\mathcal{I}^2$ is one-dimensional over $\overline{k}$ and every $\mathcal{I}^n/\mathcal{I}^{n+1}$ is one-dimensional; the normal cone $C_P\mathbb{P}^1$ of definition 12.3.6 is the affine line $\mathbb{A}^1$ over the point P. The deformation space is concrete here: $X \times \mathbb{P}^1 = \mathbb{P}^1 \times \mathbb{P}^1$, the centre is the single point (P, ∞), and $M_Z X$ is the blow-up of that surface at that point, with exceptional divisor a copy of $\mathbb{P}^1$. Removing $\mathrm{Bl}_P\mathbb{P}^1 = \mathbb{P}^1$, the strict transform of $\mathbb{P}^1 \times \{\infty\}$, leaves $M_Z^\circ X$, whose fibre over ∞ is the exceptional $\mathbb{P}^1$ with one point deleted, namely $\mathbb{A}^1 = C_P\mathbb{P}^1$.

Two computations are available, one in each dimension. In dimension one, $A_1(\mathbb{P}^1) = \mathbb{Z}\,[\mathbb{P}^1]$ by theorem 10.5.2, and the closure of $\mathbb{P}^1 \times \mathbb{A}^1$ is all of $M_Z^\circ X$, an integral surface, so the first clause of definition 11.2.1 gives $\sigma[\mathbb{P}^1] = [\mathrm{div}(\pi^\# u)]$. The zero scheme of $\pi^\# u$ is the fibre over ∞, which is the reduced curve $\mathbb{A}^1$, so by definition 10.1.1 the order of $\pi^\# u$ along it is the length of the local ring of a reduced curve at its generic point, namely one. Hence

$$\sigma\big[\mathbb{P}^1\big] \;=\; \big[\mathbb{A}^1\big] \;=\; \big[C_P\mathbb{P}^1\big] \;\in\; A_1\big(C_P\mathbb{P}^1\big) = \mathbb{Z}$$

and σ is an isomorphism in this dimension. In dimension zero the behaviour is the opposite. Let $Q \neq P$ be a closed point. The closure of $\{Q\} \times \mathbb{A}^1$ in $M_Z X$ is the strict transform of $\{Q\} \times \mathbb{P}^1$, which misses the centre (P, ∞) entirely and therefore meets the fibre over ∞ in the single point (Q, ∞); that point lies on the strict transform of $\mathbb{P}^1 \times \{\infty\}$, which was deleted. So the closure lift of $[Q]$ in $M_Z^\circ X$ does not meet $|D_\infty|$ at all, and definition 11.2.1 records the intersection class on the empty intersection:

$$\sigma[Q] \;=\; 0 \;\in\; A_0\big(C_P\mathbb{P}^1\big)$$

consistent with $A_0(\mathbb{A}^1) = 0$ (proposition 10.5.1). Since $A_0(\mathbb{P}^1) = \mathbb{Z}$ by theorem 10.5.2, specialization is not injective. A cycle disjoint from Z escapes to infinity as the family degenerates, and the operation records nothing of it.

The example computed σ on the class of a subvariety by taking the closure of its cylinder and reading the fibre at infinity, and the answer was in both cases a normal cone: the normal cone of Z in $\mathbb{P}^1$ in the first computation, and the empty cone $C_\emptyset\{Q\}$ in the second. That this always happens is the main theorem of the section, and it is what makes σ computable. Proving it requires knowing two things: that the normal cone of $V \cap Z$ in V sits inside that of Z in X, which is lemma 12.3.12, proved with the cone material of chapter 12; and that the same containment holds one level up for the whole deformation space, which is the result below.

Lemma 12.3.12 is a statement about normal cones alone: for a closed subscheme $V \subseteq X$, the normal cone of $V \cap Z$ in V has an intrinsic map to the normal cone of Z in X, obtained by restricting the ideal $\mathcal{I}$ to V. The result below is the corresponding statement one level up, for the whole family rather than its special fibre. It is stated for an arbitrary morphism because the two compatibilities at the end of the section need the proper and the flat cases, while the theorem below needs the case of a closed immersion.

Lemma 13.2.6: Functoriality of the Deformation Space

Let $f\colon X' \to X$ be a morphism of algebraic schemes, $Z \subseteq X$ a closed subscheme, and $Z' = f^{-1}(Z)$ its scheme-theoretic preimage. Write $\pi'\colon M^\circ_{Z'}X' \to \mathbb{P}^1$ for the projection of the corresponding deformation space. Then there is a unique morphism $\widetilde{f}\colon M_{Z'}X' \to M_Z X$ over $f \times \mathrm{id}_{\mathbb{P}^1}$, and it satisfies

$$\widetilde{f}^{-1}\big(M^\circ_Z X\big) \;=\; M^\circ_{Z'}X'$$

so that it restricts to a morphism $\widetilde{f}\colon M^\circ_{Z'}X' \to M^\circ_Z X$. Moreover:

1. $\pi \circ \widetilde{f} = \pi'$; over $\mathbb{A}^1$ the morphism $\widetilde{f}$ restricts to $f \times \mathrm{id}_{\mathbb{A}^1}$, and over ∞ it restricts to the morphism of normal cones $C(f)\colon C_{Z'}X' \to C_Z X$ induced by the identity $\mathcal{I}\mathcal{O}_{X'} = \mathcal{I}'$.
2. If f is proper, then $\widetilde{f}$ and $C(f)$ are proper.
3. If f is flat of relative dimension n, then $\widetilde{f}$ and $C(f)$ are flat of relative dimension n, and the square

$$\begin{array}{ccc} M_{Z'}X' & \xrightarrow{\;\widetilde{f}\;} & M_Z X \\ {\scriptstyle p'}\downarrow & & \downarrow{\scriptstyle p} \\ X' \times \mathbb{P}^1 & \xrightarrow[f\times \mathrm{id}_{\mathbb{P}^1}]{} & X \times \mathbb{P}^1 \end{array}$$

formed by $\widetilde{f}$, $f \times \mathrm{id}_{\mathbb{P}^1}$ and the two blow-down morphisms p', p is Cartesian.

***Proof*:**

Write $g = f \times \mathrm{id}_{\mathbb{P}^1}$, let $\mathcal{J} \subseteq \mathcal{O}_{X\times\mathbb{P}^1}$ be the ideal sheaf of $Z \times \{\infty\}$, and let $\mathcal{J}'$ be the ideal sheaf of $Z' \times \{\infty\}$ in $X' \times \mathbb{P}^1$.

Step 1: the ideals correspond. Scheme-theoretically $Z \times \{\infty\} = (Z \times \mathbb{P}^1) \cap (X \times \{\infty\})$, so $\mathcal{J}$ is the sum of the ideal sheaves of the two factors, and the same holds upstairs. The inverse image ideal of a sum is the sum of the inverse image ideals; the ideal of $Z \times \mathbb{P}^1$ pulls back to that of $Z' \times \mathbb{P}^1$ because $\mathcal{I}\mathcal{O}_{X'} = \mathcal{I}'$ by definition of the scheme-theoretic preimage, and the ideal of $X \times \{\infty\}$, generated by u, pulls back to the ideal of $X' \times \{\infty\}$, generated by the same u. Hence

$$\mathcal{J}\mathcal{O}_{X'\times\mathbb{P}^1} \;=\; \mathcal{J}'$$

Step 2: existence and uniqueness. On $M_{Z'}X'$ the ideal $\mathcal{J}'\mathcal{O}_{M_{Z'}X'}$ is invertible by proposition 8.4.2(3), and by Step 1 it is the inverse image ideal of $\mathcal{J}$ under the composite $M_{Z'}X' \to X' \times \mathbb{P}^1 \xrightarrow{g} X \times \mathbb{P}^1$. The universal property, proposition 8.4.2(4), therefore factors that composite uniquely through the blow-down $p\colon M_Z X \to X \times \mathbb{P}^1$, and the factorization is the asserted $\widetilde{f}$. Uniqueness of the factorization says precisely that $\widetilde{f}$ is the only morphism $M_{Z'}X' \to M_Z X$

lying over g. Since π is the second projection composed with p, and $\widetilde{f}$ lies over g, which is the identity in the second factor, $\pi \circ \widetilde{f} = \pi'$.

Step 3: the two open subschemes correspond. The assertion is local on X and on $\mathbb{P}^1$. Over $\mathbb{A}^1$ the blow-ups are isomorphisms, since the centres lie over ∞ (proposition 8.4.2(2)), and both deformation spaces contain the whole preimage of $\mathbb{A}^1$; there $\widetilde{f}^{-1}(X \times \mathbb{A}^1) = X' \times \mathbb{A}^1$ because $\pi \circ \widetilde{f} = \pi'$. Over $\mathbb{P}^1 \setminus \{0\} = \operatorname{Spec} \overline{k}[u]$, take an affine open $U = \operatorname{Spec} A$ of X with $\mathcal{I}|_U$ given by an ideal $I \subseteq A$, and put $J = IA[u] + (u) \subseteq A[u]$, the ideal of $Z \times \{\infty\}$ over $U \times (\mathbb{P}^1 \setminus \{0\})$, so that by definition 8.4.1 the deformation space is there the relative Proj of the Rees algebra $\bigoplus_{n \geq 0} J^n$, in which u is an element of degree one. By lemma 13.1.2 the open subscheme $M_Z^\circ X = M_Z \overline{X} \setminus \mathrm{Bl}_Z X$ is over $U \times (\mathbb{P}^1 \setminus \{0\})$ exactly the basic open $D_+(u)$ of that relative Proj, with coordinate ring the extended Rees algebra $A[u][I/u]$, its closed complement there being $\mathrm{Bl}_Z X$.
The same description applies upstairs over any affine open $U' = \operatorname{Spec} A'$ of $f^{-1}(U)$, with $I' = IA'$ and $J' = I'A'[u] + (u)$, giving $M_{Z'}^\circ X' = D_+(u)$ there. By Step 1, $J^n A'[u] = J'^n$ for every n, so the graded homomorphism $\bigoplus_n J^n \otimes_{A[u]} A'[u] \to \bigoplus_n J'^n$ is surjective in every degree; it therefore induces a morphism of relative Proj schemes defined on all of $M_{Z'} X'$, and that morphism lies over g; by the uniqueness of Step 2 it is $\widetilde{f}$. A morphism of Proj schemes induced by a graded homomorphism φ pulls the basic open $D_+(x)$ back to $D_+(\varphi(x))$, and $\varphi(u) = u$, so $\widetilde{f}^{-1}(D_+(u)) = D_+(u)$. Hence $\widetilde{f}^{-1}(M_Z^\circ X) = M_{Z'}^\circ X'$.

The three numbered assertions remain.

1. *The restrictions to the two fibres.* Over $\mathbb{A}^1$ both blow-ups are isomorphisms onto $X \times \mathbb{A}^1$ and $X' \times \mathbb{A}^1$, and $\widetilde{f}$ lies over g, so it restricts there to $f \times \mathrm{id}_{\mathbb{A}^1}$. Over ∞, the chart of Step 3 has coordinate ring $A[u][I/u]$, and the fibre over ∞ is cut out by u; on that chart the identification of the fibre with the normal cone given by theorem 13.1.5(2) reads

$$A[u][I/u]/(u) \;\cong\; \bigoplus_{n \geq 0} I^n / I^{n+1}$$

   carrying the class of a/u, for $a \in I$, to the class of a in degree one. The morphism $\widetilde{f}$ is induced by $A[u] \to A'[u]$ and sends a/u to $f^\#(a)/u$, so on fibres it induces the homomorphism of graded algebras determined in degree one by $\bar{a} \mapsto \overline{f^\# a}$. That is the homomorphism defining $C(f)$.

2. *Properness.* Suppose f is proper. The blow-up $M_{Z'} X' \to X' \times \mathbb{P}^1$ is proper by proposition 8.4.2(1), and g is proper as a base change of f, so the composite $M_{Z'} X' \to X \times \mathbb{P}^1$ is proper. Factor $\widetilde{f}$ as

$$M_{Z'} X' \xrightarrow{(\mathrm{id}, \widetilde{f})} M_{Z'} X' \times_{X \times \mathbb{P}^1} M_Z X \xrightarrow{\mathrm{pr}_2} M_Z X$$

   The first map is the graph of $\widetilde{f}$ over $X \times \mathbb{P}^1$, a closed immersion because $M_Z X \to X \times \mathbb{P}^1$ is separated, and the second is a base change of the proper morphism $M_{Z'} X' \to X \times \mathbb{P}^1$, hence proper. So $\widetilde{f}$ is proper. Restricting over the open subscheme $M_Z^\circ X$, whose preimage is $M_{Z'}^\circ X'$ by Step 3, preserves properness, and $C(f)$ is the base change of $\widetilde{f}$ along the closed immersion $C_Z X \hookrightarrow M_Z^\circ X$, hence proper.

3. *Flatness.* Suppose f is flat of relative dimension n; then so is g, being a base change of f. Flatness gives $\mathcal{J}^n \mathcal{O}_{X' \times \mathbb{P}^1} = g^* \mathcal{J}^n$ for every n, so the Rees algebra of $\mathcal{J}'$ is the pullback g^*

of the Rees algebra of $\mathcal{J}$, and proposition 5.3.50 identifies

$$M_{Z'}X' \;\cong\; M_Z X \times_{X\times\mathbb{P}^1} \big(X' \times \mathbb{P}^1\big)$$

over $X' \times \mathbb{P}^1$. Under this identification the second projection is a morphism over g, hence equals $\widetilde{f}$ by the uniqueness of Step 2, and the square is Cartesian. So $\widetilde{f}$ is a base change of g, therefore flat with the same fibres, that is, flat of relative dimension n. The same holds after restricting to the two open subschemes, which correspond by Step 3, and $C(f)$ is again a base change of $\widetilde{f}$, so it too is flat of relative dimension n, completing the proof.

The computation of σ on a subvariety can now be carried out. The statement is the one the construction was designed to produce: specializing a subvariety returns the normal cone of its intersection with Z, which is the linearized model of how V meets Z.

Theorem 13.2.7: Specialization of a Subvariety

Let $Z \subseteq X$ be a closed subscheme, let $V \subseteq X$ be a k-dimensional subvariety, and let $W = V \cap Z$ be the scheme-theoretic intersection. Then

$$\sigma[V] \;=\; \big[C_W V\big] \;\in\; A_k\big(C_Z X\big)$$

the fundamental cycle of the normal cone $C_W V$, regarded as a closed subscheme of $C_Z X$ through lemma 12.3.12. In particular $C_W V$ is pure of dimension k.

***Proof*:**

Step 1: the closure lift. Let $\widetilde{V}$ be the closure of $V \times \mathbb{A}^1$ in $M_Z^\circ X$, with its reduced structure, a subvariety of dimension $k+1$. Since $V \times \mathbb{A}^1$ is closed in $X \times \mathbb{A}^1$, the open restriction of $[\widetilde{V}]$ is $j^*[\widetilde{V}] = [V \times \mathbb{A}^1] = q^*[V]$ by example 10.3.4, so $[\widetilde{V}]$ is a lift of $[V]$ and $\sigma[V] = D_\infty \cdot [\widetilde{V}]$.

Step 2: the smaller deformation space. Apply lemma 13.2.6 to the closed immersion $\iota\colon V \hookrightarrow X$, whose scheme-theoretic preimage of Z is W by lemma 12.3.12. It gives a proper morphism

$$\widetilde{\iota}\colon M_W^\circ V \longrightarrow M_Z^\circ X$$

commuting with the projections to $\mathbb{P}^1$ and restricting over $\mathbb{A}^1$ to the closed immersion $V \times \mathbb{A}^1 \hookrightarrow X \times \mathbb{A}^1$. Over ∞ it restricts to the morphism $C(\iota)\colon C_W V \to C_Z X$, which is induced by the graded homomorphism attached to $\mathcal{I}\mathcal{O}_V = \mathcal{I}_W$ and is therefore the closed immersion of lemma 12.3.12.

The scheme $M_W V$ is integral. Indeed $V \times \mathbb{P}^1$ is a variety, and on an affine open $\operatorname{Spec} B \subseteq V \times \mathbb{P}^1$ the ideal $\mathfrak{b}$ of $W \times \{\infty\}$ is either the unit ideal, in which case the corresponding piece of the blow-up is $\operatorname{Spec} B$, or a nonzero proper ideal, in which case the charts of $\operatorname{Proj} \bigoplus_n \mathfrak{b}^n$ have coordinate rings $B[\mathfrak{b}/b]$ for $0 \neq b \in \mathfrak{b}$, subrings of the function field $k(V \times \mathbb{P}^1)$ containing B. Every chart is thus the spectrum of a domain with fraction field $k(V)(t)$, so $M_W V$ is reduced and irreducible, and so is its open subscheme $M_W^\circ V$. The latter has dimension $k+1$, since it contains $V \times \mathbb{A}^1$ as a nonempty, hence dense, open subscheme.

Step 3: the image and the degree. The morphism $\widetilde{\iota}$ is proper, hence closed, and $V \times \mathbb{A}^1$ is dense in $M_W^\circ V$, so the image is the closure of $\widetilde{\iota}(V \times \mathbb{A}^1) = V \times \mathbb{A}^1$, which is $\widetilde{V}$. Over $\mathbb{A}^1$ the morphism is an isomorphism onto $V \times \mathbb{A}^1$, which is dense in both $M_W^\circ V$ and $\widetilde{V}$, so the two schemes have

the same function field and $\deg\big(M^\circ_W V/\widetilde{V}\big) = 1$. By definition 10.2.1,

$$\widetilde{\iota}_*\big[M^\circ_W V\big] \;=\; \big[\widetilde{V}\big]$$

Step 4: cutting the smaller family. The projection $\pi'\colon M^\circ_W V \to \mathbb{P}^1$ is flat by theorem 13.1.5(3), applied to the closed subscheme $W \subseteq V$. Each nonempty fibre is cut out locally by one equation, so every component has dimension at least k by Krull's principal ideal theorem, and each fibre is a proper closed subset of the integral $M^\circ_W V$, so every component has dimension at most k. Thus π' is flat of relative dimension k in the sense of definition 10.3.1, and its fibre over ∞, which is $C_W V$, is pure of dimension k.

Since $\pi \circ \widetilde{\iota} = \pi'$, the pullback Cartier divisor is $\widetilde{\iota}^* D_\infty = \pi'^*(\infty)$, cut out by $\pi'^{\#}u$; it is defined because $M^\circ_W V$ is dominant over $\mathbb{P}^1$, its restriction over $\mathbb{A}^1$ being the nonempty $V \times \mathbb{A}^1$, and so is not contained in $|D_\infty|$. The first clause of definition 11.2.1 therefore gives

$$\widetilde{\iota}^* D_\infty \cdot \big[M^\circ_W V\big] \;=\; \big[\operatorname{div}\big(\pi'^{\#}u\big)\big] \;=\; \sum_T \operatorname{ord}_T\big(\pi'^{\#}u\big)\,[T]$$

the sum over the codimension-one subvarieties T of $M^\circ_W V$. By definition 10.1.1 the coefficient $\operatorname{ord}_T(\pi'^{\#}u)$ is the length of $\mathcal{O}_{M^\circ_W V,T}/(\pi'^{\#}u)$, which is the local ring at T of the zero scheme of $\pi'^{\#}u$, that is, of the fibre $C_W V$. The coefficient vanishes unless $T \subseteq C_W V$, and the k-dimensional subvarieties of $C_W V$ are exactly its irreducible components, by the purity just established. Comparing with the fundamental cycle of definition 10.1.2,

$$\widetilde{\iota}^* D_\infty \cdot \big[M^\circ_W V\big] \;=\; \big[C_W V\big]$$

Step 5: descent to $C_Z X$. Combining the previous steps with the projection formula proposition 11.3.3(1) for the proper morphism $\widetilde{\iota}$,

$$\sigma[V] \;=\; D_\infty \cdot \widetilde{\iota}_*\big[M^\circ_W V\big] \;=\; \widetilde{\iota}_*\Big(\widetilde{\iota}^* D_\infty \cdot \big[M^\circ_W V\big]\Big) \;=\; \widetilde{\iota}_*\big[C_W V\big]$$

as classes in $A_k(C_Z X)$. By Step 2 the morphism $\widetilde{\iota}$ restricts over ∞ to the closed immersion of lemma 12.3.12, and a closed immersion carries a fundamental cycle to the fundamental cycle of its image, every degree in definition 10.2.1 being 1. Hence $\widetilde{\iota}_*[C_W V] = [C_W V]$ read inside $C_Z X$, as we sought to show.

The theorem is what turns σ from a construction into a computation. It also explains the two features of example 13.2.5: for $V = \mathbb{P}^1$ the intersection $V \cap Z$ is Z itself and the answer is $[C_P \mathbb{P}^1]$, while for $V = \{Q\}$ with $Q \notin Z$ the intersection is empty, the normal cone of the empty subscheme is empty, and the answer is 0. Specialization does not preserve the geometry of V, only its normal geometry along Z: the class $[C_W V]$ remembers how V meets Z and forgets everything about V away from Z. The multiplicities carry information: the fundamental cycle of definition 10.1.2 weights each component of $C_W V$ by the length of the local ring there, so a component along which the cone is non-reduced contributes with multiplicity greater than one. In the example below the cone is reduced and every multiplicity is one, the two components recording the two tangent directions of a node; the cuspidal cubic of exercise 13.2.1 (3) is the opposite case, a single tangent line doubled. And the purity statement is not an extra hypothesis but a by-product: the normal cone of any closed subscheme in a variety is pure of the dimension of that variety, because it is a fibre of a flat family

whose other fibres are the variety itself.

Example 13.2.8: Specializing the Nodal Cubic to its Tangent Cone

Assume $\operatorname{char}\overline{k} \neq 2$, let $X = \operatorname{Spec}\overline{k}[x,y]/(y^2 - x^2 - x^3)$ be the affine nodal cubic, and let $Z = \{P\}$ be the reduced origin. The curve X is a variety of dimension one, so $A_1(X) = \mathbb{Z}[X]$ by example 10.1.6(3). Taking $V = X$ in theorem 13.2.7 gives $W = X \cap Z = Z$ and

$$\sigma[X] \;=\; \big[C_P X\big]$$

and example 12.3.7 computed the normal cone: $C_P X = \operatorname{Spec}\overline{k}[x,y]/(y^2 - x^2)$, the union of the two lines $L_+ = \{y = x\}$ and $L_- = \{y = -x\}$. The polynomial $y^2 - x^2 = (y-x)(y+x)$ is squarefree, so the cone is reduced and each component carries multiplicity one:

$$\sigma[X] \;=\; \big[L_+\big] + \big[L_-\big] \;\in\; A_1\big(C_P X\big)$$

which is free of rank two on the two lines, again by example 10.1.6(3). The specialization has replaced an irreducible curve by a reducible cone, one line for each branch of the node, and the two summands are exactly the two tangent directions along which X approaches P. The class of X in $A_1(X) = \mathbb{Z}$ carried no information about the singularity; its specialization, in a group of rank two, carries the branch structure.

What remains is to check that σ is compatible with the two functorialities of chapter 10. Both statements are forced by the shape of the construction: σ was built from the flat pullback q^*, the localization sequence, and the divisor operator, and each of the three commutes with proper pushforward and with flat pullback. The compatibilities are what allow σ, and hence the Gysin map of section 13.3, to be computed by moving to a cover or restricting to an open set.

Proposition 13.2.9: Compatibility with Proper Pushforward

Let $f\colon X' \to X$ be a proper morphism, $Z \subseteq X$ a closed subscheme, and $Z' = f^{-1}(Z)$. Write σ' for the specialization homomorphism of $Z' \subseteq X'$ and $C(f)\colon C_{Z'}X' \to C_Z X$ for the induced proper morphism of normal cones. Then for every $\alpha' \in A_k(X')$,

$$\sigma\big(f_*\alpha'\big) \;=\; C(f)_*\big(\sigma'(\alpha')\big) \quad \text{in } A_k\big(C_Z X\big)$$

***Proof*:**

Let $\widetilde{f}\colon M^\circ_{Z'}X' \to M^\circ_Z X$ be the proper morphism of lemma 13.2.6, and let β' be the closure lift of α', so that $j'^*\beta' = q'^*\alpha'$ and every component of β' dominates $\mathbb{P}^1$.

Step 1: the pushed-forward lift. Since $\pi \circ \widetilde{f} = \pi'$, the square with horizontal maps $\widetilde{f}$ and $f \times \mathrm{id}_{\mathbb{A}^1}$ and vertical maps the two open immersions j', j is Cartesian: the preimage $\widetilde{f}^{-1}(X \times \mathbb{A}^1)$ is $\pi'^{-1}(\mathbb{A}^1) = X' \times \mathbb{A}^1$, and $\widetilde{f}$ restricts there to $f \times \mathrm{id}_{\mathbb{A}^1}$ by lemma 13.2.6(1). As j is flat of relative dimension 0 and $\widetilde{f}$ is proper, proposition 10.3.6 gives

$$j^*\widetilde{f}_*\beta' \;=\; \big(f \times \mathrm{id}_{\mathbb{A}^1}\big)_* j'^*\beta' \;=\; \big(f \times \mathrm{id}_{\mathbb{A}^1}\big)_* q'^*\alpha'$$

The square with horizontal maps $f \times \mathrm{id}_{\mathbb{A}^1}$ and f and vertical maps q' and q is Cartesian as well, since $X' \times \mathbb{A}^1 = X' \times_X (X \times \mathbb{A}^1)$, so a second application of proposition 10.3.6, now with q flat of relative dimension 1 and f proper, gives $(f \times \mathrm{id}_{\mathbb{A}^1})_* q'^*\alpha' = q^* f_*\alpha'$. Hence $\widetilde{f}_*\beta'$ is a lift of

$f_*\alpha'$.

Step 2: the projection formula. Every component of β' dominates $\mathbb{P}^1$, and $\pi \circ \widetilde{f} = \pi'$, so no component of the support of β' maps into $|D_\infty| = C_Z X$; the pullback divisor $\widetilde{f}^* D_\infty$ is therefore defined, and it equals $\pi'^*(\infty) = D'_\infty$. By proposition 11.3.3(1),

$$D_\infty \cdot \widetilde{f}_* \beta' \;=\; \widetilde{f}_*\big(D'_\infty \cdot \beta'\big)$$

as classes in $A_k(C_Z X)$. The left side is $\sigma(f_*\alpha')$ by Step 1 and theorem 13.2.4, and $D'_\infty \cdot \beta' = \sigma'(\alpha')$ is a class on $C_{Z'}X'$, on which $\widetilde{f}_*$ acts as $C(f)_*$ by lemma 13.2.6(1). Therefore $\sigma(f_*\alpha') = C(f)_*(\sigma'(\alpha'))$, completing the proof.

Proposition 13.2.10: Compatibility with Flat Pullback

Let $f\colon X' \to X$ be flat of relative dimension n, $Z \subseteq X$ a closed subscheme, and $Z' = f^{-1}(Z)$. Then the induced morphism $C(f)\colon C_{Z'}X' \to C_Z X$ is flat of relative dimension n, and for every $\alpha \in A_k(X)$,

$$\sigma'\big(f^*\alpha\big) \;=\; C(f)^*\big(\sigma(\alpha)\big) \quad \text{in } A_{k+n}\big(C_{Z'}X'\big)$$

***Proof*:**

Flatness of $C(f)$ is lemma 13.2.6(3), which also makes $\widetilde{f}\colon M^\circ_{Z'}X' \to M^\circ_Z X$ flat of relative dimension n with $\widetilde{f}^{-1}(C_Z X) = C_{Z'}X'$ and $\widetilde{f}^{-1}(X \times \mathbb{A}^1) = X' \times \mathbb{A}^1$.

Step 1: the pulled-back lift. Let β be the closure lift of α. Contravariant functoriality of flat pullback (proposition 10.3.5(3)) applied to the two equal composites $j \circ (f \times \mathrm{id}_{\mathbb{A}^1}) = \widetilde{f} \circ j'$ and $q \circ (f \times \mathrm{id}_{\mathbb{A}^1}) = f \circ q'$ gives

$$j'^* \widetilde{f}^* \beta \;=\; \big(f \times \mathrm{id}_{\mathbb{A}^1}\big)^* j^* \beta \;=\; \big(f \times \mathrm{id}_{\mathbb{A}^1}\big)^* q^* \alpha \;=\; q'^* f^* \alpha$$

so $\widetilde{f}^*\beta$ is a lift of $f^*\alpha$. Its components are components of flat preimages of the components of β, each of which dominates $\mathbb{P}^1$, so they dominate $\mathbb{P}^1$ as well and none lies in $|D'_\infty|$.

Step 2: the projection formula. The pullback Cartier divisor is $\widetilde{f}^* D_\infty = \pi'^*(\infty) = D'_\infty$, again because $\pi \circ \widetilde{f} = \pi'$. By proposition 11.3.3(2),

$$\widetilde{f}^*\big(D_\infty \cdot \beta\big) \;=\; D'_\infty \cdot \widetilde{f}^* \beta$$

as classes in $A_{k+n}(\widetilde{f}^{-1}(C_Z X)) = A_{k+n}(C_{Z'}X')$. The right side is $\sigma'(f^*\alpha)$ by Step 1 and theorem 13.2.4. On the left, $D_\infty \cdot \beta = \sigma(\alpha)$ is a class on $C_Z X$, and the restriction of $\widetilde{f}^*$ to classes on $C_Z X$ is the flat pullback along the base change $C(f)$, since flat pullback is computed on preimages and $\widetilde{f}^{-1}(C_Z X) = C_{Z'}X'$. Hence $\sigma'(f^*\alpha) = C(f)^*(\sigma(\alpha))$, as we sought to show.

The two propositions say that specialization is a natural transformation, covariant for proper morphisms and contravariant for flat ones, between the Chow groups of X and those of the normal cone. The hypothesis common to both, $Z' = f^{-1}(Z)$, is not a restriction imposed for convenience: the normal cone of Z' in X' maps to that of Z in X precisely because the ideal of Z pulls back to the ideal of Z', and without that identity there is no morphism $C(f)$ to state the compatibility with.

Exercise 13.2.1

1. Take $Z = X$. Exercise 13.1.1 (1) identifies the deformation space as $M^\circ_X X = X \times \mathbb{P}^1$ with special fibre $C_X X = X$. Deduce from theorem 13.2.7 that $\sigma\colon A_k(X) \to A_k(X)$ is the identity.
2. Let $X = \mathbb{P}^2$ and let $Z = L$ be a line, an effective Cartier divisor on X. Using example 12.3.15, identify $C_L\mathbb{P}^2$ with the total space of the line bundle $N = \mathcal{O}_{\mathbb{P}^2}(1)|_L$ on $L \cong \mathbb{P}^1$, and compute $A_k(C_L\mathbb{P}^2)$ for all k by theorem 10.4.6. Then compute $\sigma[\mathbb{P}^2]$, $\sigma[L']$ for a line $L' \neq L$, and $\sigma[Q]$ for a closed point Q, and say in which dimensions σ is an isomorphism.
3. Let $X = \operatorname{Spec}\overline{k}[x,y]/(y^2 - x^3)$ be the affine cuspidal cubic and $Z = \{P\}$ the reduced origin. Taking the cone $C_P X = \operatorname{Spec}\overline{k}[x,y]/(y^2)$ and its fundamental cycle $2\,[L]$ from exercise 13.1.1 (5), compute $\sigma[X]$ as a cycle. Compare the answer with example 13.2.8 and say what distinguishes a cusp from a node in this computation. Does the answer depend on $\operatorname{char}\overline{k}$?
4. Let $\iota\colon Z \hookrightarrow C_Z X$ be the vertex of the normal cone (definition 12.3.1) and $i_Z\colon Z \hookrightarrow X$ the inclusion. Show that $\sigma \circ (i_Z)_* = \iota_*$ as homomorphisms $A_k(Z) \to A_k(C_Z X)$. (Hint: apply theorem 13.2.7 to a subvariety $V \subseteq Z$ and identify $C_V V$.)
5. Show that if $V \subseteq X$ is a subvariety with $V \cap Z = \emptyset$, then $\sigma[V] = 0$. Deduce that for $X = \mathbb{P}^n$ with $n \geq 1$ and $Z = \{P\}$ a closed point, σ vanishes on all of $A_0(\mathbb{P}^n)$, and check that this is consistent with a direct computation of $A_0(C_P\mathbb{P}^n)$.

13.3 The Gysin Map for a Regular Embedding

The specialization homomorphism of section 13.2 accepts an arbitrary closed subscheme, and its target is the Chow group of a cone that is usually not a bundle. This section takes the case in which it is. For a regular embedding the normal cone is the normal bundle (proposition 12.3.11), so specialization lands in $A_k(N)$, and flat pullback along $N \to Z$ is an isomorphism (theorem 10.4.6) that can be inverted. The composite lowers dimension by the codimension and lands on Z.

Two things have to be established beyond that one-line recipe. The first is that the recipe computes what a reader expects when the intersection is proper: the cycle $[V \cap Z]$, with the multiplicities the scheme structure gives. The second is that the construction survives base change. For any morphism $X' \to X$ the normal cone of the preimage of Z still sits inside the pulled-back normal bundle, and the same recipe produces a homomorphism landing on that preimage rather than on Z. It is this refined form, not the plain one, that chapter 14 applies to the diagonal.

Both rest on lemma 12.3.13, the comparison between the normal cone of a pullback and the pullback of the normal bundle, proved with the cone material of chapter 12. Regularity of i is what makes the comparison available: it is what makes the conormal sheaf locally free of rank d.

Lemma 12.3.13 says that regularity of i propagates one step: it is not inherited by $Z' \hookrightarrow X'$, which can be badly irregular, but the failure is confined inside a bundle of the correct rank d. The cone $C_{Z'}X'$ may be singular, may be reducible, and may have components of several dimensions, and none of that prevents it from being a closed subscheme of a rank-d bundle on Z'. That containment is what lets the same recipe be applied over X' as over X, and the discrepancy between $C_{Z'}X'$ and all of N' is what the excess intersection formula of chapter 14 measures.

With $g = \mathrm{id}_X$ the lemma reduces to the case already in hand, and the construction can be stated.

Definition 13.3.1: The Gysin Map of a Regular Embedding

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 0$ with normal bundle $\pi\colon N \to Z$. For $d = 0$ the ideal sheaf vanishes along Z, i is an open and closed immersion, N is the zero bundle over Z, and the formula below is stipulated to read as flat pullback along i in that case. That is consistent: $X = Z \sqcup X''$ and σ is the identity on the Z summand. The construction is stated for $d \geq 1$ below and the degenerate case is recorded here so that statements about codimension-zero embeddings, which occur in chapter 14, have a definition to refer to. By proposition 12.3.11 the normal cone $C_Z X$ is N, so the specialization homomorphism of definition 13.2.3 is a homomorphism $\sigma\colon A_k(X) \to A_k(N)$ (theorem 13.2.4). The *Gysin map* of i is

$$i^! \;=\; (\pi^*)^{-1} \circ \sigma \;:\; A_k(X) \longrightarrow A_{k-d}(Z)$$

where $\pi^*\colon A_{k-d}(Z) \to A_k(N)$ is flat pullback along π.

The inverse in the definition exists because N is a vector bundle of rank d, hence an affine bundle of relative dimension d (definition 10.4.5), so π^* is an isomorphism by theorem 10.4.6.

The smallest case can be run through at once. Take $X = \mathbb{A}^1$ and $Z = \{0\}$, whose ideal is generated by the single nonzerodivisor t, so that i is a regular embedding of codimension one and N is a one-dimensional vector space over the point Z, with total space $\mathbb{A}^1$. By theorem 13.2.7, $\sigma[\mathbb{A}^1] = [C_Z\mathbb{A}^1] = [N]$, and $\pi^*[Z] = [N]$ by proposition 10.3.5(2), so $i^![\mathbb{A}^1] = [Z]$ in $A_0(Z) = \mathbb{Z}$: the origin with multiplicity one.

Proposition 13.3.2: The Gysin Map is a Homomorphism of Degree $-d$

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$. Then:

1. $i^!\colon A_k(X) \to A_{k-d}(Z)$ is a well-defined homomorphism of abelian groups for every k, and it is the unique map satisfying $\pi^* \circ i^! = \sigma$;
2. $i^! = 0$ on $A_k(X)$ for $k < d$.

***Proof*:**

1. A vector bundle of rank d is an affine bundle of relative dimension d in the sense of definition 10.4.5, a local trivialization of the bundle being in particular a local product decomposition with $\mathbb{A}^d$. Theorem 10.4.6 therefore makes $\pi^*\colon A_{k-d}(Z) \to A_k(N)$ an isomorphism for every k. The specialization homomorphism $\sigma\colon A_k(X) \to A_k(N)$ is a homomorphism defined on rational equivalence classes by theorem 13.2.4, and $C_Z X = N$ by proposition 12.3.11, so the composite $(\pi^*)^{-1} \circ \sigma$ is a homomorphism $A_k(X) \to A_{k-d}(Z)$. If $\tau\colon A_k(X) \to A_{k-d}(Z)$ satisfies $\pi^* \circ \tau = \sigma$, then $\pi^*\tau = \pi^* i^!$, and injectivity of π^* gives $\tau = i^!$.
2. For $k < d$ the target $A_{k-d}(Z)$ is a Chow group in negative dimension. No scheme has a subvariety of negative dimension, so $Z_{k-d}(Z) = 0$ and hence $A_{k-d}(Z) = 0$, forcing $i^! = 0$ there, as we sought to show.

The characterization $\pi^* \circ i^! = \sigma$ is how the map is used in practice: rather than inverting π^*, one

produces a candidate class on Z and checks that its pullback to N is the specialization. The degree $-d$ matches the naive expectation that intersecting a k-dimensional cycle with a codimension-d subscheme leaves something of dimension $k-d$. What the construction adds to that expectation is that the answer is defined for every class, with no hypothesis on how Z and a representing cycle meet, and that it is a rational-equivalence invariant.

The first thing to verify is that the machinery reproduces the naive answer when the naive answer makes sense. The condition for that is exactly regularity of the induced embedding.

Proposition 13.3.3: The Gysin Map of a Regular Intersection

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$, let $V \subseteq X$ be a k-dimensional subvariety, and let $W = V \cap Z$ be the scheme-theoretic intersection, that is the preimage of Z under the inclusion $V \hookrightarrow X$. If $W \hookrightarrow V$ is a regular embedding of codimension d, then W is pure of dimension $k-d$ and

$$i^![V] \;=\; \iota_*[W] \;\in\; A_{k-d}(Z)$$

where $[W]$ is the fundamental cycle of definition 10.1.2 and $\iota\colon W \hookrightarrow Z$ is the inclusion.

***Proof*:**

Apply lemma 12.3.13 to the closed immersion $g\colon V \hookrightarrow X$, whose preimage of Z is W: it produces a closed immersion $j\colon C_W V \hookrightarrow N|_W$ of cones over W, and by part (1) of that lemma the hypothesis on $W \hookrightarrow V$ makes j an isomorphism. Thus $C_W V = N|_W$, the restriction of N to W, viewed as a closed subscheme of $C_Z X = N$, the two immersions agreeing by lemma 12.3.14.

By theorem 13.2.7 applied to the pair (Z, X), $\sigma[V] = [C_W V]$ in $A_k(N)$, the fundamental cycle of the normal cone of V along W read inside $C_Z X$. The previous paragraph identifies that cycle as $[N|_W]$. Now $\pi_W\colon N|_W \to W$ is flat of relative dimension d, being a vector bundle of rank d, so proposition 10.3.5(2) gives $\pi_W^*[W] = [N|_W]$; and flat pullback of a cycle is computed componentwise from scheme-theoretic preimages (definition 10.3.3), so the cycle $\pi_W^*[W]$ on $N|_W$ is the cycle $\pi^*\iota_*[W]$ on N. Hence

$$\pi^*\big(\iota_*[W]\big) = [N|_W] = \sigma[V]$$

and proposition 13.3.2(1) gives $i^![V] = \iota_*[W]$.

Finally, $\sigma[V]$ lies in $A_k(N)$, so $[N|_W]$ is a k-cycle; since π_W raises dimension by exactly d on each component, every irreducible component of W has dimension $k-d$, completing the proof.

The hypothesis is the scheme-theoretic form of "V meets Z properly and without excess tangency". It is not a condition on dimensions alone: a subvariety can meet Z in the expected dimension $k-d$ and still fail it, if the intersection is not cut out by d equations forming a regular sequence, and then $i^![V]$ carries multiplicities the set $V \cap Z$ does not display. When the hypothesis does hold, the Gysin map returns the fundamental cycle of the intersection scheme, so the multiplicities are the lengths that scheme records and nothing more.

Example 13.3.4: Linear Subspaces of Projective Space

Fix homogeneous coordinates $x_0, \dots, x_n$ on $\mathbb{P}^n$ and let $Z = \{x_0 = \cdots = x_{d-1} = 0\} \cong \mathbb{P}^{n-d}$ with $1 \le d \le n$. On each standard affine chart $\{x_r \neq 0\}$ meeting Z, the ideal of Z is generated by the d ratios $x_0/x_r, \dots, x_{d-1}/x_r$, which form a regular sequence in the polynomial ring of that chart: each is a nonzerodivisor modulo its predecessors, the quotients being polynomial rings in the remaining coordinates. So $i\colon Z \hookrightarrow \mathbb{P}^n$ is a regular embedding of codimension d and $i^!\colon A_m(\mathbb{P}^n) \to A_{m-d}(Z)$ is defined.

By theorem 10.5.2, $A_m(\mathbb{P}^n) = \mathbb{Z}\, h_m$ with h_m the class of a linear subspace $\mathbb{P}^m \subseteq \mathbb{P}^n$, and likewise $A_{m-d}(Z) = \mathbb{Z}\, h^Z_{m-d}$ for $Z \cong \mathbb{P}^{n-d}$. Take $m \ge d$ and represent h_m by $L = \{x_{m+1} = \cdots = x_n = 0\}$, the span of the coordinate points $e_0, \dots, e_m$. Then

$$L \cap Z \;=\; \{x_0 = \cdots = x_{d-1} = 0\} \cap L$$

is the span of $e_d, \dots, e_m$, a linear $\mathbb{P}^{m-d}$, and its ideal in $L \cong \mathbb{P}^m$ is generated by the restrictions of $x_0, \dots, x_{d-1}$, again a regular sequence of length d on every chart of L meeting it. So $L \cap Z \hookrightarrow L$ is a regular embedding of codimension d, and proposition 13.3.3 gives

$$i^!(h_m) \;=\; \big[\mathbb{P}^{m-d}\big] \;=\; h^Z_{m-d}$$

the intersection scheme being reduced and irreducible, so that its fundamental cycle carries multiplicity one. For $m < d$ the target $A_{m-d}(Z)$ vanishes and $i^!(h_m) = 0$ by proposition 13.3.2(2). The Gysin map of a linear subspace is therefore the shift $h_m \mapsto h^Z_{m-d}$, carrying generator to generator in every degree where the target is nonzero.

The computation is the expected one, and its value is that no general position was invoked to get it: the representative L was chosen for convenience, and proposition 13.3.2 guarantees that any other representative of h_m, including one contained in Z or tangent to it, returns the same class. That is the difference between this construction and a count of intersection points.

The codimension-one case can be compared with the operator built by hand in chapter 11, and the two agree wherever the first clause of definition 11.2.1 applies.

Proposition 13.3.5: Agreement with Intersection with a Divisor

Let D be an effective Cartier divisor on an algebraic scheme X with $D \neq X$, and let $i\colon D \hookrightarrow X$ be the inclusion, a regular embedding of codimension one with normal bundle $N = \mathcal{O}_X(D)|_D$ (example 12.3.15). Let $V \subseteq X$ be a k-dimensional subvariety with $V \not\subseteq |D|$, and let $W = V \cap D$ be the scheme-theoretic intersection, a closed subscheme with support $V \cap |D|$. Then W is pure of dimension $k-1$, the fundamental cycle of W and the intersection class of definition 11.2.1 agree,

$$[W] \;=\; D \cdot [V] \;\in\; A_{k-1}\big(V \cap |D|\big)$$

already as cycles and not as classes, and the Gysin class of V is their pushforward,

$$i^![V] \;=\; \iota_*\big(D \cdot [V]\big) \;\in\; A_{k-1}(D)$$

where $\iota\colon W \hookrightarrow D$ is the inclusion.

***Proof*:**
Recall that $W = V \cap D$ is the closed subscheme of V cut out by the ideal $\mathcal{I} \cdot \mathcal{O}_V$, where $\mathcal{I}$ is the ideal sheaf of D.

Step 1: the hypothesis of proposition 13.3.3 holds. Since D is an effective Cartier divisor, $\mathcal{I}$ is locally generated by a single nonzerodivisor $f \in \mathcal{O}_X(U)$. As V is integral and $V \not\subseteq |D|$, the restriction $f|_V$ is a nonzero element of the domain $\mathcal{O}_V(U \cap V)$, hence a nonzerodivisor, and it generates $\mathcal{I} \cdot \mathcal{O}_V$ there. So $W \hookrightarrow V$ is a regular embedding of codimension one, and proposition 13.3.3 gives $i^![V] = \iota_*[W]$ in $A_{k-1}(D)$, with W pure of dimension $k-1$.

Step 2: the fundamental cycle of W is the divisor of the section. The intersection class of definition 11.2.1 is computed by its first clause, V not being contained in $|D|$: the local equations of D restrict to a rational section s_V of $\mathcal{O}_X(D)|_V$, given on $U \cap V$ by $f|_V$, and $D \cdot [V] = [\operatorname{div}(s_V)] = \sum_T \operatorname{ord}_T(s_V)\,[T]$, the sum over codimension-one subvarieties $T \subseteq V$. Fix such a T and let $A = \mathcal{O}_{V,T}$, a one-dimensional local domain. The local ring of W at the generic point of T is $A/(f|_V)$, so the coefficient of $[T]$ in the fundamental cycle $[W]$ of definition 10.1.2 is $\operatorname{length}_A\big(A/(f|_V)\big)$, which is $\operatorname{ord}_T(s_V)$ by definition 10.1.1. The coefficient is zero exactly when $f|_V$ is a unit in A, that is when T is not a component of W, so the two cycles have the same components as well as the same multiplicities. Hence $[W] = [\operatorname{div}(s_V)]$ as cycles on $V \cap D$, so $[W] = D \cdot [V]$ in $A_{k-1}(V \cap |D|)$; pushing that identity forward along ι and combining it with Step 1 gives $i^![V] = \iota_*[W] = \iota_*\big(D \cdot [V]\big)$ in $A_{k-1}(D)$, completing the proof.

The proposition is the consistency check in codimension one: the operator $D \cdot -$, built in chapter 11 out of local equations and orders of vanishing, is the specialization construction in disguise. The restriction $V \not\subseteq |D|$ is exactly the first clause of definition 11.2.1; the second clause, where V lies inside the support and $D \cdot [V]$ is computed from the restricted line bundle, corresponds on the Gysin side to a cycle supported on the zero section of N, and evaluating it needs the self-intersection formula of chapter 14.

Everything so far records the answer on Z. The construction gives more: it records it on the part of Z that the cycle meets, and it does so for a cycle living on any scheme over X, not only on X itself. Lemma 12.3.13 is what makes this possible, since it gives a bundle of rank d on the preimage of Z regardless of how singular that preimage is.

Definition 13.3.6: The Refined Gysin Homomorphism

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with normal bundle N, and let $g\colon X' \to X$ be a morphism of algebraic schemes. Form the fibre square

$$\begin{array}{ccc} Z' & \xrightarrow{i'} & X' \\ {\scriptstyle h}\downarrow & & \downarrow{\scriptstyle g} \\ Z & \xrightarrow{i} & X \end{array}$$

with $Z' = g^{-1}(Z)$ and i' the induced closed immersion, and write $\pi'\colon N' = h^*N \to Z'$. Let $\sigma'\colon A_k(X') \to A_k(C_{Z'}X')$ be the specialization homomorphism of definition 13.2.3 for the pair (Z', X'), well defined by theorem 13.2.4, and let $j\colon C_{Z'}X' \hookrightarrow N'$ be the closed immersion of lemma 12.3.13. The *refined Gysin homomorphism* of i along g is

$$i^! \;=\; (\pi'^*)^{-1} \circ j_* \circ \sigma' \;:\; A_k(X') \longrightarrow A_{k-d}(Z')$$

where j_* is proper pushforward along the closed immersion j and $\pi'^*\colon A_{k-d}(Z') \to A_k(N')$ is the isomorphism of theorem 10.4.6.

The notation deliberately reuses $i^!$: the map depends on g, but the source and target groups record which g is meant, and no ambiguity arises in practice. Where the morphism does have to be named, it goes in a subscript, $i^!_g$. The statements below write $i^!_V$, $i^!_a$ and the like in that sense.

With the notation in place, proposition 13.3.3 refines: under its hypotheses the refined class is already the fundamental cycle, before any pushforward.

Corollary 13.3.7: The Refined Class of a Regular Intersection

Keep the situation of proposition 13.3.3: $i\colon Z \hookrightarrow X$ a regular embedding of codimension $d \geq 1$, $V \subseteq X$ a k-dimensional subvariety, $W = V \cap Z$, and $W \hookrightarrow V$ a regular embedding of codimension d. Then the refined Gysin map along $V \hookrightarrow X$ satisfies

$$i^!_V[V] \;=\; [W] \;\in\; A_{k-d}(W)$$

Pushing forward along $\iota\colon W \hookrightarrow Z$ recovers proposition 13.3.3.

***Proof*:**
Applying theorem 13.2.7 to the pair (W, V) and the k-dimensional subvariety $V \subseteq V$, whose intersection with W is W itself, gives $\sigma'[V] = [C_W V]$ in $A_k(C_W V)$, where σ' is the specialization of that pair. The proof of proposition 13.3.3 makes the immersion $j\colon C_W V \hookrightarrow N|_W$ of lemma 12.3.13 an isomorphism, so $j_*\sigma'[V] = [N|_W]$, and $\pi^*_W[W] = [N|_W]$ by proposition 10.3.5(2). Since π^*_W is injective (theorem 10.4.6), the definition $i^!_V = (\pi^*_W)^{-1} \circ j_* \circ \sigma'$ gives $i^!_V[V] = [W]$.

Each of the three maps is defined for the reasons already in place. Specialization for (Z', X') needs no hypothesis on Z', which is why the construction tolerates a preimage that is singular or of the wrong dimension; j_* is defined because a closed immersion is proper, and proper pushforward preserves the dimension of a cycle (definition 10.2.1); and π'^* is invertible because N' is a bundle of rank d on Z', by definition 10.4.5 and theorem 10.4.6 as before. The only step that used regularity of i is

lemma 12.3.13, and it used it to guarantee that the rank is d on the nose.

Proposition 13.3.8: The Refined Map Extends the Gysin Map

In the situation of definition 13.3.6 with $X' = X$ and $g = \mathrm{id}_X$, the refined Gysin homomorphism is the Gysin map $i^!$ of definition 13.3.1.

***Proof*:**
With $g = \mathrm{id}_X$ one has $Z' = Z$, $h = \mathrm{id}_Z$ and $N' = N$. By lemma 12.3.13(2) the closed immersion j is the identification $C_Z X = N$ of proposition 12.3.11, so j_* is the identity on $A_k(N)$ and $\sigma' = \sigma$. The composite $(\pi^*)^{-1} \circ \mathrm{id} \circ \sigma$ is definition 13.3.1, as claimed.

Example 13.3.9: Two Lines in the Plane
Let $X = \mathbb{P}^2$ and $Z = L = \{x_0 = 0\}$, an effective Cartier divisor and hence a regular embedding of codimension one with $N = \mathcal{O}_{\mathbb{P}^2}(1)|_L$ (example 12.3.15).
A transverse line. Take $g\colon X' = L' \hookrightarrow \mathbb{P}^2$ with $L' = \{x_1 = 0\}$. Then $Z' = g^{-1}(L)$ is cut out on L' by x_0, so $Z' = \{p\}$ with $p = [0:0:1]$, a reduced point, and $Z' \hookrightarrow L'$ is a regular embedding of codimension one. By lemma 12.3.13(1) the immersion j is an isomorphism, so $C_{Z'}X' = N' = N|_p$, a one-dimensional vector space over p. Specialization gives $\sigma'[L'] = [C_{Z'}L'] = [N']$ by theorem 13.2.7, and $\pi'^*[p] = [N']$ by proposition 10.3.5(2), so

$$i^![L'] \;=\; [p] \;\in\; A_0(L \cap L') = \mathbb{Z}$$

The class is recorded on the single point $L \cap L'$, not on L, and since $\{p\}$ is the scheme-theoretic intersection $L' \cap L$, proposition 13.3.5 identifies it there with the intersection class $L \cdot [L'] \in A_0(L' \cap |L|)$. Pushing it forward along $\{p\} \hookrightarrow L$ returns the class of a point on L, which by the same proposition is the plain Gysin class of L' in $A_0(L)$.
The same line. Take instead $g = i$, so $X' = L$ and $Z' = L$. The normal cone of L in itself is the zero cone of example 12.3.2(2), so $C_{Z'}X' = L$ and j is the vertex of $N' = N = \mathcal{O}_{\mathbb{P}^2}(1)|_L$, that is the zero section $\zeta\colon L \to N$. Hence

$$i^![L] \;=\; (\pi^*)^{-1}\big(\zeta_*[L]\big) \;\in\; A_0(L)$$

Nothing in this section evaluates the right-hand side. What it must equal is known from chapter 11: example 11.2.3 computes $L \cdot [L] = [q]$, the class of one point, so the class of the zero section in $A_1(N)$ has to be $\pi^*[q]$. Identifying it is the self-intersection formula, proved in chapter 14.

The two halves of the example are the two regimes the refined map is built to handle uniformly. In the first, the preimage Z' has the expected dimension and the answer is a cycle on it. In the second, Z' is far too large, the cone degenerates onto the zero section, and the answer is carried entirely by the normal bundle. No hypothesis distinguishes the cases in definition 13.3.6; the difference shows up only in how much of N' the cone $C_{Z'}X'$ fills.

13.3.10 Foreshadowing: What the Gysin Map Is Not Yet The Gysin map is a homomorphism of Chow groups, not a product. Three things it is expected to satisfy are not proved here and are the business of chapter 14: that $i^!$ applied to the diagonal $X \hookrightarrow X \times X$ of a smooth variety turns $A_*(X)$ into a commutative ring; that $i^!$ of a class supported on Z is computed by capping with the top Chern class of N, which is the self-intersection formula and the missing step in example 13.3.9; and that two refined Gysin maps for two regular embeddings commute, which is what makes the resulting product associative. Everything in the present section is input to those proofs rather than a consequence of them.
The third item is settled before this chapter ends, in section 13.4; the first two belong to chapter 14.

The properties chapter 14 uses are the two functorialities. They say that the refined Gysin map is a morphism of the theory over X: it commutes with pushing a cycle forward along a proper X-morphism and with pulling it back along a flat one, in each case through the induced morphism of preimages.

Theorem 13.3.11: Compatibility of the Refined Gysin Homomorphism

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$. Let $X' \to X$ and $X'' \to X$ be morphisms of algebraic schemes and $p\colon X'' \to X'$ a morphism over X; write $Z' \subseteq X'$ and $Z'' \subseteq X''$ for the preimages of Z and $q\colon Z'' \to Z'$ for the morphism induced by p.

1. *Proper pushforward.* If p is proper then so is q, and for every $\alpha \in A_k(X'')$,
$$i^!\big(p_*\alpha\big) \;=\; q_*\big(i^!\alpha\big) \quad \text{in } A_{k-d}(Z')$$
2. *Flat pullback.* If p is flat of relative dimension n then so is q, and for every $\beta \in A_k(X')$,
$$i^!\big(p^*\beta\big) \;=\; q^*\big(i^!\beta\big) \quad \text{in } A_{k+n-d}(Z'')$$

***Proof*:**
Write $C' = C_{Z'}X'$ and $C'' = C_{Z''}X''$, let $h'\colon Z' \to Z$ and $h''\colon Z'' \to Z$ be the structure morphisms, and set $N' = h'^*N$ and $N'' = h''^*N$ with projections π' and π''. Let $j'\colon C' \hookrightarrow N'$ and $j''\colon C'' \hookrightarrow N''$ be the closed immersions of lemma 12.3.13.

Since $X'' \to X$ factors through p, the preimage of Z in X'' is $Z'' = p^{-1}(Z')$, so q is the base change of p along $Z' \hookrightarrow X'$; properness and flatness of relative dimension n are both stable under base change, which proves the first assertion of each part. From $h'' = h' \circ q$ one gets $N'' = q^*N'$, so
$$\begin{array}{ccc} N'' & \xrightarrow{\bar{q}} & N' \\ {\scriptstyle \pi''}\downarrow & & \downarrow{\scriptstyle \pi'} \\ Z'' & \xrightarrow{q} & Z' \end{array}$$
is a fibre square, called the *bundle square* below, with $\bar{q}$ the projection. The ideal sheaves satisfy $\mathcal{I}'\mathcal{O}_{X''} = \mathcal{I}''$ because $Z'' = p^{-1}(Z')$, so p induces a morphism of graded algebras and hence a

morphism of cones $\bar{p}\colon C'' \to C'$ over q; and the *cone square*

$$\begin{array}{ccc} C'' & \xrightarrow{j''} & N'' \\ {\scriptstyle \bar{p}}\downarrow & & \downarrow{\scriptstyle \bar{q}} \\ C' & \xrightarrow{j'} & N' \end{array}$$

commutes, since j' and j'' are induced by the canonical surjections of lemma 12.3.13 and those surjections are compatible with pullback along p, being built from the single conormal surjection of $\mathcal{I}$ on X. Concretely, both composites in the corresponding square of graded algebras are maps out of $\operatorname{Sym}^\bullet\big(h'^*(\mathcal{I}/\mathcal{I}^2)\big)$, hence are determined by their degree-one parts, and in degree one both send the class of a local section a of $\mathcal{I}$ to the class of its pullback in $\mathcal{I}''/\mathcal{I}''^2$, because $\mathcal{I}\mathcal{O}_{X''} = \mathcal{I}''$.

1. Let p be proper. Then $\bar{q}$ is proper, being the base change of q along π', and $\bar{p}$ is proper as well: it is the composite $C'' \hookrightarrow N'' \to N'$ of a closed immersion and a proper morphism, corestricted to the closed subscheme $C' \subseteq N'$. The compatibility of specialization with proper pushforward (proposition 13.2.9) gives

   $$\sigma'\big(p_*\alpha\big) = \bar{p}_*\big(\sigma''\alpha\big)$$

   Pushing forward along j' and using the cone square together with functoriality of proper pushforward, established in section 10.2 after definition 10.2.1,

   $$j'_*\sigma'\big(p_*\alpha\big) = j'_*\bar{p}_*\big(\sigma''\alpha\big) = \bar{q}_*j''_*\big(\sigma''\alpha\big)$$

   It remains to move $\bar{q}_*$ past the inverse of π'^*. The bundle square has q proper and π' flat, so proposition 10.3.6 gives $\pi'^*q_* = \bar{q}_*\pi''^*$. Applying this to $\gamma = (\pi''^*)^{-1}j''_*\sigma''\alpha = i^!\alpha$,

   $$\pi'^*\big(q_*(i^!\alpha)\big) = \bar{q}_*\big(\pi''^*\gamma\big) = \bar{q}_*j''_*\big(\sigma''\alpha\big) = j'_*\sigma'\big(p_*\alpha\big) = \pi'^*\big(i^!(p_*\alpha)\big)$$

   Since π'^* is injective, $q_*(i^!\alpha) = i^!(p_*\alpha)$.

2. Let p be flat of relative dimension n. Flatness gives $\mathcal{I}'^m\mathcal{O}_{X''} = p^*\mathcal{I}'^m$ for every m and makes the formation of the quotients $\mathcal{I}'^m/\mathcal{I}'^{m+1}$ commute with pullback, so $C'' = C' \times_{Z'} Z''$ and the induced $\bar{p}\colon C'' \to C'$ is flat of relative dimension n. Consequently the cone square is a fibre square as well, both vertical maps being base change along $Z'' \to Z'$. The compatibility of specialization with flat pullback (proposition 13.2.10) gives

   $$\sigma''\big(p^*\beta\big) = \bar{p}^*\big(\sigma'\beta\big)$$

   Applying j''_* and using proposition 10.3.6 for the cone square, whose horizontal maps j', j'' are proper and whose vertical maps $\bar{p}, \bar{q}$ are flat,

   $$j''_*\sigma''\big(p^*\beta\big) = j''_*\bar{p}^*\big(\sigma'\beta\big) = \bar{q}^*j'_*\big(\sigma'\beta\big)$$

   Finally $\pi' \circ \bar{q} = q \circ \pi''$ is a composite of flat morphisms in two ways, so proposition 10.3.5(3) gives $\bar{q}^*\pi'^* = \pi''^*q^*$. Applying this to $\delta = (\pi'^*)^{-1}j'_*\sigma'\beta = i^!\beta$,

   $$\pi''^*\big(q^*(i^!\beta)\big) = \bar{q}^*\big(\pi'^*\delta\big) = \bar{q}^*j'_*\big(\sigma'\beta\big) = j''_*\sigma''\big(p^*\beta\big) = \pi''^*\big(i^!(p^*\beta)\big)$$

   and injectivity of π''^* gives $q^*(i^!\beta) = i^!(p^*\beta)$, completing the proof.

Part (1) is what makes the refined map a refinement rather than a separate construction: a class computed on a small piece of X and then pushed forward agrees with the class computed on X directly. Part (2) says that the map commutes with restriction to an open subscheme, that being flat pullback of relative dimension zero: $(i^!\alpha)|_{Z\cap U} = i^!(\alpha|_U)$. It does *not* say that $i^!\alpha$ can be reassembled from its restrictions to an open cover, and it could not: Chow groups are not a Zariski sheaf, and $A_0(\mathbb{P}^1) = \mathbb{Z}$ restricts to zero on each of the two standard charts (theorem 10.5.2, proposition 10.5.1). What the compatibility does give is the useful one-way statement of exercise 13.3.1 (4): a class vanishing on an open set containing Z has vanishing Gysin image. Both are also the form in which chapter 14 uses the map: the projection formula and the compatibility of the intersection product with proper pushforward are read off them.

The first corollary is the statement that the plain Gysin map of a subvariety is always the pushforward of a class living on the intersection.

Corollary 13.3.12: The Gysin Class of a Subvariety Lives on the Intersection

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ and let $V \subseteq X$ be a k-dimensional subvariety, with inclusion $\iota_V\colon V \hookrightarrow X$ and $W = V \cap Z = \iota_V^{-1}(Z)$. Then

$$i^![V] \;=\; \iota_*\big(i_V^![V]\big)$$

where $i_V^!\colon A_k(V) \to A_{k-d}(W)$ is the refined Gysin homomorphism along ι_V and $\iota\colon W \hookrightarrow Z$ is the inclusion.

***Proof*:**
Apply theorem 13.3.11(1) with $X' = X$, $X'' = V$ and $p = \iota_V$, which is proper as a closed immersion. The preimage of Z in V is W and the induced morphism q is ι. By definition 10.2.1 the class $[V] \in A_k(V)$ has $p_*[V] = [V] \in A_k(X)$, the extension $k(V) \subseteq k(V)$ having degree one. On the left-hand side the refined Gysin homomorphism along id_X is the Gysin map of definition 13.3.1 by proposition 13.3.8, so the identity reads $i^![V] = \iota_*(i_V^![V])$, as we sought to show.

The class $i^![V] \in A_{k-d}(Z)$ discards information: it records a cycle on all of Z, whereas the geometry produced it on $V \cap Z$, which may be much smaller. The refined class $i_V^![V] \in A_{k-d}(V \cap Z)$ retains that localization, and it is the object every localized intersection number is a degree of. Corollary 13.3.7 is the special case in which the refined class is the fundamental cycle $[V \cap Z]$ itself, and example 13.3.9 exhibits both a case where it is and a case where it is not.

Exercise 13.3.1

1. Let $Z = \{x_2 = x_3 = 0\} \subseteq \mathbb{P}^3$, a line. Show that $Z \hookrightarrow \mathbb{P}^3$ is a regular embedding of codimension two, and compute $i^!\colon A_m(\mathbb{P}^3) \to A_{m-2}(Z)$ on the generator of each group, for $m = 0, 1, 2, 3$.
2. Let X be a variety of dimension n and let $D \subseteq X$ be an effective Cartier divisor with $D \neq X$, with inclusion i. Show that $i^![X] = [D]$, the fundamental cycle of the scheme D. Then take $X = \mathbb{P}^2$ and D a smooth plane cubic, and compute the image of $i^![\mathbb{P}^2]$ in $A_1(\mathbb{P}^2)$.
3. Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ and let $V \subseteq X$ be a k-dimensional subvariety with $V \cap Z = \emptyset$. Show that $i^![V] = 0$. Then let $Z = \{0\}$ be the origin in $X = \mathbb{A}^n$ with $n \geq 1$, verify that this is a regular embedding of codimension n, and determine $i^!$ on

every group $A_k(\mathbb{A}^n)$.

4. Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ and let $u\colon U \hookrightarrow X$ be an open immersion. Show that the preimage of Z in U is $Z \cap U$ and that $i'\big(u^*\alpha\big) = \big(i^!\alpha\big)\big|_{Z\cap U}$ for every $\alpha \in A_k(X)$. Deduce that if $Z \subseteq U$ and α restricts to zero on U, then $i^!\alpha = 0$.

5. Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ and let $V \subseteq Z$ be a k-dimensional subvariety of Z. Show that $\sigma[V] = \zeta_*[V]$, where $\zeta\colon Z \to N$ is the zero section, and hence that $i^![V] = (\pi^*)^{-1}\zeta_*[V]$. Now take $X = \mathbb{A}^2$, $Z = \{y = 0\}$ and $V = Z$, and evaluate both $i^![Z]$ and $D \cdot [Z]$ of definition 11.2.1, checking that they agree.

13.4 Commutativity, Composition, and Sections

The Gysin map is built; the algebra it obeys is not yet available. Three identities are used downstream, and all three are properties of the construction of section 13.3 rather than of anything later, so they belong here.

They are not independent, and the dependency runs in a direction worth naming before starting. Commutativity of two Gysin maps looks the hardest and is in fact a consequence of the composition rule: two regular embeddings determine a single regular embedding of the product, that embedding factors through the two intermediate stages in two ways, and the composition rule applied to both factorizations equates the two orders. The work is therefore concentrated in composition, and the section is arranged accordingly. Composition in turn needs a commutativity statement of its own, but only the case of a *divisor*, and that case the construction hands over directly: specialization is intersection with a Cartier divisor, so two of them commute because divisors do.

Lemma 13.4.1: The Product of Two Regular Embeddings

Let $i\colon Z \hookrightarrow P$ and $i'\colon Z' \hookrightarrow P'$ be regular embeddings of codimensions d and d'. Then

$$i \times i' \;:\; Z \times Z' \;\hookrightarrow\; P \times P'$$

is a regular embedding of codimension $d + d'$, and it factors in two ways as a composite of regular embeddings,

$$Z \times Z' \xhookrightarrow{\mathrm{id}_Z \times i'} Z \times P' \xhookrightarrow{i \times \mathrm{id}_{P'}} P \times P', \qquad Z \times Z' \xhookrightarrow{i \times \mathrm{id}_{Z'}} P \times Z' \xhookrightarrow{\mathrm{id}_P \times i'} P \times P'$$

the four factors being regular of codimensions d', d, d and d' respectively.

***Proof*:**
Step 1: each factor is regular. The morphism $i \times \mathrm{id}_{P'}$ is the base change of i along the projection $\mathrm{pr}_1\colon P \times P' \to P$, which is flat, and the scheme-theoretic preimage of Z under that projection is $Z \times P'$. A regular embedding pulls back along a flat morphism to a regular embedding of the same codimension (proposition 5.1.49), so $i \times \mathrm{id}_{P'}$ is regular of codimension d. The same argument along pr_2 makes $\mathrm{id}_P \times i'$ and $\mathrm{id}_Z \times i'$ regular of codimension d', the latter as the base change of i' along $Z \times P' \to P'$; and $i \times \mathrm{id}_{Z'}$ is regular of codimension d, being the base change of i along the flat projection $P \times Z' \to P$. That accounts for all four factors named in

the statement.

Step 2: the composite is regular. Work on affine opens $\operatorname{Spec} A \subseteq P$ and $\operatorname{Spec} A' \subseteq P'$ over which the ideals of Z and Z' are generated by regular sequences $f_1, \dots, f_d$ and $g_1, \dots, g_{d'}$. On $\operatorname{Spec}(A \otimes_{\overline{k}} A')$ the ideal of $Z \times Z'$ is generated by the images of the f's and the g's together, and that concatenation is a regular sequence. Indeed $A \to A \otimes_{\overline{k}} A'$ is flat, so the f's remain a regular sequence after it by the argument of Step 1; and modulo them the ring is $(A/(f)) \otimes_{\overline{k}} A'$, which is a flat base change of A', so the g's are regular there by the same argument with the two factors exchanged. Hence $i \times i'$ is a regular embedding of codimension $d + d'$.

The two factorizations are immediate from the definitions of the four morphisms, and Step 1 identified each factor as a regular embedding of the stated codimension, completing the proof.

The first identity says that the Gysin map of a section undoes the flat pullback along the morphism it is a section of. It is the only one of the three that can be proved directly from the proper-intersection computation already available.

Theorem 13.4.2: Gysin Maps of Sections

Let $\pi\colon P \to S$ be smooth of relative dimension $e \geq 1$ and let $s\colon S \to P$ be a section, so that $\pi \circ s = \mathrm{id}_S$. Then s is a regular embedding of codimension e and

$$s^! \circ \pi^* \;=\; \mathrm{id} \quad \text{on } A_k(S) \text{ for every } k$$

***Proof*:**

That s is a regular embedding of codimension e is proposition 5.1.48. Both $s^!$ and π^* are homomorphisms, so it suffices to prove the identity on the class of a k-dimensional subvariety $V \subseteq S$.

Step 1: the preimage and its components. The morphism π is flat of relative dimension e by proposition 2.7.12, so π^* is defined and $\pi^*[V] = [P_V]$ for $P_V = \pi^{-1}(V)$ the scheme-theoretic preimage (definition 10.3.3). The projection $\pi_V\colon P_V \to V$ is smooth of relative dimension e, being the base change of π along $V \hookrightarrow S$ (proposition 2.7.11(1)), hence flat by the same citation as above; since its base V is a variety, proposition 10.3.2 applies to π_V and P_V is pure of dimension $k + e$. Because $\pi \circ s = \mathrm{id}_S$, the section restricts to a section $s_V\colon V \to P_V$ of π_V, and indeed $s^{-1}(P_V) = (\pi \circ s)^{-1}(V) = V$ scheme-theoretically, so $s(S) \cap P_V = s_V(V)$.

Flatness of π_V makes every irreducible component of P_V dominate V, by the going-down argument already used in the proof of proposition 10.3.2. So the generic point of each component lies in the generic fibre, which is smooth over the field $k(V)$ and therefore regular (proposition 2.7.14); its local rings are consequently domains. In fact P_V is reduced outright, being smooth over the reduced V ([95, Tag 034E], which the series does not prove), which is what Step 3 needs in order to transport regularity of an embedding from an open of P_V into V_1. Generic reducedness alone would not do, since regularity of an embedding is sensitive to nilpotents in the ambient. In particular P_V is generically reduced along every component, so $[P_V] = \sum_j [V_j]$ with all multiplicities one (definition 10.1.2), and no two components share a generic point of the generic fibre. The subvariety $s_V(V)$ dominates V, so its generic point lies in the generic fibre and therefore in exactly one component, which is moreover the unique component containing $s_V(V)$; call it V_1, and let $V_2, \dots, V_r$ be the others.

Step 2: the other components miss the section altogether. Let $j \geq 2$ and put $W_j = V_j \cap s(S) =$

$V_j \cap s_V(V)$, using Step 1's identification of $s(S) \cap P_V$. Suppose $W_j \neq \emptyset$. Applying theorem 13.2.7 to the subvariety $V_j \subseteq P_V$, of dimension $k+e$, its normal cone $C_{W_j} V_j$ is pure of dimension $k+e$, and lemma 12.3.12 embeds it in $C_{s_V(V)} P_V$ over the inclusion $W_j \hookrightarrow s_V(V)$. Now $s_V(V) \hookrightarrow P_V$ is a section of the smooth morphism π_V, hence a regular embedding of codimension e (proposition 5.1.48), so that cone is the normal bundle N_V, of rank e over $s_V(V) \cong V$ (proposition 12.3.11). The part of N_V lying over W_j has dimension $\dim W_j + e$, so purity forces $\dim W_j = k$. But W_j is then a k-dimensional closed subscheme of the k-dimensional variety $s_V(V)$, hence all of it, so $V_j \supseteq s_V(V)$, contradicting the uniqueness of V_1 in Step 1. Therefore $W_j = \emptyset$ for every $j \geq 2$, and in particular $s^![V_j] = 0$: by corollary 13.3.12 that class is pushed forward from $A_k(V_j \cap s(S)) = A_k(\emptyset) = 0$.

Step 3: the remaining component. Step 2 has a consequence worth isolating, because the naive statement it replaces is false: an irreducible component of a smooth V-scheme need not itself be smooth over V, so one may not argue that $V_1 \to V$ is smooth because V_1 is the component through the section. What is true, and all that is needed, is that

$$U \;=\; P_V \setminus \bigcup_{j \geq 2} V_j$$

is an open subscheme of P_V containing $s_V(V)$, by Step 2, and $U \subseteq V_1$. Being a regular embedding of a given codimension is a local condition along the subscheme (definition 5.1.43), and $s_V(V) \hookrightarrow P_V$ is regular of codimension e as recorded in Step 2. Restricting to the open U and using that U is also open in V_1, the embedding $s_V(V) \hookrightarrow V_1$ is regular of codimension e.

The scheme-theoretic intersection $V_1 \cap s(S)$ is $s_V(V)$: this is a scheme-theoretic and not a set-theoretic claim, so it needs an argument rather than a comparison of points. By Step 1, $s^{-1}(P_V) = V$ scheme-theoretically; $s^{-1}(V_1)$ is a closed subscheme of V because the ideal sheaf of V_1 contains that of P_V; it has full support since $V_1 \supseteq s_V(V)$; and V is reduced, so $s^{-1}(V_1) = V$.

Proposition 13.3.3 therefore applies to the regular embedding s of codimension e and the $(k+e)$-dimensional subvariety V_1, and gives

$$s^![V_1] \;=\; \iota_*\big[s_V(V)\big] \;\in\; A_k\big(s(S)\big)$$

Identifying $s(S)$ with S through the isomorphism s, the right side is $[V]$.

Summing Steps 2 and 3 gives $s^!\big(\pi^*[V]\big) = s^![P_V] = [V]$, as we sought to show.

The remaining two identities concern a pair of Gysin maps rather than a single one, and both rest on one observation about definition 13.3.6 that is worth isolating first. The refined map is built from the specialization of the pair (Z', X'), the cone $C_{Z'}X'$, and the bundle N' into which that cone embeds. Nothing else about the ambient X enters. So an embedding may be enlarged, or crossed with a further factor, without changing the resulting homomorphism, provided the preimage and the normal bundle come along unchanged.

Lemma 13.4.3: The Refined Gysin Map Does Not See the Ambient Scheme

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with ideal sheaf $\mathcal{I}$, and let $\varphi\colon \widetilde{X} \to X$ be a morphism whose preimage $\widetilde{Z} = \varphi^{-1}(Z)$, with ideal sheaf $\widetilde{\mathcal{I}} = \mathcal{I}\mathcal{O}_{\widetilde{X}}$, is again a regular embedding $\widetilde{i}\colon \widetilde{Z} \hookrightarrow \widetilde{X}$ *of the same codimension* d. Then for every morphism $g\colon X' \to \widetilde{X}$, writing $Z' = g^{-1}(\widetilde{Z}) = (\varphi \circ g)^{-1}(Z)$,

$$\widetilde{i}^{!}_{g} \;=\; i^{!}_{\varphi\circ g} \;:\; A_k(X') \longrightarrow A_{k-d}(Z')$$

***Proof*:**
First, the hypothesis on codimensions already forces the conormal sheaf to be the pullback. The canonical map

$$\varphi_Z^*\big(\mathcal{I}/\mathcal{I}^2\big) \;\longrightarrow\; \widetilde{\mathcal{I}}/\widetilde{\mathcal{I}}^2, \qquad \varphi_Z\colon \widetilde{Z} \to Z,$$

is surjective, since $\widetilde{\mathcal{I}} = \mathcal{I}\mathcal{O}_{\widetilde{X}}$ is generated by the image of $\mathcal{I}$. Both sides are locally free of rank d (proposition 5.1.44), the source as the pullback of a rank-d bundle and the target because $\widetilde{i}$ is regular of codimension d. A surjection of locally free sheaves of equal rank is an isomorphism, its kernel being locally free of rank zero. So the canonical map is an isomorphism, and we may use it below.

The two closed subschemes $g^{-1}(\widetilde{Z})$ and $(\varphi \circ g)^{-1}(Z)$ of X' coincide because $\widetilde{\mathcal{I}} = \mathcal{I}\mathcal{O}_{\widetilde{X}}$ and pullback of ideals is transitive, so the target group is the same and both homomorphisms are the composite of definition 13.3.6 for one and the same pair (Z', X'). In particular they use the same specialization σ' and the same cone $C_{Z'}X'$, neither of which mentions the ambient scheme at all.

What must be compared is the bundle and the embedding of the cone in it. Write $h\colon Z' \to Z$ and $\widetilde{h}\colon Z' \to \widetilde{Z}$ for the structure morphisms, so $h = \varphi_Z \circ \widetilde{h}$. The hypothesis gives a canonical isomorphism $\widetilde{h}^*(\widetilde{\mathcal{I}}/\widetilde{\mathcal{I}}^2) \cong \widetilde{h}^*\varphi_Z^*(\mathcal{I}/\mathcal{I}^2) = h^*(\mathcal{I}/\mathcal{I}^2)$, that is $\widetilde{N}' \cong N'$ as bundles on Z', and hence π' is the same projection in both constructions.

It remains to see that the closed immersion j of lemma 12.3.13 is carried to the other by this isomorphism. That immersion is induced by a surjection of graded $\mathcal{O}_{Z'}$-algebras out of $\mathrm{Sym}^\bullet$ of the pullback conormal sheaf, and such a morphism is determined by its degree-one part. For i the degree-one part sends the class of a local section α of $\mathcal{I}$ to the class of $\alpha\mathcal{O}_{X'}$ in $\mathcal{I}'/\mathcal{I}'^2$; for $\widetilde{i}$ it sends the class of a local section of $\widetilde{\mathcal{I}}$ to the class of its extension to X'. The hypothesis isomorphism identifies the class of α with the class of $\alpha\mathcal{O}_{\widetilde{X}}$, and $(\alpha\mathcal{O}_{\widetilde{X}})\mathcal{O}_{X'} = \alpha\mathcal{O}_{X'}$ by transitivity of extension of ideals along $X' \to \widetilde{X} \to X$. So the two degree-one parts correspond, the two immersions j agree, and the three factors $(\pi'^*)^{-1}$, j_*, σ' agree one by one.

The hypothesis is satisfied whenever φ is flat, by proposition 5.1.49. Where φ is not flat, the hypothesis is checked by hand at the point of use: this happens at the inclusion of a fibre in theorem 13.4.7, and at the projection $g^*E \to E$ in lemma 13.4.5, where g is an arbitrary morphism.

Three lemmas stand between here and the composition rule. The first is the only place a genuine commutativity statement is needed, and it is needed only for a divisor, where the construction delivers it directly: specialization *is* intersection with a Cartier divisor (definition 13.2.3), so two such intersections commute by theorem 11.3.2.

Lemma 13.4.4: The Gysin Map Commutes with Intersection by a Divisor

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$, let $g\colon X' \to X$ be a morphism with $Z' = g^{-1}(Z)$, and let D be a Cartier divisor on X' whose restriction to Z' is again a Cartier divisor. Then for every $\alpha \in A_k(X')$,

$$i^!\big(D \cdot \alpha\big) \;=\; D \cdot \big(i^!\alpha\big) \quad \text{in } A_{k-d-1}(Z')$$

both sides being read through corollary 11.4.5, on X' for the left and on the closed subscheme Z' for the right.
The hypothesis on $D|_{Z'}$ is needed by the proof, not by the statement: both sides above are defined for any Cartier D through corollary 11.4.5, but Steps 2 and 3 pass through the bundle N', which is not a closed subscheme of X', so that corollary cannot carry them and D has to be an honest Cartier divisor on Z' to be pulled back along π'. Removing the hypothesis would need an intersection theory for pseudo-divisors (definition 11.1.5), which this book records but does not develop. The one place the lemma is used, in theorem 13.4.7, checks the hypothesis explicitly.

***Proof*:**
Write $M = M^\circ_{Z'}X'$ for the deformation space of definition 13.1.4, with blow-down $\rho\colon M \to X'$, fibre $D_\infty = C_{Z'}X'$ over ∞, and $\kappa\colon C_{Z'}X' \hookrightarrow N'$, $\pi'\colon N' \to Z'$ as in definition 13.3.6, so that $i^! = (\pi'^*)^{-1} \circ \kappa_* \circ \sigma'$. Throughout, a Cartier divisor is intersected against classes on closed subschemes of the ambient through corollary 11.4.5; the relevant restrictions are in general *not* Cartier on those subschemes, and it is to avoid needing them to be that the corollary was stated.

Step 0: ρ^*D is a Cartier divisor on M. The blow-down is not flat, its fibre at infinity being a cone, so this needs an argument. Over $\mathbb{A}^1$ the map is the projection $X' \times \mathbb{A}^1 \to X'$, which is flat, and flat pullback of a Cartier divisor is Cartier. Over the chart at infinity, lemma 13.1.2 and (13.1) present $\mathcal{O}_M$ as the extended Rees algebra, a graded subsheaf of $\mathcal{O}_{X'}[u, u^{-1}]$. A local datum of D is a ratio $f = a/b$ with a and b non-zero divisors on $\mathcal{O}_{X'}$, the divisor not being assumed effective. Each of a and b is a non-zero divisor on the free module $\mathcal{O}_{X'}[u, u^{-1}]$, hence on any subsheaf of it; so $\rho^\# f$ is again such a ratio and ρ^*D is Cartier.

Step 1: specialization. Let $\beta \in A_{k+1}(M)$ be a lift of α in the sense of definition 13.2.3, so that β restricts to $q^*\alpha$ on $X' \times \mathbb{A}^1$. Then $\rho^*D \cdot \beta$ is a lift of $D \cdot \alpha$: restriction along that open immersion is flat pullback of relative dimension zero, proposition 11.3.3(2) applies with no hypothesis on supports, and ρ^*D restricts to q^*D there by theorem 13.1.5(1). Hence, by theorem 13.2.4 and by theorem 11.3.2 applied on M to the Cartier divisors D_∞ and ρ^*D, the first by theorem 13.1.5(2) and the second by Step 0,

$$\sigma'\big(D \cdot \alpha\big) \;=\; D_\infty \cdot \big(\rho^*D \cdot \beta\big) \;=\; \rho^*D \cdot \big(D_\infty \cdot \beta\big) \;=\; \rho^*D \cdot \sigma'(\alpha)$$

an identity of classes on the cone, the refined form of theorem 11.3.2 placing both sides in the Chow group of $|D_\infty| \cap |\rho^*D| \cap \operatorname{supp}\beta$.

Step 2: pushforward along the cone. On N' put $D_{N'} = \pi'^*D$, the flat pullback along π' of D restricted to Z'; it is a Cartier divisor there, π' being flat. Its restriction to the cone and the restriction of ρ^*D agree, both being computed from the line bundle $\mathcal{O}_{X'}(D)$ pulled back to the cone with its canonical section. A closed immersion carries a cycle to itself, so corollary 11.4.5,

applied to $C_{Z'}X' \subseteq N'$, gives

$$\kappa_*\big(\rho^* D \cdot \gamma\big) \;=\; D_{N'} \cdot \kappa_* \gamma$$

for every class γ on the cone, with no hypothesis on its support. This is the step at which the projection formula would otherwise be invoked, and proposition 11.3.3(1) could not be: its hypothesis is that no component of the support maps into $|D|$, which $\sigma'(\alpha)$ need not satisfy.

Step 3: the bundle inverse. Since π' is flat, proposition 11.3.3(2) gives $\pi'^*\big(D \cdot \delta\big) = D_{N'} \cdot \pi'^* \delta$ for every $\delta \in A_*(Z')$, again with no support hypothesis. Applying this to $\delta = i^!\alpha$ and using Steps 1 and 2,

$$\pi'^*\Big(D \cdot i^!\alpha\Big) = D_{N'} \cdot \pi'^*\big(i^!\alpha\big) = D_{N'} \cdot \kappa_*\sigma'(\alpha) = \kappa_*\sigma'\big(D \cdot \alpha\big) = \pi'^*\Big(i^!\big(D \cdot \alpha\big)\Big)$$

and π'^* is injective by theorem 10.4.6, which gives the identity.

The second lemma settles the composition rule when the outer embedding is the zero section of a vector bundle. This is the case in which the normal bundle of the composite genuinely splits, and it is where the conormal sequence of a chain does its work.

Lemma 13.4.5: Composition Through a Zero Section

Let E be a vector bundle of rank $e \geq 1$ on an algebraic scheme Y with zero section $\zeta\colon Y \hookrightarrow E$, and let $i\colon Z \hookrightarrow Y$ be a regular embedding of codimension $d \geq 1$. Let $g\colon S \to Y$ be a morphism, $E' = g^*E$ with projection $\pi'\colon E' \to S$, and let $\mathrm{pr}\colon E' \to E$ be the induced morphism. Then for every $\alpha \in A_k(E')$,

$$(\zeta \circ i)^!_{\mathrm{pr}}(\alpha) \;=\; i^!_g\Big(\zeta^!_{\mathrm{pr}}(\alpha)\Big) \quad \text{in } A_{k-d-e}\big(g^{-1}(Z)\big)$$

***Proof*:**
Write $S_Z = g^{-1}(Z)$. The preimage of Y under pr is the zero section of E', which we identify with S; the preimage of Z is S_Z. Both refined maps are therefore defined and land as stated. That $\zeta^!_{\mathrm{pr}} = (\pi'^*)^{-1}$ is not merely the observation that the normal cone of a zero section is the bundle itself, which is the case $\mathcal{I} = 0$ of (13.6) below: that identifies the cone and the bundle and makes the immersion of lemma 12.3.13 an identity, but leaves $\zeta^!$ equal to $(\pi'^*)^{-1} \circ \sigma'$, and specialization is emphatically not the identity in general (example 13.2.5). What settles it is that the preimage of Y under pr is the zero section of E', a regular embedding of codimension e, so lemma 13.4.3 identifies $\zeta^!_{\mathrm{pr}}$ with the refined Gysin map of that zero section along id, which is its plain Gysin map (proposition 13.3.8); and $\pi'\colon E' \to S$ is smooth of relative dimension e with the zero section as a section, so theorem 13.4.2 gives $\zeta^! \circ \pi'^* = \mathrm{id}$, that is $\zeta^! = (\pi'^*)^{-1}$.

Step 1: the cone of the composite splits off the bundle. Let $\mathcal{I}$ be the ideal sheaf of S_Z in S and let $\mathcal{E}$ be the sheaf of sections of E' over S, so that $E' = \operatorname{Spec}_S \mathcal{S}^\bullet$ with $\mathcal{S}^\bullet = \mathrm{Sym}^\bullet(\mathcal{E}^\vee)$, and $\mathcal{S}^0 = \mathcal{O}_S$ and $\mathcal{S}^1 = \mathcal{E}^\vee$. The ideal $\mathcal{J}$ of S_Z in E' is generated by $\mathcal{I}$ in degree zero together with all of $\mathcal{S}^1$: a function vanishes on the zero section over S_Z exactly when its degree-zero part lies in $\mathcal{I}$. Consequently

$$\mathcal{J}^n \;=\; \bigoplus_{q \leq n} \mathcal{I}^{n-q}\,\mathcal{S}^q \;\oplus\; \bigoplus_{q > n} \mathcal{S}^q, \qquad \mathcal{J}^n/\mathcal{J}^{n+1} \;=\; \bigoplus_{p+q=n} \big(\mathcal{I}^p/\mathcal{I}^{p+1}\big) \otimes \mathcal{S}^q$$

so that the total graded algebra factors, $\bigoplus_n \mathcal{J}^n/\mathcal{J}^{n+1} = \big(\bigoplus_p \mathcal{I}^p/\mathcal{I}^{p+1}\big) \otimes_{\mathcal{O}_{S_Z}} \mathcal{S}^\bullet$. Taking Spec and using definition 12.3.6 this reads

$$C_{S_Z}E' \;\cong\; C_{S_Z}S \times_{S_Z} E'|_{S_Z} \tag{13.6}$$

Applied with $S = Y$ and $g = \mathrm{id}$ it identifies the normal bundle of the composite as $N_Z E = N_Z Y \oplus i^*E$, which is the splitting of proposition 5.1.47 for the chain $Z \subseteq Y \subseteq E$; the splitting is the one induced by the bundle projection.

Step 2: reduction. By theorem 10.4.6 every class on E' is $\pi'^*\beta$ for a unique $\beta \in A_{k-e}(S)$, and by linearity we may take $\beta = [V]$ for $V \subseteq S$ a subvariety. Both sides of the assertion commute with proper pushforward along $V \hookrightarrow S$ and its base change $V \times_S E' \hookrightarrow E'$, by theorem 13.3.11(1), so we may replace S by V. Then S is a variety, $\alpha = [E']$, and $\zeta^!\alpha = [S]$.

Step 3: comparison of fundamental cycles. Write $h\colon S_Z \to Z$ for the induced morphism, $r\colon h^*N_Z Y \to S_Z$ and $q\colon h^*N_Z E \to h^*N_Z Y$ for the projections, the latter using the splitting of Step 1, so that $r \circ q$ is the projection of $h^*N_Z E$. Both S and E' are varieties, so theorem 13.2.7 gives $\sigma[S] = [C_{S_Z}S]$ and $\sigma[E'] = [C_{S_Z}E']$. By (13.6) the second cone is the preimage of the first under q, so $q^*[C_{S_Z}S] = [C_{S_Z}E']$ by definition 10.3.3. Now definition 13.3.6 reads the two Gysin classes as

$$r^*\big(i^![S]\big) = [C_{S_Z}S], \qquad (r\circ q)^*\big((\zeta i)^![E']\big) = [C_{S_Z}E']$$

Combining the three displays, $(r\circ q)^*\big((\zeta i)^![E']\big) = q^*r^*\big(i^![S]\big) = (r\circ q)^*\big(i^![S]\big)$ by proposition 10.3.5(3), and $(r\circ q)^*$ is injective by theorem 10.4.6. Hence $(\zeta i)^![E'] = i^![S] = i^!\zeta^![E']$, which by Step 2 is the assertion in general.

The third lemma is the only input that is not about Gysin maps at all. It says that cutting a class on $X \times \mathbb{P}^1$ by a fibre gives an answer that does not depend on which fibre.

Lemma 13.4.6: Cutting by a Fibre of $X \times \mathbb{P}^1$ Is Independent of the Fibre

Let X be an algebraic scheme and for $t \in \mathbb{P}^1$ a closed point let D_t denote the Cartier divisor $X \times \{t\}$ on $X \times \mathbb{P}^1$. Then for every $\beta \in A_k(X \times \mathbb{P}^1)$ the class

$$D_t \cdot \beta \;\in\; A_{k-1}\big(X \times \{t\}\big) \;=\; A_{k-1}(X)$$

is the same for all t, the identification being the projection $X \times \{t\} \to X$.

***Proof*:**
Write $X \times \mathbb{P}^1 = \mathbb{P}(\mathcal{O}_X^{\oplus 2})$ with projection p and tautological class ξ; for the trivial bundle $\mathcal{O}_{\mathbb{P}(E)}(1)$ is pulled back from $\mathbb{P}^1$, and D_t is the divisor of the section of it cutting out t, so $\mathcal{O}(D_t) = \mathcal{O}_{\mathbb{P}(E)}(1)$ for every t. By theorem 12.1.9 with $r = 1$ there are unique classes $\alpha_0 \in A_{k-1}(X)$ and $\alpha_1 \in A_k(X)$ with

$$\beta \;=\; p^*\alpha_0 \;+\; \xi \cap p^*\alpha_1$$

It suffices to evaluate $D_t\cdot$ on each summand. For the first, take $\alpha_0 = [V]$ with $V \subseteq X$ a subvariety; then $p^*[V] = [V \times \mathbb{P}^1]$, which is not contained in $|D_t|$, so definition 11.2.1(1) computes $D_t \cdot p^*[V] = [V \times \{t\}]$, the divisor of the restricted section, and under $X \times \{t\} \cong X$ this is $[V]$. For the second, $D_t \cdot (\xi \cap p^*\alpha_1) = \xi^2 \cap p^*\alpha_1$ once pushed into $A_{k-1}(X \times \mathbb{P}^1)$, and $\xi^2 = 0$ by theorem 12.2.9, the bundle being trivial. To descend that vanishing to the refined class on $X \times \{t\}$, note that the

first computation identifies the pushforward $\iota_{t*}\colon A_m(X) = A_m(X \times \{t\}) \to A_m(X \times \mathbb{P}^1)$ with $\gamma \mapsto \xi \cap p^*\gamma$, and that map is injective by the uniqueness clause of theorem 12.1.9, being the restriction of the isomorphism Ψ to the summand $\alpha_0 = 0$. Hence the refined class vanishes as well, and $D_t \cdot \beta = \alpha_0$ for every t, as we sought to show.

Theorem 13.4.7: Composition of Gysin Maps

Let $i\colon Z \hookrightarrow Y$ and $j\colon Y \hookrightarrow P$ be regular embeddings of codimensions $d \geq 1$ and $e \geq 1$. Then $j \circ i$ is a regular embedding of codimension $d+e$, and for every morphism $a\colon W \to P$, writing $W_Y = a^{-1}(Y)$, $W_Z = a^{-1}(Z)$ and $a'\colon W_Y \to Y$ for the induced morphism,

$$(j \circ i)^!_a \;=\; i^!_{a'} \circ j^!_a \;:\; A_k(W) \longrightarrow A_{k-d-e}(W_Z)$$

***Proof*:**
That $j \circ i$ is a regular embedding of codimension $d+e$ is the first assertion of proposition 5.1.47. Both sides commute with proper pushforward (theorem 13.3.11(1)), and $A_k(W)$ is generated by the classes of k-dimensional subvarieties, so it suffices to prove the identity for W a variety and the class $[W]$.

The two deformations. Let $M = M^\circ_Y P$ and $M' = M^\circ_{W_Y} W$ be the deformation spaces of definition 13.1.4, with projections to $\mathbb{P}^1$ written π and π'. The morphism a induces $\widetilde{a}\colon M' \to M$ over $\mathbb{P}^1$ by lemma 13.2.6, whose hypothesis $W_Y = a^{-1}(Y)$ holds by definition. Let

$$\chi \;:\; Z \times \mathbb{P}^1 \xhookrightarrow{i \times \mathrm{id}} Y \times \mathbb{P}^1 \hookrightarrow M$$

be the composite of $i \times \mathrm{id}$ with the closed immersion of theorem 13.1.5(4). Its first factor is a regular embedding of codimension d, being the base change of i along the flat projection $Y \times \mathbb{P}^1 \to Y$ (proposition 5.1.49); its second is a regular embedding of codimension e. This last point needs the charts rather than the fibres: $\pi^{-1}(\mathbb{A}^1)$ is open, and there the immersion is $j \times \mathrm{id}$, but $\pi^{-1}(\infty)$ is closed, so regularity of the immersion into it says nothing about a neighbourhood. On the complementary chart $\pi^{-1}(\mathbb{P}^1 \setminus \{0\})$, lemma 13.1.2 presents the coordinate ring as an extended Rees algebra $\mathcal{R}$, in which the ideal of $Y \times \mathbb{P}^1$ is generated by $g_1/u, \dots, g_e/u$ for $g_1, \dots, g_e$ a local regular sequence cutting out Y in P. Here u is a non-zero divisor on $\mathcal{R}$ and $\mathcal{R}/u\mathcal{R} = \mathrm{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)$, in which the images of the g_m/u are the coordinates and so form a regular sequence; hence $u, g_1/u, \dots, g_e/u$ is a regular sequence. Regularity of an embedding is checked at each point (definition 5.1.43), and the points of $Y \times \mathbb{P}^1$ with $u \neq 0$ lie over $\mathbb{A}^1$, where the immersion is $j \times \mathrm{id}$ and regularity is already settled. So fix a point of $Y \times \mathbb{P}^1$ with $u = 0$ and localize $\mathcal{R}$ there; permuting a regular sequence in a Noetherian local ring leaves it regular, so $g_1/u, \dots, g_e/u$ is a regular sequence in that local ring. So χ is a regular embedding of codimension $d+e$, again by the chain result cited above, and $\widetilde{a}^{-1}(Z \times \mathbb{P}^1) = W_Z \times \mathbb{P}^1$.

Cutting by a fibre. For a closed point $t \in \mathbb{P}^1$ let D_t be the fibre $\pi'^{-1}(t)$ on M'. It is an effective Cartier divisor: for $t = \infty$ by theorem 13.1.5(2), and for $t \neq \infty$ because M' is a variety, as the proof of theorem 13.2.7 records, so that any nonzero local equation is a non-zero divisor. Theorem 13.1.5(1),(2) identify the fibres. Over $\mathbb{A}^1$ the fibre is $W \times \{t\}$, which is reduced, so definition 11.2.1(1) computes $D_t \cdot [M']$ as its fundamental cycle with multiplicity one; over ∞

the same intersection is by definition the specialization, which theorem 13.2.7 evaluates. So

$$D_t \cdot [M'] \;=\; [M'_t] \;=\; \begin{cases} [W] & t \neq \infty \\ [C_{W_Y} W] & t = \infty \end{cases} \tag{13.7}$$

Now apply $\chi^!$ along $\widetilde{a}$. The scheme M'_t maps to M_t, the inclusion $M_t \hookrightarrow M$ pulls $Z \times \mathbb{P}^1$ back to $Z \times \{t\}$, and the induced embedding is $j \circ i$ for $t \neq \infty$ and $\widetilde{j} \circ i$ for $t = \infty$, where $\widetilde{j}$ is the zero section of $N_Y P$; both are regular of codimension $d + e$. So lemma 13.4.3, applied with φ the inclusion of the fibre, gives

$$\chi^!\big(D_t \cdot [M']\big) \;=\; \begin{cases} (j \circ i)^! [W] & t \neq \infty \\ (\widetilde{j} \circ i)^! [C_{W_Y} W] & t = \infty \end{cases} \tag{13.8}$$

The value at infinity. The cone $C_{W_Y} W$ is a closed subscheme of the pullback bundle $(a')^* N_Y P$ over W_Y (lemma 12.3.13), and the restriction of $\widetilde{a}$ to the fibre over ∞ is the composite of that immersion with the bundle map $(a')^* N_Y P \to N_Y P$. Lemma 12.3.14 is stated for a closed subscheme and a here is an arbitrary morphism, so the identification is made directly, by the same argument: both morphisms are induced by graded surjections out of $\operatorname{Sym}^\bullet(\mathcal{I}_Y / \mathcal{I}_Y^2)$, using proposition 12.3.11 for the regular j, so both are determined by their degree-one components, and in each case that component is the map induced by $\mathcal{I}_Y \mathcal{O}_W = \mathcal{I}_{W_Y}$. Lemma 13.4.5, stated for an arbitrary class on that bundle, therefore applies with $E = N_Y P$ and $S = W_Y$ to the pushforward of $[C_{W_Y} W]$; and theorem 13.3.11(1), for the closed immersion $C_{W_Y} W \hookrightarrow (a')^* N_Y P$, says that computing before or after that pushforward gives the same answer, the induced morphism on the preimages of Z being the identity of W_Z because the vertex of $C_{W_Y} W$ is W_Y, the cone algebra being generated in degree one. This gives

$$(\widetilde{j} \circ i)^! [C_{W_Y} W] \;=\; i^!\Big(\widetilde{j}^! [C_{W_Y} W]\Big) \;=\; i^!_{a'}\Big(j^!_a [W]\Big)$$

the last equality because $\widetilde{j}^!$ is the inverse of the bundle pullback and $\sigma[W] = [C_{W_Y} W]$, which is exactly how definition 13.3.6 computes $j^!_a [W]$.

Independence of t. By lemma 13.4.4, applied to the regular embedding χ and the divisor D_t, whose restriction to $W_Z \times \mathbb{P}^1$ is the Cartier divisor $W_Z \times \{t\}$,

$$\chi^!\big(D_t \cdot [M']\big) \;=\; D_t \cdot \big(\chi^! [M']\big)$$

and $\chi^! [M']$ is a class on $W_Z \times \mathbb{P}^1$ not depending on t, so lemma 13.4.6 makes the right-hand side independent of t.

One point of bookkeeping remains. Lemma 13.4.4 records its identity in $A_*(W_Z \times \mathbb{P}^1)$, whereas (13.8) produces classes on $W_Z \times \{t\}$; the two are related by the pushforward ι_{t*} along the closed immersion $W_Z \times \{t\} \hookrightarrow W_Z \times \mathbb{P}^1$, through theorem 13.3.11(1) applied to $M'_t \hookrightarrow M'$. That is harmless, because the proof of lemma 13.4.6 identifies ι_{t*} with $\gamma \mapsto \xi \cap p^* \gamma$, which is one and the same map for every t and is injective. Comparing the two lines of (13.8) at $t \neq \infty$ and at $t = \infty$, their images under ι_{t*} agree, hence so do the classes themselves, and $(j \circ i)^! [W] = i^!_{a'}\big(j^!_a [W]\big)$, as we sought to show.

Commutativity now follows, and the route is the one announced at the start of the section: the two embeddings are made into a single embedding of a product, which factors in two ways.

Corollary 13.4.8: Commutativity of Gysin Maps

Let $i\colon Z \hookrightarrow P$ and $i'\colon Z' \hookrightarrow P'$ be regular embeddings of codimensions $d \geq 1$ and $d' \geq 1$, let W be an algebraic scheme, and let $a\colon W \to P$ and $b\colon W \to P'$ be morphisms. Put $W_1 = a^{-1}(Z)$, $W_2 = b^{-1}(Z')$ and $W_{12} = W_1 \cap W_2$. Then for every $\alpha \in A_k(W)$,

$$i^!_{a|_{W_2}}\bigl(i'^!_b \alpha\bigr) \;=\; i'^!_{b|_{W_1}}\bigl(i^!_a \alpha\bigr) \quad \text{in } A_{k-d-d'}(W_{12})$$

***Proof*:**
Let $c = (a, b)\colon W \to P \times P'$. Lemma 13.4.1 makes $i \times i'$ a regular embedding of codimension $d + d'$ and exhibits its two factorizations through $Z \times P'$ and through $P \times Z'$, all four factors being regular embeddings. The preimages under c are

$$c^{-1}(Z \times P') = W_1, \qquad c^{-1}(P \times Z') = W_2, \qquad c^{-1}(Z \times Z') = W_{12},$$

because the ideal of $Z \times P'$ is $\mathcal{I}_Z \mathcal{O}_{P\times P'}$ and $\mathrm{pr}_1 \circ c = a$, and symmetrically. The third follows from the first two: the ideal of $Z \times Z'$ is the sum $\mathcal{I}_Z \mathcal{O}_{P\times P'} + \mathcal{I}_{Z'} \mathcal{O}_{P\times P'}$, so $Z \times Z'$ is the scheme-theoretic intersection of $Z \times P'$ and $P \times Z'$, and extension of ideals along c carries a sum of ideals to the sum of the extensions.

Each of the four factors is the preimage of i or of i' along a projection off a product. Such a projection is the base change of a structure morphism to $\operatorname{Spec} \overline{k}$, hence flat, so lemma 13.4.3 applies to each factor and identifies its refined Gysin map with that of i or of i' along the corresponding composite. Explicitly, with $\varphi = \mathrm{pr}_1$ one gets $(i \times \mathrm{id}_{P'})^!_c = i^!_a$ and $(i \times \mathrm{id}_{Z'})^!_{c''} = i^!_{a|_{W_2}}$ for $c''\colon W_2 \to P \times Z'$, and with $\varphi = \mathrm{pr}_2$ one gets $(\mathrm{id}_P \times i')^!_c = i'^!_b$ and $(\mathrm{id}_Z \times i')^!_{c'} = i'^!_{b|_{W_1}}$ for $c'\colon W_1 \to Z \times P'$. Here c' and c'' are the morphisms induced by c on the preimages W_1 and W_2, so that $\mathrm{pr}_2 \circ c' = b|_{W_1}$ and $\mathrm{pr}_1 \circ c'' = a|_{W_2}$; they are exactly the morphisms that theorem 13.4.7 calls a', for the two factorizations respectively.

Apply theorem 13.4.7 to each factorization in turn, with c as the morphism to $P \times P'$. The first gives $(i \times i')^!_c = i'^!_{b|_{W_1}} \circ i^!_a$ and the second gives $(i \times i')^!_c = i^!_{a|_{W_2}} \circ i'^!_b$. The left sides agree, so the right sides do, which is the assertion.

Exercise 13.4.1

1. Theorem 13.4.2 assumes $e \geq 1$, and so does definition 13.3.6. Show that for $e = 0$ a section s of a smooth $\pi\colon P \to S$ of relative dimension zero is an open and closed immersion, so that the only sensible reading of $s^!$ is flat pullback along s, and that with that reading $s^! \circ \pi^* = \mathrm{id}$ follows from proposition 10.3.5(3) with no deformation at all.

2. In lemma 13.4.1, show that the normal bundle of $i \times i'$ is $\mathrm{pr}_1^* N \oplus \mathrm{pr}_2^* N'$, and that the two factorizations exhibit the two summands as the normal bundles of the two intermediate stages. Which of the two summands does lemma 13.4.3 match to N when applied with $\varphi = \mathrm{pr}_1$?

3. Let $i\colon Z \hookrightarrow P$ be a regular embedding of codimension $d \geq 1$ and take $P' = P$ and $i' = i$, but keep two distinct morphisms $a, b\colon W \to P$. Write out what corollary 13.4.8 asserts, and identify the regular embedding of $P \times P$ to which lemma 13.4.1 applies. Then show that for $a = b$ the identity degenerates to a tautology, and explain why the corollary is in no case a

statement about $i^!$ commuting with itself as an endomorphism.

4. Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ and $\varphi\colon U \hookrightarrow X$ an open immersion with $Z \subseteq U$. Check that φ satisfies the hypotheses of lemma 13.4.3, and deduce that the refined Gysin map of i may be computed in any open neighbourhood of Z.

5. In theorem 13.4.7 verify directly, from the definition of a regular embedding, that a local regular sequence for Z in Y lifted to P and appended to one for Y in P generates the ideal of Z in P, and that the concatenation is regular. Then write out the sequence $0 \to N_Z Y \to N_Z P \to N_Y P|_Z \to 0$ of proposition 5.1.47 for $Z = \{0\} \subseteq Y = \mathbb{A}^1 \subseteq P = \mathbb{A}^2$, identifying all three bundles and the splitting.

14

Intersection Products

The refined Gysin map of chapter 13 intersects a cycle with a regularly embedded subscheme. It is not yet a product: it takes a cycle on the ambient scheme and a regular embedding, not two cycles. The step that converts it into one is a piece of bookkeeping that needs nothing and gives everything.

For X smooth, the diagonal $\delta\colon X \hookrightarrow X \times X$ is a regular embedding, and two cycles α, β on X determine a single cycle $\alpha \times \beta$ on $X \times X$. Applying $\delta^!$ to it lands back on X and, as this chapter shows, the result is bilinear, commutative, associative, and has $[X]$ as a unit. That is a ring, and it is the Chow ring $A^*(X)$: the object the classical geometers were computing in when they counted, and which *Algebraic Geometry* [9] could construct only on a surface, by hand.

Nothing here needs a moving lemma. The cycles are never perturbed; the diagonal is what gets degenerated, and chapter 13 already did that work. The moving lemma is stated in its place, both because it is true and because seeing what it would have been used for is the clearest way to see why the deformation replaced it.

The chapter closes by paying two debts. The self-intersection formula computes i^*i_* as capping with the top Chern class, which recovers the $E^2 = -1$ of a blown-up surface as a special case of a general theorem; and the agreement theorem shows that on a smooth projective surface this product is the one built cohomologically upstream, so the surface theory that book developed by hand is subsumed rather than paralleled.

14.1 The Intersection Product

The first ingredient is a way of assembling a cycle on X and a cycle on Y into a single cycle on $X \times Y$. On cycles the rule is forced, $[V] \times [W] = [V \times W]$, and the content is that it survives rational equivalence. The mechanism that makes it survive is flat pullback along the two projections, which is already known to preserve rational equivalence (proposition 10.3.7), so the whole construction is

arranged to be a composite of operations that do.

Lemma 14.1.1: Projections of a Product Are Flat

Let X and Y be algebraic schemes with Y pure of dimension l, and let $p\colon X \times Y \to X$ be the projection. Then p is flat of relative dimension l, and for every k-dimensional subvariety $V \subseteq X$ the scheme-theoretic preimage is $p^{-1}(V) = V \times Y$, so that

$$p^*[V] \;=\; [V \times Y]$$

the fundamental cycle of $V \times Y$, which is pure of dimension $k + l$.

***Proof*:**

The product is taken over $\operatorname{Spec}\overline{k}$, so p is the base change of the structure morphism $Y \to \operatorname{Spec}\overline{k}$ along $X \to \operatorname{Spec}\overline{k}$. Every module over a field is free, hence flat, so $Y \to \operatorname{Spec}\overline{k}$ is flat, and flatness is stable under base change; thus p is flat. The fibre of p over a point $x \in X$ is $Y \times_{\operatorname{Spec}\overline{k}} \operatorname{Spec} k(x)$, which is pure of dimension l, extension of the ground field preserving the dimension of a scheme of finite type. So p is flat of relative dimension l in the sense of definition 10.3.3.

The scheme-theoretic preimage of V is $p^{-1}(V) = (X \times Y) \times_X V = V \times Y$, and definition 10.3.3 computes $p^*[V]$ as the fundamental cycle of that preimage. For the dimension, restrict p to V: the induced morphism $V \times Y \to V$ is again flat with all fibres of pure dimension l, and its base V is a variety, so proposition 10.3.2 applies and every irreducible component of $V \times Y$ has dimension $k + l$, as we sought to show.

The lemma gives both the cycle and the guarantee that it has the expected dimension, so the exterior product can be defined by the geometric formula and its bookkeeping checked afterwards.

Definition 14.1.2: The Exterior Product of Cycles

Let X and Y be algebraic schemes. For a k-dimensional subvariety $V \subseteq X$ and an l-dimensional subvariety $W \subseteq Y$, the product $V \times W$ is a closed subscheme of $X \times Y$, pure of dimension $k + l$ by lemma 14.1.1. The *exterior product* of $[V]$ and $[W]$ is its fundamental cycle (definition 10.1.2),

$$[V] \times [W] \;=\; [V \times W] \;\in\; Z_{k+l}(X \times Y)$$

Extending bilinearly gives the exterior product of cycles

$$\times \;:\; Z_k(X) \times Z_l(Y) \longrightarrow Z_{k+l}(X \times Y)$$

Example 14.1.3: The Two Rulings of a Quadric Surface

Take $X = Y = \mathbb{P}^1$. By theorem 10.5.2, $A_1(\mathbb{P}^1) = \mathbb{Z}\,[\mathbb{P}^1]$ and $A_0(\mathbb{P}^1) = \mathbb{Z}\,[\mathrm{pt}]$, the second generated by the class of any closed point. Fix closed points $p, q \in \mathbb{P}^1$. The four exterior products of generators are

$$[\mathbb{P}^1] \times [\mathbb{P}^1] = [\mathbb{P}^1 \times \mathbb{P}^1], \qquad [\mathbb{P}^1] \times [q] = [\mathbb{P}^1 \times \{q\}], \qquad [p] \times [\mathbb{P}^1] = [\{p\} \times \mathbb{P}^1], \qquad [p] \times [q] = [(p, q)]$$

each product of varieties being a variety here: $\mathbb{P}^1 \times \mathbb{P}^1$ is covered by four copies of $\mathbb{A}^2$, any two of

which meet, so it is irreducible, and it is reduced because those charts are.
The geometry is visible through the Segre embedding $\mathbb{P}^1 \times \mathbb{P}^1 \hookrightarrow \mathbb{P}^3$, $([a:b],[c:d]) \mapsto [ac:ad:bc:bd]$, whose image is the quadric surface $\{x_0x_3 = x_1x_2\}$. The middle two classes are the classes of the two families of lines on that quadric: $\mathbb{P}^1 \times \{q\}$ and $\{p\} \times \mathbb{P}^1$ each map to a line, and two members of the same family are disjoint while members of opposite families meet in one point. The first class is the fundamental class of the surface and the last is the class of a point.
Not every subvariety of a product is a product. The diagonal $\Delta = \{([a:b],[a:b])\} \subseteq \mathbb{P}^1 \times \mathbb{P}^1$ is a curve meeting both families, so it is neither of the form $V \times \mathbb{P}^1$ nor of the form $\mathbb{P}^1 \times W$; its class is nonetheless a sum of exterior products, $[\Delta] = [\mathbb{P}^1] \times [q] + [p] \times [\mathbb{P}^1]$, which exercise 14.1.1 (2) verifies by exhibiting a rational function.

Rational equivalence is not visible in definition 14.1.2, which is written on cycles. The route to it is to recognize the exterior product as a composite of a flat pullback and a proper pushforward, one factor at a time.

Proposition 14.1.4: The Exterior Product Descends to Rational Equivalence

Let X and Y be algebraic schemes.

1. *Flat descriptions.* Let $W \subseteq Y$ be an l-dimensional subvariety, let $p_W \colon X \times W \to X$ be the projection and $\iota_W \colon X \times W \hookrightarrow X \times Y$ the closed immersion. Then for every $\alpha \in Z_k(X)$,
$$\alpha \times [W] \;=\; (\iota_W)_*\big(p_W^*\alpha\big)$$
Symmetrically, if $V \subseteq X$ is a k-dimensional subvariety, $q_V \colon V \times Y \to Y$ the projection and $\iota_V \colon V \times Y \hookrightarrow X \times Y$ the closed immersion, then $[V] \times \beta = (\iota_V)_*(q_V^*\beta)$ for every $\beta \in Z_l(Y)$.

2. *Descent.* The exterior product carries $\mathrm{Rat}_k(X) \times Z_l(Y)$ and $Z_k(X) \times \mathrm{Rat}_l(Y)$ into $\mathrm{Rat}_{k+l}(X \times Y)$, so it induces a bilinear map
$$\times \;:\; A_k(X) \times A_l(Y) \longrightarrow A_{k+l}(X \times Y)$$

3. *Closed immersions.* If $f \colon X' \hookrightarrow X$ and $g \colon Y' \hookrightarrow Y$ are closed immersions of algebraic schemes, then $(f \times g)_*(\alpha \times \beta) = f_*\alpha \times g_*\beta$ for all $\alpha \in A_k(X')$ and $\beta \in A_l(Y')$.

***Proof*:**

1. Both sides are additive in α, so it suffices to take $\alpha = [V]$ for a k-dimensional subvariety $V \subseteq X$. The subscheme W is a variety, hence pure of dimension l, so lemma 14.1.1 applies to p_W and gives $p_W^*[V] = [V \times W]$, the fundamental cycle of $V \times W$ computed inside $X \times W$. Its components are the components of $V \times W$, each carrying the same length whether $V \times W$ is regarded in $X \times W$ or in $X \times Y$, and each maps isomorphically to itself under the closed immersion ι_W; so $(\iota_W)_*[V \times W] = [V \times W]$ by definition 10.2.1, the field extension in each degree being trivial. This is $[V] \times [W]$. The symmetric statement is the same argument with the roles of the two factors exchanged.

2. Let $\alpha \in \mathrm{Rat}_k(X)$ and $\beta \in Z_l(Y)$. Writing $\beta = \sum_j n_j[W_j]$ and using bilinearity, it is enough to show $\alpha \times [W] \in \mathrm{Rat}_{k+l}(X \times Y)$ for a single l-dimensional subvariety W. By

part (1) this class is $(\iota_W)_*(p_W^*\alpha)$. Flat pullback carries cycles rationally equivalent to zero to cycles rationally equivalent to zero (proposition 10.3.7), and so does proper pushforward along the closed immersion ι_W (theorem 10.2.3); hence $\alpha \times [W] \in \mathrm{Rat}_{k+l}(X \times Y)$. The symmetric half is identical, using the second formula of part (1) and additivity in the first variable.
For classes, let $\alpha \sim \alpha'$ in $Z_k(X)$ and $\beta \sim \beta'$ in $Z_l(Y)$. Then

$$\alpha \times \beta - \alpha' \times \beta' \;=\; (\alpha - \alpha') \times \beta \;+\; \alpha' \times (\beta - \beta')$$

and both terms on the right lie in $\mathrm{Rat}_{k+l}(X \times Y)$ by the previous paragraph. So the product of the classes is well defined, and it is bilinear because it is bilinear on cycles.

3. Both sides are bilinear, so it suffices to check on $\alpha = [V']$ and $\beta = [W']$ for subvarieties $V' \subseteq X'$ and $W' \subseteq Y'$. A closed immersion identifies V' with its image $f(V')$ and W' with $g(W')$, so $V' \times W'$ and $f(V') \times g(W')$ are the same closed subscheme of $X \times Y$; their fundamental cycles therefore agree, and each component of $V' \times W'$ maps isomorphically under $f \times g$. Hence $(f \times g)_*[V' \times W'] = [f(V') \times g(W')] = f_*[V'] \times g_*[W']$ by definition 10.2.1, completing the proof.

The proof is short because the exterior product was built out of the two functorialities of chapter 10 rather than defined by an independent construction, and that is the only reason it respects rational equivalence: nothing about a product of schemes is used beyond the flatness of its projections. Part (3) is the compatibility that lets a product computed on small closed subschemes be compared with the same product computed on the ambient scheme, and it is what the refined form of the intersection product below rests on.

What the exterior product does not do is produce a class on X. A class on $X \times X$ is returned to X by pulling back along the diagonal, and chapter 13 gives the pullback provided the diagonal is a regular embedding. The diagonal morphism $\delta\colon X \to X \times X$ exists for every scheme, and it is a closed immersion exactly when X is separated, that being the definition of separatedness; every variety appearing from here on is separated, and the hypothesis is carried in the statements that use it.

The first step is to identify the conormal sheaf of the diagonal. It requires no hypothesis on X beyond separatedness, and it is what converts smoothness into the regularity of δ.

Lemma 14.1.5: The Conormal Sheaf of the Diagonal

Let X be an algebraic scheme, let $\delta\colon X \to X \times X$ be the diagonal and let $\mathcal{J} \subseteq \mathcal{O}_{X\times X}$ be the ideal sheaf of the closed subscheme $\delta(X)$. Regard $\mathcal{J}/\mathcal{J}^2$ as a sheaf of $\mathcal{O}_X$-modules through the isomorphism $\delta\colon X \to \delta(X)$. Then there is a canonical isomorphism

$$\mathcal{J}/\mathcal{J}^2 \;\cong\; \Omega_X$$

of $\mathcal{O}_X$-modules, under which the class of $1 \otimes a - a \otimes 1$ corresponds to da.

***Proof*:**
There is nothing to prove: this is how the sheaf of differentials is defined upstream. The cotangent sheaf is $\Omega_{X/Y} := \Delta^*(\mathscr{I}/\mathscr{I}^2)$ for $\mathscr{I}$ the ideal sheaf of the diagonal, with universal derivation $d(b) = 1 \otimes b - b \otimes 1$ modulo $\mathscr{I}^2$ (definition 5.5.14); taking $Y = \operatorname{Spec}\overline{k}$ and using that δ is a closed immersion gives the statement. The affine content, that I/I^2 with this d satisfies the

universal property of $\Omega_{B/A}$, is proposition 5.5.3, as we sought to show.

The identification uses no smoothness, and it is the reason the sheaf of differentials can be constructed from the diagonal in the first place: Ω_X is the conormal sheaf of δ, so it records the first infinitesimal neighbourhood of the diagonal and nothing more. What smoothness adds is that Ω_X is then locally free of the right rank, and local freeness of the conormal sheaf is the visible half of being a regular embedding. The other half, that the ideal is generated by a regular sequence and not by the right number of elements, is where the local rings of $X \times X$ enter.

Theorem 14.1.6: The Diagonal of a Smooth Variety Is a Regular Embedding

Let X be a separated smooth variety of dimension n over $\overline{k}$ and let $\delta\colon X \to X \times X$ be the diagonal. Then δ is a regular embedding of codimension n (definition 5.1.45), and its normal bundle is the tangent bundle of X,

$$N_\delta \;=\; T_X$$

***Proof*:**

Write $\Delta = \delta(X)$ and let $\mathcal{J}$ be its ideal sheaf.

Step 1: the diagonal is closed of codimension n. Separatedness of X says exactly that δ is a closed immersion, and δ is an isomorphism onto Δ, so Δ is a closed subscheme of $X \times X$ isomorphic to X and of dimension n. Smoothness is stable under products and dimensions add, so $X \times X$ is smooth of dimension $2n$ (proposition 2.7.11(3)); moreover $X \times X$ is pure of dimension $2n$ by lemma 14.1.1 applied with $V = X$. Its local rings are therefore regular, of dimension $2n$ at every closed point. The codimension of Δ in $X \times X$ is $2n - n = n$.

Step 2: the ideal is generated by n elements along the diagonal. Fix an affine open $U = \operatorname{Spec} A$ of X and keep the notation of lemma 14.1.5, so that $U \times U = \operatorname{Spec} B$ with $B = A \otimes_{\overline{k}} A$, and $J = \ker \mu$ is the ideal of $\delta(U)$. By lemma 14.1.5 there is an isomorphism $\Omega_A \cong J/J^2$ of A-modules, and smoothness of X makes Ω_A locally free of rank n.

The differentials da generate Ω_A, so after shrinking U around a chosen closed point there are $t_1, \dots, t_n \in A$ whose differentials generate Ω_A: pick elements whose differentials span the fibre of Ω_A at the point, which has dimension n, and apply Nakayama together with coherence to spread the generation to a neighbourhood. The resulting surjection $A^n \to \Omega_A$ onto a locally free module of rank n is an isomorphism, since after localizing at any prime it becomes a surjective endomorphism of a finitely generated module over a commutative ring and every such endomorphism is injective. So $dt_1, \dots, dt_n$ is a basis of Ω_A.

Transporting through lemma 14.1.5, the classes of

$$u_i \;=\; t_i \otimes 1 - 1 \otimes t_i, \qquad i = 1, \dots, n$$

form a basis of J/J^2 over A. In particular $J = (u_1, \dots, u_n) + J^2$. Let $z \in \delta(U)$ and put $R = \mathcal{O}_{X \times X, z}$ with maximal ideal $\mathfrak{m}$. Localizing the last equality gives $JR = (u_1, \dots, u_n)R + J^2R$, and $J \subseteq \mathfrak{m}$ forces $J^2R \subseteq \mathfrak{m}\,JR$; so the finitely generated R-module $N = JR/(u_1, \dots, u_n)R$ satisfies $N = \mathfrak{m}N$ and vanishes by Nakayama. Hence

$$JR \;=\; (u_1, \dots, u_n)R \quad \text{for every } z \in \delta(U)$$

The coherent sheaf $\mathcal{J}/(u_1, \dots, u_n)\mathcal{O}_{U \times U}$ therefore has vanishing stalk at every point of $\delta(U)$,

so its support is a closed subset of $U \times U$ disjoint from $\delta(U)$, and on the open complement, an open neighbourhood of $\delta(U)$ in $X \times X$, the ideal sheaf of Δ is generated by $u_1, \dots, u_n$.

Step 3: the generators form a regular sequence. Let $z \in \delta(U)$ be a closed point, corresponding to the closed point $x \in U$, and keep $R = \mathcal{O}_{X\times X,z}$. By Step 1 the ring R is regular local of dimension $2n$, and

$$R/JR \;=\; \mathcal{O}_{\Delta,z} \;=\; \mathcal{O}_{X,x}$$

is regular local of dimension n, again by smoothness of X. Regularity makes the embedding dimensions equal to the Krull dimensions, so $\dim_{\overline{k}} \mathfrak{m}/\mathfrak{m}^2 = 2n$ while the quotient $\mathfrak{m}/(\mathfrak{m}^2 + JR)$, which is the corresponding space for R/JR, has dimension n. The image of JR in $\mathfrak{m}/\mathfrak{m}^2$ is therefore n-dimensional, and it is spanned by the images of $u_1, \dots, u_n$ by Step 2; those n images are consequently linearly independent in $\mathfrak{m}/\mathfrak{m}^2$, that is, $u_1, \dots, u_n$ is part of a regular system of parameters of R. A regular system of parameters of a regular local ring is a regular sequence, and so is any part of one: extend $u_1, \dots, u_n$ to a regular system of parameters $u_1, \dots, u_{2n}$ of R and put $R_i = R/(u_1, \dots, u_i)$, whose maximal ideal is generated by the images of $u_{i+1}, \dots, u_{2n}$. Its embedding dimension is therefore at most $2n - i$, while its dimension is at least $2n - i$, since killing one element drops the dimension by at most one; the two agree, so R_i is regular local and hence a domain, and the image of u_{i+1} in it is nonzero, since otherwise $\mathfrak{m}R_i$ would be generated by $2n - i - 1$ elements. Each u_{i+1} is thus a nonzerodivisor on R_i, that is, $u_1, \dots, u_n$ is a regular sequence in R.

This was proved at closed points, and it propagates to the rest of Δ by localization. If $z' \in \Delta$ is arbitrary, its closure meets the closed points of $X \times X$, since closed points are dense in a closed subset of a scheme of finite type over a field; choosing a closed point z in that closure, $\mathcal{O}_{X\times X,z'}$ is a localization of $\mathcal{O}_{X\times X,z}$ at a prime containing J. Localization is exact, so a nonzerodivisor stays a nonzerodivisor and a regular sequence stays one, the quotient remaining nonzero because $z' \in \Delta$. Thus every point of Δ has a neighbourhood in $X \times X$ on which $\mathcal{J}$ is generated by n sections whose images in the local rings along Δ form a regular sequence, which is the local condition of definition 5.1.43. Since Δ has codimension n by Step 1, δ is a regular embedding of codimension n.

Step 4: the normal bundle. The normal bundle of a regular embedding is the vector bundle whose sheaf of sections is the dual of the conormal sheaf (definition 5.1.45), and lemma 14.1.5 identifies that conormal sheaf $\mathcal{J}/\mathcal{J}^2$ with Ω_X. The dual of Ω_X is the tangent sheaf (definition 5.5.28), whose associated bundle is T_X. Hence $N_\delta = T_X$, completing the proof.

Two features of the statement are worth separating. The codimension is n, which is what makes $\delta^!$ lower dimension by exactly n and so makes the product of a k-cycle and an l-cycle a cycle of dimension $k + l - n$, the dimension a transverse intersection would have. The normal bundle is T_X, which is where the geometry of X enters the product: every formula below in which a Chern class of the tangent bundle appears is tracing back to this identification, and the self-intersection formula of section 14.3 is the first of them. Smoothness is used twice and cannot be weakened to either half alone: the local rings of $X \times X$ must be regular for Step 3, and Ω_X must be locally free for Step 2.

Example 14.1.7: The Diagonal of Affine Space

Let $X = \mathbb{A}^n = \operatorname{Spec} \overline{k}[t_1, \dots, t_n]$. Then $X \times X = \operatorname{Spec} \overline{k}[t_1, \dots, t_n, s_1, \dots, s_n] = \mathbb{A}^{2n}$, and the ideal of the diagonal is $J = (t_1 - s_1, \dots, t_n - s_n)$, so the generators of theorem 14.1.6 are visible globally: $u_i = t_i - s_i$. That they form a regular sequence needs no local algebra here, since $\overline{k}[t, s] = \overline{k}[t_1, \dots, t_n, u_1, \dots, u_n]$ is again a polynomial ring and each successive quotient

$\overline{k}[t,u]/(u_1,\dots,u_i)$ is a polynomial ring, hence a domain, in which u_{i+1} is a nonzero element and therefore a nonzerodivisor. The conormal sheaf is free on the classes of the u_i, matching the basis $dt_1,\dots,dt_n$ of $\Omega_{\mathbb{A}^n}$ under lemma 14.1.5, and N_δ is the trivial bundle of rank n, which is $T_{\mathbb{A}^n}$. The Chow groups are as small as possible: $A_k(\mathbb{A}^m)=0$ for $k<m$ and $A_m(\mathbb{A}^m)=\mathbb{Z}\,[\mathbb{A}^m]$ by proposition 10.5.1. So the only product that can be nonzero is $[\mathbb{A}^n]\cdot[\mathbb{A}^n]$, and it is computed by the exterior product $[\mathbb{A}^n]\times[\mathbb{A}^n]=[\mathbb{A}^{2n}]$ followed by $\delta^!$. The intersection $\mathbb{A}^{2n}\cap\Delta$ is Δ itself, and $\Delta\hookrightarrow\mathbb{A}^{2n}$ is a regular embedding of codimension n, so proposition 13.3.3 gives $\delta^![\mathbb{A}^{2n}]=[\Delta]$, that is

$$[\mathbb{A}^n]\cdot[\mathbb{A}^n] \;=\; [\mathbb{A}^n]$$

the fundamental class reproducing itself.

The exterior product turns a pair of classes on X into one class on $X\times X$, and the diagonal is a regular embedding, so the Gysin map of definition 13.3.1 returns a class on X.

Definition 14.1.8: The Intersection Product

Let X be a separated smooth variety of dimension n over $\overline{k}$, with diagonal $\delta\colon X\hookrightarrow X\times X$, a regular embedding of codimension n by theorem 14.1.6. For $\alpha\in A_k(X)$ and $\beta\in A_l(X)$ the *intersection product* is

$$\alpha\cdot\beta \;=\; \delta^!\big(\alpha\times\beta\big) \;\in\; A_{k+l-n}(X)$$

where $\alpha\times\beta\in A_{k+l}(X\times X)$ is the exterior product of proposition 14.1.4 and $\delta^!\colon A_{k+l}(X\times X)\to A_{k+l-n}(X)$ is the Gysin map of definition 13.3.1.

The definition is the whole of the construction, and every property of the product is a property of one of its two inputs. It is defined for arbitrary classes, with no hypothesis on how representing cycles meet, because the Gysin map has none; and it depends only on the rational equivalence classes of the two factors, because both the exterior product and the Gysin map do. The dimension bookkeeping is the expected one: $k+l-n$ is the dimension of a transverse intersection of a k-dimensional and an l-dimensional subvariety of an n-dimensional variety, so in codimension the product adds. That grading, and the ring axioms it grades, are established in section 14.2; until then the product is exactly what definition 14.1.8 says it is.

Bilinearity and the vanishing below the expected dimension are inherited from the two inputs, and are recorded here for the computations that use them.

Proposition 14.1.9: Bilinearity and Vanishing in Low Dimension

Let X be a separated smooth variety of dimension n.

1. The product $A_k(X)\times A_l(X)\to A_{k+l-n}(X)$ is bilinear.
2. If $k+l<n$ then $\alpha\cdot\beta=0$ for all $\alpha\in A_k(X)$ and $\beta\in A_l(X)$.

***Proof*:**

1. The exterior product is bilinear by proposition 14.1.4(2) and $\delta^!$ is a homomorphism of abelian groups by proposition 13.3.2(1), so the composite is bilinear in each variable.
2. The class $\alpha\times\beta$ lies in $A_{k+l}(X\times X)$ with $k+l<n$, and the codimension of δ is n, so

proposition 13.3.2(2) gives $\delta^!(\alpha \times \beta) = 0$. Equivalently the target group $A_{k+l-n}(X)$ is a Chow group in negative dimension and vanishes, as we sought to show.

The product of definition 14.1.8 records its answer on all of X, and that discards information the construction has available. If α is carried by a closed subscheme V and β by a closed subscheme W, the intersection ought to be carried by $V \cap W$, and the refined Gysin homomorphism of definition 13.3.6 delivers exactly that, because the preimage of $V \times W$ under the diagonal is the scheme-theoretic intersection. Indeed the ideal sheaf of $V \times W$ in $X \times X$ is generated by the pullbacks of $\mathcal{I}_V$ and $\mathcal{I}_W$ along the two projections, and composing either projection with δ is the identity, so that ideal pulls back to $\mathcal{I}_V + \mathcal{I}_W$, the ideal of $V \cap W$.

Definition 14.1.10: The Refined Intersection Product

Let X be a separated smooth variety of dimension n and let $V, W \subseteq X$ be closed subschemes, with $g\colon V \times W \to X \times X$ the closed immersion. Since $\delta^{-1}(V \times W) = V \cap W$, the refined Gysin homomorphism of definition 13.3.6 along g is a homomorphism

$$\delta^! \;:\; A_m(V \times W) \longrightarrow A_{m-n}(V \cap W)$$

For $\alpha \in A_k(V)$ and $\beta \in A_l(W)$ the *refined intersection product* is

$$\alpha \cdot_X \beta \;=\; \delta^!\big(\alpha \times \beta\big) \;\in\; A_{k+l-n}(V \cap W)$$

Proposition 14.1.11: The Refined Product Determines the Product

Let X be a separated smooth variety of dimension n, let $V, W \subseteq X$ be closed subschemes with inclusions i_V and i_W, and let $\iota\colon V \cap W \hookrightarrow X$ be the inclusion. For all $\alpha \in A_k(V)$ and $\beta \in A_l(W)$,

$$\iota_*\big(\alpha \cdot_X \beta\big) \;=\; \big(i_{V*}\alpha\big) \cdot \big(i_{W*}\beta\big) \;\in\; A_{k+l-n}(X)$$

***Proof*:**
Apply theorem 13.3.11(1) to the regular embedding δ with $X' = X \times X$, $X'' = V \times W$ and $p = g$ the closed immersion, which is proper. The preimage of $\delta(X)$ in X' is $\delta(X)$ itself and the preimage in X'' is $V \cap W$, so the induced morphism q of preimages is ι, read through the isomorphism $\delta\colon X \to \delta(X)$. The theorem gives

$$\delta^!\big(g_*\gamma\big) \;=\; \iota_*\big(\delta^!\gamma\big)$$

for $\gamma \in A_{k+l}(V \times W)$, where the left-hand $\delta^!$ is the refined map along $\mathrm{id}_{X\times X}$, which is the Gysin map of definition 13.3.1 by proposition 13.3.8. Take $\gamma = \alpha \times \beta$. By proposition 14.1.4(3) applied to the closed immersions i_V and i_W,

$$g_*(\alpha \times \beta) \;=\; i_{V*}\alpha \times i_{W*}\beta$$

so the left-hand side is $\delta^!\big(i_{V*}\alpha \times i_{W*}\beta\big)$, which is $(i_{V*}\alpha) \cdot (i_{W*}\beta)$ by definition 14.1.8, and the right-hand side is $\iota_*(\alpha \cdot_X \beta)$ by definition 14.1.10, as we sought to show.

The pattern is the one recorded in corollary 13.3.12 for a single subvariety: the class computed on

the ambient scheme is the pushforward of a class computed on the intersection. The refined product is the finer object, and every localized intersection number in the classical sense is a degree taken of it; the product of definition 14.1.8 is its pushforward to X.

Example 14.1.12: Two Lines in the Projective Plane

Let $X = \mathbb{P}^2$, which is a smooth variety of dimension 2, and let $L = \{x_0 = 0\}$ and $L' = \{x_1 = 0\}$ be two distinct lines, meeting in the single reduced point $P = [0 : 0 : 1]$.

The exterior product. By definition 14.1.2, $[L] \times [L'] = [L \times L']$, and $L \times L' \cong \mathbb{P}^1 \times \mathbb{P}^1$ is a variety of dimension 2 by the argument of example 14.1.3, so the exterior product is the class of a single subvariety of $\mathbb{P}^2 \times \mathbb{P}^2$ with multiplicity one.

The Gysin pullback. The intersection of $L \times L'$ with the diagonal is $\delta^{-1}(L \times L') = L \cap L' = \{P\}$, a reduced point. In the affine chart of $L \times L'$ around (P, P), with coordinates y on $L \setminus \{x_2 = 0\}$ and z on $L' \setminus \{x_2 = 0\}$, that point is the origin of $\mathbb{A}^2$, cut out by the regular sequence y, z; so $\{P\} \hookrightarrow L \times L'$ is a regular embedding of codimension $2 = \operatorname{codim}(\delta)$. Proposition 13.3.3 therefore applies to δ and the subvariety $L \times L'$ and gives

$$[L] \cdot [L'] \;=\; \delta^!\big[L \times L'\big] \;=\; [P] \;\in\; A_0(\mathbb{P}^2)$$

The refined form of definition 14.1.10 records a class on $L \cap L' = \{P\}$, and that class is the generator of $A_0(\{P\}) = \mathbb{Z}$: by proposition 14.1.11 its image in $A_0(\mathbb{P}^2)$ is $[P]$, and the pushforward $A_0(\{P\}) \to A_0(\mathbb{P}^2)$ carries generator to generator.

The self-intersection. By theorem 10.5.2 the two lines have the same class, $[L] = [L'] = h_1$ in $A_1(\mathbb{P}^2)$. Since the product is defined on classes, the computation just made also evaluates

$$[L] \cdot [L] \;=\; h_1 \cdot h_1 \;=\; [P]$$

No cycle was perturbed to get this, and no representative of h_1 was required to meet L properly: the two factors were replaced by equal classes, which proposition 14.1.4(2) and proposition 13.3.2(1) permit. The refined product, by contrast, does depend on the representatives: computed on L against L it lives on $A_0(L)$ rather than on $A_0(\{P\})$, and evaluating it there is the business of section 14.3.

Exercise 14.1.1

1. Let $P = \operatorname{Spec} \overline{k}$ and let X be an algebraic scheme. Show that $A_0(P) = \mathbb{Z}\,[P]$, and that under the canonical isomorphism $X \times P \cong X$ the exterior product of proposition 14.1.4 sends $(\alpha, m[P])$ to $m\alpha$. Then show that the exterior product of cycles is associative: for algebraic schemes X, Y, T and cycles α, β, γ on them, $(\alpha \times \beta) \times \gamma = \alpha \times (\beta \times \gamma)$ under the identification $(X \times Y) \times T = X \times (Y \times T)$.

2. Let $S = \mathbb{P}^1 \times \mathbb{P}^1$ with coordinates $([a : b], [c : d])$, let $\Delta \subseteq S$ be the diagonal, and let $F = \mathbb{P}^1 \times \{[1 : 0]\}$ and $G = \{[0 : 1]\} \times \mathbb{P}^1$. Show that

$$[\Delta] \;=\; [\mathbb{P}^1] \times [\mathrm{pt}] + [\mathrm{pt}] \times [\mathbb{P}^1] \quad \text{in } A_1(S)$$

   by computing the divisor of the rational function $f = (ad - bc)/(ad)$ on S chart by chart.

3. Let $X = \operatorname{Spec} \overline{k}[x, y]/(y^2 - x^3)$, a curve with a cusp at the origin p. Using lemma 14.1.5 and the presentation $\Omega_X = \big(\mathcal{O}_X\, dx \oplus \mathcal{O}_X\, dy\big)/\big(d(y^2 - x^3)\big)$, show that the conormal sheaf of the diagonal of X is not locally free of rank one, and deduce that $\delta\colon X \to X \times X$ is not a regular

embedding of codimension one. Where does the proof of theorem 14.1.6 break down for this X?

4. Let X be a separated smooth variety of dimension n and let $V, W \subseteq X$ be closed subschemes with $V \cap W = \emptyset$. Show that $[V] \cdot [W] = 0$ in $A_*(X)$, where $[V]$ and $[W]$ denote the images in $A_*(X)$ of the fundamental cycles. Give a second proof of the vanishing when $\dim V + \dim W < n$ that does not use disjointness.

5. Fix $0 \leq a, b \leq n$ with $a + b \geq n$, and let $L = \{x_{a+1} = \cdots = x_n = 0\}$ and $M = \{x_0 = \cdots = x_{n-b-1} = 0\}$ be coordinate subspaces of $\mathbb{P}^n$, so that $L \cong \mathbb{P}^a$, $M \cong \mathbb{P}^b$ and $L \cap M \cong \mathbb{P}^{a+b-n}$. Show that $L \cap M \hookrightarrow L \times M$ is a regular embedding of codimension n, and deduce from proposition 13.3.3 that $h_a \cdot h_b = h_{a+b-n}$ in $A_*(\mathbb{P}^n)$, where h_m is the class of a linear $\mathbb{P}^m$ as in example 13.3.4.

14.2 The Chow Ring

Section 14.1 produced a biadditive pairing on the Chow groups of a smooth variety. This section proves that the pairing obeys the three laws that make it a ring, and it indexes the groups by codimension so that the degrees add rather than subtract. The ring is then made contravariant: a morphism of smooth varieties pulls classes back, and so does a local complete intersection morphism between arbitrary algebraic schemes, which is the form Grothendieck-Riemann-Roch will need.

Two ingredients are imported rather than built. One is a pair of statements about regular embeddings that belong to scheme theory; the other is the commutativity of two Gysin maps, which chapter 13 flagged and did not prove. Both are isolated below, so that everything resting on them is visible at a glance.

14.2.1 Convention: Subscripts on Refined Gysin Maps When several refinements of one Gysin map occur in the same formula, the morphism along which the map is refined is written as a subscript: $i^!_g$ is the refined homomorphism of definition 13.3.6 for the morphism g, and an unadorned $i^!$ is the Gysin map of definition 13.3.1.

One reading has to be fixed first. Definition 13.3.1 is stated in codimension $d \geq 1$, whereas a regular embedding of codimension 0 is an open and closed immersion, its ideal sheaf vanishing locally. For such an $i\colon Z \hookrightarrow P$ both $i^!$ and its refinements $i^!_g$ mean flat pullback throughout this section, along i and along the induced immersion $g^{-1}(Z) \hookrightarrow P'$ for $g\colon P' \to P$; this is the reading definition 14.2.11 uses again. When the case arises from a diagonal or a graph the smooth variety in question has dimension 0, hence is $\operatorname{Spec} \overline{k}$: the embedding is then the identity under the canonical identification of $W \times \operatorname{Spec} \overline{k}$ with W, its flat pullback is the identity on Chow groups, and every statement below in which that happens holds by inspection. The arguments are written for the remaining case.

A cycle class on a smooth n-dimensional variety carries two equally good indices, its dimension and its codimension, and the product adds the second while subtracting the first from $2n$. A ring wants its grading to be additive, so the codimension index is the one to record.

Definition 14.2.2: The Chow Ring

Let X be a smooth variety of dimension n. For $0 \le p \le n$ write

$$A^p(X) \;=\; A_{n-p}(X)$$

and call $A^p(X)$ the group of cycle classes of *codimension* p. The graded abelian group

$$A^*(X) \;=\; \bigoplus_{p=0}^{n} A^p(X)$$

equipped with the intersection product $\alpha \cdot \beta = \delta^!(\alpha \times \beta)$ of section 14.1, is the *Chow ring* of X. That the product makes it a ring is theorem 14.2.7.

The two indices are interchangeable data, and both are used: a statement about the geometry of cycles is usually cleaner in dimension, a statement about the ring is cleaner in codimension. The class $[X]$ lies in $A^0(X)$, a divisor class lies in $A^1(X)$, and the class of a point on a complete X lies in $A^n(X)$.

Projective space is the first ring that can be written down, and it can be written down before the ring axioms are available, because each product in it is a single application of proposition 13.3.3.

Example 14.2.3: The Chow Ring of Projective Space

Let $X = \mathbb{P}^n$ with homogeneous coordinates $x_0, \dots, x_n$. By theorem 10.5.2, $A_k(\mathbb{P}^n) = \mathbb{Z}\, h_k$ with h_k the class of a linear subspace $\mathbb{P}^k$, so $A^p(\mathbb{P}^n) = \mathbb{Z}\, h_{n-p}$ is infinite cyclic for $0 \le p \le n$ and zero otherwise.

Fix $p, q \ge 0$ with $p + q \le n$ and take the linear subspaces

$$L = \{x_0 = \cdots = x_{p-1} = 0\}, \qquad L' = \{x_p = \cdots = x_{p+q-1} = 0\}$$

of dimensions $n-p$ and $n-q$, so that $[L] = h_{n-p}$ and $[L'] = h_{n-q}$. Their product is $\delta^!\big([L]\times[L']\big) = \delta^![L\times L']$, and proposition 13.3.3 evaluates it once the scheme-theoretic intersection $W = (L\times L')\cap\Delta$ is known to be regularly embedded in $L \times L'$ with codimension n. Set-theoretically W consists of the pairs (z, z) with $z \in L \cap L'$, so $W \cong L \cap L' = \{x_0 = \cdots = x_{p+q-1} = 0\} \cong \mathbb{P}^{n-p-q}$.

Work on the chart $\{x_n \neq 0\}$ of each factor, which meets W because the coordinate point e_n lies in $L \cap L'$. Writing $u_i = x_i/x_n$ for the affine coordinates on the first factor and $v_i = x_i/x_n$ for those on the second, the chart of $L \times L'$ is the affine space with coordinate ring

$$\overline{k}\big[u_p, \dots, u_{n-1};\; v_0, \dots, v_{p-1},\; v_{p+q}, \dots, v_{n-1}\big]$$

the coordinates $u_0, \dots, u_{p-1}$ vanishing on L and $v_p, \dots, v_{p+q-1}$ on L'. The diagonal is cut out on $\mathbb{P}^n \times \mathbb{P}^n$ in this chart by the n equations $u_i = v_i$ with $0 \le i \le n-1$, and restricting them to $L \times L'$ leaves

$$v_0,\; \dots,\; v_{p-1}, \qquad u_p,\; \dots,\; u_{p+q-1}, \qquad u_i - v_i \;\; (p+q \le i \le n-1)$$

a list of n linear forms in distinct variables. Each is a nonzerodivisor modulo its predecessors, every successive quotient being a polynomial ring, so the list is a regular sequence and $W \hookrightarrow L \times L'$ is a regular embedding of codimension n; the quotient is the polynomial ring on the remaining $n - p - q$ variables, so W is reduced and irreducible with fundamental cycle $[\mathbb{P}^{n-p-q}]$. The same

computation runs on every chart meeting W. Proposition 13.3.3 therefore gives

$$h_{n-p} \cdot h_{n-q} \;=\; h_{n-p-q}$$

For $p+q > n$ the product lands in $A^{p+q}(\mathbb{P}^n) = A_{n-p-q}(\mathbb{P}^n) = 0$ and is zero, by proposition 13.3.2(2). Writing $h = h_{n-1}$ for the class of a hyperplane, induction on p gives $h^p = h_{n-p}$, and

$$A^*(\mathbb{P}^n) \;\cong\; \mathbb{Z}[h]/(h^{n+1})$$

once the ring axioms below justify the power notation.

No general position argument entered the computation. The two subspaces were chosen in special position relative to the coordinates but in general position relative to each other, and proposition 13.3.2 guarantees that any other pair of representatives, including two equal ones, returns the same product. What the example does not show is that the answer depends on the two classes through a ring structure, and that is the content of the rest of the section.

The first import is scheme-theoretic. Both of its statements concern regular embeddings and smooth morphisms rather than cycles, so both belong to the scheme theory upstream, where they are now proved. Neither is re-derived here.

Lemma 14.2.4: Sections, Flat Base Change, and Graphs

1. Let $\pi\colon P \to S$ be a smooth morphism of relative dimension $e \geq 0$ and $s\colon S \to P$ a section of it. Then s is a regular embedding of codimension e with normal bundle $s^*T_{P/S}$.
2. Let $i\colon Z \hookrightarrow P$ be a regular embedding of codimension d and $g\colon P' \to P$ a flat morphism. Then $g^{-1}(Z) \hookrightarrow P'$ is a regular embedding of codimension d, with normal bundle the pullback of the normal bundle of i.
3. Let X be a smooth variety of dimension $n \geq 0$, let V be an algebraic scheme, and let $f\colon V \to X$ be a morphism. Then the scheme-theoretic preimage of the diagonal under $f \times \mathrm{id}_X\colon V \times X \to X \times X$ is the graph Γ_f, the first projection restricts to an isomorphism $\Gamma_f \to V$, and $\gamma_f\colon V \to V \times X$ is a regular embedding of codimension n with normal bundle f^*T_X.

***Proof*:**
Part (2) is an upstream result, cited rather than re-derived, being a statement about regular embeddings as such. For part (1) the regular-embedding half is proposition 5.1.48, which is all that proposition asserts; the normal bundle needs a further step. Let $\mathcal{I}$ be the ideal sheaf of $s(S)$ in P. The conormal sequence of the composite $\pi \circ s = \mathrm{id}_S$ splits: applying s^* to $\pi^*\Omega_S \to \Omega_P \to \Omega_{P/S} \to 0$ and using $s^*\Omega_P \to \Omega_S$ from $\pi s = \mathrm{id}$ identifies $\mathcal{I}/\mathcal{I}^2$ with $s^*\Omega_{P/S}$, locally free of rank e because π is smooth of relative dimension e. Dualizing gives normal bundle $s^*T_{P/S}$. Part (2) is proposition 5.1.49. Part (3) follows from part (1). A T-valued point of $(f \times \mathrm{id}_X)^{-1}(\Delta)$ is a pair (t_V, t_X) of T-points of V and X with $f \circ t_V = t_X$, so the functor of points of the preimage is that of V, and the isomorphism is induced by the first projection, with inverse γ_f. The projection $\mathrm{pr}_1\colon V \times X \to V$ is the base change of $X \to \operatorname{Spec} \overline{k}$, hence smooth of relative dimension n, and γ_f is a section of it, so part (1) applies. Its relative tangent bundle is

$\mathrm{pr}_2^* T_X$, whose pullback along γ_f is $f^* T_X$, completing the proof.

Part (3) extends the diagonal computation of section 14.1 from the identity morphism to an arbitrary one, and it is the reason the intersection product can be transported along a map. Taking $V = X$ and $f = \mathrm{id}_X$ returns the diagonal.

The second import is about Gysin maps. That two regular embeddings can be intersected against in either order is what makes the product associative, and that the Gysin map of a composite of two regular embeddings factors is what makes the pullback along a local complete intersection morphism well defined. Both are proved in section 13.4, as corollary 13.4.8 and theorem 13.4.7, and are used here without further comment; the section identity theorem 13.4.2 of the same section is the third.

This theorem and parts (1) and (2) of lemma 14.2.4 are the only results the arguments below use whose proofs are cited rather than given. On the theorem rest the associativity of the intersection product, the identity of theorem 14.2.10(1) between intersecting with the graph and pulling back, and with it the projection formula, the multiplicativity and functoriality of pullback, and the independence of the local complete intersection pullback from its factorization. On the lemma rests everything that passes through a graph: its part (3) is deduced from part (1), so the unit law, definition 14.2.8 and all four parts of theorem 14.2.10 rest on it, and Step 1 of theorem 14.2.12(1) uses parts (1) and (2) directly. Commutativity of the product itself and the grading rest on neither.

The last preparation is bookkeeping. A Gysin map applied to an exterior product in which one factor is inert should return that factor untouched.

Lemma 14.2.5: Gysin Maps and Exterior Products

Let $i\colon Z \hookrightarrow P$ be a regular embedding of codimension $d \geq 1$, let W be an algebraic scheme, and let $\mathrm{pr}\colon P \times W \to P$ and $\mathrm{pr}'\colon W \times P \to P$ be the projections, whose scheme-theoretic preimages of Z are $Z \times W$ and $W \times Z$. Then for all $\xi \in A_k(P)$ and $\gamma \in A_l(W)$,

$$i^!_{\mathrm{pr}}(\xi \times \gamma) = (i^!\xi) \times \gamma, \qquad i^!_{\mathrm{pr}'}(\gamma \times \xi) = \gamma \times (i^!\xi)$$

***Proof*:**
Both sides are additive in γ, so it suffices to treat $\gamma = [W']$ for a subvariety $W' \subseteq W$ of dimension l, with inclusion $\iota\colon W' \hookrightarrow W$. Write $u = \mathrm{id}_P \times \iota\colon P \times W' \to P \times W$, a closed immersion and hence proper, and $\rho\colon P \times W' \to P$ for the projection. As W' is a variety of dimension l over $\overline{k}$, the structure morphism $W' \to \operatorname{Spec} \overline{k}$ is flat with l-dimensional fibre, so its base change ρ is flat of relative dimension l; and $\rho = \mathrm{pr} \circ u$, so u is a morphism over P.

Step 1: the exterior product as a pullback followed by a pushforward. For a subvariety $V \subseteq P$ the preimage $\rho^{-1}(V)$ is $V \times W'$, so $\rho^*[V] = [V \times W']$ by definition 10.3.3, and $u_*[V \times W'] = [V \times W']$ by definition 10.2.1, the immersion u carrying $V \times W'$ isomorphically onto its image. Hence $\xi \times [W'] = u_*(\rho^*\xi)$ for every ξ. The same computation on Z gives $q^*\eta = \eta \times [W']$ for the projection $q\colon Z \times W' \to Z$ and every $\eta \in A_*(Z)$.

Step 2: the two compatibilities. Theorem 13.3.11(2), applied with $X' = P$ and the identity, $X'' = P \times W'$ and ρ, and with ρ itself as the morphism over P, gives

$$i^!_\rho(\rho^*\xi) \;=\; q^*(i^!\xi) \;=\; (i^!\xi) \times [W']$$

where proposition 13.3.8 was used to read the refined map along the identity as $i^!$. Theorem 13.3.11(1), applied with $X' = P \times W$ and pr, $X'' = P \times W'$ and ρ, and with the proper

morphism u over P, gives

$$i'^{!}_{\mathrm{pr}}(u_*\eta) \;=\; q'_*(i^{!}_{\rho}\eta)$$

for the closed immersion $q'\colon Z\times W'\hookrightarrow Z\times W$ induced by u. Combining the two with Step 1, and using $q'_*\big(\zeta\times[W']\big)=\zeta\times[W']$ by definition 10.2.1 again, yields the first identity. Exchanging the two factors throughout gives the second, as we sought to show.

One comparison is used repeatedly below: when the preimage of Z is as well behaved as Z itself, the refined map is the plain one.

Proposition 14.2.6: Refined Gysin Maps with a Regular Preimage

Let $i\colon Z\hookrightarrow P$ be a regular embedding of codimension $d\geq 1$ and $g\colon P'\to P$ a morphism of algebraic schemes such that $Z'=g^{-1}(Z)$ is regularly embedded in P' with codimension d. Then the refined Gysin homomorphism $i^{!}_{g}$ of definition 13.3.6 is the Gysin map $(i')^{!}$ of definition 13.3.1 for $i'\colon Z'\hookrightarrow P'$.

***Proof*:**
Write $C=C_{Z'}P'$ and $N'=h^*N$ as in definition 13.3.6, and let $j\colon C\hookrightarrow N'$ be the immersion of lemma 12.3.13. By part (1) of that lemma j is an isomorphism, and it is a morphism of cones over Z', so the projections satisfy $\pi_{N'}\circ j=\pi_C$. Since i' is a regular embedding, proposition 12.3.11 identifies C with the normal bundle of i', and definition 13.3.1 reads $(i')^{!}=(\pi_C^*)^{-1}\circ\sigma'$. Flat pullback along the isomorphism j is inverse to proper pushforward along it, each carrying a subvariety to its preimage or image with multiplicity one, so $j_*\pi_C^*=j_*j^*\pi_{N'}^*=\pi_{N'}^*$ by proposition 10.3.5(3). Hence $(\pi_{N'}^*)^{-1}\circ j_*=(\pi_C^*)^{-1}$, and composing with σ' turns definition 13.3.6 into definition 13.3.1, as we sought to show.

Theorem 14.2.7: The Chow Ring of a Smooth Variety

Let X be a smooth variety of dimension n, with diagonal $\delta\colon X\hookrightarrow X\times X$. Then, for all $\alpha,\beta,\gamma\in A^*(X)$:

1. the product is biadditive and $A^p(X)\cdot A^q(X)\subseteq A^{p+q}(X)$;
2. $\alpha\cdot\beta=\beta\cdot\alpha$;
3. $(\alpha\cdot\beta)\cdot\gamma=\alpha\cdot(\beta\cdot\gamma)$;
4. $[X]\cdot\alpha=\alpha$.

Thus $A^*(X)$ is a commutative graded ring with unit $[X]$.

***Proof*:**

1. Biadditivity is proposition 14.1.9(1). For the degrees, let $\alpha\in A^p(X)=A_{n-p}(X)$ and $\beta\in A^q(X)=A_{n-q}(X)$. Their exterior product lies in $A_{2n-p-q}(X\times X)$, and δ is a regular embedding of codimension n (theorem 14.1.6), so $\delta^!$ lowers dimension by n by proposition 13.3.2(1). The product therefore lies in $A_{n-p-q}(X)=A^{p+q}(X)$.
2. Let $\tau\colon X\times X\to X\times X$ exchange the two factors. It carries a product of subvarieties $V\times W$

isomorphically onto $W \times V$, so $\tau_*(\alpha \times \beta) = \beta \times \alpha$ by definition 10.2.1, the exchange inducing an isomorphism of function fields. Since τ is an involution fixing the diagonal pointwise, $\tau^{-1}(\Delta) = \Delta$, which is regularly embedded in $X \times X$ with codimension n; proposition 14.2.6 therefore identifies $\delta^!_\tau$ with $\delta^!$. Applying theorem 13.3.11(1) with $X' = X \times X$ and the identity, $X'' = X \times X$ and τ, and with τ itself as the morphism over $X \times X$, which is proper because it is an isomorphism, and noting that the induced morphism of preimages is $\tau|_\Delta = \mathrm{id}_\Delta$,

$$\delta^!\big(\tau_*\xi\big) \;=\; \delta^!_\tau(\xi) \;=\; \delta^!(\xi)$$

for every $\xi \in A_*(X \times X)$. With $\xi = \alpha \times \beta$ this reads $\beta \cdot \alpha = \alpha \cdot \beta$.

3. Write $\Xi = \alpha \times \beta \times \gamma \in A_*(X \times X \times X)$, which is unambiguous because the exterior product is associative on cycles, and let $\mathrm{pr}_{12}, \mathrm{pr}_{23} \colon X \times X \times X \to X \times X$ be the two projections. Their preimages of the diagonal are $W_1 = \Delta \times X$ and $W_2 = X \times \Delta$, each identified with $X \times X$ by the two projections that are not constrained; under those identifications $\mathrm{pr}_{23}|_{W_1}$ and $\mathrm{pr}_{12}|_{W_2}$ are the identity of $X \times X$, so the refined maps along them are $\delta^!$ by proposition 13.3.8. By lemma 14.2.5, applied to $i = \delta$ with $W = X$ on each side in turn,

$$(\alpha \cdot \beta) \times \gamma = \delta^!_{\mathrm{pr}_{12}}(\Xi), \qquad \alpha \times (\beta \cdot \gamma) = \delta^!_{\mathrm{pr}_{23}}(\Xi)$$

Applying $\delta^!$ to each and using corollary 13.4.8 with $i = i' = \delta$, $W = X \times X \times X$ and the two projections,

$$(\alpha \cdot \beta) \cdot \gamma = \delta^!\big(\delta^!_{\mathrm{pr}_{12}}\Xi\big) = \delta^!\big(\delta^!_{\mathrm{pr}_{23}}\Xi\big) = \alpha \cdot (\beta \cdot \gamma)$$

both sides being computed on $W_{12} = (\Delta \times X) \cap (X \times \Delta)$, the small diagonal, which the first projection identifies with X.

4. By additivity it suffices to take $\alpha = [V]$ for a k-dimensional subvariety $V \subseteq X$, and by part (2) it suffices to evaluate $[V] \cdot [X] = \delta^![V \times X]$, the exterior product of the two fundamental cycles being the fundamental cycle of the variety $V \times X$ of dimension $k + n$ (definition 14.1.2). Apply lemma 14.2.4(3) to the inclusion $f \colon V \hookrightarrow X$: the scheme-theoretic intersection $(V \times X) \cap \Delta$, which is the preimage of Δ under $f \times \mathrm{id}_X$, is the graph Γ_f, isomorphic to V and regularly embedded in $V \times X$ with codimension n. Proposition 13.3.3 therefore gives $\delta^![V \times X] = \iota_*[\Gamma_f] = [V]$ in $A_k(\Delta) = A_k(X)$, where ι is the inclusion of the graph in the diagonal, which the projections identify with the inclusion of V in X, completing the proof.

The ring exists, and its two ends are already familiar: $A^0(X) = \mathbb{Z}\,[X]$ because a variety has only itself as a subvariety of top dimension, and $A^1(X) = A_{n-1}(X)$ is the group of divisor classes on which chapter 11 built the operator $D \cdot -$ by hand. The operators of section 12.2 can now be recorded as elements: for a vector bundle E on X the class $c_i(E) \cap [X]$ lies in $A^i(X)$, so Chern classes become members of a ring rather than endomorphisms of a graded group, and an identity of operators may be read as an identity in $A^*(X)$ by evaluating both sides on $[X]$.

The grading also explains an absence. On $\mathbb{P}^3$ two distinct lines meeting in a point have classes in A^2, so their product lies in $A^4(\mathbb{P}^3) = 0$: the ring records no trace of the point in which they meet. The computation is not defective. The intersection is not proper, one of the two lines can be moved off the other within its rational equivalence class, and the invariant answer to "how much do they meet" is zero.

A morphism $f \colon X \to Y$ of smooth varieties does not act on cycles in either direction in any naive

way, but its graph is a regular embedding by lemma 14.2.4(3), and intersecting with the graph is a pullback.

Definition 14.2.8: Pullback Along a Morphism of Smooth Varieties

Let $f\colon X \to Y$ be a morphism of smooth varieties, of dimensions m and n, and let $\gamma_f\colon X \to X \times Y$ be its graph, a regular embedding of codimension n by lemma 14.2.4(3); for $n = 0$, where $Y = \operatorname{Spec} \overline{k}$ and γ_f is an isomorphism, $\gamma_f^!$ is flat pullback along it. The *pullback* along f is

$$f^*\colon A_l(Y) \longrightarrow A_{l+m-n}(X), \qquad f^*\beta \;=\; \gamma_f^!\big([X] \times \beta\big)$$

Equivalently $f^*\beta = \gamma_f^!\big(\mathrm{pr}_Y^*\beta\big)$, since $\mathrm{pr}_Y\colon X \times Y \to Y$ is flat of relative dimension m with $\mathrm{pr}_Y^*\beta = [X] \times \beta$.

In codimension the map preserves degree: $\beta \in A^q(Y)$ means $l = n - q$, and then $l + m - n = m - q$, so $f^*\beta \in A^q(X)$. The definition is the one the geometry suggests. To pull a cycle on Y back to X, place it on $X \times Y$, where it is inert in the first factor, and intersect with the graph, which is the locus where the second coordinate is the image of the first.

Example 14.2.9: Pullback to a Linear Subspace

Let $i\colon \mathbb{P}^m \hookrightarrow \mathbb{P}^n$ be the linear subspace $\{x_0 = \cdots = x_{n-m-1} = 0\}$ with $1 \le m < n$, and write h and h' for the hyperplane classes of $\mathbb{P}^n$ and $\mathbb{P}^m$. On the chart where $x_n \neq 0$ in both factors, with affine coordinates u_j on $\mathbb{P}^m$ for $n - m \le j \le n - 1$ and v_j on $\mathbb{P}^n$ for $0 \le j \le n - 1$, the graph $\Gamma_i = \{(z, z) \big| z \in \mathbb{P}^m\}$ is cut out of $\mathbb{P}^m \times \mathbb{P}^n$ by the n equations

$$v_j \;\; (j < n - m), \qquad v_j - u_j \;\; (j \ge n - m)$$

Fix $1 \le p \le m$ and represent h_{n-p} by $L = \{x_{n-m} = \cdots = x_{n-m+p-1} = 0\}$, a linear subspace of dimension $n - p$ meeting $\mathbb{P}^m$ in the linear subspace $\mathbb{P}^{m-p}$. Then $[\mathbb{P}^m] \times h_{n-p}$ is represented by the subvariety $\mathbb{P}^m \times L$, of dimension $m + n - p$, whose intersection with Γ_i is $\{(z, z) \big| z \in \mathbb{P}^{m-p}\}$. On the chart above, the coordinates $v_{n-m}, \ldots, v_{n-m+p-1}$ vanish on L, so restricting the n equations of the graph to $\mathbb{P}^m \times L$ leaves

$$v_j \;\; (j < n - m), \qquad u_j \;\; (n - m \le j < n - m + p), \qquad v_j - u_j \;\; (j \ge n - m + p)$$

again n coordinates and coordinate differences in distinct variables, hence a regular sequence exactly as in example 14.2.3. The intersection is therefore regularly embedded of codimension n, and reduced and irreducible, so proposition 13.3.3 gives

$$i^*h_{n-p} \;=\; \big[\mathbb{P}^{m-p}\big] \;=\; h'^{\,}_{m-p}$$

For $p > m$ the target $A_{m-p}(\mathbb{P}^m)$ vanishes and the pullback is zero. The restriction of the class of a linear subspace is the class of a linear subspace of the same codimension, which is what a subspace meeting $\mathbb{P}^m$ properly should give; in the notation of example 14.2.3 this reads $i^*(h^p) = (h')^p$ for $p \le m$.

Theorem 14.2.10: Properties of Pullback

Let $f\colon X \to Y$ be a morphism of smooth varieties, of dimensions m and n.

1. For $\alpha \in A_*(X)$ and $\beta \in A_*(Y)$,
$$\gamma_f^!\big(\alpha \times \beta\big) \;=\; \alpha \cdot f^*\beta$$
and in particular $f^*[Y] = [X]$.
2. If f is proper then $f_*\big(\alpha \cdot f^*\beta\big) = f_*\alpha \cdot \beta$ for all $\alpha \in A_*(X)$ and $\beta \in A_*(Y)$.
3. $f^*\colon A^*(Y) \to A^*(X)$ is a homomorphism of graded rings.
4. $\mathrm{id}_X^* = \mathrm{id}$, and $(g \circ f)^* = f^* \circ g^*$ for a further morphism $g\colon Y \to Z$ of smooth varieties.

***Proof*:**
Throughout, $\Gamma_f \subseteq X \times Y$ is the graph and $\gamma_f\colon X \to X \times Y$ the regular embedding of codimension n onto it (lemma 14.2.4(3)).

1. By lemma 14.2.5, applied to γ_f with an inert factor X on the left,
$$\alpha \times f^*\beta \;=\; \alpha \times \gamma_f^!\big([X] \times \beta\big) \;=\; (\gamma_f)^!_{\mathrm{pr}_{23}}\big(\alpha \times [X] \times \beta\big)$$
where $\mathrm{pr}_{23}\colon X \times X \times Y \to X \times Y$ is the projection, whose preimage of Γ_f is $X \times \Gamma_f$, identified with $X \times X$ by the first two projections. Applying $\delta^!$ and invoking corollary 13.4.8 for the regular embeddings δ and γ_f with the projections pr_{12} and pr_{23},
$$\alpha \cdot f^*\beta \;=\; \delta^!\Big((\gamma_f)^!_{\mathrm{pr}_{23}}\big(\alpha \times [X] \times \beta\big)\Big) \;=\; (\gamma_f)^!_{\rho}\Big(\delta^!_{\mathrm{pr}_{12}}\big(\alpha \times [X] \times \beta\big)\Big)$$
On the left the outer map is refined along $\mathrm{pr}_{12}|_{X\times\Gamma_f}$, which is the identity of $X \times X$ under the identification above, so it is $\delta^!$ by proposition 13.3.8. On the right the preimage of Δ under pr_{12} is $\Delta \times Y$, identified with $X \times Y$, and ρ is the restriction of pr_{23} to it, which is the identity of $X \times Y$; so the outer map is $\gamma_f^!$, again by proposition 13.3.8. The inner map is evaluated by lemma 14.2.5 and the unit law theorem 14.2.7(4):
$$\delta^!_{\mathrm{pr}_{12}}\big((\alpha \times [X]) \times \beta\big) = \big(\alpha \cdot [X]\big) \times \beta = \alpha \times \beta$$
which gives the stated identity. Taking $\alpha = [X]$ and $\beta = [Y]$, the left side is $\gamma_f^![X \times Y]$; the variety $X \times Y$ meets Γ_f in Γ_f itself, a regular embedding of codimension n, so proposition 13.3.3 gives $\gamma_f^![X \times Y] = [\Gamma_f] = [X]$. Hence $[X] \cdot f^*[Y] = [X]$, and $f^*[Y] = [X]$ by the unit law.

2. Let f be proper. On cycles, $(f \times \mathrm{id}_Y)_*\big(\alpha \times \beta\big) = f_*\alpha \times \beta$: for subvarieties $V \subseteq X$ and $W \subseteq Y$ the image of $V \times W$ is $f(V) \times W$, and the field extension $k(f(V) \times W) \subseteq k(V \times W)$ is obtained from $k(f(V)) \subseteq k(V)$ by tensoring with $k(W)$ over $\overline{k}$ and passing to fraction fields, so the two degrees agree and definition 10.2.1 applies. Now $(f \times \mathrm{id}_Y)^{-1}(\Delta_Y) = \Gamma_f$ by lemma 14.2.4(3), and Γ_f is regularly embedded of codimension n, so proposition 14.2.6 identifies $(\delta_Y)^!_{f\times\mathrm{id}}$ with $\gamma_f^!$. Applying theorem 13.3.11(1) with $X' = Y \times Y$ and the identity,

$X'' = X \times Y$ and $f \times \mathrm{id}_Y$, and with $f \times \mathrm{id}_Y$ as the proper morphism over $Y \times Y$, whose induced morphism of preimages is f itself,

$$f_*\alpha \cdot \beta \;=\; \delta_Y^!\big((f \times \mathrm{id}_Y)_*(\alpha \times \beta)\big) \;=\; f_*\Big(\gamma_f^!\big(\alpha \times \beta\big)\Big) \;=\; f_*\big(\alpha \cdot f^*\beta\big)$$

the last step by part (1).

3. Degrees were checked after definition 14.2.8, additivity is clear from the definition, and $f^*[Y] = [X]$ is part (1). For multiplicativity, let $\beta, \beta' \in A_*(Y)$ and put $\Xi = [X] \times \beta \times \beta' \in A_*(X \times Y \times Y)$. By lemma 14.2.5,

$$[X] \times \big(\beta \cdot \beta'\big) = (\delta_Y)^!_{\mathrm{pr}_{23}}(\Xi), \qquad \big(f^*\beta\big) \times \beta' = (\gamma_f)^!_{\mathrm{pr}_{12}}(\Xi)$$

with $\mathrm{pr}_{23}\colon X \times Y \times Y \to Y \times Y$ and $\mathrm{pr}_{12}\colon X \times Y \times Y \to X \times Y$. Applying $\gamma_f^!$ to the first identity gives $f^*(\beta \cdot \beta')$, the map being refined along $\mathrm{pr}_{12}|_{X \times \Delta_Y}$, which is the identity of $X \times Y$. Corollary 13.4.8, for the regular embeddings γ_f and δ_Y with the projections pr_{12} and pr_{23}, exchanges the order:

$$f^*\big(\beta \cdot \beta'\big) = \gamma_f^!\Big((\delta_Y)^!_{\mathrm{pr}_{23}}\Xi\Big) = (\delta_Y)^!_{\psi}\Big((\gamma_f)^!_{\mathrm{pr}_{12}}\Xi\Big)$$

where $\psi\colon \Gamma_f \times Y \to Y \times Y$ is the restriction of pr_{23}. The first and third projections identify $\Gamma_f \times Y$ with $X \times Y$, and under that identification ψ is $f \times \mathrm{id}_Y$, whose preimage of Δ_Y is Γ_f; so $(\delta_Y)^!_\psi = \gamma_f^!$ by proposition 14.2.6. Hence

$$f^*\big(\beta \cdot \beta'\big) = \gamma_f^!\big(f^*\beta \times \beta'\big) = f^*\beta \cdot f^*\beta'$$

the last equality by part (1) with $\alpha = f^*\beta$.

4. For $f = \mathrm{id}_X$ the graph is the diagonal, and part (1) with $\alpha = [X]$ gives $\mathrm{id}^*\beta = [X] \cdot \beta = \beta$. For the composite, let $\zeta \in A_*(Z)$ and put $\Theta = [X \times Y] \times \zeta \in A_*(X \times Y \times Z)$. By lemma 14.2.5 and $[X \times Y] = [X] \times [Y]$,

$$[X] \times g^*\zeta = [X] \times \gamma_g^!\big([Y] \times \zeta\big) = (\gamma_g)^!_{\mathrm{pr}_{23}}(\Theta)$$

with $\mathrm{pr}_{23}\colon X \times Y \times Z \to Y \times Z$, so $f^*g^*\zeta = \gamma_f^!\big((\gamma_g)^!_{\mathrm{pr}_{23}}\Theta\big)$, the outer map being read on $X \times \Gamma_g \cong X \times Y$. Corollary 13.4.8, for the regular embeddings γ_f and γ_g with the projections pr_{12} and pr_{23}, exchanges the order, giving $(\gamma_g)^!_\rho\big((\gamma_f)^!_{\mathrm{pr}_{12}}\Theta\big)$ with $\rho\colon \Gamma_f \times Z \to Y \times Z$ the restriction of pr_{23}. By lemma 14.2.5 and part (1),

$$(\gamma_f)^!_{\mathrm{pr}_{12}}\Theta = \gamma_f^![X \times Y] \times \zeta = [X] \times \zeta$$

Identifying $\Gamma_f \times Z$ with $X \times Z$, the morphism ρ becomes $f \times \mathrm{id}_Z$, whose preimage of Γ_g is $\{(x, z) \big| z = g(f(x))\} = \Gamma_{g \circ f}$, regularly embedded of codimension $\dim Z$ by lemma 14.2.4(3). So proposition 14.2.6 identifies $(\gamma_g)^!_\rho$ with $\gamma^!_{g \circ f}$, and

$$f^*g^*\zeta \;=\; \gamma^!_{g \circ f}\big([X] \times \zeta\big) \;=\; (g \circ f)^*\zeta$$

completing the proof.

Part (1) says that intersecting with the graph is the same as pulling back and then multiplying,

which is what makes part (2) a statement about a ring rather than about a Gysin map. The projection formula is the identity used most often downstream: it converts a computation on X into a computation on Y whenever a class on X arose by restriction, and it is how an intersection number computed on a subvariety is compared with one computed on the ambient variety.

Smoothness of the source is more than the construction needs. What was used about X is that its graph in $X \times Y$ is regularly embedded, and by lemma 14.2.4(3) that holds for any algebraic scheme mapping to a smooth variety. Dropping smoothness of the target as well requires a hypothesis on the morphism instead: it must factor as a regular embedding followed by a smooth morphism.

Definition 14.2.11: Gysin Pullback for a Local Complete Intersection Morphism

Throughout this definition f is assumed to admit a *global* factorization $f = p \circ i$ with i a regular embedding and p smooth. The upstream definition (definition 5.1.50) requires such a factorization only locally on the source, which is strictly weaker and does not suffice to fix a single i and p; the global hypothesis is Fulton's convention and is what the construction below needs. Let $f\colon X \to Y$ be a local complete intersection morphism of algebraic schemes (definition 5.1.50) which admits a factorization on all of X, and fix one: $f = p \circ i$ with $i\colon X \hookrightarrow P$ a regular embedding of codimension d and $p\colon P \to Y$ smooth of relative dimension e. The *Gysin pullback* of f is

$$f^! \;=\; i^! \circ p^* \;:\; A_k(Y) \longrightarrow A_{k+e-d}(X)$$

where p^* is flat pullback (definition 10.3.3) and $i^!$ is the Gysin map of definition 13.3.1, read for $d = 0$ as flat pullback along i, which is then an open and closed immersion. The integer $e - d$ is the *virtual relative dimension* of f.

The factorization on all of X is a hypothesis, not a consequence. The definition just cited asks only that every point of X have a neighbourhood on which f factors in this way, and local factorizations need not be glued into one on all of X; without one there is no p^* and no $i^!$ to compose, and $f^!$ is not defined. Wherever $f^!$ is written a factorization on all of X is therefore part of the data. The cases used below carry an evident one: a regular embedding and a smooth morphism are their own factorizations, and a morphism of smooth varieties is factored by its graph.

Theorem 14.2.12: The Gysin Pullback Is Well Defined

Let $f\colon X \to Y$ be a local complete intersection morphism admitting a factorization on all of X.

1. $f^!$ and the virtual relative dimension $e - d$ are independent of the chosen factorization.
2. If f is smooth of relative dimension e then $f^!$ is flat pullback, and if f is a regular embedding then $f^!$ is its Gysin map.
3. If X and Y are smooth varieties then every morphism $f\colon X \to Y$ meets the hypotheses above, its graph giving a factorization on all of X, and $f^!$ is the pullback f^* of definition 14.2.8.

***Proof*:**

1. Let $f = p \circ i = p' \circ i'$ be two factorizations, with data (P, i, p, d, e) and (P', i', p', d', e'). Form $P'' = P \times_Y P'$ with projections $q\colon P'' \to P$ and $q'\colon P'' \to P'$, and set $p'' = p \circ q = p' \circ q'$. Being base changes of p' and p, the morphisms q and q' are smooth of relative dimensions e' and e, so p'' is smooth of relative dimension $e + e'$. It suffices to prove $i^! \circ p^* = (i'')^! \circ (p'')^*$ for $i'' = (i, i')\colon X \to P''$, since the same argument with the roles of the two factorizations exchanged gives $i'^! \circ p'^* = (i'')^! \circ (p'')^*$.

   Step 1: factoring i''. Write $W_1 = q^{-1}(X) = X \times_Y P'$, a closed subscheme of P'', and let $\tilde{i}\colon W_1 \hookrightarrow P''$ be its inclusion; since q is flat, lemma 14.2.4(2) makes $\tilde{i}$ a regular embedding of codimension d. The projection $\bar{q}\colon W_1 \to X$ is the base change of p' along f, hence smooth of relative dimension e', and $\gamma = (\mathrm{id}_X, i')\colon X \to W_1$ is a section of it, hence a regular embedding of codimension e' by lemma 14.2.4(1). As $i'' = \tilde{i} \circ \gamma$, theorem 13.4.7 gives $(i'')^! = \gamma^! \circ \tilde{i}^!$ and makes i'' a regular embedding of codimension $d + e'$.

   Step 2: the comparison. Let $\beta \in A_k(Y)$. Flat pullback is functorial by proposition 10.3.5(3), so $(p'')^*\beta = q^*\big(p^*\beta\big)$. Applying theorem 13.3.11(2) to the regular embedding i with $X' = P$ and the identity, $X'' = P''$ and q, and with the flat q as the morphism over P, and using proposition 14.2.6 to read the refined map along q as $\tilde{i}^!$,

$$\tilde{i}^!\big((p'')^*\beta\big) \;=\; \bar{q}^*\big(i^!p^*\beta\big)$$

   Since γ is a section of the smooth morphism $\bar{q}$, theorem 13.4.2 gives $\gamma^! \circ \bar{q}^* = \mathrm{id}$, whence

$$(i'')^!(p'')^*\beta \;=\; \gamma^!\bar{q}^*\big(i^!p^*\beta\big) \;=\; i^!p^*\beta$$

   Step 3: the degree. Step 1 exhibits i'' as a regular embedding of codimension $d + e'$, and the same step applied to the other factorization exhibits it as one of codimension $d' + e$. The codimension of a regular embedding is determined by the rank of its conormal sheaf, so $d + e' = d' + e$ and therefore $e - d = e' - d'$.

2. If f is smooth, take $P = X$ with $i = \mathrm{id}_X$, a regular embedding of codimension zero, and $p = f$; then $f^! = \mathrm{id}^* \circ f^* = f^*$. If f is a regular embedding, take $P = Y$ with $p = \mathrm{id}_Y$, smooth of relative dimension zero, and $i = f$; then $f^!$ is the Gysin map of f. Part (1) makes both readings legitimate.

3. Let X and Y be smooth of dimensions m and n. Factor f as

$$X \xrightarrow{\;\gamma_f\;} X \times Y \xrightarrow{\;\mathrm{pr}_Y\;} Y$$

   The first map is a regular embedding of codimension n by lemma 14.2.4(3), and the second is smooth of relative dimension m, being the base change of $X \to \operatorname{Spec} \overline{k}$. So f is a local complete intersection morphism with a factorization on all of X, and by part (1) its Gysin pullback may be computed from this factorization: $f^!\beta = \gamma_f^!\big(\mathrm{pr}_Y^*\beta\big)$, which is definition 14.2.8, completing the proof.

The virtual relative dimension is the bookkeeping device the name suggests: for a smooth morphism it is the actual relative dimension, for a regular embedding it is minus the codimension, and for a general local complete intersection morphism it is the difference of the two, which need not be realized

by any fibre. That generality is what Grothendieck-Riemann-Roch is stated in, the morphisms there being proper local complete intersection morphisms between possibly singular schemes.

One classical statement remains to be placed. The construction in this chapter never moved a cycle; the ambient embedding was degenerated instead. The classical construction did the opposite, and it rested on the following.

Theorem 14.2.13: The Moving Lemma

Let X be a smooth quasi-projective variety of dimension n, let α be a k-cycle on X and β an l-cycle on X. Then there is a k-cycle α' rationally equivalent to α such that α' and β intersect properly: every irreducible component of $|\alpha'| \cap |\beta|$ has dimension $k+l-n$. Moreover the cycle class obtained by counting the components of $|\alpha'| \cap |\beta|$ with their intersection multiplicities depends only on the classes of α and β.

No proof is given, and none is used. The lemma is stated because it is what the intersection product looked like before chapter 13: a product defined for cycles in general position and extended to all pairs by first moving one of them, the whole construction resting on the second assertion above, that the answer does not depend on how the cycle was moved. That second assertion is the difficult half, and it is what makes the moving lemma a theorem rather than a definition; the argument goes back to Chow. Fulton does not prove it, writing that the moving lemma is used neither for the foundations nor for the applications and referring to the examples and the literature ([38, §11.4]).

Two costs were paid on that route and are not paid here. The lemma requires quasi-projectivity, so the classical product exists only on quasi-projective varieties, whereas theorem 14.2.7 holds on every smooth variety. And a product defined by moving is defined only up to the choice made, so every property of it, commutativity included, has to be proved compatible with all choices. The deformation construction makes no choice: $\delta^!$ is a homomorphism on classes from the outset, and the proofs above use only its functorialities.

Exercise 14.2.1

1. Let L and L' be distinct lines in $\mathbb{P}^3$ meeting in a point. Compute $[L]\cdot[L']$ in $A^*(\mathbb{P}^3)$ from the grading alone, and compute $[L]\cdot[H]$ for a plane H containing neither line. Then explain why the first answer is not a defect of the theory, by exhibiting a cycle rationally equivalent to $[L]$ whose support misses L'.

2. Let X be a smooth variety and let $V, W \subseteq X$ be subvarieties with $V \cap W = \emptyset$. Show that $[V]\cdot[W] = 0$ in $A^*(X)$, working from the definition of the product rather than from the grading.

3. Let $f\colon X \to Y$ be a proper morphism of smooth varieties of the same dimension n, with $\deg f$ the degree of definition 10.2.1. Show that $f_*\big(f^*\beta\big) = (\deg f)\,\beta$ for every $\beta \in A^*(Y)$, and deduce that f^* is injective on $A^*(Y)\otimes\mathbb{Q}$ when $\deg f \neq 0$.

4. Let $p\colon P \to Y$ be smooth of relative dimension e and let $i\colon Z \hookrightarrow P$ be a regular embedding of codimension $d \geq 1$. Show that $p\circ i$ is a local complete intersection morphism of virtual relative dimension $e-d$. Then take $Y = \operatorname{Spec}\overline{k}$, $P = \mathbb{P}^n$ and $Z = \mathbb{P}^{n-d}$ a linear subspace, and compute the image of the generator of $A_0(\operatorname{Spec}\overline{k})$ under $(p\circ i)^!$.

5. Let $i\colon \mathbb{P}^2 \hookrightarrow \mathbb{P}^3$ be a plane and let $D \subseteq \mathbb{P}^3$ be a surface of degree r not containing it, so that

$[D] = r\,h$ in $A^1(\mathbb{P}^3)$ by example 10.5.4. Compute $i^*[D]$ in $A^1(\mathbb{P}^2)$, and verify the projection formula $i_*\big(i^*[D]\big) = [D]\cdot[\mathbb{P}^2]$ by computing both sides in $A^*(\mathbb{P}^3)$.

14.3 Self-Intersection and Excess

The Gysin map returns the fundamental cycle of the intersection scheme when the intersection is as proper as it can be (proposition 13.3.3). At the opposite extreme, when the cycle being intersected already lies inside Z, nothing proved so far evaluates it at all: the second half of example 13.3.9 left exactly that computation open, and for the same reason proposition 13.3.5 reached only the first clause of definition 11.2.1. This section closes the gap. The answer is the top Chern class of the normal bundle, and the statement interpolating between the two extremes, in which the intersection has the wrong dimension by a prescribed amount, is the excess intersection formula.

Everything below is stated for the Gysin map of a regular embedding, so by section 14.1 it is at the same time a statement about the product: on a smooth variety the product is $\delta^!$ of an exterior product, and δ is a regular embedding like any other. The formulas are then spent on blow-ups, which is where a subvariety is forced to meet the locus it is intersected with in the worst possible way.

Throughout, $i\colon Z \hookrightarrow X$ is a regular embedding of codimension $d \geq 1$ of algebraic schemes, with ideal sheaf $\mathcal{I} \subseteq \mathcal{O}_X$ and normal bundle $\pi\colon N \to Z$.

The reduction to a single computation is immediate from the construction. Apply definition 13.3.6 to the morphism $g = i$ itself: the preimage of Z in Z is Z, so the normal cone in question is $C_Z Z$, the zero cone of example 12.3.2(2), and the immersion of that cone into N is the vertex, that is the zero section. Specialization is therefore the identity, and the whole matter is the identification of the class of the zero section inside the Chow group of the total space of the bundle.

Lemma 14.3.1: The Class of the Zero Section

Let $\pi\colon N \to Z$ be a vector bundle of rank $d \geq 1$ on an algebraic scheme Z, with zero section $\zeta\colon Z \to N$. Then for every $\alpha \in A_k(Z)$,

$$\zeta_*\alpha \;=\; \pi^*\big(c_d(N)\cap\alpha\big) \quad \text{in } A_k(N)$$

equivalently $(\pi^*)^{-1}\zeta_*\alpha = c_d(N)\cap\alpha$, the top Chern class of N applied to α.

***Proof*:**
Write $P = \mathbb{P}(N\oplus 1)$ for the projective completion of definition 12.3.3, where $N\oplus 1 = N\oplus\mathcal{O}_Z$ has rank $d+1$, with projection $p\colon P\to Z$ and tautological class $\eta = c_1(\mathcal{O}_P(1))$. Let $u\colon N \hookrightarrow P$ be the open immersion, so that $p\circ u = \pi$, and let $\bar\zeta = u\circ\zeta\colon Z\to P$, a section of p and hence a closed immersion. Fix $\alpha\in A_k(Z)$ and put $\beta = \bar\zeta_*\alpha \in A_k(P)$.

Step 1: two trivializations. Writing $S^\bullet = \mathrm{Sym}^\bullet(N^\vee)$, the completion is $P = \mathrm{Proj}\,\big(S^\bullet[z]\big)$ with z the degree-one variable dual to the trivial summand, and N is the chart $D_+(z)$. On that chart the sheaf $\mathcal{O}_P(1)$ is free on the generator z, so

$$\mathcal{O}_P(1)\big|_N \;\cong\; \mathcal{O}_N$$

Since $\bar\zeta$ factors through N, it follows that $\bar\zeta^*\mathcal{O}_P(1)\cong\mathcal{O}_Z$ as well. Finally, the exact sequence $0\to N\to N\oplus 1\to\mathcal{O}_Z\to 0$ and theorem 12.2.15 give $c(N\oplus 1) = c(N)\,c(\mathcal{O}_Z) = c(N)$, the

total Chern class of a trivial bundle being the identity (example 12.2.12(1)); in particular $c_i(N \oplus 1) = c_i(N)$ for every i, and this vanishes for $i > d$ by theorem 12.2.9(2).

Step 2: η annihilates β. The morphism $\bar{\zeta}$ is proper, being a closed immersion, so the projection formula (proposition 11.4.4(4)) and Step 1 give

$$\eta \cap \bar{\zeta}_*\alpha \;=\; \bar{\zeta}_*\Big(c_1\big(\bar{\zeta}^*\mathcal{O}_P(1)\big) \cap \alpha\Big) \;=\; \bar{\zeta}_*\big(c_1(\mathcal{O}_Z) \cap \alpha\big) \;=\; 0$$

the last equality because c_1 of a trivial line bundle is the zero operator (example 11.4.3).

Step 3: the top coefficient. The bundle $N \oplus 1$ has rank $d+1$, so theorem 12.1.9 writes β uniquely as

$$\beta \;=\; \sum_{j=0}^{d} \eta^j \cap p^*\alpha_j, \qquad \alpha_j \in A_{k-d+j}(Z) \tag{14.1}$$

By definition 12.1.3 applied to $N \oplus 1$, whose projective bundle has relative dimension d, one has $p_*\big(\eta^j \cap p^*\gamma\big) = s_{j-d}(N \oplus 1) \cap \gamma$, which vanishes for $j < d$ and is γ for $j = d$ by proposition 12.1.5(1),(2). Applying p_* to (14.1) therefore gives $p_*\beta = \alpha_d$. On the other hand $p \circ \bar{\zeta} = \mathrm{id}_Z$, so functoriality of proper pushforward (definition 10.2.1) gives $p_*\beta = \alpha$. Hence $\alpha_d = \alpha$.

Step 4: the remaining coefficients. Theorem 12.2.9(1) applied to $N \oplus 1$, together with the identification of its Chern classes in Step 1, reads

$$\sum_{i=0}^{d} \eta^{\,d+1-i} \cap p^*\big(c_i(N) \cap \gamma\big) \;=\; 0$$

for every $\gamma \in A_*(Z)$, so that $\eta^{\,d+1} \cap p^*\gamma = -\sum_{i=1}^{d} \eta^{\,d+1-i} \cap p^*(c_i(N) \cap \gamma)$. Capping (14.1) with η, using Step 2 on the left and this relation on the term $j = d$, and reindexing the resulting sum by $j = d - i$,

$$0 \;=\; \sum_{j=0}^{d-1} \eta^{j+1} \cap p^*\alpha_j \;-\; \sum_{j=0}^{d-1} \eta^{j+1} \cap p^*\big(c_{d-j}(N) \cap \alpha_d\big) \;=\; \sum_{m=1}^{d} \eta^{\,m} \cap p^*\big(\alpha_{m-1} - c_{d-m+1}(N) \cap \alpha_d\big)$$

The exponents occurring lie in $\{0, 1, \ldots, d\}$, so this is a representation of the zero class in the form of theorem 12.1.9, and uniqueness forces every coefficient to vanish: $\alpha_{m-1} = c_{d-m+1}(N) \cap \alpha_d$ for $1 \le m \le d$. Taking $m = 1$ and using Step 3,

$$\alpha_0 \;=\; c_d(N) \cap \alpha$$

Step 5: restriction to the bundle. The open immersion u is flat of relative dimension zero. The square with $\bar{\zeta}$ and ζ over u is a fibre square, $\bar{\zeta}$ factoring through N, so proposition 10.3.6 gives $u^*\beta = \zeta_*\alpha$. Applying u^* to (14.1), every term with $j \ge 1$ contains a factor $\eta \cap -$, whose pullback is $c_1(\mathcal{O}_P(1)|_N) \cap u^*(-) = 0$ by proposition 11.4.4(4) and Step 1; and the term $j = 0$ is $u^*p^*\alpha_0 = \pi^*\alpha_0$ by proposition 10.3.5(3). Hence $\zeta_*\alpha = \pi^*\alpha_0 = \pi^*(c_d(N) \cap \alpha)$, as we sought to show.

The zero section meets every fibre of N in exactly one point, and yet the class it carries is not the pullback of α but the pullback of α cut down by the top Chern class. On a trivial bundle of rank $d \ge 1$ the top Chern class vanishes and the zero section therefore carries the zero class, and the same

holds whenever N admits a nowhere-vanishing section: such a section spans a trivial line subbundle with locally free quotient Q of rank $d-1$, so theorem 12.2.15 gives $c(N)=c(Q)$ and $c_d(N)=0$, no bundle carrying a nonzero Chern class above its rank. Nonvanishing of $\zeta_*\alpha$ is therefore an obstruction to the existence of such a section and not a criterion for one. On $\mathbb{P}^1$ the bundle $\mathcal{O}_{\mathbb{P}^1}(-1)\oplus\mathcal{O}_{\mathbb{P}^1}(1)$ has c_2 the zero operator, the groups $A_{k-2}(\mathbb{P}^1)$ vanishing for every $k\le 1$, and yet $\mathcal{O}_{\mathbb{P}^1}(-1)$ has no nonzero section, so every section of the sum vanishes wherever its second coordinate does. Since π^* is an isomorphism (theorem 10.4.6), the identity is equivalent to the evaluation of $(\pi^*)^{-1}$ on classes supported on the zero section, and that is what the Gysin map of chapter 13 was waiting for.

Theorem 14.3.2: The Self-Intersection Formula

Let $i\colon Z\hookrightarrow X$ be a regular embedding of codimension $d\ge 1$ with normal bundle N. Then for every $\alpha\in A_k(Z)$:

1. the refined Gysin homomorphism of i along i itself is the operator $c_d(N)\cap -$, that is $i_i^!\alpha = c_d(N)\cap\alpha$ in $A_{k-d}(Z)$, in the notation of box 14.2.1;
2. the Gysin map of definition 13.3.1 satisfies

$$i^!\big(i_*\alpha\big) \;=\; c_d(N)\cap\alpha \quad \text{in } A_{k-d}(Z)$$

***Proof*:**

1. Apply definition 13.3.6 with $X'=Z$ and $g=i$. The ideal sheaf of Z in Z is zero, so the preimage $Z'=i^{-1}(Z)$ is Z itself, $h=\mathrm{id}_Z$ and $N'=h^*N=N$. The associated graded algebra of the zero ideal is $\mathcal{O}_Z$ concentrated in degree zero, so $C_{Z'}X'=C_ZZ$ is the zero cone of example 12.3.2(2), whose total space is Z; and the immersion $j\colon C_ZZ\hookrightarrow N$ of lemma 12.3.13 is induced by the surjection of graded algebras $\mathrm{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)\to\mathcal{O}_Z$ killing every positive degree, which is the vertex of definition 12.3.1, that is the zero section ζ. For the specialization homomorphism $\sigma'\colon A_k(Z)\to A_k(C_ZZ)=A_k(Z)$ of the pair (Z,Z), theorem 13.2.7 gives $\sigma'[V]=[C_VV]=[V]$ for every k-dimensional subvariety $V\subseteq Z$, the preimage of Z in V being V. Such classes generate $A_k(Z)$ (definition 10.1.4), so σ' is the identity. Therefore

$$i_i^!\alpha \;=\; (\pi^*)^{-1}j_*\sigma'\alpha \;=\; (\pi^*)^{-1}\zeta_*\alpha \;=\; c_d(N)\cap\alpha$$

   the last equality by lemma 14.3.1.

2. Apply theorem 13.3.11(1) with $X'=X$, $X''=Z$ and $p=i$, which is proper as a closed immersion. The preimage of Z in Z is Z and the induced morphism q is id_Z, so the identity reads $i^!(i_*\alpha)=i_i^!\alpha$, where the left-hand side is the refined map along id_X, which is the Gysin map of definition 13.3.1 by proposition 13.3.8, and the right-hand side is the refined map along i evaluated in part (1). Combining the two gives $i^!(i_*\alpha)=c_d(N)\cap\alpha$, completing the proof.

The theorem says what it means to intersect a subvariety with itself. Pushing α into X and pulling it back records no information about how Z sits inside X except through the normal bundle, and the whole of that information is the single operator $c_d(N)$. Two consequences are worth separating. The composite $i^!i_*$ is not the identity, and it is not even injective: on a subvariety with trivial normal

bundle it is zero. And the sign of a self-intersection number, which has no counterpart in a naive count of intersection points, is the sign of a Chern number of N; this is why the exceptional curve of a blow-up can meet itself a negative number of times. Since the Gysin pullback of an l.c.i. morphism restricts to the Gysin map on a regular embedding (theorem 14.2.12(2)), part (2) is at the same time a statement about the pullback of definition 14.2.11: for the l.c.i. morphism i the composite $i^! \circ i_*$ is the operator $c_d(N) \cap -$.

In codimension one the theorem completes the comparison begun in proposition 13.3.5, which matched the Gysin map with the operator $D \cdot -$ of chapter 11 only for cycles not contained in the support of D.

Corollary 14.3.3: The Gysin Map on a Divisor Class

Let D be an effective Cartier divisor on an algebraic scheme X with $D \neq X$, and let $i\colon D \hookrightarrow X$ be the inclusion. Then for every $\alpha \in A_k(D)$,

$$i^!\big(i_*\alpha\big) \;=\; c_1\big(\mathcal{O}_X(D)|_D\big) \cap \alpha$$

In particular, for a k-dimensional subvariety $V \subseteq D$ the class $i^![V]$ is the image in $A_{k-1}(D)$ of the intersection class $D \cdot [V]$ computed by the second clause of definition 11.2.1.

***Proof*:**
The inclusion of an effective Cartier divisor is a regular embedding of codimension one with normal bundle $N = \mathcal{O}_X(D)|_D$ (example 12.3.15), and $c_1(N)$ is the top Chern class of a line bundle, so theorem 14.3.2(2) gives the displayed identity. For the second assertion, let $V \subseteq D$ be a k-dimensional subvariety with inclusion ι_V into D. Since V is contained in $|D|$, the second clause of definition 11.2.1 computes $D \cdot [V] = c_1(\mathcal{O}_X(D)|_V) \cap [V]$ in $A_{k-1}(V)$. Pushing that class forward along ι_V and applying the projection formula (proposition 11.4.4(4)) to the proper morphism ι_V, whose pullback of $\mathcal{O}_X(D)|_D$ is $\mathcal{O}_X(D)|_V$, gives $\iota_{V*}(D \cdot [V]) = c_1(\mathcal{O}_X(D)|_D) \cap [V]$, which is $i^!(i_*[V])$ by the first assertion, as we sought to show.

Example 14.3.4: A Line Meeting Itself in the Plane
Let $X = \mathbb{P}^2$ and $L = \{x_0 = 0\}$, an effective Cartier divisor with $\mathcal{O}_{\mathbb{P}^2}(L) \cong \mathcal{O}_{\mathbb{P}^2}(1)$ (example 11.1.4), so that $N = \mathcal{O}_{\mathbb{P}^2}(1)|_L \cong \mathcal{O}_{\mathbb{P}^1}(1)$ (example 13.1.7). The second half of example 13.3.9 produced the class $i_i^![L] = (\pi^*)^{-1}\zeta_*[L]$, the refined Gysin map along i applied to $[L]$, and could go no further. Theorem 14.3.2(1) evaluates it:

$$i_i^![L] \;=\; c_1\big(\mathcal{O}_{\mathbb{P}^1}(1)\big) \cap [L] \;=\; [\mathrm{pt}]$$

by example 11.4.7, a single point of L with multiplicity one. This is the value predicted there from example 11.2.3, where $L \cdot [L] = [q]$ was computed from the restricted line bundle, and corollary 14.3.3 identifies the two computations in general rather than in this instance.
For a smooth conic $C \subseteq \mathbb{P}^2$ the same argument gives $N = \mathcal{O}_{\mathbb{P}^2}(2)|_C$, and example 12.3.15 evaluated $c_1(\mathcal{O}_{\mathbb{P}^2}(2)|_C) \cap [C] = 4\,[\mathrm{pt}]$, so $i^!(i_*[C]) = 4\,[\mathrm{pt}]$. The self-intersection number of a plane curve of degree m is m^2, and the Gysin map records it on the curve itself rather than in $A_0(\mathbb{P}^2)$.

The examples so far are divisors, where the normal bundle is a line bundle and $c_d(N)$ is the operator of chapter 11. The construction that gives higher codimension, and with it the geometry the formula

was built for, is the blow-up: its exceptional divisor is a projectivized normal bundle, and it meets itself in every point.

Lemma 14.3.5: The Exceptional Divisor of a Blow-up Along a Regular Centre

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with $Z \neq \emptyset$, ideal sheaf $\mathcal{I}$ and normal bundle N. Let $f\colon \widetilde{X} = \mathrm{Bl}_Z X \to X$ be the blow-up (definition 8.4.1) and let $\widetilde{Z} = f^{-1}(Z)$ be the closed subscheme cut out by $\mathcal{I}' = \mathcal{I}\mathcal{O}_{\widetilde{X}}$. Then:

1. $\widetilde{Z} = \mathbb{P}(N)$, with the restriction $g\colon \mathbb{P}(N) \to Z$ of f as its bundle projection;
2. $j\colon \widetilde{Z} \hookrightarrow \widetilde{X}$ is a regular embedding of codimension one whose conormal surjection $g^*(\mathcal{I}/\mathcal{I}^2) \to \mathcal{I}'/\mathcal{I}'^2$ is the universal surjection $g^*(N^\vee) \to \mathcal{O}_{\mathbb{P}(N)}(1)$ of box 12.2.5. In particular the normal bundle of j is $\mathcal{O}_{\mathbb{P}(N)}(-1)$, sitting inside g^*N as the tautological subbundle with quotient the universal quotient bundle Q of rank $d-1$.

This chapter calls $\widetilde{Z}$ the *exceptional divisor*, following Fulton, and means by it the scheme-theoretic preimage: that is the object carrying the codimension-one regular embedding of (2), and it is what the blow-up formula below uses. The companion definition 8.4.1 uses the same scheme-theoretic preimage. By (1) the scheme $\widetilde{Z}$ is a projective bundle over Z, hence reduced exactly when Z is, so it differs from the reduced preimage $f^{-1}(Z)_{\mathrm{red}}$ whenever Z is not reduced, and regular embeddings with non-reduced centre do occur here, as $Z = V(x^2) \subseteq \mathbb{A}^1$ already shows.

***Proof*:**

Realize the Rees algebra as the subalgebra $S = \bigoplus_{n\geq 0} \mathcal{I}^n t^n$ of $\mathcal{O}_X[t]$, so that $\widetilde{X} = \mathrm{Proj}\,(S)$ over X by definition 8.4.1. The algebra S is generated in degree one, so the affine charts $D_+(at)$ attached to local sections a of $\mathcal{I}$ cover $\widetilde{X}$; on such a chart $\widetilde{X}$ is $\mathrm{Spec}\,(S_{(at)})$, whose elements are the fractions y/a^n with y a local section of $\mathcal{I}^n$.

1. The homogeneous ideal $\mathcal{I}S \subseteq S$ has degree-n part $\mathcal{I}\cdot\mathcal{I}^n t^n = \mathcal{I}^{n+1}t^n$, so
$$S/\mathcal{I}S \;=\; \bigoplus_{n\geq 0} \mathcal{I}^n/\mathcal{I}^{n+1}$$
which is $\mathrm{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)$ by lemma 12.3.10, glued over an affine cover as in the proof of proposition 12.3.11. Taking relative Proj of the surjection $S \to S/\mathcal{I}S$ exhibits $\mathrm{Proj}\,\big(\mathrm{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)\big)$ as the closed subscheme of $\widetilde{X}$ cut out by the ideal generated by $\mathcal{I}$, that is by $\mathcal{I}'$, and its structure morphism to Z is the restriction of f. Since N has $(\mathcal{I}/\mathcal{I}^2)^\vee$ as its sheaf of sections (definition 5.1.45), that relative Proj is $\mathbb{P}(N)$ in the convention of box 9.0.2.
2. *The ideal is invertible.* On the chart $D_+(at)$ the ideal $\mathcal{I}'$ is generated by the image of a, since every local section y of $\mathcal{I}$ satisfies $y = a\cdot(y/a)$ with y/a in $S_{(at)}$. That generator is a nonzerodivisor: if $a\cdot(y/a^n) = 0$ in $S_{(at)}$ with y a local section of $\mathcal{I}^n$, then $(at)^m\, a\, y\, t^n = 0$ in $\mathcal{O}_X[t]$ for some $m \geq 0$, that is $a^{m+1}y = 0$, and the same relation forces $y/a^n = 0$ in $S_{(at)}$. Hence $\widetilde{Z}$ is an effective Cartier divisor and j is a regular embedding of codimension one (example 12.3.15), which also recovers proposition 8.4.2(3); its conormal sheaf is $\mathcal{I}'/\mathcal{I}'^2 = \mathcal{I}' \otimes \mathcal{O}_{\widetilde{Z}}$, invertible on $\widetilde{Z}$.
Which invertible sheaf. The ideal $\mathcal{I}'$ is generated by the image of $\mathcal{I}$, so the canonical map

$g^*(\mathcal{I}/\mathcal{I}^2) \to \mathcal{I}'/\mathcal{I}'^2$ is surjective. Compare it on $D_+(at) \cap \widetilde{Z}$ with the universal surjection of $\mathbb{P}(N) = \operatorname{Proj} \operatorname{Sym}^\bullet(\mathcal{I}/\mathcal{I}^2)$. There $\mathcal{I}'/\mathcal{I}'^2$ is free on the class of a by the previous paragraph, while $\mathcal{O}_{\mathbb{P}(N)}(1)$ is free on the image $\bar{a}$ of the degree-one element at. A local section b of $\mathcal{I}$ satisfies $b = a \cdot (b/a)$ upstairs, and its class satisfies $\bar{b} = \bar{a} \cdot \overline{b/a}$ downstairs, the reduction $S \to S/\mathcal{I}S$ carrying b/a to $\overline{b/a}$. Under the two trivializations the two surjections therefore have the same coefficient on every local section, so they agree and $\mathcal{I}'/\mathcal{I}'^2 = \mathcal{O}_{\mathbb{P}(N)}(1)$. Dualizing gives the inclusion $\mathcal{O}_{\mathbb{P}(N)}(-1) \hookrightarrow g^*N$, which is the tautological subbundle of box 12.2.5, whose quotient Q is locally free of rank $d-1$, completing the proof.

The lemma is the reason the blow-up is the standard source of examples for the self-intersection formula: the exceptional divisor is a divisor whose normal bundle is the tautological line bundle, with first Chern class $-\xi$ for the tautological class ξ of section 12.1. In the smallest case the resulting number was computed by hand upstream, and the general formula reproduces it.

Example 14.3.6: The Exceptional Curve of a Blown-up Surface

Let $X = \mathbb{P}^2$ and let $Z = \{P\}$ with $P = [0:0:1]$. On the affine chart $\{x_2 \neq 0\}$ the ideal of P is $(x_0/x_2, x_1/x_2)$, a regular sequence of length two in the polynomial ring of the chart, so $Z \hookrightarrow X$ is a regular embedding of codimension two whose normal bundle N is a rank-two vector bundle over a point, that is a two-dimensional vector space. Write $f\colon \widetilde{X} = \operatorname{Bl}_P \mathbb{P}^2 \to \mathbb{P}^2$ for the blow-up, $\widetilde{Z}$ for its exceptional divisor, written E in theorem 8.4.6, and $j\colon \widetilde{Z} \hookrightarrow \widetilde{X}$ for its inclusion. By lemma 14.3.5,

$$\widetilde{Z} \;=\; \mathbb{P}(N) \;\cong\; \mathbb{P}^1, \qquad N_{\widetilde{Z}}\widetilde{X} \;=\; \mathcal{O}_{\mathbb{P}^1}(-1)$$

The self-intersection formula now evaluates the intersection of $\widetilde{Z}$ with itself. By corollary 14.3.3 and additivity of the first Chern class (proposition 11.4.4(3)),

$$j^!\big(j_*[\widetilde{Z}]\big) \;=\; c_1\big(\mathcal{O}_{\mathbb{P}^1}(-1)\big) \cap [\mathbb{P}^1] \;=\; -\,c_1\big(\mathcal{O}_{\mathbb{P}^1}(1)\big) \cap [\mathbb{P}^1] \;=\; -[\mathrm{pt}]$$

using example 11.4.7. Its degree (definition 10.2.4) is -1, which is the self-intersection number $E^2 = -1$ recorded upstream. The same computation applies at any point of any smooth surface, differing only in the verification that the maximal ideal at that point is generated by a regular sequence of length two; what the general formula contributes is that the number -1 is not an accident of the plane but the degree of the tautological line bundle on the projectivized normal space.

The negative sign is where the Gysin map departs furthest from counting points. A cycle contained in Z has no intersection points with Z to count that are not already in it, and the number the formula returns is a Chern number of the normal bundle, with whatever sign that bundle has. The upstream proof of $E^2 = -1$ argued from the surface pairing and the geometry of the blow-down; the argument here uses no property of surfaces and no property of blow-ups beyond lemma 14.3.5.

Between the proper case, where the answer is the fundamental cycle of $V \cap Z$, and the self-intersection case, where it is a top Chern class, lies everything else: the preimage Z' has some dimension between the expected one and $\dim X'$, and the normal cone fills only part of the pulled-back normal bundle. When the preimage is itself regularly embedded the discrepancy is a vector bundle, and it is the only new input the general formula needs.

The comparison rests on the conormal sheaves. For a regular embedding of codimension d' the conormal sheaf $\mathcal{I}'/\mathcal{I}'^2$ is locally free of rank d' (proposition 5.1.44), and since $\mathcal{I}' = \mathcal{I}\mathcal{O}_{X'}$ is generated

by the image of $\mathcal{I}$, the canonical map $h^*(\mathcal{I}/\mathcal{I}^2) \to \mathcal{I}'/\mathcal{I}'^2$ is a surjection of vector bundles. A surjection of vector bundles has locally free kernel, being locally split, so dualizing gives an inclusion of vector bundles with locally free cokernel; in particular $d' \leq d$.

Definition 14.3.7: The Excess Bundle

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with normal bundle N and ideal sheaf $\mathcal{I}$, let $g\colon X' \to X$ be a morphism of algebraic schemes, and form the fibre square of definition 13.3.6, with $Z' = g^{-1}(Z)$, ideal sheaf $\mathcal{I}' = \mathcal{I}\mathcal{O}_{X'}$, and $h\colon Z' \to Z$. Suppose $i'\colon Z' \hookrightarrow X'$ is a regular embedding of codimension d' with normal bundle N'. The dual of the conormal surjection $h^*(\mathcal{I}/\mathcal{I}^2) \to \mathcal{I}'/\mathcal{I}'^2$ is an inclusion of vector bundles $N' \hookrightarrow h^*N$ on Z', and the *excess bundle* of the square is its cokernel

$$E \;=\; h^*N/N'$$

a vector bundle of rank $e = d - d'$ on Z'. When $e = 0$ the excess bundle is the zero bundle, and the operator $c_0(E)$ is then read as the identity, definition 12.2.3 being stated for bundles of positive rank.

The excess bundle measures how much of the normal directions to Z fail to be normal directions to Z' after base change. It vanishes exactly when $d' = d$, that is when the preimage has the expected codimension and the two normal bundles agree; at the other extreme, when $X' = Z$ and $g = i$, the subbundle N' is zero and the excess bundle is all of N. Its rank is the number of dimensions by which the intersection is too large.

The identity that converts the excess bundle into a correction term is the following, which contains lemma 14.3.1 as the case $N' = 0$ and is deduced from it.

Lemma 14.3.8: The Class of a Subbundle

Let $0 \to N' \xrightarrow{j} N \to E \to 0$ be an exact sequence of vector bundles on an algebraic scheme Z, with $\operatorname{rank} E = e$ and $\operatorname{rank} N' = d'$, and write $\pi\colon N \to Z$ and $\pi'\colon N' \to Z$ for the projections. Then for every $\gamma \in A_m(Z)$,

$$j_*\pi'^*\gamma \;=\; \pi^*\big(c_e(E) \cap \gamma\big) \quad \text{in } A_{m+d'}(N)$$

***Proof*:**
If $e = 0$ then j is an isomorphism of bundles and both sides are $\pi^*\gamma$, the operator $c_0(E)$ being the identity by the convention of definition 14.3.7. So assume $e \geq 1$, write $\pi_E\colon E \to Z$ for the projection and $\zeta_E\colon Z \to E$ for the zero section, and let $\rho\colon N \to E$ be the morphism of total spaces induced by the surjection $N \to E$.

Step 1: the square is a fibre square with ρ flat. Both assertions are local on Z. Over an affine open on which N', N and E are free, the surjection $N \to E$ splits, so there $N \cong N' \times E$ over the base with ρ the second projection, which is flat of relative dimension d', and the scheme-theoretic

preimage $\rho^{-1}\big(\zeta_E(Z)\big)$ is N' embedded by j. Hence ρ is flat of relative dimension d' and

$$\begin{array}{ccc} N' & \xrightarrow{\;j\;} & N \\ {\scriptstyle\pi'}\downarrow & & \downarrow{\scriptstyle\rho} \\ Z & \xrightarrow{\;\zeta_E\;} & E \end{array}$$

is a fibre square, with proper horizontal maps and flat vertical maps.

Step 2: transport the zero-section identity. Proposition 10.3.6 applied to that square gives $\rho^*\zeta_{E*}\gamma = j_*\pi'^*\gamma$. By lemma 14.3.1 applied to the bundle E, the left-hand side is $\rho^*\pi_E^*(c_e(E)\cap\gamma)$, and $\pi_E\circ\rho=\pi$, so proposition 10.3.5(3) rewrites it as $\pi^*(c_e(E)\cap\gamma)$. Combining the two displays gives the assertion, completing the proof.

The refined Gysin map is built from a specialization followed by a pushforward into the pulled-back normal bundle, and when the preimage is regularly embedded the specialization is already the Gysin map of the preimage; the pushforward is then the subbundle inclusion, and lemma 14.3.8 evaluates it.

Theorem 14.3.9: The Excess Intersection Formula

Let $i\colon Z\hookrightarrow X$ be a regular embedding of codimension $d\geq 1$ with normal bundle N, let $g\colon X'\to X$ be a morphism of algebraic schemes, and suppose the preimage $Z'=g^{-1}(Z)$ is regularly embedded in X' of codimension $d'\geq 1$. Let E be the excess bundle of definition 14.3.7, of rank $e=d-d'$. Then for every $\alpha\in A_k(X')$,

$$i_g^!\alpha \;=\; c_e(E)\cap i'^!\alpha \quad \text{in } A_{k-d}(Z')$$

where $i_g^!$ is the refined Gysin homomorphism of i along g and $i'^!$ is the Gysin map of i', in the notation of box 14.2.1.

***Proof*:**
Write $\mathcal{I}$ and $\mathcal{I}'$ for the ideal sheaves of Z in X and of Z' in X', let $N'=N_{Z'}X'$ with projection π', and let $\varpi\colon h^*N\to Z'$ be the projection of the pulled-back normal bundle.

Step 1: the immersion of the cone is the subbundle inclusion. By lemma 12.3.13 the closed immersion $j\colon C_{Z'}X'\hookrightarrow h^*N$ is induced by the canonical surjection of graded $\mathcal{O}_{Z'}$-algebras

$$\operatorname{Sym}^\bullet\big(h^*(\mathcal{I}/\mathcal{I}^2)\big)\longrightarrow\bigoplus_{n\geq 0}\mathcal{I}'^n/\mathcal{I}'^{n+1}$$

Since i' is a regular embedding, lemma 12.3.10 identifies the target with $\operatorname{Sym}^\bullet(\mathcal{I}'/\mathcal{I}'^2)$ by the canonical surjection, which is the identity in degree one, and identifies $C_{Z'}X'$ with N' (proposition 12.3.11). A homomorphism of graded algebras out of a symmetric algebra is determined by its degree-one part, so the displayed map is $\operatorname{Sym}^\bullet(\varphi)$ for $\varphi\colon h^*(\mathcal{I}/\mathcal{I}^2)\to\mathcal{I}'/\mathcal{I}'^2$ the conormal surjection. Taking relative spectra, $j\colon N'\to h^*N$ is the inclusion of vector bundles dual to φ, that is the inclusion of definition 14.3.7, with cokernel E of rank e.

Step 2: evaluation. Let $\sigma'\colon A_k(X')\to A_k(C_{Z'}X')=A_k(N')$ be the specialization homomorphism of the pair (Z',X'). By definition 13.3.1 applied to i', the Gysin map is $i'^!=(\pi'^*)^{-1}\circ\sigma'$, so

$\sigma'\alpha = \pi'^*(i'^!\alpha)$. Hence, using definition 13.3.6 and then lemma 14.3.8 with $\gamma = i''^!\alpha$,

$$\varpi^*\big(i_g^!\alpha\big) \;=\; j_*\sigma'\alpha \;=\; j_*\pi'^*\big(i'^!\alpha\big) \;=\; \varpi^*\Big(c_e(E)\cap i'^!\alpha\Big)$$

The pullback ϖ^* is injective, being an isomorphism by theorem 10.4.6, so $i_g^!\alpha = c_e(E)\cap i'^!\alpha$, as we sought to show.

The formula says that an intersection of the wrong dimension is computed by intersecting properly on the preimage and then correcting by the top Chern class of what was left over. When $e = 0$ the correction is the identity and the two Gysin maps agree, which is the regime of proposition 13.3.3: the preimage has the expected codimension and the answer is read off it directly. When $e = d$, so that $d' = 0$ and $Z' = X'$, the hypothesis $d' \geq 1$ puts the case outside the statement, though only nominally: definition 14.2.11 reads the Gysin map of a codimension-zero embedding as flat pullback along it, which for $i' = \mathrm{id}_{X'}$ is the identity, so with that reading the uncorrected term is α itself, the correction is all of $c_d(h^*N)$, and for $g = i$ the formula returns theorem 14.3.2(1). The formula also explains the role of the normal cone in the general construction: without a regularity hypothesis on Z' there is no excess bundle, and the discrepancy between $C_{Z'}X'$ and h^*N is recorded by a Segre class instead.

Example 14.3.10: A Plane Through a Line in Three-Space

Let $X = \mathbb{P}^3$ with coordinates $x_0, \dots, x_3$, let $Z = L = \{x_2 = x_3 = 0\}$ be a line and let $X' = H = \{x_3 = 0\}$ be a plane containing it, with $g\colon H \hookrightarrow \mathbb{P}^3$ the inclusion. By exercise 12.3.1 (2) the embedding i is regular of codimension two with $N = \mathcal{O}_{\mathbb{P}^1}(1)^{\oplus 2}$. The expected dimension of $H \cap L$ is $\dim H - 2 = 0$, but the preimage is $Z' = g^{-1}(L) = L$, of dimension one.

The excess bundle. The line L is an effective Cartier divisor on $H \cong \mathbb{P}^2$ cut out by x_2, so i' is a regular embedding of codimension $d' = 1$ with $N' = \mathcal{O}_{\mathbb{P}^2}(1)|_L \cong \mathcal{O}_{\mathbb{P}^1}(1)$ (example 11.1.4, example 12.3.15). The excess bundle has rank $e = 2 - 1 = 1$, and the Whitney formula (theorem 12.2.15) applied to $0 \to N' \to N \to E \to 0$ gives, with $h = c_1(\mathcal{O}_{\mathbb{P}^1}(1))$,

$$c(E) \;=\; c(N)\,c(N')^{-1} \;=\; (\mathrm{id}+h)^2(\mathrm{id}+h)^{-1} \;=\; \mathrm{id}+h$$

so $c_1(E) = h$.

The class. The plane H is a variety not contained in $|L|$, and its scheme-theoretic intersection with L is L, so $i'^![H] = [L]$ by proposition 13.3.5, which is the computation of exercise 13.3.1 (2). Theorem 14.3.9 then gives

$$i_g^![H] \;=\; c_1(E)\cap[L] \;=\; h\cap[L] \;=\; [\mathrm{pt}]$$

in $A_0(L)$, of degree one. The uncorrected answer $[L]$ has the wrong dimension and the wrong degree; the correction cuts it down by one dimension and returns the intersection number a plane and a line in general position would have. What the refined map adds is that the class is recorded on L, the locus where the two meet, and not only as a number.

Applying the formula to a blow-up produces the statement that lets Chow groups be computed after blowing up. The square in question is the defining one for the exceptional divisor, and lemma 14.3.5 has already identified all of its data.

Chern classes were built in chapter 12 as *operators* on Chow groups, and box 12.2.4 was careful to say that they are not elements. On a smooth variety they may be read as elements after all,

because the ring gives a canonical one to read them as: the class $c_i(E) \cap [X]$. That the operator and multiplication by that class agree is not a definition and not formal, and chapter 17 leans on it whenever a Schubert class is identified with a Chern class.

Before that, one criterion for reading a product as a count. It is the precise form of the classical principle that transverse intersections may simply be counted, and chapter 17 appeals to it in every enumerative computation.

Proposition 14.3.11: Multiplicity One at a Transverse Point

Let X be a smooth variety and let $V_1, V_2 \subseteq X$ be closed subvarieties with $e = \dim V_1 + \dim V_2 - \dim X$, and suppose $Z = V_1 \cap V_2$ is irreducible of dimension e. If there is a closed point $p \in Z$ at which V_1 and V_2 are both smooth and $\dim(T_pV_1 \cap T_pV_2) = e$, then

$$[V_1] \cdot [V_2] = [Z]$$

***Proof*:**
V_1 and V_2 meet properly, Z being their only component, so definition 14.4.8 gives $[V_1] \cdot [V_2] = i(Z; V_1 \cdot V_2; X)\,[Z]$, and the claim is that the multiplicity is 1. The ideal of the scheme $V_1 \cap V_2$ is $\mathcal{I}_{V_1} + \mathcal{I}_{V_2}$, so $T_p(V_1 \cap V_2) = T_pV_1 \cap T_pV_2$ has dimension e, while $\dim \mathcal{O}_{V_1 \cap V_2, p} = e$ because Z is irreducible of dimension e; a local ring whose Zariski tangent space has dimension equal to its Krull dimension is regular, hence a domain. Let η be the generic point of Z and $\mathcal{O} = \mathcal{O}_{X,\eta}$, a regular local ring of dimension $\dim X - e$. Localizing the domain $\mathcal{O}_{V_1 \cap V_2, p}$ at its minimal prime gives a field, so

$$\mathcal{O}/(\mathcal{I}_{V_1} + \mathcal{I}_{V_2}) \;=\; \mathcal{O}_{V_1 \cap V_2, \eta}$$

is a field, that is, $\mathcal{I}_{V_1} + \mathcal{I}_{V_2} = \mathfrak{m}$, the maximal ideal of $\mathcal{O}$. Each V_t is smooth at p, hence on an open set meeting Z, hence at η; so $\mathcal{O}/\mathcal{I}_{V_t}$ is regular of dimension $\dim V_t - e$, and the image of $\mathcal{I}_{V_t}$ in $\mathfrak{m}/\mathfrak{m}^2$ has dimension $(\dim X - e) - (\dim V_t - e) = \dim X - \dim V_t$, the codimension d_t of V_t. Choose $x_1, \dots, x_{d_t} \in \mathcal{I}_{V_t}$ lifting a basis of that image. Then $\mathcal{O}/(x_1, \dots, x_{d_t})$ is regular of dimension $\dim X - e - d_t$, hence a domain, and it surjects onto $\mathcal{O}/\mathcal{I}_{V_t}$, a ring of the same dimension. That ring is a catenary domain, being regular, so a nonzero ideal in it lowers the dimension; the kernel of the surjection is therefore zero and $\mathcal{I}_{V_t} = (x_1, \dots, x_{d_t})$. Now $d_1 + d_2 = \dim X - e = \dim \mathcal{O}$, and the two chosen sets of elements together generate $\mathfrak{m}$, so they form a regular system of parameters of $\mathcal{O}$ and in particular a regular sequence. The Koszul complex on the generators of $\mathcal{I}_{V_2}$ is therefore a free resolution of $\mathcal{O}/\mathcal{I}_{V_2}$ over $\mathcal{O}$, and tensoring it with $\mathcal{O}/\mathcal{I}_{V_1}$ gives the Koszul complex on the images of those generators in the regular local ring $\mathcal{O}/\mathcal{I}_{V_1}$, where they again form a regular sequence, being a system of $d_2 = \dim \mathcal{O}/\mathcal{I}_{V_1}$ generators of its maximal ideal. Hence $\operatorname{Tor}_j^{\mathcal{O}}(\mathcal{O}/\mathcal{I}_{V_1}, \mathcal{O}/\mathcal{I}_{V_2}) = 0$ for $j \geq 1$, while the term $j = 0$ is $\mathcal{O}/\mathfrak{m}$, of length one. By theorem 14.4.9 the multiplicity is 1.

Proposition 14.3.12: Degree of a Transverse Intersection

Let X be a smooth *complete* variety of dimension N, so that the degree of a zero-cycle is defined (definition 10.2.4), and let $Z_1, \dots, Z_s \subseteq X$ be closed subvarieties. If $\sum_i \operatorname{codim} Z_i > N$ then $[Z_1] \cdots [Z_s] = 0$, the product lying in a Chow group of negative dimension. If $\sum_i \operatorname{codim} Z_i = N$, the intersection $Z_1 \cap \cdots \cap Z_s$ is finite, and at each point P of it every Z_i is smooth with $T_P Z_1 \cap \cdots \cap T_P Z_s = 0$, then

$$\deg\big([Z_1] \cdots [Z_s]\big) = \#\big(Z_1 \cap \cdots \cap Z_s\big)$$

each point counting once.

***Proof*:**
Iterating the two-factor case (theorem 13.4.7), the product is the refined Gysin class (definition 13.3.6) of the small diagonal $\delta\colon X \to X^s$, a regular embedding whose normal bundle is $T^{\oplus(s-1)}$ for T the tangent bundle, applied to $[Z_1 \times \cdots \times Z_s]$. At a point P of the intersection the intersection scheme has tangent space $\bigcap_i T_P Z_i = 0$ and so is the reduced point P there; the normal cone to it in $Z_1 \times \cdots \times Z_s$ is the tangent space $T_P Z_1 \oplus \cdots \oplus T_P Z_s$, of dimension $\sum_i (N - \operatorname{codim} Z_i) = (s-1)N$; and the map $(u_1, \dots, u_s) \mapsto (u_1 - u_2, \dots, u_{s-1} - u_s)$ carrying it into the fibre $T_P^{\oplus(s-1)}$ has kernel $\bigcap_i T_P Z_i = 0$, hence is an isomorphism. So the cone fills the normal space and the Gysin class is $[P]$. Summing over the finitely many points gives the count; when the codimensions overshoot, the same computation places the class in a Chow group of negative dimension, which vanishes, as we sought to show.

Proposition 14.3.13: Capping with a Chern Class Is Multiplication

Let X be a smooth variety and E a vector bundle on X. Then for every $\alpha \in A_*(X)$ and every i,

$$c_i(E) \cap \alpha \;=\; \big(c_i(E) \cap [X]\big) \cdot \alpha$$

the product on the right being that of theorem 14.2.7. Consequently the total Chern class may be treated as the element $c(E) \cap [X]$ of $A^*(X)$, and an identity of Chern class operators is an identity in the ring.

***Proof*:**
Step 1: reduction to a line bundle. Both sides are additive in α and, as functions of E, are determined by the Chern classes of line bundles: the splitting principle (theorem 12.2.14) produces a flat morphism $f\colon X' \to X$ with f^* injective on Chow groups and f^*E filtered with line bundle quotients, and both sides commute with f^*, the left by proposition 12.2.10(3) and the right because f^* is a ring homomorphism (theorem 14.2.10). Since the Chern classes of E are the elementary symmetric functions of the Chern roots (lemma 12.2.11), it suffices to treat $c_1(L)$ for a line bundle L.

Step 2: reduction to an effective divisor. Write $L = \mathcal{O}_X(D)$ for a Cartier divisor D, possible because X is smooth, hence locally factorial, so that $\operatorname{Pic} X \to A^1(X)$ is the isomorphism of proposition 11.1.3. On a smooth variety every divisor is a difference $D = D_+ - D_-$ of effective ones, and both sides of the claim are additive: the left because c_1 is additive on tensor products

(proposition 11.4.4(3)), the right by biadditivity of the product (theorem 14.2.7(1)). So it suffices to treat D effective with $D \neq X$.

Step 3: the effective case. Let $i\colon D \hookrightarrow X$ be the inclusion, a regular embedding of codimension one, and let $V \subseteq X$ be a k-dimensional subvariety; by additivity it is enough to prove $D\cdot[V] = [D]\cdot[V]$. By proposition 14.1.11, applied with the two closed subschemes D and X, the ring product $[D]\cdot[V]$ is the pushforward along $D \cap V \hookrightarrow X$ of the refined product, which for the class of a divisor is the refined Gysin map $i^![V]$ of definition 13.3.6.

It remains to identify $i^![V]$ with $D\cdot[V]$, and the two clauses of definition 11.2.1 are covered by two separate results. If $V \not\subseteq |D|$, then proposition 13.3.5 gives $i^![V] = \iota_*(D\cdot[V])$ directly, its hypothesis $V \not\subseteq |D|$ being exactly this case. If $V \subseteq |D|$, then corollary 14.3.3 applies instead and identifies $i^![V]$ with the class that the second clause of definition 11.2.1 computes from the restricted line bundle, which is $D\cdot[V]$ by definition. Since $c_1(L)\cap[V] = D\cdot[V]$ by definition 11.4.1 and $c_1(L)\cap[X] = [D]$, this is the assertion for a line bundle.

Step 4. Steps 1 to 3 give the identity for every E and every α. The last sentence follows by evaluating an operator identity on $[X]$ and reading the result through the identity just proved, as we sought to show.

A section of a bundle whose zero scheme has the expected codimension cuts out a class that the top Chern class already knows. This is the form in which Chern classes do enumerative work, and chapter 17 uses it throughout.

Lemma 14.3.14: The Class of a Zero Scheme

Let Y be a smooth variety, G a vector bundle of rank h on Y, and $\psi \in \Gamma(Y, G)$ a section whose zero scheme $Z = Z(\psi)$ is empty or of pure codimension h. Writing $\iota\colon Z \to Y$ for the inclusion,

$$\iota_*[Z] = c_h(G)\cap[Y]$$

***Proof*:**
Write $\pi\colon G \to Y$ also for the total space of the bundle, $z\colon Y \to G$ for the zero section and $\psi\colon Y \to G$ for the section. By definition $Z = \psi^{-1}(z(Y))$ as schemes.

Step 1: Z is regularly embedded with normal bundle $G|_Z$. Over an open set trivializing G, the section ψ is an h-tuple of regular functions and Z is their common zero scheme. The local rings of Y are regular, hence Cohen-Macaulay, and in a Cohen-Macaulay local ring h elements generating an ideal of height h form a regular sequence ([25, Height-Many Elements in a Cohen-Macaulay Ring Form a Regular Sequence]); the height is h precisely because Z has pure codimension h. So $Z \subseteq Y$ is a regular embedding of codimension h (definition 5.1.43) with conormal sheaf $\mathcal{I}/\mathcal{I}^2$ locally free of rank h. The bundle map $G^\vee \to \mathcal{I}/\mathcal{I}^2$ sending a functional ℓ to the class of $\ell(\psi)$ is surjective, since the components of ψ generate $\mathcal{I}$; a surjection between locally free sheaves of the same finite rank is an isomorphism, so the normal bundle is $G|_Z$.

Step 2: the two sections carry $[Y]$ to the same class on G. Let $T \subseteq G \times \mathbb{P}^1$ be the closure of the image of the morphism $Y \times \mathbb{A}^1 \to G \times \mathbb{A}^1$, $(y, \lambda) \mapsto (\lambda\psi(y), \lambda)$. That morphism is a section of the projection $G \times \mathbb{A}^1 \to Y \times \mathbb{A}^1$, hence the pullback of a diagonal and so a closed immersion; thus $T \cap (G \times \mathbb{A}^1) \cong Y \times \mathbb{A}^1$ is a variety of dimension $\dim Y + 1$ and T is a variety dominating

$\mathbb{P}^1$. On T the coordinate λ is a rational function whose divisor, computed on $Y \times \mathbb{A}^1$ where λ is the second coordinate, is $Y \times \{0\}$ with multiplicity one together with a part supported over $\lambda = \infty$; the divisor of $\lambda - 1$ is $Y \times \{1\}$ with multiplicity one together with the same part over $\lambda = \infty$, since a rational function and its translate by 1 have equal orders along any subvariety where that order is negative. Subtracting the two divisors and applying definition 10.1.4,

$$[T \cap (G \times \{0\})] - [T \cap (G \times \{1\})] = [\mathrm{div}(\lambda)] - [\mathrm{div}(\lambda - 1)] \sim 0$$

in $A_{\dim Y}(G \times \mathbb{P}^1)$. Pushing forward along the projection $G \times \mathbb{P}^1 \to G$, which is proper because $\mathbb{P}^1$ is complete and which carries the two fibres isomorphically onto $z(Y)$ and $\psi(Y)$, gives $z_*[Y] = \psi_*[Y]$ in $A_{\dim Y}(G)$.

Step 3: computation of the Gysin pullback. The zero section z is a regular embedding of codimension h with normal bundle G, and Z is the fibre product of z and ψ. By Step 1 the induced embedding $Z \subseteq Y$ is regular of codimension h as well, so the excess bundle of that fibre square is the zero bundle and theorem 14.3.9 identifies the refined Gysin class of definition 13.3.6 as $z^![Y] = [Z]$ in $A_{\dim Y - h}(Z)$. Its image in $A_{\dim Y - h}(Y)$ is $z^!(\psi_*[Y])$ by theorem 13.3.11; the zero section z is a regular embedding and not flat, so the operator is the Gysin map $z^!$ of box 14.2.1, not a pullback z^*. Combining with Step 2 and then with the self-intersection formula theorem 14.3.2 applied to z, whose normal bundle is G,

$$\iota_*[Z] = z^!(\psi_*[Y]) = z^!(z_*[Y]) = c_h(G) \cap [Y]$$

as we sought to show. When Z is empty the same chain reads $0 = c_h(G) \cap [Y]$.

Theorem 14.3.15: The Blow-up Formula

Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \geq 1$ with $Z \neq \emptyset$ and normal bundle N, let $f\colon \widetilde{X} = \mathrm{Bl}_Z X \to X$ be the blow-up with exceptional divisor $j\colon \widetilde{Z} = \mathbb{P}(N) \hookrightarrow \widetilde{X}$ and $g\colon \widetilde{Z} \to Z$, and let Q be the universal quotient bundle of rank $d-1$ on $\mathbb{P}(N)$. Then for every $\beta \in A_k(\widetilde{X})$:

1. $i_f^!\beta = c_{d-1}(Q) \cap j^!\beta$ in $A_{k-d}(\widetilde{Z})$, where $i_f^!$ is the refined Gysin homomorphism of i along f and $j^!$ is the Gysin map of j;
2. $i^!\big(f_*\beta\big) = g_*\Big(c_{d-1}(Q) \cap j^!\beta\Big)$ in $A_{k-d}(Z)$, where the left-hand $i^!$ is the Gysin map of definition 13.3.1.

***Proof*:**

1. The exceptional divisor is the scheme-theoretic preimage $f^{-1}(Z)$, so the square formed by j, f, i and g is the square of definition 13.3.6 for the morphism f. By lemma 14.3.5(2) the preimage $\widetilde{Z}$ is regularly embedded in $\widetilde{X}$ of codimension $d' = 1$, and its conormal surjection, which is the one definition 14.3.7 dualizes, is there identified with the universal surjection; so the excess bundle of the square is the universal quotient Q, of rank $e = d - 1$. Theorem 14.3.9 therefore gives $i_f^!\beta = c_{d-1}(Q) \cap j^!\beta$.
2. The blow-down f is proper (proposition 8.4.2(1)), so theorem 13.3.11(1) applies with

$X' = X$, $X'' = \widetilde{X}$ and $p = f$. The preimage of Z in $\widetilde{X}$ is $\widetilde{Z}$ and the induced morphism on preimages is g, so $i^!(f_*\beta) = g_*(i'^!_f\beta)$, the left-hand side being the Gysin map of i by proposition 13.3.8. Substituting part (1) completes the proof.

Part (1) computes an intersection with Z upstairs, where the geometry is a divisor and therefore elementary, and introduces one Chern class of the universal quotient bundle. Part (2) is the form used in practice: it computes the Gysin image of any class pushed down from the blow-up, and it is the identity from which the Chow groups of $\widetilde{X}$ are assembled from those of X and of $\mathbb{P}(N)$. The smallest instance is a consistency check that can be run in both directions.

Example 14.3.16: The Fundamental Class of a Blow-up
Let X be a variety of dimension n and $Z \subseteq X$ a nonempty subvariety with $Z \neq X$, regularly embedded of codimension $d \geq 1$, and take $\beta = [\widetilde{X}]$. The Rees algebra is a graded subalgebra of $\mathcal{O}_X[t]$ and hence a sheaf of domains, so $\widetilde{X}$ is integral, that is a variety; and f restricts to an isomorphism over $X \setminus Z$ (proposition 8.4.2(2)), so the two function fields agree and $f_*[\widetilde{X}] = [X]$ by definition 10.2.1. Also $i^![X] = [Z]$ by proposition 13.3.3, the intersection of X with Z being Z itself, and $j^![\widetilde{X}] = [\widetilde{Z}]$ by proposition 13.3.5 applied to the subvariety $\widetilde{X}$ of itself. Substituting into theorem 14.3.15(2),

$$[Z] \;=\; g_*\Big(c_{d-1}(Q) \cap \big[\mathbb{P}(N)\big]\Big)$$

The identity can be checked directly, and the check is a use of the Segre operators rather than of anything proved in this section. The tautological sequence $0 \to \mathcal{O}_{\mathbb{P}(N)}(-1) \to g^*N \to Q \to 0$ and the Whitney formula (theorem 12.2.15) give $c(Q) = c(g^*N)\,(\mathrm{id} - \xi)^{-1}$ with $\xi = c_1(\mathcal{O}_{\mathbb{P}(N)}(1))$, the inverse being the terminating series $\sum_{m\geq 0} \xi^m$, so

$$c_{d-1}(Q) \;=\; \sum_{m=0}^{d-1} \xi^m \circ c_{d-1-m}\big(g^*N\big)$$

Capping with $[\mathbb{P}(N)] = g^*[Z]$ and pushing forward, naturality of the Chern operators for the flat morphism g (proposition 12.2.10(3)) and the definition of the Segre operators (definition 12.1.3), for which $\mathbb{P}(N) \to Z$ has relative dimension $d-1$, give

$$g_*\Big(\xi^m \cap g^*\big(c_{d-1-m}(N) \cap [Z]\big)\Big) \;=\; s_{m-d+1}(N) \cap \big(c_{d-1-m}(N) \cap [Z]\big)$$

for each m. Every term with $m < d-1$ vanishes, the Segre operator having negative index, and the term $m = d-1$ is $s_0(N) \cap [Z] = [Z]$; summing over m gives $g_*\big(c_{d-1}(Q) \cap [\mathbb{P}(N)]\big) = [Z]$, so the two computations agree.

Exercise 14.3.1

1. Let $Y \subseteq \mathbb{P}^2$ be a smooth plane curve of degree m, with inclusion i. Show that $i\colon Y \hookrightarrow \mathbb{P}^2$ is a regular embedding of codimension one, identify its normal bundle, and compute the degree of $i^!(i_*[Y]) \in A_0(Y)$. Then explain why the answer determines $i^!(i_*[Y])$ itself when $m \leq 2$ but not when $m \geq 3$.
2. Let $Z = \{x_0 = 0\} \cong \mathbb{P}^{n-1}$ be a hyperplane in $\mathbb{P}^n$ with $n \geq 1$, with inclusion i. Identify

the normal bundle of i and compute $i^!(i_*\alpha)$ for α the generator h_m^Z of $A_m(Z)$ for each $0 \le m \le n-1$. Compare the answer with the Gysin map $i^!$ of example 13.3.4 in the case $d = 1$.

3. Let $i\colon Z \hookrightarrow X$ be a regular embedding of codimension $d \ge 1$ whose normal bundle is trivial, $N \cong \mathcal{O}_Z^{\oplus d}$. Show that $i^! \circ i_* = 0$ on $A_k(Z)$ for every k. Then let $X = \mathbb{P}^1 \times \mathbb{P}^1$, let $Z = \{q\} \times \mathbb{P}^1$ for a point $q \in \mathbb{P}^1$, and verify the hypothesis, deducing that the ruling has self-intersection zero.

4. In $\mathbb{P}^4$ with coordinates $x_0, \dots, x_4$, let $Z = \{x_3 = x_4 = 0\}$ and $X' = \{x_2 = x_4 = 0\}$ be two planes, so that $Z \cap X' = \{x_2 = x_3 = x_4 = 0\}$ is a line L, and let $g\colon X' \hookrightarrow \mathbb{P}^4$ be the inclusion. Show that $Z \hookrightarrow \mathbb{P}^4$ is a regular embedding of codimension two with $N = \mathcal{O}_{\mathbb{P}^2}(1)^{\oplus 2}$, identify the preimage Z' of Z in X' and its normal bundle, compute the excess bundle, and evaluate $i_g^![X']$. Interpret the degree of the answer.

5. Let $\widetilde{X} = \mathrm{Bl}_P\mathbb{P}^2$ as in example 14.3.6, with exceptional divisor $\widetilde{Z} \cong \mathbb{P}^1$ and the remaining notation that of theorem 14.3.15. Identify the universal quotient bundle Q on $\widetilde{Z}$ and compute $c_1(Q)$. Then verify theorem 14.3.15(2) for $\beta = [\widetilde{X}]$ by computing both sides, and compute $i^!\big(f_*j_*[\widetilde{Z}]\big)$.

14.4 Bézout and the Agreement Theorem

Two counts were recorded on credit. Example 10.2.6 asserted that two plane curves of degrees c and d meet in a zero-cycle of degree cd, and example 10.5.4 read that assertion off an identity $h_1 \cdot h_1 = h_0$ in a ring that did not then exist. Both are settled here, in the sharp form: not only the total count, but its distribution over the points of $C \cap D$, which is what an intersection multiplicity is.

Every enumerative count in projective space reduces to one computation, the product of the classes of two linear subspaces, because theorem 10.5.2 leaves nothing else in $A_*(\mathbb{P}^n)$ to compute, and that computation was carried out in example 14.2.3. Written in dimension rather than codimension, with $h_k = [\mathbb{P}^k] \in A_k(\mathbb{P}^n)$ the class of a linear subspace of dimension k and $h = h_{n-1}$ the hyperplane class, it reads

$$h_r \cdot h_s \;=\; \begin{cases} h_{r+s-n} & \text{if } r+s \ge n \\ 0 & \text{if } r+s < n \end{cases}$$

for $0 \le r, s \le n$, together with $h^p = h_{n-p}$ for $0 \le p \le n$, the vanishing $h^{n+1} = 0$, and the presentation

$$A^*(\mathbb{P}^n) \;\cong\; \mathbb{Z}[h]/(h^{n+1})$$

as a graded ring with h in codimension one. Nothing else about $\mathbb{P}^n$ is needed below.

The presentation converts every question about cycles on $\mathbb{P}^n$ into a question about polynomials in one variable. A class in $A^*(\mathbb{P}^n)$ is a polynomial in h of degree at most n; multiplying two of them and truncating above degree n is the whole intersection calculus of projective space. The truncation is geometric: $h^p h^q = 0$ for $p + q > n$ says that two subvarieties whose codimensions exceed the ambient dimension can be moved apart, and rational equivalence records that they have been.

The single integer attached to a subvariety by theorem 10.5.2 now deserves a name, since it is the only input Bézout's theorem takes.

Definition 14.4.1: Degree of a Subvariety of Projective Space

Let $V \subseteq \mathbb{P}^n$ be a closed subvariety of dimension k. Since $A_k(\mathbb{P}^n) = \mathbb{Z}\, h_k$ is free of rank one (theorem 10.5.2), there is a unique integer $\deg V$ with

$$[V] \;=\; (\deg V)\, h_k \;\in\; A_k(\mathbb{P}^n)$$

called the *degree* of V. The same definition applies to a closed subscheme pure of dimension k, using its fundamental cycle.

The definition is a tautology until the integer is computed, and the two computations that matter are the classical ones: a hypersurface has the degree of its equation, and the degree of anything is the number of points it cuts on a complementary linear space.

Proposition 14.4.2: Degrees of Hypersurfaces and Hyperplane Sections

Let $H \subseteq \mathbb{P}^n$ be a hyperplane, so that $\mathcal{O}_{\mathbb{P}^n}(H) \cong \mathcal{O}_{\mathbb{P}^n}(1)$.

1. If $V \subseteq \mathbb{P}^n$ is a closed subvariety of dimension k, then $H^k \cdot [V] = (\deg V)\, h_0$ in $A_0(\mathbb{P}^n)$, so $\deg V = \int_{\mathbb{P}^n} \left(H^k \cdot [V]\right)$, the iterated divisor operator of definition 11.2.1 applied k times.
2. A linear subspace $\mathbb{P}^k \subseteq \mathbb{P}^n$ has degree 1.
3. If F is a nonzero homogeneous form of degree $d \geq 1$ on $\mathbb{P}^n$, the hypersurface $V(F)$ has degree d.

***Proof*:**

1. Example 11.2.5 computes $H \cdot h_j = h_{j-1}$ for $1 \leq j \leq n$. The operator $H \cdot -$ is a homomorphism of Chow groups (proposition 11.4.4(1)), so from $[V] = (\deg V)\, h_k$ one gets $H \cdot [V] = (\deg V)\, h_{k-1}$, and iterating k times gives $H^k \cdot [V] = (\deg V)\, h_0$. The class h_0 is that of a single closed point, of degree $[\overline{k} : \overline{k}] = 1$ by definition 10.2.4, whence $\int_{\mathbb{P}^n}(H^k \cdot [V]) = \deg V$.
2. By theorem 10.5.2 the class of a linear $\mathbb{P}^k$ is the generator h_k itself, so the coefficient is 1.
3. Write $Z = V(F)$ for the closed subscheme cut out by F, a hypersurface, and let D be the associated effective Cartier divisor, with $\mathcal{O}_{\mathbb{P}^n}(D) \cong \mathcal{O}_{\mathbb{P}^n}(d)$ because F is a section of $\mathcal{O}_{\mathbb{P}^n}(d)$. Applying proposition 13.3.5 with $V = \mathbb{P}^n$, which is legitimate since $\mathbb{P}^n$ is a variety not contained in $|D|$, the fundamental cycle of Z is $[Z] = D \cdot [\mathbb{P}^n]$. By definition 11.4.1 this is $c_1(\mathcal{O}_{\mathbb{P}^n}(d)) \cap [\mathbb{P}^n]$, and $\mathcal{O}_{\mathbb{P}^n}(d) \cong \mathcal{O}_{\mathbb{P}^n}(1)^{\otimes d}$, so additivity of the first Chern class (proposition 11.4.4(3)) gives

   $$[Z] \;=\; d\left(c_1(\mathcal{O}_{\mathbb{P}^n}(1)) \cap [\mathbb{P}^n]\right) \;=\; d\, h_{n-1}$$

   the last equality being example 11.4.3(2). Hence $\deg Z = d$, completing the proof.

Part (1) is the reason the word "degree" is the same word as in the classical theory: cutting a

k-dimensional subvariety by k hyperplanes leaves a zero-cycle whose degree is the invariant, and by proposition 11.4.6 the hyperplanes need not be chosen in general position for the answer to come out right. Part (3) recovers the plane-curve count of example 10.5.4(2) as the case $n = 2$. Degrees of subvarieties that are not hypersurfaces are computed by pushing forward from a parametrization, as the next example illustrates.

Example 14.4.3: The Twisted Cubic

Let $\nu\colon \mathbb{P}^1 \to \mathbb{P}^3$ be the third Veronese embedding, $[s:t] \mapsto [s^3 : s^2t : st^2 : t^3]$, and let $C = \nu(\mathbb{P}^1)$ be the twisted cubic, a closed subvariety of $\mathbb{P}^3$ of dimension one. Since ν is a closed immersion, $\nu_*[\mathbb{P}^1] = [C]$ by definition 10.2.1, the extension of function fields being trivial.
Let $H = \{x_0 = 0\} \subseteq \mathbb{P}^3$. The pullback ν^*H is the Cartier divisor on $\mathbb{P}^1$ cut by s^3, that is $3\,[0:1]$, so $\nu^*H \cdot [\mathbb{P}^1] = 3\,\big[[0:1]\big]$ by definition 11.2.1. The projection formula for divisors (proposition 11.3.3(1)) applied to the proper morphism ν gives

$$H \cdot [C] \;=\; \nu_*\big(\nu^*H \cdot [\mathbb{P}^1]\big) \;=\; 3\,[P], \qquad P = \nu([0:1]) = [0:0:0:1]$$

a zero-cycle of degree 3. By proposition 14.4.2(1) with $k = 1$, $\deg C = 3$: the twisted cubic has degree three, all of it concentrated at the single point where H is tangent to C to order three. A general plane, by contrast, meets C in three distinct points, and proposition 11.4.6 is what makes the two computations agree without either being privileged.

With degrees in hand, Bézout's theorem is a restatement of example 14.2.3.

Theorem 14.4.4: Bézout's Theorem

Let $V, W \subseteq \mathbb{P}^n$ be closed subvarieties of dimensions r and s. If $r + s \geq n$, then

$$[V] \cdot [W] \;=\; (\deg V)(\deg W)\, h_{r+s-n} \;\in\; A_{r+s-n}(\mathbb{P}^n)$$

and if $r + s < n$ then $[V] \cdot [W] = 0$. In the boundary case $r + s = n$,

$$\int_{\mathbb{P}^n} \big([V] \cdot [W]\big) \;=\; (\deg V)(\deg W)$$

***Proof*:**

By definition 14.4.1 the classes are $[V] = (\deg V)\, h_r$ and $[W] = (\deg W)\, h_s$. The intersection product is $\mathbb{Z}$-bilinear (proposition 14.1.9(1)), so

$$[V] \cdot [W] \;=\; (\deg V)(\deg W)\,(h_r \cdot h_s)$$

and example 14.2.3 evaluates $h_r \cdot h_s$ as h_{r+s-n} when $r + s \geq n$ and as 0 otherwise. For $r + s = n$ the class h_0 is that of a single reduced closed point, of degree one by definition 10.2.4, and the degree map is a homomorphism, so $\int_{\mathbb{P}^n}([V] \cdot [W]) = (\deg V)(\deg W)$, as we sought to show.

The theorem is stated for classes, and in that form it needs nothing beyond the ring structure. What it does not yet say is how the count is recovered. The product $[V] \cdot [W]$ is defined as $\delta^!([V] \times [W])$, and the refined form of the Gysin map records that class on the preimage of the diagonal, that is on $V \cap W$ (corollary 13.3.12 and definition 14.1.10). Reading the refined class off requires knowing that $V \cap W$ sits inside $V \times W$ as a regular embedding, which is a hypothesis and not a theorem. The

following lemma verifies it in the case where the verification is cheapest and most used: two curves on a smooth surface.

Lemma 14.4.5: Distinct Curves on a Smooth Surface Meet Regularly

Let S be a smooth variety of dimension two over $\overline{k}$ and let $C, D \subseteq S$ be distinct one-dimensional closed subvarieties. Then:

1. $C \cap D$ is a finite set of closed points, and for $P \in C \cap D$ with local equations $f, g \in \mathcal{O}_{S,P}$ of C and D, the local ring of the scheme $C \cap D$ at P is $\mathcal{O}_{S,P}/(f,g)$, of length equal to its dimension $\dim_{\overline{k}} \mathcal{O}_{S,P}/(f,g)$ as a $\overline{k}$-vector space;
2. the closed immersion $C \cap D \hookrightarrow C \times D$ induced by the diagonal is a regular embedding of codimension two;
3. consequently

$$[C] \cdot [D] \;=\; \sum_{P \in C \cap D} \dim_{\overline{k}} \big(\mathcal{O}_{S,P}/(f,g)\big)\,[P] \;\in\; A_0(S)$$

***Proof*:**
Since S is smooth its local rings are regular, hence factorial, so each of C and D is an effective Cartier divisor and the local equations f, g exist and are nonzerodivisors.

1. $C \cap D$ is a closed subscheme of the irreducible curve C not equal to C, because $D \neq C$ and both are irreducible of dimension one; a proper closed subscheme of a curve is finite. Scheme-theoretically $C \cap D$ is cut out on S by the ideal (f,g), so its local ring at P is $\mathcal{O}_{S,P}/(f,g)$. That ring is Artinian local with residue field $\overline{k}$, since $\overline{k}$ is algebraically closed and P is a closed point, so each factor of a composition series is a copy of $\overline{k}$ and its length equals its $\overline{k}$-dimension.
2. Fix $P \in C \cap D$ and write $\mathcal{O} = \mathcal{O}_{S,P}$, a regular local ring of dimension two with residue field $\overline{k}$, and $A = \mathcal{O}/(f)$, $B = \mathcal{O}/(g)$, the local rings of C and D at P. Let R be the local ring of $C \times D$ at (P,P), that is the localization of $A \otimes_{\overline{k}} B$ at the maximal ideal corresponding to (P,P).
   Step 1: R is Cohen-Macaulay of dimension two. The product of two curves over $\overline{k}$ is a surface, so $\dim R = 2$. Because $\mathcal{O}$ is regular of dimension two and f is a nonzerodivisor, A has depth one, so $\mathfrak{m}_A$ contains a nonzerodivisor a; likewise $\mathfrak{m}_B$ contains a nonzerodivisor b. Now B is free as a $\overline{k}$-module, so $A \to A \otimes_{\overline{k}} B$ is flat and $a \otimes 1$ is a nonzerodivisor, with quotient $(A/aA) \otimes_{\overline{k}} B$; and A/aA is again free over $\overline{k}$, so $B \to (A/aA) \otimes_{\overline{k}} B$ is flat and $1 \otimes b$ is a nonzerodivisor on that quotient. Localizing at the maximal ideal, the pair $a \otimes 1$, $1 \otimes b$ is a regular sequence in R of length two, so $\operatorname{depth} R \geq 2 = \dim R$ and R is Cohen-Macaulay.
   Step 2: the diagonal cuts R by a system of parameters. The diagonal $\delta\colon S \hookrightarrow S \times S$ is a regular embedding of codimension two (theorem 14.1.6), so its ideal is generated near (P,P) by two elements θ_1, θ_2. The scheme-theoretic preimage of $\delta(S)$ under $C \times D \hookrightarrow S \times S$ is $C \cap D$, whose ideal in R is therefore generated by the images of θ_1 and θ_2. By part (1) that quotient is Artinian, so the two images form a system of parameters of the two-dimensional local ring R. In a Cohen-Macaulay local ring every system of parameters is a regular

sequence ([25, A System of Parameters in a Cohen-Macaulay Local Ring Is a Regular Sequence]), so $C \cap D \hookrightarrow C \times D$ is a regular embedding of codimension two.

3. The subvarieties C and D are integral over the algebraically closed field $\overline{k}$, so $C \times D$ is a subvariety of $S \times S$ of dimension two, with $[C] \times [D] = [C \times D]$ (definition 14.1.2). Part (2) gives the hypothesis of proposition 13.3.3 for the regular embedding δ of codimension two and the subvariety $C \times D$, so

$$[C] \cdot [D] \;=\; \delta^![C \times D] \;=\; [C \cap D]$$

the fundamental cycle of the scheme $C \cap D$ read on S through δ. By definition 10.1.2 that cycle is $\sum_P \operatorname{length}(\mathcal{O}_{C\cap D,P})\,[P]$, and part (1) identifies each length with $\dim_{\overline{k}} \mathcal{O}_{S,P}/(f,g)$, completing the proof.

The lemma is the bridge from a statement about classes to a statement about points. In $\mathbb{P}^2$ every curve is a hypersurface, so its degree is the degree of its equation by proposition 14.4.2(3); the lemma settles a pair of distinct integral curves, and additivity of the local count in each argument extends it to arbitrary curves without a common component. Bézout's theorem then acquires its classical form.

Corollary 14.4.6: Bézout's Theorem for Plane Curves

Let F and G be nonzero forms on $\mathbb{P}^2$ of degrees c and d with no common irreducible factor, and let $C = V(F)$ and $D = V(G)$ be the plane curves they cut out, so that C and D have no common component; neither is assumed irreducible or reduced. Then $C \cap D$ is finite and

$$\sum_{P \in C\cap D} \dim_{\overline{k}} \left(\mathcal{O}_{\mathbb{P}^2,P}/(f_P, g_P)\right) \;=\; cd$$

where f_P and g_P are the local equations of C and D at P, obtained by dehomogenizing F and G.

***Proof*:**

Factor $F = \prod_i F_i^{m_i}$ and $G = \prod_j G_j^{n_j}$ into powers of pairwise nonassociate irreducible forms; by hypothesis no F_i is an associate of any G_j. The curves $C_i = V(F_i)$ and $D_j = V(G_j)$ are one-dimensional closed subvarieties of $\mathbb{P}^2$, of degrees $\deg F_i$ and $\deg G_j$ by proposition 14.4.2(3), and $C_i \neq D_j$ for all i, j. For a form u and a point P write $u_P \in \mathcal{O}_{\mathbb{P}^2,P}$ for the dehomogenization of u at P, so that $f_P = F_P$ and $g_P = G_P$.

Step 1: the count for a pair of components. The plane $\mathbb{P}^2$ is a smooth variety of dimension two and $C_i \neq D_j$ are distinct one-dimensional closed subvarieties, so lemma 14.4.5 applies to the pair (C_i, D_j): the intersection $C_i \cap D_j$ is finite and $[C_i] \cdot [D_j] = \sum_P \dim_{\overline{k}}(\mathcal{O}_{\mathbb{P}^2,P}/(F_{i,P}, G_{j,P}))\,[P]$ in $A_0(\mathbb{P}^2)$. Each point is closed with residue field $\overline{k}$, so taking degrees (definition 10.2.4) and comparing with theorem 14.4.4 for $n = 2$, $r = s = 1$ gives

$$\sum_{P \in C_i \cap D_j} \dim_{\overline{k}} \left(\mathcal{O}_{\mathbb{P}^2,P}/(F_{i,P}, G_{j,P})\right) \;=\; (\deg F_i)(\deg G_j)$$

Since $C \cap D = \bigcup_{i,j} C_i \cap D_j$ as sets, $C \cap D$ is finite.

Step 2: the local count is additive in each argument. Fix P and write $\mathcal{O} = \mathcal{O}_{\mathbb{P}^2,P}$, a regular local ring of dimension two. Let u be a divisor of F and let v, w be divisors of G, or the same with the

roles of F and G exchanged; then $V(u)\cap V(vw)\subseteq C\cap D$ is finite by Step 1, so $\mathcal{O}/(u_P,(vw)_P)$ and its two companions below are Artinian as in lemma 14.4.5(1), of finite $\overline{k}$-dimension. We may assume u_P and w_P lie in the maximal ideal, since otherwise one of the three quotients is zero and the additivity claimed below is trivial. Being Artinian, $\mathcal{O}/(u_P,w_P)$ exhibits u_P,w_P as a system of parameters of $\mathcal{O}$, hence as a regular sequence ([25, A System of Parameters in a Cohen-Macaulay Local Ring Is a Regular Sequence]); in particular w_P is a nonzerodivisor on $A=\mathcal{O}/(u_P)$. The sequence

$$0\longrightarrow A/(v_P)\xrightarrow{w_P}A/(v_Pw_P)\longrightarrow A/(w_P)\longrightarrow 0$$

is then exact: surjectivity on the right and exactness in the middle are immediate, and if $w_Ph\in(v_Pw_P)A$ then $w_P(h-v_Pa)=0$ in A for some a, so $h\in(v_P)A$ because w_P is a nonzerodivisor on A. Counting $\overline{k}$-dimensions gives

$$\dim_{\overline{k}}\mathcal{O}/(u_P,v_Pw_P)\;=\;\dim_{\overline{k}}\mathcal{O}/(u_P,v_P)\;+\;\dim_{\overline{k}}\mathcal{O}/(u_P,w_P)$$

that is, additivity in the second argument, and the exchanged case gives additivity in the first. Iterating over the two factorizations,

$$\dim_{\overline{k}}\left(\mathcal{O}_{\mathbb{P}^2,P}/(f_P,g_P)\right)\;=\;\sum_{i,j}m_in_j\,\dim_{\overline{k}}\left(\mathcal{O}_{\mathbb{P}^2,P}/(F_{i,P},G_{j,P})\right)$$

Step 3: summation. Sum the last display over the finitely many points of $C\cap D$; a point outside $C_i\cap D_j$ contributes nothing to the (i,j) term, since there $F_{i,P}$ or $G_{j,P}$ is a unit, so Step 1 evaluates each term and

$$\begin{aligned}\sum_{P\in C\cap D}\dim_{\overline{k}}\left(\mathcal{O}_{\mathbb{P}^2,P}/(f_P,g_P)\right)&=\sum_{i,j}m_in_j(\deg F_i)(\deg G_j)\\&=\Big(\sum_i m_i\deg F_i\Big)\Big(\sum_j n_j\deg G_j\Big)\;=\;cd\end{aligned}$$

the last equality because $\deg F=\sum_i m_i\deg F_i$ and $\deg G=\sum_j n_j\deg G_j$, completing the proof.

This is the count promised in example 10.2.6 and the identity $h_1\cdot h_1=h_0$ anticipated in example 10.5.4(2), now with the local distribution attached: the integer $\dim_{\overline{k}}\mathcal{O}_{\mathbb{P}^2,P}/(f_P,g_P)$ says how many of the cd units of intersection are spent at P. Nothing in the argument assumed that the curves are irreducible, reduced, smooth, or that they meet transversally; only that they share no component, which is exactly what makes the intersection finite.

Example 14.4.7: A Cuspidal Cubic and Its Cuspidal Tangent

Let $C=\{y^2z=x^3\}\subseteq\mathbb{P}^2$, a cubic curve with a cusp at $P=[0:0:1]$, and let $D=\{y=0\}$, the tangent line to C at the cusp. The cubic is irreducible and is not the line, so the two share no component and corollary 14.4.6 predicts a total of $3\cdot1=3$.

Set-theoretically, $y=0$ together with $y^2z=x^3$ forces $x^3=0$, hence $x=0$: the only intersection point is P. Working in the chart $z=1$ with $\mathcal{O}=\overline{k}[x,y]_{(x,y)}$, the local equations are $f=y^2-x^3$ and $g=y$, and

$$\mathcal{O}/(f,g)\;=\;\overline{k}[x,y]_{(x,y)}/(y^2-x^3,\,y)\;\cong\;\overline{k}[x]_{(x)}/(x^3)$$

of dimension 3 over $\overline{k}$, with basis $1,x,x^2$. So all three units of intersection sit at the cusp, and

$[C]\cdot[D] = 3\,[P]$. Compare example 11.2.2, where a conic met its tangent line in a single point of multiplicity two: in both cases the multiplicity is the order to which the equation of the line vanishes along the curve, and here the cusp raises it from two to three.

The integer attached to P in the example is not special to curves in a plane. Whenever two subvarieties of a smooth variety meet in the expected dimension, the product distributes over the components of the intersection with well-defined integer coefficients, and those coefficients are the intersection multiplicities.

Definition 14.4.8: Proper Intersection and Intersection Multiplicity

Let X be a smooth variety of pure dimension n and let $V, W \subseteq X$ be closed subvarieties of dimensions r and s. Say that V and W *meet properly* if every irreducible component of $V \cap W$ has dimension exactly $m = r + s - n$. In that case $V \cap W$ is pure of dimension m, so $A_m(V \cap W) = Z_m(V \cap W)$ is free on the classes of its irreducible components $Z_1, \dots, Z_t$ (example 10.1.6(3)), and the refined intersection class of definition 14.1.10 may be written uniquely as

$$[V]\cdot[W] \;=\; \sum_{j=1}^{t} i(Z_j;\, V\cdot W;\, X)\,[Z_j] \;\in\; A_m(V\cap W)$$

The integer $i(Z_j;\, V\cdot W;\, X)$ is the *intersection multiplicity* of V and W along Z_j.

The definition would be empty without the refinement: the class $[V]\cdot[W]$ read in $A_m(X)$ carries no information about where the intersection happens, and it is the localization on $V \cap W$ given by the refined Gysin map (definition 13.3.6, corollary 13.3.12) that makes the coefficients meaningful. The proper-intersection hypothesis is what makes the coefficients unique, since A_m of an m-dimensional scheme is free on components; drop it and the class still exists but no longer decomposes canonically.

When the scheme-theoretic intersection is as good as its dimension suggests, the multiplicities are lengths and nothing else. Proposition 13.3.3 says that if $V \cap W \hookrightarrow V \times W$ is a regular embedding of codimension n, then $[V]\cdot[W] = [V \cap W]$ is the fundamental cycle, so $i(Z_j; V\cdot W; X)$ is the length of the local ring of $V \cap W$ at the generic point of Z_j. That is exactly what lemma 14.4.5 verified for curves on a surface, and it is the source of the numbers computed in example 14.4.7. In general the regularity hypothesis can fail, and then the multiplicity and the naive length part company. The correction is homological.

Theorem 14.4.9: Serre's Tor Formula

Let X be a smooth variety of pure dimension n and let $V, W \subseteq X$ be closed subvarieties meeting properly, with Z an irreducible component of $V \cap W$ and $\mathcal{O} = \mathcal{O}_{X,Z}$ the local ring of X at the generic point of Z. Then

$$i(Z;\, V\cdot W;\, X) \;=\; \sum_{j\geq 0} (-1)^j \operatorname{length}_{\mathcal{O}} \operatorname{Tor}_j^{\mathcal{O}}\big(\mathcal{O}/\mathcal{I}_V,\, \mathcal{O}/\mathcal{I}_W\big)$$

where $\mathcal{I}_V$ and $\mathcal{I}_W$ are the ideals of V and W in $\mathcal{O}$. The sum is finite, each term having finite length and all terms vanishing for $j > n$.

The proof is omitted: it runs entirely through homological algebra over regular local rings, in particular the vanishing, finite-length and additivity theorems for Tor that this book does not develop,

and it is genuinely outside the scope of a treatment built on deformation to the normal cone. Serre proved the formula in *Algèbre locale, multiplicités*, and the comparison with the multiplicities of definition 14.4.8 is carried out in Fulton [38]. The formula matters here because it exhibits the multiplicity as a purely local, purely algebraic invariant of the two local rings, with no reference to the deformation that defined it.

The correction terms are invisible in the case the previous results have been using, and that is worth recording, since it says the classical count of plane curves needs no homological algebra at all.

Proposition 14.4.10: Vanishing of the Higher Terms for Divisors

Let X be a smooth variety of pure dimension n and let $C, D \subseteq X$ be closed subvarieties of dimension $n-1$ with $C \neq D$, so that C and D meet properly. For every irreducible component Z of $C \cap D$, with $\mathcal{O} = \mathcal{O}_{X,Z}$ and local equations $f, g \in \mathcal{O}$,

$$\operatorname{Tor}_j^{\mathcal{O}}\big(\mathcal{O}/(f),\, \mathcal{O}/(g)\big) = 0 \quad \text{for } j \geq 1$$

so Serre's formula reduces to $i(Z;\, C \cdot D;\, X) = \operatorname{length}_{\mathcal{O}} \mathcal{O}/(f, g)$.

***Proof*:**
Since X is smooth, $\mathcal{O}$ is a regular local ring and C, D are effective Cartier divisors near Z, so f and g are nonzerodivisors and

$$0 \longrightarrow \mathcal{O} \xrightarrow{\,f\,} \mathcal{O} \longrightarrow \mathcal{O}/(f) \longrightarrow 0$$

is a free resolution of $\mathcal{O}/(f)$ of length one. Hence $\operatorname{Tor}_j(\mathcal{O}/(f), \mathcal{O}/(g)) = 0$ for $j \geq 2$, while Tor_1 is the kernel of multiplication by f on $\mathcal{O}/(g)$. Because $\mathcal{O}$ is regular and g is a nonzerodivisor, $\mathcal{O}/(g)$ is Cohen-Macaulay, hence has no embedded associated primes ([25, A Cohen-Macaulay Ring Has No Embedded Associated Primes]), so its associated primes are the minimal primes of (g), which are the primes corresponding to the components of D passing through Z. As C and D share no component, f lies in none of them, so multiplication by f on $\mathcal{O}/(g)$ is injective and $\operatorname{Tor}_1 = 0$. The remaining term is $\operatorname{Tor}_0(\mathcal{O}/(f), \mathcal{O}/(g)) = \mathcal{O}/(f, g)$, and theorem 14.4.9 therefore reads $i(Z; C \cdot D; X) = \operatorname{length}_{\mathcal{O}} \mathcal{O}/(f, g)$, as we sought to show.

Everything so far has been internal to this book: a product, a ring, a count. The comparison that remains is external. *Algebraic Geometry* [9, Intersection Number (Cohomological)] builds a pairing on the divisors of a smooth projective surface without any of this machinery, setting $C \cdot D = \chi(\mathcal{O}_S) - \chi(\mathcal{O}_S(-C)) - \chi(\mathcal{O}_S(-D)) + \chi(\mathcal{O}_S(-C-D))$, and derives adjunction, the behaviour of self-intersection, and the classification of surfaces from it. Two constructions with nothing in common beyond the answer they are supposed to give must be shown to give it.

Theorem 14.4.11: The Agreement Theorem for Surfaces

Let S be a smooth projective surface over $\overline{k}$ and let C, D be Cartier divisors on S, with associated classes $[C] = c_1(\mathcal{O}_S(C)) \cap [S]$ and $[D] = c_1(\mathcal{O}_S(D)) \cap [S]$ in $A^1(S) = A_1(S)$. Then

$$\int_S \big([C] \cdot [D]\big) \;=\; \int_S \big(C \cdot (D \cdot [S])\big) \;=\; C \cdot D$$

where the first is the intersection product of section 14.1, the second the iterated divisor operator of definition 11.2.1, and the third the cohomological intersection number definition 8.2.1.

***Proof*:**

Write $\langle C, D\rangle_1$, $\langle C, D\rangle_2$ and $\langle C, D\rangle_3$ for the three quantities.

Step 1: all three are $\mathbb{Z}$-bilinear and depend only on linear equivalence. For the first, $C \mapsto [C] = C \cdot [S]$ is additive in C by additivity of the first Chern class (proposition 11.4.4(3)) and depends only on $\mathcal{O}_S(C)$ by proposition 11.4.2; the product is $\mathbb{Z}$-bilinear (proposition 14.1.9(1)) and $\int_S$ is a homomorphism (definition 10.2.4). For the second, $D \mapsto D \cdot [S]$ is additive and linear-equivalence invariant for the same two reasons, and $C \cdot -$ is a homomorphism of Chow groups additive in C by proposition 11.4.4(1),(3). For the third, bilinearity and invariance under linear equivalence are proposition 8.2.2(1),(3).

Step 2: the three agree for distinct prime divisors. Let C and D be distinct one-dimensional closed subvarieties of S, with local equations f, g at a point P. Lemma 14.4.5(3) gives

$$\langle C, D\rangle_1 \;=\; \int_S \Big(\sum_{P \in C \cap D} \dim_{\overline{k}} \big(\mathcal{O}_{S,P}/(f,g)\big)\,[P] \Big) \;=\; \sum_{P \in C \cap D} \dim_{\overline{k}} \big(\mathcal{O}_{S,P}/(f,g)\big)$$

each P being a closed point with residue field $\overline{k}$. For the second quantity, $S \not\subseteq |D|$ and $D \not\subseteq |C|$, so the first clause of definition 11.2.1 applies twice: $D \cdot [S] = [\mathrm{div}(s_S)] = [D]$, and $C \cdot [D] = [\mathrm{div}(f|_D)] = \sum_P \mathrm{ord}_P(f|_D)\,[P]$. By definition 10.1.1 the coefficient is $\mathrm{ord}_P(f|_D) = \mathrm{length}_{\mathcal{O}_{D,P}}\big(\mathcal{O}_{D,P}/(f|_D)\big)$, and $\mathcal{O}_{D,P}/(f|_D) = \mathcal{O}_{S,P}/(f,g)$, whose length equals its $\overline{k}$-dimension. Hence $\langle C, D\rangle_2$ is the same sum. For the third, proposition 8.2.2(5) evaluates $C \cdot D$ on effective divisors with no common component as $\sum_P \dim_{\overline{k}} \mathcal{O}_{S,P}/(f,g)$, again the same sum. So the three agree on such a pair.

Step 3: reduction of the general case to Step 2. Fix a very ample divisor H on the projective surface S. By Serre's theorem on global generation after an ample twist (theorem 5.3.26) there is an $m \geq 1$ such that $\mathcal{O}_S(C + mH)$, $\mathcal{O}_S(D + mH)$ and $\mathcal{O}_S(mH)$ are all generated by their global sections. Set

$$A_1 = C + mH, \quad A_2 = mH, \quad B_1 = D + mH, \quad B_2 = mH$$

so that $C = A_1 - A_2$ and $D = B_1 - B_2$ as Cartier divisors, and by Step 1 it suffices to prove the agreement for each of the four pairs (A_i, B_j).

A globally generated line bundle has a nonzero global section, so each A_i is linearly equivalent to an effective divisor A_i'; let $\Gamma_1, \ldots, \Gamma_t$ be the finitely many prime components of A_1' and A_2' and choose a closed point $p_a \in \Gamma_a$ for each. For a fixed j, the sections of $\mathcal{O}_S(B_j)$ vanishing at p_a form a proper linear subspace of the finite-dimensional space $H^0(S, \mathcal{O}_S(B_j))$, since that bundle is globally generated; a vector space over the infinite field $\overline{k}$ is not a finite union of proper

subspaces, so some section τ_j vanishes at no p_a. Its divisor $B'_j = \operatorname{div}(\tau_j)$ is effective, linearly equivalent to B_j, and contains none of the Γ_a.
Writing $A'_i = \sum_a m_a \Gamma_a$ and $B'_j = \sum_b n_b \Lambda_b$ as nonnegative combinations of prime divisors, no Γ_a equals any Λ_b, so bilinearity reduces each $\langle A'_i, B'_j \rangle_\bullet$ to $\sum_{a,b} m_a n_b \langle \Gamma_a, \Lambda_b \rangle_\bullet$, and every term is covered by Step 2. Invariance under linear equivalence transfers the conclusion back from A'_i, B'_j to A_i, B_j, and Step 1 assembles the four pairs into the general case, completing the proof.

The theorem is what connects the two. Every numerical statement about divisors on a smooth projective surface proved in *Algebraic Geometry* [9] out of Euler characteristics, the adjunction formula, the identification of C^2 with the degree of the normal bundle, the Hodge index theorem, is a statement about the product of this chapter, and conversely every general theorem proved here specializes to a surface fact that book had to obtain by hand. The surface theory is subsumed rather than paralleled, and section 14.3 already used that when it recovered $E^2 = -1$ from the self-intersection formula.

The middle term of the theorem is worth isolating. It says that on a smooth projective surface the ring product of two divisor classes computes the same integer as the iterated divisor operator built in chapter 11, so the operator calculus of that chapter, commutativity and the projection formula included, transfers verbatim to the ring. The two constructions were built from different material: one from local equations and orders of vanishing, the other from a degeneration of the diagonal. Nothing forced them to agree except that both were built to count.

Exercise 14.4.1

1. Let $V, W \subseteq \mathbb{P}^3$ be surfaces of degrees 2 and 3 with no common component. Compute $[V] \cdot [W]$ in $A_1(\mathbb{P}^3)$ and read off the degree of the curve $V \cap W$. Then let $V_1, V_2, V_3 \subseteq \mathbb{P}^3$ be surfaces of degrees d_1, d_2, d_3 and compute $\int_{\mathbb{P}^3} \big([V_1] \cdot [V_2] \cdot [V_3]\big)$.

2. Let $L \cong \mathbb{P}^r$ and $M \cong \mathbb{P}^s$ be linear subspaces of $\mathbb{P}^n$ with $r + s < n$. Show that $[L] \cdot [M] = 0$, and explain why this conclusion is *not* a consequence of the observation that L and M can be chosen disjoint. (Consider the case $L = M$.)

3. Keep $C = \{y^2 z = x^3\} \subseteq \mathbb{P}^2$ from example 14.4.7 and take instead $D' = \{x = 0\}$, the line joining the cusp $[0:0:1]$ to the inflection point $[0:1:0]$. Compute $C \cap D'$ and the multiplicity of $[C] \cdot [D']$ at each of its points, and verify corollary 14.4.6.

4. Let $Q = \mathbb{P}^1 \times \mathbb{P}^1$, with rulings $f_1 = \{a\} \times \mathbb{P}^1$ and $f_2 = \mathbb{P}^1 \times \{b\}$ as in exercise 11.2.1 (5), where $\mathcal{O}_Q(f_1) = \operatorname{pr}_1^* \mathcal{O}_{\mathbb{P}^1}(1)$ and $\mathcal{O}_Q(f_2) = \operatorname{pr}_2^* \mathcal{O}_{\mathbb{P}^1}(1)$. Using theorem 14.4.11, write down the three numbers $\int_Q([f_1] \cdot [f_2])$, $\int_Q([f_1] \cdot [f_1])$ and $\int_Q([f_2] \cdot [f_2])$. Then show that the diagonal $\Delta \subseteq Q$ satisfies $\Delta \sim f_1 + f_2$ and compute $\int_Q([\Delta] \cdot [\Delta])$.

5. Let $L \subseteq \mathbb{P}^2$ be a line. Compute $\int_{\mathbb{P}^2}([L] \cdot [L])$ from example 14.2.3, and identify precisely which conclusion of lemma 14.4.5 fails when $C = D = L$. Explain how the intersection product still returns an answer, and reconcile it with example 11.2.3.

14.5 Summary

The product is constructed once and then used in several forms, each with its own hypotheses and its own habitat. They are worth separating, because most later citations want one specific form.

Form	Defined for	Stated in
$\alpha \cdot \beta$	X smooth, via the diagonal	definition 14.1.8
Refined product	lands on the intersection of supports	definition 14.1.10
f^* for f a morphism of smooth varieties	through the graph	definition 14.2.8
$f^!$ for f an l.c.i. morphism	independent of the factorization	theorem 14.2.12

The diagonal of a smooth variety is a regular embedding (theorem 14.1.6), which is what makes the first line possible; the refined product determines the unrefined one by pushforward (proposition 14.1.11), and $A^*(X)$ is a commutative graded ring with unit $[X]$ (theorem 14.2.7, definition 14.2.2), with f^* a ring homomorphism (theorem 14.2.10).

Four formulas compute the product where naive transversality fails, and they are the ones cited most often from outside:

Situation	Formula
$Z \subseteq X$ regular, self-intersection	$i^![Z] = c_d(N) \cap [Z]$, theorem 14.3.2
Preimage regular of the wrong codimension	excess bundle E, theorem 14.3.9
Blow-up along a regular centre	theorem 14.3.15
Proper intersection, non-transverse	$\sum_i (-1)^i \operatorname{length} \operatorname{Tor}_i$, theorem 14.4.9

Transverse intersections carry multiplicity one (proposition 14.3.11) and their degree is the product of degrees, which is Bézout (theorem 14.4.4, with the plane-curve case corollary 14.4.6). Theorem 14.4.11 checks the whole construction against the classical intersection pairing on a surface, and theorem 14.2.13 records what the classical route to the product would have required and this one does not.

Part III

Cycle Classes, Riemann-Roch, and Enumerative Geometry

The Chow ring is built, and with it the question that motivated the construction has an answer: two subvarieties of a smooth variety can be intersected, and the result is a class that behaves. What the ring does not yet do is talk to anything else. A cycle class is an algebraic invariant of an algebraic object, and the classical invariants of a complex variety are topological; until the two are compared, the theory is self-contained in the unhelpful sense.

This part makes the comparison and then spends it. Chapter 15 maps cycles to cohomology and finds that the map is far from injective, which turns a single equivalence relation into a tower of four: rational, algebraic, homological, numerical. Where the tower collapses is, in almost every case, an open problem, and two of the gaps are among the most famous questions in the subject. Chapter 16 pays the comparison forward: the Chern character carries K-theory into the Chow ring, and Grothendieck-Riemann-Roch measures its failure to commute with pushforward by a Todd class, recovering the classical Riemann-Roch theorems as the case of a map to a point. Chapter 17 then uses the whole apparatus for the purpose the subject was invented for, which is counting.

15

Cycle Classes and Adequate Equivalence Relations

Rational equivalence was chosen in chapter 10 for its formal properties, not because it was the only candidate, and it is in fact the finest of a family. Coarsening it produces new groups, each with its own virtues: algebraic equivalence brings in families over curves and makes the quotient finitely generated; homological equivalence is whatever cohomology cannot distinguish; numerical equivalence remembers only intersection numbers. The four sit in a tower, each contained in the next, and the inclusions are the subject of this chapter.

The comparison that generates the tower is the cycle class map. For a smooth complex variety a subvariety carries a fundamental class in homology, and Poincaré duality turns it into a cohomology class; the content of section 15.2 is that this assignment is blind to rational equivalence and respects everything the Chow ring can do. Once it exists, homological equivalence is defined as its kernel, and the question of how much information the map loses becomes precise.

It loses some. Cohomology sees a cycle only through its class, and the Hodge conjecture asks whether every cohomology class that looks algebraic is algebraic. Whether homological and numerical equivalence agree is the standard conjecture D. Neither is proved here or anywhere; what this chapter owes the reader is exact statements, correct attributions, and a clear account of which implications are theorems.

The chapter closes with correspondences. A cycle on $X \times Y$ acts on cycles and on cohomology by pulling back, intersecting, and pushing forward, and composing two such cycles is again the intersection product. That is the operation the theory of motives is built from, and it is the form in which [8] uses this book.

15.1 Algebraic Equivalence

A cycle rationally equivalent to zero is a sum of divisors of rational functions, and a nonzero rational function on a $(k+1)$-dimensional subvariety W is a morphism from a dense open subset of W to $\mathbb{P}^1$. The parameter along which such a cycle moves is therefore always the same rational curve. Algebraic equivalence allows that parameter to be an arbitrary smooth curve, and the relation it defines is coarser. Its quotient in codimension one is the group that definition 8.1.4 attaches to divisors, and that quotient, unlike the Chow group itself, is finitely generated.

The data that moves a cycle is a single cycle on $X \times T$ whose components are spread over the parameter curve T rather than sitting inside one fibre. Cutting such a cycle with a fibre produces a cycle on X, and the first point to settle is that the cut has the expected dimension, since only then is there a k-cycle to compare across two parameter values. Throughout, pr_X and pr_T are the two projections of $X \times T$, and for a closed point $t \in T$

$$\iota_t \colon X \longrightarrow X \times T, \qquad x \longmapsto (x, t)$$

is the closed immersion with image $X \times \{t\}$, an isomorphism onto that fibre; cycles on $X \times \{t\}$ are identified with cycles on X along it without further comment.

Lemma 15.1.1: Fibres of a Dominating Subvariety

Let X be an algebraic scheme, T a smooth curve, and $W \subseteq X \times T$ a $(k+1)$-dimensional subvariety whose image under pr_T is dense in T. For a closed point $t \in T$ let $W_t = W \times_T \{t\}$ be the scheme-theoretic fibre, a closed subscheme of $X \times \{t\}$. Then W_t is either empty or of pure dimension k.

***Proof*:**
Write $\pi \colon W \to T$ for the restriction of pr_T. It is a dominant morphism of integral schemes of finite type over $\overline{k}$, and $\dim W - \dim T = (k+1) - 1 = k$. Suppose $W_t \neq \emptyset$, so that $t \in \pi(W)$, and let Z be an irreducible component of W_t.

For the lower bound, the fibre-dimension theorem for a dominant morphism of integral schemes of finite type over a field ([50, Exercise II.3.22]) applies to π at the point $t \in \pi(W)$ and gives $\dim Z \geq k$.

For the upper bound, Z is a closed irreducible subset of the irreducible $(k+1)$-dimensional W, so $\dim Z \leq k+1$, with equality only if $Z = W$. Equality is impossible: from $Z \subseteq W_t \subseteq X \times \{t\}$, the equality $Z = W$ would give $\pi(W) = \{t\}$, a single closed point of the curve T, which is closed and proper in T and hence not dense, contradicting the hypothesis. So $\dim Z = k$ for every component Z of W_t, as we sought to show.

By the lemma, a subvariety spread over T meets each fibre in a scheme of pure dimension k, and the fundamental cycle of that scheme (definition 10.1.2) is a k-cycle on X. A family of cycles is a $\mathbb{Z}$-combination of such subvarieties.

Definition 15.1.2: Family of Cycles over a Curve

Let X be an algebraic scheme and T a *smooth curve*, by which is meant a smooth variety of dimension one, not necessarily complete. A *family of k-cycles on X parametrized by T* is a $(k+1)$-cycle

$$V = \sum_i n_i \, [V_i] \in Z_{k+1}(X \times T)$$

each of whose components V_i has dense image under pr_T. For a closed point $t \in T$, the *fibre of V over t* is the k-cycle

$$V(t) = \sum_i n_i \, \big[(V_i)_t\big] \in Z_k(X)$$

where $(V_i)_t$ is the scheme-theoretic fibre of lemma 15.1.1 and $[(V_i)_t]$ its fundamental cycle, read on X through ι_t. A fibre may be zero, since $(V_i)_t$ is empty for t outside the image of V_i.

Two features of the definition are worth separating. The condition on components is what makes the fibres k-cycles rather than cycles of jumping dimension: a component contained in a single fibre would contribute its whole $(k+1)$-dimensional self there and nothing elsewhere. And $t \mapsto V(t)$ is additive in V by construction, so a sum of families over one curve has for fibres the sums of the fibres.

Definition 15.1.3: Algebraic Equivalence

Let X be an algebraic scheme. The subgroup $\mathrm{Alg}_k(X) \subseteq Z_k(X)$ of *cycles algebraically equivalent to zero* is the subgroup generated by all differences

$$V(t_0) - V(t_1)$$

taken over all smooth curves T, all families V of k-cycles on X parametrized by T, and all pairs of closed points $t_0, t_1 \in T$. Two cycles $\alpha, \beta \in Z_k(X)$ are *algebraically equivalent*, written $\alpha \sim_{\mathrm{alg}} \beta$, if $\alpha - \beta \in \mathrm{Alg}_k(X)$.

Proposition 15.1.4: Algebraic Equivalence is a Graded Equivalence Relation

Let X be an algebraic scheme. Then $\sim_{\mathrm{alg}}$ is an equivalence relation on $Z_k(X)$ compatible with addition of cycles, and $\mathrm{Alg}_*(X) = \bigoplus_k \mathrm{Alg}_k(X)$ is a graded subgroup of $Z_*(X)$.

***Proof*:**
The relation is defined by membership of a difference in a subgroup, so it is reflexive ($0 \in \mathrm{Alg}_k(X)$), symmetric (subgroups are closed under negation) and transitive (subgroups are closed under addition); and from $\alpha - \beta, \alpha' - \beta' \in \mathrm{Alg}_k(X)$ one gets $(\alpha + \alpha') - (\beta + \beta') \in \mathrm{Alg}_k(X)$, which is compatibility with addition. Each generator $V(t_0) - V(t_1)$ lies in the single summand $Z_k(X)$, because V is a $(k+1)$-cycle and its fibres are k-cycles by definition 15.1.2; hence the subgroup they generate inside $Z_*(X)$ is the direct sum of the $\mathrm{Alg}_k(X)$, as we sought to show.

Example 15.1.5: Points on a Curve

Let C be a smooth projective curve and take $T = C$ as the parameter. The diagonal $\Delta \subseteq C \times C$ is a subvariety of dimension one, and pr_2 carries it isomorphically onto C, so its image is dense and $[\Delta]$ is a family of 0-cycles on C parametrized by C. Since $\mathrm{pr}_2|_\Delta$ is an isomorphism, the scheme-theoretic fibre $\Delta_t = \Delta \times_C \{t\}$ is one reduced point, namely (t,t), so

$$\Delta(t) = [t] \in Z_0(C)$$

Hence $[p] - [q] = \Delta(p) - \Delta(q)$ lies in $\mathrm{Alg}_0(C)$ for every pair of closed points p, q. A zero-cycle $\sum_i n_i[p_i]$ with $\sum_i n_i = 0$ is a $\mathbb{Z}$-combination of such differences, so every zero-cycle of degree zero on C is algebraically equivalent to zero.

The contrast with rational equivalence is visible already here. By proposition 11.1.1, applied to the smooth curve C, the group $A_0(C) = \mathrm{Cl}\, C$ is the full divisor class group, in which a degree-zero class need not vanish; under algebraic equivalence every degree-zero class does vanish.

The example exhibits one relation as coarser than the other in a single case. The general statement is that every cycle rationally equivalent to zero is algebraically equivalent to zero, and its proof is the observation the definition was built around: a rational function is a family of cycles parametrized by $\mathbb{P}^1$, whose two marked fibres are the divisor of zeros and the divisor of poles.

Theorem 15.1.6: Rational Equivalence Implies Algebraic Equivalence

For every algebraic scheme X and every k,

$$\mathrm{Rat}_k(X) \subseteq \mathrm{Alg}_k(X)$$

so $\alpha \sim \beta$ implies $\alpha \sim_{\mathrm{alg}} \beta$, with $\mathbb{P}^1$ as the parameter curve.

***Proof*:**

Step 1: reduction to one function. By definition 10.1.3 the group $\mathrm{Rat}_k(X)$ is generated by the cycles $[\mathrm{div}(r)]$ with $W \subseteq X$ a $(k+1)$-dimensional subvariety and $r \in K(W)^*$, and $\mathrm{Alg}_k(X)$ is a subgroup, so it suffices to prove $[\mathrm{div}(r)] \in \mathrm{Alg}_k(X)$ for one such pair (W, r).

If $r \in \overline{k}^*$, then r is a unit in the local ring $\mathcal{O}_{W,\eta_Y}$ at the generic point of every prime divisor $Y \subseteq W$, so $\mathrm{ord}_Y(r) = 0$ for all Y and $[\mathrm{div}(r)] = 0$, which lies in $\mathrm{Alg}_k(X)$. Assume from now on that r is nonconstant.

Step 2: the graph of r. Let $U \subseteq W$ be the union of the locus where r is regular with the locus where r^{-1} is regular; it is a dense open subset on which r defines a morphism $r|_U : U \to \mathbb{P}^1$. Put

$$\Gamma = \overline{\{(x, r(x)) \,|\, x \in U\}} \subseteq W \times \mathbb{P}^1 \subseteq X \times \mathbb{P}^1$$

the closure of the graph, with its reduced structure. The graph of $r|_U$ is the image of the immersion $(\mathrm{id}, r|_U) : U \to W \times \mathbb{P}^1$, hence irreducible of dimension $\dim U = k+1$, so Γ is a $(k+1)$-dimensional subvariety of $X \times \mathbb{P}^1$.

The projection $p = \mathrm{pr}_W|_\Gamma : \Gamma \to W$ is proper, being the restriction to a closed subscheme of the projection $W \times \mathbb{P}^1 \to W$, which is proper because $\mathbb{P}^1$ is complete. Its image contains U and is closed, hence is W, so p is surjective; and p restricts to an isomorphism over U, where Γ is the

graph of a morphism, so p is birational and $p^*\colon K(W) \to K(\Gamma)$ is an isomorphism.

The projection $g = \mathrm{pr}_{\mathbb{P}^1}|_\Gamma\colon \Gamma \to \mathbb{P}^1$ is a morphism whose image contains $r(U)$, dense in $\mathbb{P}^1$ because r is nonconstant. So Γ has dense image in $\mathbb{P}^1$ and $[\Gamma]$ is a family of k-cycles on X parametrized by $T = \mathbb{P}^1$. As an element of $K(\Gamma)^*$ the function g is p^*r, since the two agree on the dense open $p^{-1}(U)$, where $g(x, r(x)) = r(x)$.

Step 3: the two fibres are the zeros and the poles of g. Write Γ_0 and Γ_∞ for the scheme-theoretic fibres of g over 0 and ∞, each empty or pure of dimension k by lemma 15.1.1. The claim is

$$[\mathrm{div}(g)] = [\Gamma_0] - [\Gamma_\infty] \quad \text{in } Z_k(\Gamma) \tag{15.1}$$

Let $Y \subseteq \Gamma$ be a k-dimensional subvariety with generic point η, and compare the coefficients of $[Y]$ on the two sides. Recall that for a function regular at η the order along Y is the length of the quotient of $\mathcal{O}_{\Gamma,\eta}$ by the ideal it generates, and that ord_Y is multiplicative.

Suppose $g(\eta) = 0$. On the open set $\Gamma \setminus \Gamma_\infty = g^{-1}(\mathbb{A}^1)$ the morphism g is a regular function whose zero scheme is Γ_0, so $\mathcal{O}_{\Gamma_0,\eta} = \mathcal{O}_{\Gamma,\eta}/(g)$. By definition 10.1.2 the coefficient of $[Y]$ in $[\Gamma_0]$ is $\mathrm{length}_{\mathcal{O}_{\Gamma,\eta}}\big(\mathcal{O}_{\Gamma,\eta}/(g)\big) = \mathrm{ord}_Y(g)$, which is the coefficient of $[Y]$ in $[\mathrm{div}(g)]$; and Y is not a component of Γ_∞, so it contributes nothing there.

Suppose $g(\eta) = \infty$. The same computation applied to g^{-1}, a regular function on $\Gamma \setminus \Gamma_0$ with zero scheme Γ_∞, gives the coefficient of $[Y]$ in $[\Gamma_\infty]$ as $\mathrm{ord}_Y(g^{-1}) = -\mathrm{ord}_Y(g)$, by multiplicativity of the order; and Y contributes nothing to $[\Gamma_0]$.

In the remaining case $g(\eta) \notin \{0, \infty\}$, so g is regular and nonvanishing at η, hence a unit in $\mathcal{O}_{\Gamma,\eta}$ and $\mathrm{ord}_Y(g) = 0$; and Y is a component of neither fibre, since g maps a component of Γ_0 to 0 and a component of Γ_∞ to ∞. Every k-dimensional subvariety of Γ falls under one of the three cases, and by lemma 15.1.1 the components of the two fibres are k-dimensional, so (15.1) holds.

Step 4: pushing down to W. The morphism p is proper and surjective between varieties of the same dimension $k+1$, so proposition 10.2.2(2) applies to $g = p^*r \in K(\Gamma)^*$ and gives $p_*[\mathrm{div}(g)] = [\mathrm{div}(N(g))]$, where N is the norm of the extension $p^*\colon K(W) \hookrightarrow K(\Gamma)$. That extension is an isomorphism by Step 2, so multiplication by g on the one-dimensional $K(W)$-vector space $K(\Gamma)$ has determinant $N(g) = r$, and therefore

$$p_*[\mathrm{div}(g)] = [\mathrm{div}(r)]$$

On the other side, $\Gamma_0 = \Gamma \cap (W \times \{0\})$ is a closed subscheme of $W \times \{0\}$, and p restricted to it is that closed immersion followed by the isomorphism $W \times \{0\} \cong W$. A closed immersion has $\deg(V/p(V)) = 1$ for every subvariety V of its source (definition 10.2.1), so $p_*[\Gamma_0]$ is the fibre $[\Gamma](0)$ of definition 15.1.2, and likewise $p_*[\Gamma_\infty] = [\Gamma](\infty)$. Applying p_* to (15.1),

$$[\mathrm{div}(r)] = [\Gamma](0) - [\Gamma](\infty)$$

a generator of $\mathrm{Alg}_k(X)$ attached to the family $[\Gamma]$ over $\mathbb{P}^1$ and the marked points $0, \infty$. With Step 1 this gives $\mathrm{Rat}_k(X) \subseteq \mathrm{Alg}_k(X)$, completing the proof.

The theorem makes algebraic equivalence a relation on Chow classes and not only on cycles, so the quotient below may be formed from either. Step 3 identifies the two marked fibres of the graph as the divisor of zeros and the divisor of poles of r, whose difference is $\mathrm{div}(r)$; the content of the

theorem is that rational equivalence permits exactly this one motion, along the fixed curve $\mathbb{P}^1$, while algebraic equivalence permits motion along any smooth curve.

Definition 15.1.7: Néron-Severi Group in Codimension k

Let X be an algebraic scheme. Write $A_k(X)_{\mathrm{alg}}$ for the image of $\mathrm{Alg}_k(X)$ in $A_k(X)$ and set

$$\mathrm{NS}_k(X) = A_k(X)/A_k(X)_{\mathrm{alg}}$$

the *Néron-Severi group of X in dimension k*. When X is a smooth variety of dimension n, so that $A^k(X) = A_{n-k}(X)$ carries the codimension grading of theorem 14.2.7, write $\mathrm{NS}^k(X) = \mathrm{NS}_{n-k}(X) = A^k(X)/A^k(X)_{\mathrm{alg}}$.

Corollary 15.1.8: The Néron-Severi Group Computed from Cycles

For every algebraic scheme X the quotient map $Z_k(X) \to A_k(X)$ induces an isomorphism

$$Z_k(X)/\mathrm{Alg}_k(X) \xrightarrow{\sim} \mathrm{NS}_k(X)$$

***Proof*:**
By theorem 15.1.6 the subgroup $\mathrm{Rat}_k(X)$ is contained in $\mathrm{Alg}_k(X)$, and $A_k(X) = Z_k(X)/\mathrm{Rat}_k(X)$ by definition 10.1.4. Hence the image $A_k(X)_{\mathrm{alg}}$ of $\mathrm{Alg}_k(X)$ in $A_k(X)$ is $\mathrm{Alg}_k(X)/\mathrm{Rat}_k(X)$, and the third isomorphism theorem gives

$$\mathrm{NS}_k(X) = \big(Z_k(X)/\mathrm{Rat}_k(X)\big)\big/\big(\mathrm{Alg}_k(X)/\mathrm{Rat}_k(X)\big) \cong Z_k(X)/\mathrm{Alg}_k(X)$$

as we sought to show.

For a smooth projective curve C the corollary and example 15.1.5 already determine the answer: every degree-zero zero-cycle lies in $\mathrm{Alg}_0(C)$, so $\mathrm{NS}_0(C)$ is generated by the class of a single closed point.

In codimension one the group carries a name and a history predating the Chow group. A divisor on a smooth projective variety is a line bundle, a family of divisors over a curve is a line bundle on $X \times T$, and the classical Néron-Severi group is Pic modulo the subgroup swept out by such families. The two descriptions define the same subgroup of $A^1(X)$, and the proof of that is not formal: on one side the family is a cycle on $X \times T$, on the other a line bundle, and passing between them is the Weil-Cartier comparison applied on $X \times T$ rather than on X.

Definition 15.1.9: Algebraic Equivalence of Line Bundles

Let X be a smooth projective variety. A line bundle L on X is *algebraically equivalent to zero* if there are a smooth curve T, a line bundle $\mathcal{L}$ on $X \times T$, and closed points $t_0, t_1 \in T$ with

$$\iota_{t_0}^*\mathcal{L} \cong L, \qquad \iota_{t_1}^*\mathcal{L} \cong \mathcal{O}_X$$

The subgroup of $\mathrm{Pic}\, X$ generated by all such L is written $\mathrm{Pic}^0(X)$.

definition 8.1.4 writes $\mathrm{Pic}^0(X)$ for the group of line bundles algebraically equivalent to zero, and

characterizes it as the group of $\overline{k}$-points of the identity component of the Picard scheme. That this is the same subgroup as the one just defined is a theorem rather than a matter of notation, and it is the one place in this section where the divisor-level theory is taken on trust rather than rebuilt.

Proposition 15.1.10: The Two Descriptions of Pic^0 Agree

Let X be a smooth projective variety. The subgroup $\mathrm{Pic}^0(X) \subseteq \mathrm{Pic}\, X$ generated by the line bundles of definition 15.1.9 is the group of $\overline{k}$-points of the identity component of the Picard scheme, that is the $\mathrm{Pic}^0(X)$ of definition 8.1.4.

***Proof Cited*:**
The content is that a *curve* parameter base suffices: a family of line bundles over an arbitrary connected base may be replaced by a chain of families over smooth curves joining the same two members, after which the generators above already exhaust the group. That reduction, and the representability of the Picard functor that gives the identity component its meaning, are both outside this book; they are treated in [38] and in the standard accounts of the Picard scheme.

The dependency is worth naming, because the rest of the section rests on it: corollary 15.1.14 obtains finite generation of $\mathrm{NS}^1(X)$ by transporting theorem 8.1.5, which is a statement about the upstream Pic^0, across theorem 15.1.12, which is proved for the curve-generated one. If the two subgroups differed, that transport would fail.

Passing between the two descriptions rests on one computation, made once and used in both directions: restricting the line bundle of a family of divisors to a fibre gives the line bundle of the fibre cycle. Here and below, for a Weil divisor α on a smooth variety Y the notation $\mathcal{O}_Y(\alpha)$ means the line bundle attached to α by the isomorphism $\mathrm{WDiv}\, Y \cong \mathrm{CDiv}\, Y$ and the correspondence $\mathrm{CDiv}\, Y \to \mathrm{Pic}\, Y$ of proposition 11.1.1(2).

Lemma 15.1.11: Restriction of a Family of Divisors to a Fibre

Let X be a smooth variety of dimension n and T a smooth curve, so that $X \times T$ is a smooth variety of dimension $n+1$: smoothness is stable under products, and a product of varieties over the algebraically closed field $\overline{k}$ is again irreducible. Let D be a family of $(n-1)$-cycles on X parametrized by T, that is, an n-cycle on $X \times T$ each of whose components has dense image in T. Then for every closed point $t \in T$,

$$\iota_t^*\, \mathcal{O}_{X\times T}(D) \cong \mathcal{O}_X\big(D(t)\big)$$

***Proof*:**
Both sides are homomorphisms in D: the left because $\alpha \mapsto \mathcal{O}_{X\times T}(\alpha)$ is a homomorphism $\mathrm{WDiv}\,(X\times T) \to \mathrm{Pic}\,(X\times T)$ by proposition 11.1.1(2) and ι_t^* is a homomorphism of Picard groups, the right because $D \mapsto D(t)$ is additive by definition 15.1.2 and $\alpha \mapsto \mathcal{O}_X(\alpha)$ is a homomorphism. Each component of D is itself a family, so it suffices to treat $D = [W]$ for a single subvariety $W \subseteq X \times T$ of dimension n with dense image in T.

Since $X \times T$ is smooth it is locally factorial, so by proposition 11.1.1(2) the prime divisor W is locally principal: there are an open cover $\{U_i\}$ of $X \times T$ and regular functions $f_i \in \mathcal{O}_{X\times T}(U_i)$ generating the ideal sheaf of W on U_i, and $\{(U_i, f_i)\}$ is Cartier data for a divisor with associated

line bundle $\mathcal{O}_{X\times T}(W)$ and associated Weil cycle $[W]$.

Fix a closed point t. The subvariety W is not contained in $X \times \{t\}$: the two have the same dimension n and $X \times \{t\}$ is irreducible, so containment would force $W = X \times \{t\}$ and hence $\mathrm{pr}_T(W) = \{t\}$, contradicting density. Therefore each f_i restricts to a nonzero rational function on the variety $X \times \{t\}$, so $\{(U_i \cap (X \times \{t\}),\ f_i|)\}$ is Cartier data on $X \times \{t\}$ whose line bundle is $\iota_t^*\mathcal{O}_{X\times T}(W)$. Applying proposition 11.1.1(1) on the smooth variety $X \times \{t\}$, the Weil cycle of that restricted Cartier divisor is

$$\sum_Y \nu_Y(f_i|)\,[Y]$$

the sum over prime divisors $Y \subseteq X \times \{t\}$, with i any index whose U_i contains the generic point η of Y.

It remains to identify this cycle with $[W_t]$. Since $X \times \{t\} \cong X$ is smooth, the local ring $A = \mathcal{O}_{X\times\{t\},\eta}$ is regular of dimension one, hence a discrete valuation ring whose valuation is ν_Y; let ϖ be a uniformizer. Near η the scheme W_t is the zero scheme of $f_i|$, so $\mathcal{O}_{W_t,\eta} = A/(f_i|)$. Writing $m = \nu_Y(f_i|)$ gives $(f_i|) = (\varpi^m)$, and the chain $A \supsetneq (\varpi) \supsetneq \cdots \supsetneq (\varpi^m)$ has m successive quotients, each isomorphic to $A/(\varpi)$, so

$$\mathrm{length}_A\left(A/(f_i|)\right) = m = \nu_Y(f_i|)$$

The left-hand side is the coefficient of $[Y]$ in the fundamental cycle $[W_t]$ (definition 10.1.2), and W_t is empty or pure of dimension $n-1$ by lemma 15.1.1, so the two cycles have the same components with the same multiplicities. Hence $\sum_Y \nu_Y(f_i|)[Y] = [W_t]$, which read on X is $W(t)$, and therefore $\iota_t^*\mathcal{O}_{X\times T}(W) \cong \mathcal{O}_X(W(t))$, completing the proof.

Theorem 15.1.12: Agreement with the Divisor-Level Néron-Severi Group

Let X be a smooth projective variety of dimension n. The class map $c\colon \mathrm{Pic}\,X \to A_{n-1}(X) = A^1(X)$ of proposition 11.1.3 is an isomorphism carrying $\mathrm{Pic}^{\,0}(X)$ onto $A^1(X)_{\mathrm{alg}}$, and therefore induces an isomorphism

$$\mathrm{NS}(X) \xrightarrow{\sim} \mathrm{NS}^1(X)$$

from the divisor-level Néron-Severi group of definition 8.1.4 to the codimension-one group of definition 15.1.7.

***Proof*:**
That c is an isomorphism is the last clause of proposition 11.1.3, whose hypothesis holds because a smooth variety is locally factorial; the same statement, through proposition 11.1.1(2), gives $c(\mathcal{O}_X(E)) = [E]$ in $A_{n-1}(X)$ for every Weil divisor E on X. Granting the isomorphism, the induced map on quotients is an isomorphism as soon as $c(\mathrm{Pic}^{\,0}(X)) = A^1(X)_{\mathrm{alg}}$, and since both subgroups are generated by the elements described in definition 15.1.9 and definition 15.1.3, it suffices to match generators in the two directions.

Step 1: a family of cycles produces a family of line bundles. Let V be a family of $(n-1)$-cycles on X parametrized by a smooth curve T, with marked points t_0, t_1; the class of $V(t_0) - V(t_1)$ is the general generator of $A^1(X)_{\mathrm{alg}}$. The product $X \times T$ is a smooth variety of dimension $n+1$ (lemma 15.1.11), so the n-cycle V has an associated line bundle $\mathcal{O}_{X\times T}(V)$; and $V(t_1)$, an

$(n-1)$-cycle on the smooth X, has an associated line bundle $\mathcal{O}_X(V(t_1))$. Set

$$\mathcal{L} = \mathcal{O}_{X\times T}(V) \otimes \mathrm{pr}_X^*\, \mathcal{O}_X\big(V(t_1)\big)^{-1}$$

Since $\mathrm{pr}_X \circ \iota_t = \mathrm{id}_X$, one has $\iota_t^* \mathrm{pr}_X^* N \cong N$ for every line bundle N on X, so lemma 15.1.11 gives

$$\iota_t^* \mathcal{L} \cong \mathcal{O}_X\big(V(t)\big) \otimes \mathcal{O}_X\big(V(t_1)\big)^{-1} = \mathcal{O}_X\big(V(t) - V(t_1)\big)$$

for every closed $t \in T$. At $t = t_1$ this is $\mathcal{O}_X$, and at $t = t_0$ it is $L := \mathcal{O}_X(V(t_0) - V(t_1))$, so $L \in \mathrm{Pic}^0(X)$ by definition 15.1.9. As c is a homomorphism sending $\mathcal{O}_X(E)$ to $[E]$, its value is $c(L) = [V(t_0)] - [V(t_1)]$. Every generator of $A^1(X)_{\mathrm{alg}}$ therefore lies in $c(\mathrm{Pic}^0(X))$.

Step 2: a family of line bundles produces a family of cycles. Let L be a generator of $\mathrm{Pic}^0(X)$, given by a smooth curve T, a line bundle $\mathcal{L}$ on $X \times T$ and closed points t_0, t_1 with $\iota_{t_0}^* \mathcal{L} \cong L$ and $\iota_{t_1}^* \mathcal{L} \cong \mathcal{O}_X$. Since $X \times T$ is smooth, proposition 11.1.1(2) gives an n-cycle E on $X \times T$ with $\mathcal{L} \cong \mathcal{O}_{X\times T}(E)$. Separate the components of E with dense image in T, which make up a cycle V, from those without:

$$E = V + \sum_j m_j \, [X \times \{s_j\}]$$

Indeed a component D' of E whose image in T is not dense has image a single closed point s, so $D' \subseteq X \times \{s\}$, and both being n-dimensional with $X \times \{s\}$ irreducible forces $D' = X \times \{s\}$. Thus V is a family of $(n-1)$-cycles on X parametrized by T.

The correction terms restrict trivially to every fibre. Let ϖ_s be a uniformizer of the discrete valuation ring $\mathcal{O}_{T,s}$, so that ϖ_s generates the ideal sheaf of $\{s\}$ near s. Then $\mathrm{pr}_T^* \varpi_s$ generates the ideal sheaf of $\mathrm{pr}_T^{-1}(s) = X \times \{s\}$ near the generic point of $X \times \{s\}$, so the Cartier divisor $\mathrm{pr}_T^*(s)$ has Weil cycle $[X \times \{s\}]$ with multiplicity one and

$$\mathcal{O}_{X\times T}\big([X \times \{s\}]\big) \cong \mathrm{pr}_T^* \mathcal{O}_T(s)$$

Restricting along ι_t, the composite $\mathrm{pr}_T \circ \iota_t$ is the constant morphism $X \to T$ with value t, which factors through $\mathrm{Spec}\, \overline{k}$; a line bundle pulled back along such a morphism is trivial, so $\iota_t^* \mathrm{pr}_T^* \mathcal{O}_T(s) \cong \mathcal{O}_X$. Combining this with lemma 15.1.11 applied to V,

$$\iota_t^* \mathcal{L} \cong \mathcal{O}_X\big(V(t)\big)$$

for every closed $t \in T$. At $t = t_1$ this reads $\mathcal{O}_X(V(t_1)) \cong \mathcal{O}_X$, so $[V(t_1)] = c(\mathcal{O}_X(V(t_1))) = c(\mathcal{O}_X) = 0$ in $A^1(X)$; at $t = t_0$ it reads $L \cong \mathcal{O}_X(V(t_0))$, so

$$c(L) = [V(t_0)] = [V(t_0)] - [V(t_1)]$$

which is a generator of $A^1(X)_{\mathrm{alg}}$.

Steps 1 and 2 give $c(\mathrm{Pic}^0(X)) = A^1(X)_{\mathrm{alg}}$, and an isomorphism carrying one subgroup onto the other descends to an isomorphism of the quotients $\mathrm{NS}(X) \cong \mathrm{NS}^1(X)$, completing the proof.

The theorem lets the divisor theory of a smooth projective variety be read inside the Chow ring without translation: a class in $A^1(X)$ is a line bundle, and the two ways of moving it in a family, by cycles and by line bundles, cut out the same subgroup. It also fixes the meaning of the phrase used at the divisor level, since $\mathrm{Pic}^0(X)$ is now the image of a construction performed on cycles.

Example 15.1.13: Néron-Severi Groups of the Plane and of an Abelian Surface

For $X = \mathbb{P}^2$ the Picard group is $\mathbb{Z}$, generated by the class of a line, and $\mathrm{Pic}^0(\mathbb{P}^2) = 0$; both are computed in example 8.1.7. By theorem 15.1.12 the subgroup $A^1(\mathbb{P}^2)_{\mathrm{alg}} = c(\mathrm{Pic}^0(\mathbb{P}^2))$ is zero, so

$$\mathrm{NS}^1(\mathbb{P}^2) = A^1(\mathbb{P}^2) = \mathbb{Z}$$

the last group being $\mathbb{Z}[\mathbb{P}^1]$ by theorem 10.5.2. In codimension one on the plane, algebraic equivalence adds nothing to rational equivalence.

For an abelian surface A the two differ. There $\mathrm{Pic}^0(A)$ is the dual abelian variety $\widehat{A}$, of dimension two, and $\mathrm{NS}(A)$ has rank between 1 and 4, again by example 8.1.7. So $A^1(A)_{\mathrm{alg}} = c(\mathrm{Pic}^0(A))$ is the two-dimensional family $\widehat{A}$ inside $A^1(A) = \mathrm{Pic}(A)$, and $\mathrm{NS}^1(A)$ is the proper quotient by it, of rank at most 4.

Finite generation of the codimension-one quotient is the theorem of the base, proved upstream for the divisor-level group, and theorem 15.1.12 transports it to the Chow-theoretic one.

Corollary 15.1.14: Finite Generation in Codimension One

Let X be a smooth projective variety. Then $\mathrm{NS}^1(X)$ is a finitely generated abelian group whose rank is the Picard number $\rho(X)$, and over $\mathbb{C}$ one has $\rho(X) \leq h^{1,1}(X)$.

***Proof*:**

The scheme X is a smooth projective variety over the algebraically closed field $\overline{k}$, which is the hypothesis of theorem 8.1.5; that result gives that $\mathrm{NS}(X) = \mathrm{Pic}(X)/\mathrm{Pic}^0(X)$ is finitely generated of rank $\rho(X)$, with $\rho(X) \leq h^{1,1}(X)$ when $\overline{k} = \mathbb{C}$. By theorem 15.1.12 the group $\mathrm{NS}^1(X)$ is isomorphic to $\mathrm{NS}(X)$, so it is finitely generated of the same rank and satisfies the same bound, as we sought to show.

Nothing of the sort holds in higher codimension, and the failure is not a gap in the proof. For $2 \leq k \leq n-1$ the group $\mathrm{NS}^k(X)$ can have infinite rank. Clemens, in *Homological equivalence, modulo algebraic equivalence, is not finitely generated* (1983), proved that on a very general quintic threefold $X \subseteq \mathbb{P}^4$ the subgroup of $\mathrm{NS}^2(X)$ of classes killed by the cycle class map of section 15.2 has infinite rank, so $\mathrm{NS}^2(X) \otimes \mathbb{Q}$ is not finite dimensional. What survives in every codimension is the definition and the tower of inclusions it enters, taken up in section 15.3 once that cycle class map is available; for the further theory of algebraic equivalence, including the parametrization of $A^k(X)_{\mathrm{alg}}$ by an abelian variety in the cases where one exists, see [38, Ch. 19].

Exercise 15.1.1

1. Let $p, q \in \mathbb{P}^n$ be distinct closed points, let $L \subseteq \mathbb{P}^n$ be the line through them, and fix an isomorphism $\gamma\colon \mathbb{P}^1 \xrightarrow{\sim} L$. Show that $\Gamma = \{(\gamma(t), t) \,|\, t \in \mathbb{P}^1\} \subseteq \mathbb{P}^n \times \mathbb{P}^1$ is a family of 0-cycles on $\mathbb{P}^n$ parametrized by $\mathbb{P}^1$ with $\Gamma(t) = [\gamma(t)]$, and deduce that every zero-cycle of degree zero on $\mathbb{P}^n$ is algebraically equivalent to zero.

2. Let X be a variety of dimension n and T a smooth curve. Show that the only $(n+1)$-dimensional subvariety of $X \times T$ is $X \times T$ itself, compute its fibres, and conclude that $\mathrm{Alg}_n(X) = 0$ and hence $\mathrm{NS}_n(X) = A_n(X) = \mathbb{Z}[X]$, the last equality by example 10.1.6.

3. Show that the set of differences $V(t_0) - V(t_1)$ generating $\mathrm{Alg}_k(X)$ in definition 15.1.3 is closed under negation, and that the sum of two such differences taken over the same parameter curve at the same pair of marked points is again a difference of the same kind. Identify the step that fails when the two families are parametrized by different curves, and say why the definition therefore takes the subgroup generated rather than the set of differences itself.

4. Let ℓ_0, ℓ_1 be linearly independent linear forms on $\mathbb{P}^2$, with zero loci the lines L_0, L_1, and let $r = \ell_1/\ell_0 \in K(\mathbb{P}^2)^*$. Show that the closure of the graph of r is

$$\Gamma = \big\{(x, [u : v]) \big| v\,\ell_0(x) = u\,\ell_1(x)\big\} \subseteq \mathbb{P}^2 \times \mathbb{P}^1$$

   where $\mathbb{P}^1$ has affine coordinate $t = v/u$, compute the fibres $\Gamma(0)$ and $\Gamma(\infty)$ as cycles on $\mathbb{P}^2$, and verify the identity $[\mathrm{div}(r)] = \Gamma(0) - \Gamma(\infty)$ of Step 4 of theorem 15.1.6 in this case.

5. Let S be a smooth projective surface with $\mathrm{Pic}^0(S) = 0$. Show that $\mathrm{NS}^1(S) = A^1(S)$, and compute both groups for $S = \mathbb{P}^1 \times \mathbb{P}^1$, whose Picard group is $\mathbb{Z}^2$ generated by the classes of the two rulings and whose Pic^0 vanishes by example 8.1.7.

6. Let C be a smooth projective curve. Using example 15.1.5 and corollary 15.1.8, show that $\mathrm{NS}_0(C)$ is cyclic, generated by the class of any closed point. Identify it with the divisor-level group $\mathrm{NS}(C)$ through theorem 15.1.12, and contrast the answer with $A_0(C) = \mathrm{Cl}\,C$ of proposition 11.1.1.

15.2 The Cycle Class Map

Over the complex numbers a k-dimensional subvariety V of a variety X is also a compact subset of X of real dimension $2k$, oriented wherever it is smooth by its complex structure. Such a subset carries a fundamental class in H_{2k}, and on a smooth ambient variety Poincaré duality turns that class into a cohomology class whose degree is twice the codimension of V. This section constructs the resulting map, proves that it depends only on the rational equivalence class of a cycle, and computes its behaviour under proper pushforward, flat pullback and the intersection product.

15.2.1 Convention: The Complex Setting For the rest of this section and section 15.3 the ground field is $\overline{k} = \mathbb{C}$. A scheme is identified with its set of closed points carrying the analytic topology, and $H^i(-)$, $H_i(-)$ denote singular cohomology and homology with $\mathbb{Z}$ coefficients unless other coefficients are written. Every scheme entering a homological statement is projective over $\mathbb{C}$. For a smooth variety that is not complete the construction below produces classes in a homology theory adapted to noncompact spaces (Borel-Moore homology), which this book does not develop.

For a smooth projective V of dimension k the set of closed points is a compact oriented $2k$-manifold, and its fundamental class is **??**. A subvariety is rarely smooth, and the manifold statement says nothing at a singular point. What repairs this is that the singular locus is small: V_{sing} is a closed subvariety of dimension at most $k-1$, hence of real dimension at most $2k-2$, so it is invisible to chains of dimension $2k$ and $2k-1$. The following theorem records the consequence. Its proof rests on the triangulability of complex algebraic varieties, a result of Łojasiewicz and Hironaka on semianalytic and subanalytic sets that this book does not prove; what is written out is the derivation of the four clauses from a triangulation.

Theorem 15.2.2: Fundamental Class of a Complex Projective Variety

Let V be an irreducible projective variety over $\mathbb{C}$ of dimension k, with smooth locus V_{reg}.

1. $H_i(V) = 0$ for $i > 2k$.
2. $H_{2k}(V)$ is infinite cyclic, and for every $p \in V_{\mathrm{reg}}$ the map $H_{2k}(V) \to H_{2k}(V, V \setminus \{p\}) \cong \mathbb{Z}$ is an isomorphism. The *fundamental class* $\mu_V \in H_{2k}(V)$ is the generator sent to the generator determined by the complex orientation of V_{reg} at p; this description does not depend on p.
3. If V is smooth, μ_V is the fundamental class of the compact oriented $2k$-manifold V in the sense of **??**.
4. If $\iota\colon V \to X$ is a closed immersion into a smooth projective variety X and ω is a closed C^∞ form of degree $2k$ on X, then ω is absolutely integrable on V_{reg} and
$$\langle \omega, \iota_* \mu_V \rangle = \int_{V_{\mathrm{reg}}} \omega$$
where $\langle -, - \rangle$ is the de Rham pairing between $H^{2k}(X; \mathbb{C})$ and $H_{2k}(X; \mathbb{C})$.

***Proof Key ideas*:**
A complex projective variety admits a triangulation by real-analytic simplices in which every closed subvariety is a subcomplex. Fix one for V, with V_{sing} a subcomplex; the complex has dimension $2k$ and the subcomplex V_{sing} has dimension at most $2k-2$. Since simplicial and singular homology agree, clause (1) is the absence of simplices in dimensions above $2k$.

Let c be the sum of the $2k$-simplices, each oriented by the complex orientation of V_{reg}; the interior of such a simplex lies in V_{reg}, because V_{sing} is a subcomplex of smaller dimension. The same dimension count puts the interior of every $(2k-1)$-simplex τ in V_{reg}, near which V is a $2k$-manifold; so τ is a face of exactly two $2k$-simplices, and the complex orientation induces opposite orientations on τ from the two sides. Hence $\partial c = 0$. If $z = \sum_\sigma a_\sigma \sigma$ is any $2k$-cycle, the same two-sided count forces $a_\sigma = a_{\sigma'}$ whenever σ, σ' share a $(2k-1)$-face, and V_{reg} is connected, being a nonempty Zariski-open subset of the irreducible variety V and hence connected in the analytic topology, and remains connected after deleting a subset of real codimension two, so all the coefficients agree: z is a multiple of c. There are no $(2k+1)$-simplices, so no $2k$-boundaries, and $H_{2k}(V) = \mathbb{Z}c$. The image of c in $H_{2k}(V, V \setminus \{p\})$ for p interior to a top simplex is the local complex orientation, which gives clause (2), and clause (3) because the manifold fundamental class is characterized by the same local condition.

For clause (4), c is a finite sum of compact simplices whose interiors are disjoint and cover V_{reg} outside a set of measure zero, so $\int_{V_{\mathrm{reg}}} \omega$ is a finite sum of integrals of a smooth form over compact simplices, hence absolutely convergent and equal to the de Rham pairing of ω with the chain c, completing the account of the four clauses.

The theorem makes the assignment $V \mapsto \mu_V$ available for every subvariety, so a cycle can be pushed into the homology of the ambient scheme coefficient by coefficient.

Definition 15.2.3: Cycle Class Map

Let T be a projective scheme over $\mathbb{C}$. The *homological cycle class* of a k-cycle $\alpha = \sum_i n_i[V_i]$ on T is

$$\mathrm{cl}^{\mathrm{top}}(\alpha) = \sum_i n_i \, (\iota_i)_* \mu_{V_i} \in H_{2k}(T)$$

where $\iota_i \colon V_i \to T$ is the inclusion; this is a homomorphism $\mathrm{cl}^{\mathrm{top}} \colon Z_k(T) \to H_{2k}(T)$.

Let X be a smooth projective variety over $\mathbb{C}$ of dimension n and let $\mathcal{D}_X \colon H^i(X) \to H_{2n-i}(X)$, $u \mapsto \mu_X \frown u$, be the Poincaré duality isomorphism **??**. The *cycle class map* is

$$\mathrm{cl} = \mathcal{D}_X^{-1} \circ \mathrm{cl}^{\mathrm{top}} \colon Z_k(X) \longrightarrow H^{2(n-k)}(X)$$

In codimension indexing the map reads $\mathrm{cl} \colon Z^k(X) \to H^{2k}(X)$: a subvariety of complex codimension k has real codimension $2k$, and its class sits in cohomology of that degree. The smallest case already shows what the map forgets.

Example 15.2.4: Zero-Cycles on a Curve

Let C be a smooth projective connected curve over $\mathbb{C}$ and $\alpha = \sum_i n_i[p_i]$ a zero-cycle. Each p_i is a point, so μ_{p_i} is the generator of $H_0(\{p_i\}) = \mathbb{Z}$, and its image in $H_0(C)$ is the class of a point. As C is connected, $H_0(C) = \mathbb{Z}$ generated by that class, so

$$\mathrm{cl}^{\mathrm{top}}(\alpha) = \Big(\sum_i n_i\Big) \cdot [\text{point}] \in H_0(C)$$

Applying $\mathcal{D}_C^{-1}$, the cycle class of α in $H^2(C) \cong \mathbb{Z}$ is the degree $\sum_i n_i$ of α. Two distinct points therefore have the same cycle class, while they are rationally equivalent only when $C \cong \mathbb{P}^1$.

On a curve the cycle class map is the degree, and the degree annihilates the divisor of a rational function; whether the same happens in every dimension is what has to be proved. Two steps prepare it. The first is that the homological cycle class is compatible with proper pushforward already at the level of cycles, which is the topological counterpart of definition 10.2.1 and is proved from the local characterization in theorem 15.2.2(2).

Proposition 15.2.5: Pushforward of Homological Cycle Classes

Let $h \colon T \to T'$ be a morphism of projective schemes over $\mathbb{C}$. Then for every $\alpha \in Z_k(T)$,

$$h_* \mathrm{cl}^{\mathrm{top}}(\alpha) = \mathrm{cl}^{\mathrm{top}}(h_* \alpha)$$

in $H_{2k}(T')$, where h_* on the left is the map induced on homology and on the right the pushforward of cycles.

***Proof*:**

Both sides are additive in α, so it suffices to treat $\alpha = [V]$ for $V \subseteq T$ a k-dimensional subvariety. A morphism of projective schemes is proper, so $V' = h(V)$ is a closed subvariety of T'; write $h_V \colon V \to V'$ for the restriction, so that $h \circ \iota_V = \iota_{V'} \circ h_V$. Functoriality of pushforward in

homology gives

$$h_*\mathrm{cl}^{\mathrm{top}}([V]) = h_*(\iota_V)_*\mu_V = (\iota_{V'})_*(h_V)_*\mu_V$$

so, comparing with definition 10.2.1, the claim is that $(h_V)_*\mu_V$ equals $d\,\mu_{V'}$ when $\dim V' = k$, where d is the degree of the function field of V over that of V', and 0 when $\dim V' < k$.

The case $\dim V' < k$. Then $2k > 2\dim V'$, so $H_{2k}(V') = 0$ by theorem 15.2.2(1) and $(h_V)_*\mu_V = 0$, which is what definition 10.2.1 assigns to $h_*[V]$ in this case.

The case $\dim V' = k$. Here h_V is dominant, hence surjective because its image is closed, and generically finite of degree d. Delete from V', at the outset, the closed subsets V'_{sing} and $h_V(V_{\mathrm{sing}})$, the second closed because h_V is proper and both of dimension $< k$; what is left is a dense open $V'_0 \subseteq V'_{\mathrm{reg}}$ whose preimage $V_0 = h_V^{-1}(V'_0)$ is a nonempty open subset of V_{reg}, hence a smooth variety, mapping onto V'_0. The order matters: generic smoothness is a statement about a morphism with smooth source, and only after the deletion is there one. The restriction of h_V over V'_0 is proper and dominant between varieties of the same dimension, so proposition 5.2.14 gives a dense open $U' \subseteq V'_0 \subseteq V'_{\mathrm{reg}}$ over which it is finite and étale of degree d, with every fibre exactly d reduced points. Then $h_V^{-1}(U') \subseteq V_0 \subseteq V_{\mathrm{reg}}$ and h_V is a d-sheeted covering map there in the analytic topology.

Fix $p \in U'$ and write $h_V^{-1}(p) = \{q_1, \dots, q_d\}$. Choose an open $B \subseteq U'$ containing p and biholomorphic to a ball, small enough that $h_V^{-1}(B) = B_1 \sqcup \cdots \sqcup B_d$ with $q_j \in B_j$ and $h_V \colon B_j \to B$ biholomorphic; the covering property provides such a B. Excision identifies

$$H_{2k}\big(V, V \setminus h_V^{-1}(p)\big) \cong \bigoplus_{j=1}^{d} H_{2k}(B_j, B_j \setminus \{q_j\})$$

and the projection to the j-th summand is the map to $H_{2k}(V, V \setminus \{q_j\})$. By theorem 15.2.2(2) applied at each $q_j \in V_{\mathrm{reg}}$, the image of μ_V has the complex orientation generator in every summand. The map of pairs $(V, V \setminus h_V^{-1}(p)) \to (V', V' \setminus \{p\})$ carries the j-th summand isomorphically by the biholomorphism $h_V|_{B_j}$, and a biholomorphism preserves the complex orientation, so each summand contributes the complex orientation generator at p. Naturality of the map $H_{2k}(-) \to H_{2k}(-, - \setminus \text{point})$ therefore sends $(h_V)_*\mu_V$ to d times that generator. By theorem 15.2.2(2) for V' this determines the class: $(h_V)_*\mu_V = d\,\mu_{V'}$, as we sought to show.

The second step is the topological fact that makes rational equivalence invisible. A rational function on a $(k+1)$-dimensional variety is a map to $\mathbb{P}^1$, and $\mathbb{P}^1$ is connected, so its two fibres over 0 and ∞ ought to be joined by a path of fibres. Sweeping the fibre along a path from 0 to ∞ takes place inside the preimage of that path, a compact set because the variety is projective, and inside it the two end fibres carry the same class.

Lemma 15.2.6: Fibres of a Family over $\mathbb{P}^1$

Let Γ be an irreducible projective variety over $\mathbb{C}$ of dimension $m \geq 1$ and $g\colon \Gamma \to \mathbb{P}^1$ a nonconstant morphism. For $t \in \mathbb{P}^1$ let Γ_t be the scheme-theoretic fibre and $[\Gamma_t] \in Z_{m-1}(\Gamma)$ its fundamental cycle. Then

$$\mathrm{cl}^{\mathrm{top}}([\Gamma_s]) = \mathrm{cl}^{\mathrm{top}}([\Gamma_t])$$

in $H_{2m-2}(\Gamma)$ for all $s, t \in \mathbb{P}^1$.

Each fibre is cut out locally by one equation and is not all of Γ, so by Krull's principal ideal theorem every component of Γ_t has dimension $m-1$ and the fundamental cycle in the statement is indeed an $(m-1)$-cycle. Write $\mu_T \in H_{2d}(T)$ for the class of the fundamental cycle of a projective scheme T of pure dimension d, so that $\mathrm{cl}^{\mathrm{top}}([\Gamma_t])$ is the image of μ_{Γ_t} under $H_{2m-2}(\Gamma_t) \to H_{2m-2}(\Gamma)$. Since Γ is projective the morphism g is proper, so the preimage of a compact arc is again compact and the sweep runs in the ordinary homology of box 15.2.1; nothing below leaves the compact setting. One local statement is taken on trust, granted here exactly as the triangulability of varieties is granted for theorem 15.2.2 and belonging to the same stratification theory of algebraic maps: there is a finite set $S \subseteq \mathbb{P}^1$ such that g is a topologically locally trivial fibration over $\mathbb{P}^1 \setminus S$ and Γ_u is reduced for every $u \notin S$, and such that every $t \in \mathbb{P}^1$ has a closed disc neighbourhood D with $D \cap S \subseteq \{t\}$ for which $g^{-1}(D)$ deformation retracts onto Γ_t and the retraction carries μ_{Γ_u} to μ_{Γ_t} for $u \in D \setminus \{t\}$. The last clause is where the multiplicities of the scheme-theoretic fibre enter; it is a statement about a neighbourhood of a single fibre, and it is the only part of the sweep that is not carried out below.

***Proof Key ideas*:**

Two values outside S. Let $s, t \notin S$ and let $\gamma \subseteq \mathbb{P}^1 \setminus S$ be an embedded arc from s to t, which exists because a finite set does not disconnect $\mathbb{P}^1$. The preimage $E = g^{-1}(\gamma)$ is compact, g being proper, and local triviality over the contractible compact arc γ trivializes g over γ; the trivialization gives a retraction $r\colon E \to \Gamma_s$, which is a homotopy equivalence and restricts on Γ_t to a homeomorphism $\Gamma_t \to \Gamma_s$. That homeomorphism matches the components of the two fibres and their complex orientations, the comparison sign at a smooth point being locally constant along the connected arc and equal to $+1$ at s; both fibres are reduced, so it carries μ_{Γ_t} to μ_{Γ_s}. Hence r_* sends the images of μ_{Γ_s} and of μ_{Γ_t} in $H_{2m-2}(E)$ to the same class, and r_* is an isomorphism, so those two images agree in $H_{2m-2}(E)$ and therefore in $H_{2m-2}(\Gamma)$: $\mathrm{cl}^{\mathrm{top}}([\Gamma_s]) = \mathrm{cl}^{\mathrm{top}}([\Gamma_t])$.

A fibre against a nearby one. Let $t \in \mathbb{P}^1$ be arbitrary, let D be a disc as granted above, and let $u \in D \setminus \{t\}$, so that $u \notin S$. The retraction $\rho\colon g^{-1}(D) \to \Gamma_t$ is a homotopy inverse of the inclusion and carries μ_{Γ_u} to μ_{Γ_t}, so the two classes have the same image in $H_{2m-2}(g^{-1}(D))$ and hence in $H_{2m-2}(\Gamma)$: $\mathrm{cl}^{\mathrm{top}}([\Gamma_t]) = \mathrm{cl}^{\mathrm{top}}([\Gamma_u])$.

Arbitrary s and t. Choose u and u' outside S as in the second step, so that $\mathrm{cl}^{\mathrm{top}}([\Gamma_s]) = \mathrm{cl}^{\mathrm{top}}([\Gamma_u])$ and $\mathrm{cl}^{\mathrm{top}}([\Gamma_t]) = \mathrm{cl}^{\mathrm{top}}([\Gamma_{u'}])$; the first step equates the two right-hand sides, as we sought to show.

The two preceding results combine into the statement that the homological cycle class annihilates rational equivalence. The proof replaces a rational function by a morphism to $\mathbb{P}^1$, and the variety it lives on by the closure of the graph.

Theorem 15.2.7: The Cycle Class Map on Chow Groups

Let T be a projective scheme over $\mathbb{C}$.

1. If $\alpha \in Z_k(T)$ is rationally equivalent to zero, then $\mathrm{cl}^{\mathrm{top}}(\alpha) = 0$; hence $\mathrm{cl}^{\mathrm{top}}$ descends to a homomorphism $A_k(T) \to H_{2k}(T)$.
2. If X is a smooth projective variety over $\mathbb{C}$ of dimension n, the cycle class map descends to a homomorphism
$$\mathrm{cl}\colon A^k(X) \longrightarrow H^{2k}(X)$$

***Proof*:**

1. By definition 10.1.3 a cycle rationally equivalent to zero is a finite sum of cycles $[\mathrm{div}(f)]$, with $W \subseteq T$ a closed subvariety of dimension $k+1$ and f a nonzero rational function on W; since $\mathrm{cl}^{\mathrm{top}}$ is additive it is enough to kill one such summand. The components of $\mathrm{div}(f)$ are subvarieties of W, so by functoriality of pushforward in homology the class of $[\mathrm{div}(f)]$ in $H_{2k}(T)$ is the image of its class in $H_{2k}(W)$ under the inclusion; it suffices to show the latter vanishes. If f is constant then $\mathrm{div}(f) = 0$, so assume f nonconstant.

   Step 1: the graph and the divisor of g. Apply Steps 2 and 3 of theorem 15.1.6 to f on W: writing $\Gamma \subseteq W \times \mathbb{P}^1$ for the closure of the graph of f and $p\colon \Gamma \to W$, $g\colon \Gamma \to \mathbb{P}^1$ for the two projections, Γ is an irreducible projective variety of dimension $k+1$, p is proper and birational, g is a nonconstant morphism, and the order of g along the k-dimensional subvarieties of Γ is computed there to give (15.1),
$$[\mathrm{div}(g)] = [\Gamma_0] - [\Gamma_\infty]$$

   Step 2: descent to W and conclusion. Under the isomorphism of function fields induced by the birational morphism p, the function g corresponds to f, so the pushforward formula for the divisor of a rational function along a proper surjective morphism, applied to the birational p, gives $p_*[\mathrm{div}(g)] = [\mathrm{div}(f)]$ by proposition 10.2.2(2). Both Γ and W are projective, so proposition 15.2.5 applies to p and gives
$$\mathrm{cl}^{\mathrm{top}}([\mathrm{div}(f)]) = \mathrm{cl}^{\mathrm{top}}(p_*[\mathrm{div}(g)]) = p_*\mathrm{cl}^{\mathrm{top}}([\Gamma_0] - [\Gamma_\infty])$$
   and the class inside the pushforward vanishes by lemma 15.2.6, whose hypotheses hold: Γ is an irreducible projective variety of dimension $k+1$ and g is nonconstant. Hence $\mathrm{cl}^{\mathrm{top}}([\mathrm{div}(f)]) = 0$ in $H_{2k}(W)$, and part (1) follows.

2. For X smooth projective of dimension n the map cl is $\mathcal{D}_X^{-1} \circ \mathrm{cl}^{\mathrm{top}}$ by definition 15.2.3, and $\mathcal{D}_X^{-1}$ is an isomorphism, so cl kills exactly what $\mathrm{cl}^{\mathrm{top}}$ kills. By part (1) it descends to $A_{n-k}(X) = A^k(X)$, with values in $H^{2k}(X)$ by the degree count of definition 15.2.3, completing the proof.

Every operation built on Chow groups in the preceding chapters has a topological counterpart, and the cycle class map intertwines them: proper pushforward with the umkehr map, pullback with the

induced map on cohomology, the intersection product with the cup product. Pushforward comes first, and stating it needs the cohomological form of the pushforward map.

Definition 15.2.8: Umkehr Map

Let $f\colon X \to Y$ be a morphism of smooth projective varieties over $\mathbb{C}$ of dimensions n and m. The *umkehr map* (or Gysin map in cohomology) is

$$f_! = \mathcal{D}_Y^{-1} \circ f_* \circ \mathcal{D}_X \colon H^i(X) \longrightarrow H^{i+2(m-n)}(Y)$$

where f_* is the map induced on homology.

Theorem 15.2.9: Compatibility with Proper Pushforward

Let $f\colon X \to Y$ be a morphism of smooth projective varieties over $\mathbb{C}$. Then $\mathrm{cl}_Y(f_*\alpha) = f_!\,\mathrm{cl}_X(\alpha)$ for every $\alpha \in A_k(X)$.

***Proof*:**
A morphism of projective schemes is proper, so f_* on Chow groups is defined. Both X and Y are projective schemes, so proposition 15.2.5 applies to f and gives $f_*\mathrm{cl}^{\mathrm{top}}(\alpha) = \mathrm{cl}^{\mathrm{top}}(f_*\alpha)$ for a cycle representing α; the two sides depend only on the rational equivalence class by theorem 15.2.7(1). Therefore

$$\mathrm{cl}_Y(f_*\alpha) = \mathcal{D}_Y^{-1}\mathrm{cl}^{\mathrm{top}}(f_*\alpha) = \mathcal{D}_Y^{-1} f_* \mathrm{cl}^{\mathrm{top}}(\alpha) = \mathcal{D}_Y^{-1} f_* \mathcal{D}_X \mathrm{cl}_X(\alpha) = f_!\,\mathrm{cl}_X(\alpha)$$

where the third equality is $\mathrm{cl}^{\mathrm{top}} = \mathcal{D}_X \circ \mathrm{cl}$ from definition 15.2.3 and the last is definition 15.2.8, completing the proof.

Taking Y to be a point turns the theorem into a statement about degrees, and identifies the top cohomology class of a zero-cycle with the integer that definition 10.2.4 attaches to it.

Corollary 15.2.10: Cycle Classes of Zero-Cycles

Let X be a smooth projective variety over $\mathbb{C}$ of dimension n and $\alpha \in A_0(X)$. Then

$$\langle \mathrm{cl}(\alpha), \mu_X \rangle = \int_X \alpha$$

where $\langle -, - \rangle$ is the Kronecker pairing between $H^{2n}(X)$ and $H_{2n}(X)$.

***Proof*:**
Let $f\colon X \to \operatorname{Spec}\mathbb{C}$ be the structure morphism, a morphism of smooth projective varieties with target of dimension 0. By definition 10.2.4, $f_*\alpha = \left(\int_X \alpha\right)[\operatorname{Spec}\mathbb{C}]$ in $A_0(\operatorname{Spec}\mathbb{C}) = \mathbb{Z}$, and $\mathrm{cl}(f_*\alpha) = \int_X \alpha$ under $H^0(\operatorname{Spec}\mathbb{C}) = \mathbb{Z}$, since the fundamental class of a point is the generator of H_0. On the other side, $\mathcal{D}_X(\mathrm{cl}(\alpha)) = \mu_X \frown \mathrm{cl}(\alpha) \in H_0(X)$, and f_* carries $H_0(X)$ to $H_0(\operatorname{Spec}\mathbb{C}) = \mathbb{Z}$ by the augmentation, which sends $\mu_X \frown u$ to $\langle u, \mu_X \rangle$. Hence $f_!\,\mathrm{cl}(\alpha) = \langle \mathrm{cl}(\alpha), \mu_X \rangle$, and theorem 15.2.9 equates the two, as we sought to show.

Pullback and the product are handled together, because on a smooth variety the product is a pullback: the intersection product is the pullback of an exterior product along the diagonal. The exterior product is the case that the topology computes directly, through the Künneth cross product.

Proposition 15.2.11: Cycle Classes of Exterior Products

Let X and Y be smooth projective varieties over $\mathbb{C}$, $\alpha \in A_k(X)$ and $\beta \in A_l(Y)$. Then

$$\mathrm{cl}_{X\times Y}(\alpha \times \beta) = \mathrm{cl}_X(\alpha) \times \mathrm{cl}_Y(\beta)$$

where $\times$ on the left is the exterior product of definition 14.1.2 and on the right the cohomology cross product.

***Proof*:**
Both sides are bilinear, so take $\alpha = [V]$ and $\beta = [W]$ for subvarieties $V \subseteq X$ and $W \subseteq Y$ of dimensions k and l; then $\alpha \times \beta = [V \times W]$ by definition 14.1.2. The smooth locus of $V \times W$ is $V_{\mathrm{reg}} \times W_{\mathrm{reg}}$, and at a point (p, q) of it the local homology of the product is the tensor product of the local homologies, with the complex orientation of the product corresponding to the product of the complex orientations. By theorem 15.2.2(2), applied to $V \times W$ at (p, q) and to V at p and W at q, this identifies

$$\mu_{V\times W} = \mu_V \times \mu_W$$

and the same computation with $V = X$, $W = Y$ gives $\mu_{X\times Y} = \mu_X \times \mu_Y$. Pushing forward along $V \times W \to X \times Y$ and using that the cross product commutes with maps induced by products of maps, $\mathrm{cl}^{\mathrm{top}}([V \times W]) = \mathrm{cl}^{\mathrm{top}}([V]) \times \mathrm{cl}^{\mathrm{top}}([W])$.

It remains to compare the two Poincaré dualities. For classes $u \in H^i(X)$ and $v \in H^j(Y)$ the cap product satisfies $(a \times b) \frown (u \times v) = (-1)^{|b||u|}(a \frown u) \times (b \frown v)$; here $a = \mu_X$, $b = \mu_Y$, and all four classes have even degree, so the sign is $+1$ and

$$\mathcal{D}_{X\times Y}(u \times v) = (\mu_X \times \mu_Y) \frown (u \times v) = \mathcal{D}_X(u) \times \mathcal{D}_Y(v)$$

Applying this with $u = \mathrm{cl}_X(\alpha)$ and $v = \mathrm{cl}_Y(\beta)$ and comparing with the previous display gives $\mathcal{D}_{X\times Y}(\mathrm{cl}_X(\alpha) \times \mathrm{cl}_Y(\beta)) = \mathrm{cl}^{\mathrm{top}}(\alpha \times \beta)$, which is the claim after applying $\mathcal{D}^{-1}_{X\times Y}$, completing the proof.

Pullback along an arbitrary morphism of smooth projective varieties is the one compatibility this book does not carry. Factoring such a morphism f through its graph splits the question into two cases: the projection, which the results already proved settle and which is the flat case stated below, and the regular embedding, where comparing $\mathrm{cl}(f^*\beta)$ with $f^*\mathrm{cl}(\beta)$ needs a class refined to the support of the pullback cycle. Such a class lives in the homology of a noncompact space, which box 15.2.1 places outside this book, so the theorem below is stated for a projection only.

Lemma 15.2.12: The Class of the Ambient Variety

Let X be a smooth projective variety over $\mathbb{C}$. Then $\mathrm{cl}([X]) = 1$ in $H^0(X; \mathbb{Z})$.

***Proof*:**
The inclusion of X in itself is the identity, so $\mathrm{cl}^{\mathrm{top}}([X]) = \mu_X$ by definition 15.2.3, the class μ_X being the fundamental class of the compact oriented manifold X by theorem 15.2.2(3). Since $\mathcal{D}_X(1) = \mu_X \frown 1 = \mu_X$, applying $\mathcal{D}_X^{-1}$ gives $\mathrm{cl}([X]) = \mathcal{D}_X^{-1}\mathrm{cl}^{\mathrm{top}}([X]) = 1$, as we sought to show.

Theorem 15.2.13: Compatibility with Pullback along a Projection

Let Z and Y be smooth projective varieties over $\mathbb{C}$ and let $\mathrm{pr}_Y \colon Z \times Y \to Y$ be the projection. Then

$$\mathrm{cl}_{Z\times Y}(\mathrm{pr}_Y^*\beta) = \mathrm{pr}_Y^*\mathrm{cl}_Y(\beta)$$

for every $\beta \in A^k(Y)$, where pr_Y^* on the left is the pullback of definition 14.2.11 and on the right the map induced on cohomology.

***Proof*:**
The projection is flat, and $\mathrm{pr}_Y^{-1}(V) = Z \times V$ for a subvariety $V \subseteq Y$, so $\mathrm{pr}_Y^*\beta = [Z] \times \beta$ by definition 10.3.3 together with the agreement of definition 14.2.11 with flat pullback for a smooth morphism (theorem 14.2.12(2)), pr_Y being smooth. By proposition 15.2.11 and lemma 15.2.12,

$$\mathrm{cl}_{Z\times Y}(\mathrm{pr}_Y^*\beta) = \mathrm{cl}_Z([Z]) \times \mathrm{cl}_Y(\beta) = 1 \times \mathrm{cl}_Y(\beta) = \mathrm{pr}_Y^*\mathrm{cl}_Y(\beta)$$

the last equality being the definition of the cross product with 1, completing the proof.

The corollary that cl is a ring homomorphism therefore needs the excluded case for the diagonal alone, and only in the form

$$\mathrm{cl}_X(\Delta^*\gamma) = \Delta^*\mathrm{cl}_{X\times X}(\gamma) \quad \text{for } \gamma \in A^*(X \times X), \quad \Delta \colon X \to X \times X \text{ the diagonal} \tag{15.2}$$

which is an input here and not a theorem of this book.

Corollary 15.2.14: The Cycle Class Map is a Ring Homomorphism

Let X be a smooth projective variety over $\mathbb{C}$ and grant (15.2). Then

$$\mathrm{cl}(\alpha \cdot \beta) = \mathrm{cl}(\alpha) \cup \mathrm{cl}(\beta)$$

for all $\alpha, \beta \in A^*(X)$, and $\mathrm{cl} \colon A^*(X) \to H^{2*}(X)$ is a homomorphism of graded rings carrying $1 = [X]$ to 1.

***Proof*:**
Let $\Delta \colon X \to X \times X$ be the diagonal, a regular embedding by theorem 14.1.6, and recall from theorem 14.2.7 that the product on $A^*(X)$ is computed by reduction to the diagonal, $\alpha \cdot \beta = \Delta^*(\alpha \times \beta)$. Granting (15.2) for Δ and applying proposition 15.2.11 to the exterior product,

$$\mathrm{cl}(\alpha \cdot \beta) = \mathrm{cl}(\Delta^*(\alpha \times \beta)) = \Delta^*\mathrm{cl}_{X\times X}(\alpha \times \beta) = \Delta^*\big(\mathrm{cl}(\alpha) \times \mathrm{cl}(\beta)\big) = \mathrm{cl}(\alpha) \cup \mathrm{cl}(\beta)$$

the last equality because the cup product is the pullback of the cross product along the diagonal. That $\mathrm{cl}([X]) = 1$ is lemma 15.2.12, and cl doubles degrees by theorem 15.2.7(2), completing the

proof.

On projective space the comparison is an isomorphism, and the verification uses nothing beyond the degree formula and multiplicativity.

Example 15.2.15: Cycle Classes on $\mathbb{P}^n$

Let $h \in A^1(\mathbb{P}^n)$ be the class of a hyperplane, so that $A^*(\mathbb{P}^n) = \mathbb{Z}[h]/(h^{n+1})$ with h^k the class of a linear subspace of codimension k and $\int_{\mathbb{P}^n} h^n = 1$ (theorem 10.5.2). The singular cohomology ring is $H^*(\mathbb{P}^n;\mathbb{Z}) = \mathbb{Z}[\xi]/(\xi^{n+1})$ with ξ a generator of H^2 and ξ^n a generator of H^{2n} **??**. Write $\mathrm{cl}(h) = c\,\xi$ with $c \in \mathbb{Z}$. By corollary 15.2.14, $\mathrm{cl}(h^n) = c^n\xi^n$, and by corollary 15.2.10,

$$\langle \mathrm{cl}(h^n), \mu_{\mathbb{P}^n} \rangle = \int_{\mathbb{P}^n} h^n = 1$$

while $\langle \xi^n, \mu_{\mathbb{P}^n} \rangle = \pm 1$ because ξ^n generates $H^{2n}(\mathbb{P}^n;\mathbb{Z})$ and the Kronecker pairing with $\mu_{\mathbb{P}^n}$ is an isomorphism $H^{2n}(\mathbb{P}^n;\mathbb{Z}) \to \mathbb{Z}$. Hence $c^n = \pm 1$, so $c = \pm 1$ and $\mathrm{cl}(h)$ generates $H^2(\mathbb{P}^n;\mathbb{Z})$. Multiplicativity then makes cl carry the basis $1, h, \dots, h^n$ of $A^*(\mathbb{P}^n)$ to the basis $1, \mathrm{cl}(h), \dots, \mathrm{cl}(h)^n$ of $H^{2*}(\mathbb{P}^n;\mathbb{Z})$, so $\mathrm{cl}\colon A^*(\mathbb{P}^n) \to H^{2*}(\mathbb{P}^n;\mathbb{Z})$ is an isomorphism of rings. The odd cohomology of $\mathbb{P}^n$ vanishes, so cl is onto all of $H^*(\mathbb{P}^n;\mathbb{Z})$: on projective space the Chow ring and the cohomology ring carry the same information.

The same construction runs over any base field with ℓ-adic étale cohomology in place of singular cohomology, producing $\mathrm{cl}\colon A^k(X) \to H^{2k}_{\text{ét}}(X, \mathbb{Q}_\ell(k))$; the étale topology it requires is not developed in this book. Over $\mathbb{C}$ there is a constraint on the image that has no counterpart in the purely topological picture, and it comes from the Hodge decomposition of the cohomology of a smooth projective variety.

A smooth projective variety over $\mathbb{C}$ is a compact Kähler manifold in its analytic topology, so theorem 0.6.28 applies: $H^k(X;\mathbb{C})$ decomposes as $\bigoplus_{p+q=k} H^{p,q}(X)$, and $H^{p,q}(X)$ denotes throughout the summand of $H^{p+q}(X;\mathbb{C})$ consisting of the classes represented by a closed form of type (p,q). Under GAGA that summand is $H^q(X, \Omega^p_{X/\mathbb{C}})$, which is the reading in corollary 6.9.10.

Theorem 15.2.16: Algebraic Cycles Have Hodge Type (k,k)

Let X be a smooth projective variety over $\mathbb{C}$ of dimension n and $\alpha \in A^k(X)$. Then the image of $\mathrm{cl}(\alpha)$ in $H^{2k}(X;\mathbb{C})$ lies in the summand $H^{k,k}(X)$ of the Hodge decomposition.

***Proof*:**

By linearity take $\alpha = [V]$ with $V \subseteq X$ an irreducible closed subvariety of codimension k, so $\dim V = d = n - k$. Let ω be a closed form on X of type (p,q) with $p+q = 2d$ and $(p,q) \neq (d,d)$. Then $p > d$ or $q > d$, and a form of type (p,q) with $p > d$ or $q > d$ restricts to zero on any complex manifold of complex dimension d, since its restriction involves a wedge of more than d of the dz_i or more than d of the $d\bar{z}_i$. In particular ω restricts to zero on V_{reg}, so $\int_{V_{\mathrm{reg}}} \omega = 0$, and theorem 15.2.2(4) gives

$$\langle \omega, \mathrm{cl}^{\mathrm{top}}([V]) \rangle = 0$$

By the Hodge decomposition theorem 0.6.28, every class in $H^{p,q}(X)$ is represented by a closed form of type (p,q), so $\mathrm{cl}^{\mathrm{top}}([V])$ pairs to zero with $H^{p,q}(X)$ for every $(p,q) \neq (d,d)$ with $p+q = 2d$.

Rewrite this as a statement about cup products. For $u \in H^{2k}(X;\mathbb{C})$ and $v \in H^{2d}(X;\mathbb{C})$ set $(u,v) = \langle u \cup v, \mu_X\rangle$; with field coefficients Poincaré duality makes this pairing perfect. The paragraph above says $(\mathrm{cl}([V]), v) = 0$ for $v \in H^{p,q}(X)$, $(p,q) \neq (d,d)$, because $\langle \mathrm{cl}([V]) \cup v, \mu_X\rangle = \langle v, \mu_X \frown \mathrm{cl}([V])\rangle = \langle v, \mathrm{cl}^{\mathrm{top}}([V])\rangle$.

Now decompose $\mathrm{cl}([V]) = \sum_{a+b=2k} c^{a,b}$ with $c^{a,b} \in H^{a,b}(X)$. A form of type (a,b) wedged with a form of type (p,q) has type $(a+p, b+q)$, and a form of type (s,t) with $s+t = 2n$ vanishes unless $s = t = n$, so $(c^{a,b}, H^{p,q}(X)) = 0$ unless $(p,q) = (n-a, n-b)$. Perfectness of the pairing on $H^{2k} \times H^{2d}$ therefore restricts to a perfect pairing between $H^{a,b}(X)$ and $H^{n-a,n-b}(X)$. Fix $(a,b) \neq (k,k)$ with $a+b = 2k$. Then $(n-a, n-b) \neq (d,d)$, so the first paragraph gives $(\mathrm{cl}([V]), H^{n-a,n-b}(X)) = 0$; and among the summands $c^{a',b'}$ only $c^{a,b}$ pairs nontrivially with $H^{n-a,n-b}(X)$, so $(c^{a,b}, H^{n-a,n-b}(X)) = 0$ and perfectness gives $c^{a,b} = 0$. Every summand other than $c^{k,k}$ vanishes, so $\mathrm{cl}([V]) \in H^{k,k}(X)$, as we sought to show.

The theorem cuts the target of the cycle class map down to a subgroup that is in general much smaller than $H^{2k}(X;\mathbb{Z})$.

Definition 15.2.17: Hodge Class

Let X be a smooth projective variety over $\mathbb{C}$. The group of *Hodge classes* of degree $2k$ is

$$\mathrm{Hdg}^k(X) = \left\{ u \in H^{2k}(X;\mathbb{Z}) \;\middle|\; \text{the image of } u \text{ in } H^{2k}(X;\mathbb{C}) \text{ lies in } H^{k,k}(X) \right\}$$

Theorem 15.2.16 says that cl takes values in $\mathrm{Hdg}^k(X)$. Whether it fills that group after tensoring with $\mathbb{Q}$ is the Hodge conjecture, open in general for $2 \leq k \leq n-2$, where $n = \dim X$; for $k = 1$ the answer is yes, by theorem 8.1.6, which identifies $\mathrm{NS}(X)$ with $\mathrm{Hdg}^1(X)$. That statement speaks of *the* cycle class map without constructing one, and its proof there runs through the connecting map $\mathrm{Pic}\,(X) \to H^2(X;\mathbb{Z})$ of the exponential sequence; reading it for the cl of definition 15.2.3, built from topological fundamental classes, uses the comparison $\mathrm{cl}([D]) = c_1(\mathcal{O}_X(D))$ in H^2, which neither book proves and which is taken here as an input alongside (15.2). The two top codimensions are known as well. For $k = n$ every class in $H^{2n}(X;\mathbb{C})$ has type (n,n), so $\mathrm{Hdg}^n(X) = H^{2n}(X;\mathbb{Z})$, which exercise 15.2.1 (4) identifies with $\mathbb{Z}$ by pairing against μ_X; the class of a point pairs to 1 by corollary 15.2.10 and so generates. For $k = n-1$ the hard Lefschetz isomorphism $H^2(X;\mathbb{Q}) \to H^{2n-2}(X;\mathbb{Q})$ is cup product with $\mathrm{cl}(h)^{n-2}$ for $h \in A^1(X)$ the class of a hyperplane section, so it carries rational Hodge classes onto rational Hodge classes and, by corollary 15.2.14, algebraic classes to algebraic classes; that case therefore reduces to $k = 1$. The conjecture has content only in the middle range named above, and none at all when $\dim X \leq 3$. On a curve the condition is empty, since H^2 of a curve is all of type $(1,1)$, and cl is then the degree map of example 15.2.4, whose kernel is the group of degree-zero divisor classes.

Exercise 15.2.1

1. Let $X = \mathbb{P}^1 \times \mathbb{P}^1$ and put $a = [\{p\} \times \mathbb{P}^1]$ and $b = [\mathbb{P}^1 \times \{q\}]$ in $A^1(X)$. Using theorem 12.1.9 for $X = \mathbb{P}(\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1})$, or otherwise, show that $A^*(X)$ is free with basis $1, a, b, ab$ and that $a^2 = b^2 = 0$. Deduce that $\mathrm{cl}\colon A^*(X) \to H^{2*}(X;\mathbb{Z})$ is a ring isomorphism. The diagonal class $[\Delta] = a + b$ is exercise 14.1.1 (2); check that $\mathrm{cl}[\Delta]$ is the Künneth class of the diagonal, and read off $\deg([\Delta] \cdot [\Delta])$.

2. Let E be a smooth projective curve of genus 1 over $\mathbb{C}$ and let $p \neq q$ be two points of E. Show that $\mathrm{cl}([p]-[q]) = 0$ while $[p]-[q] \neq 0$ in $A^1(E)$, so that cl is not injective. (Use that a degree-zero divisor $p-q$ with $p \neq q$ on a curve of genus at least one is not the divisor of a rational function.)

3. Let X be a smooth projective variety over $\mathbb{C}$ of dimension n, and let $\alpha \in A^k(X)$ and $\beta \in A^{n-k}(X)$. Show that
$$\int_X (\alpha \cdot \beta) = \langle \mathrm{cl}(\alpha) \cup \mathrm{cl}(\beta), \mu_X \rangle$$
so that intersection numbers of complementary-dimensional cycles are computed by the cup product in cohomology.

4. Let X be a smooth projective connected variety over $\mathbb{C}$ of dimension n. Show that $u \mapsto \langle u, \mu_X \rangle$ is an isomorphism $H^{2n}(X;\mathbb{Z}) \to \mathbb{Z}$, and deduce that $\mathrm{cl}(\alpha) = 0$ for $\alpha \in A_0(X)$ if and only if $\int_X \alpha = 0$. Conclude that cl is injective on $A_0(X)$ exactly when every zero-cycle of degree zero is rationally equivalent to zero.

5. Let $Z \subseteq \mathbb{P}^n$ be the hypersurface cut out by an irreducible form F of degree d, and let H be the hyperplane $x_0 = 0$. By computing the divisor of the rational function F/x_0^d, show that $[Z] = d\,h$ in $A^1(\mathbb{P}^n)$, where $h = [H]$, and deduce that $\mathrm{cl}([Z]) = d\,\mathrm{cl}(h)$.

6. Let C be a smooth projective connected curve over $\mathbb{C}$. Show that $H^2(C;\mathbb{C}) = H^{1,1}(C)$, so that $\mathrm{Hdg}^1(C) = H^2(C;\mathbb{Z})$, and show that $\mathrm{cl}\colon A^1(C) \to H^2(C;\mathbb{Z})$ is surjective.

7. Let $i\colon Y \to X$ be a closed immersion of smooth projective varieties over $\mathbb{C}$. Show that $\mathrm{cl}_X([Y]) = i_!(1)$, where $1 \in H^0(Y;\mathbb{Z})$ and $i_!$ is the umkehr map of definition 15.2.8.

8. Let Γ be a smooth projective surface over $\mathbb{C}$ and $g\colon \Gamma \to \mathbb{P}^1$ a nonconstant morphism. Show that the fibres of g all have the same cycle class $\varphi \in H^2(\Gamma;\mathbb{Z})$, and that $\langle \varphi \cup \varphi, \mu_\Gamma \rangle = 0$. (Two distinct fibres are disjoint; use corollary 13.3.12 to evaluate their intersection product, and exercise 15.2.1 (3).)

15.3 Homological and Numerical Equivalence

Section 15.2 sent a cycle class to a cohomology class. Calling a cycle trivial when that image vanishes is one way to coarsen rational equivalence; calling it trivial when every intersection number formed against it vanishes is another, and it asks less. This section defines both, isolates the three properties the four relations of this chapter share, and proves the tower they form.

Throughout, X is a smooth projective variety over $\mathbb{C}$ of dimension n, the setting fixed in section 15.2. Every relation below is a relation on the Chow ring $A^*(X)$ of definition 14.2.2, so each is specified by naming a graded subgroup of $A^*(X)$: the classes it declares trivial. Three properties of the cycle class map are used repeatedly, and they do not all stand on the same footing. Two are proved outright in section 15.2: the map $\mathrm{cl}\colon A^*(X) \to H^{2*}(X;\mathbb{Z})$ commutes with proper pushforward (theorem 15.2.9), and on zero-cycles it computes the degree, in the sense that $\int_X \mathrm{cl}(\alpha) = \deg(\alpha)$ for $\alpha \in A^n(X)$, where $\int_X\colon H^{2n}(X;\mathbb{Z}) \to \mathbb{Z}$ is evaluation against the fundamental class of $X(\mathbb{C})$.

The third is conditional, and it is worth being exact about what on. That cl is a homomorphism of graded rings, and that it commutes with pullback along an *arbitrary* morphism of smooth projective varieties, both rest on (15.2): the ring structure is the diagonal case directly, and a general f^* factors

through the graph embedding γ_f, which the ring structure then handles, which section 15.2 isolates as an input and not a theorem of this book: theorem 15.2.13 is proved for a projection only, and a general f^* factors through the graph embedding, which is exactly the excluded case. Corollary 15.2.14 is therefore stated subject to that grant. *The grant applies from that corollary onward*, which includes uses inside section 15.2 itself: example 15.2.15, exercise 15.2.1 (1) and exercise 15.2.1 (3) all read the ring structure off it, and their conclusions are conditional for that reason. Every result below that uses the ring structure of cl or a general pullback inherits it too, including theorem 15.3.9(3), theorem 15.3.11, proposition 15.4.12 and corollary 15.4.13.

It is not the chapter's only external input. There are six, and a book citing this chapter takes on all of them:

1. (15.2), as above.
2. Triangulability of complex algebraic varieties, granted at theorem 15.2.2, on which all of section 15.2 rests.
3. The local specialization statement granted in lemma 15.2.6: that the preimage of a disc deformation retracts onto the special fibre, carrying fundamental class to fundamental class. Theorem 15.2.7(1) rests on it, and through that so does every cycle-class result in the chapter. This is the deepest of the five and the easiest to miss.
4. The identification $\mathrm{cl}([D]) = c_1(\mathcal{O}_X(D))$ on divisor classes. It is load-bearing for the Enriques computation and for box 15.3.3.
5. Finite generation of $H^*(X;\mathbb{Z})$, used for theorem 15.3.13.
6. The hard Lefschetz theorem, used for the $k = n-1$ reduction of the Hodge conjecture.

Definition 15.3.1: Homological Equivalence

Let X be a smooth projective variety over $\mathbb{C}$. A class $\alpha \in A^k(X)$ is *homologically equivalent to zero*, written $\alpha \sim_{\mathrm{hom}} 0$, if $\mathrm{cl}(\alpha) = 0$ in $H^{2k}(X;\mathbb{Z})$. Two classes are homologically equivalent if their difference is. Write

$$\mathcal{R}_{\mathrm{hom}}(X) \;=\; \ker\big(\mathrm{cl}\colon A^*(X) \to H^{2*}(X;\mathbb{Z})\big) \;\subseteq\; A^*(X)$$

and $A^*_{\mathrm{hom}}(X) = A^*(X)/\mathcal{R}_{\mathrm{hom}}(X)$.

The quotient $A^*_{\mathrm{hom}}(X)$ is by construction the image of the cycle class map, the subring of $H^{2*}(X;\mathbb{Z})$ consisting of the classes of algebraic cycles. Passing to it discards exactly the information the topology of $X(\mathbb{C})$ cannot see, which is what makes it the object a Hodge-theoretic question about cycles is posed in.

Example 15.3.2: Homological Equivalence of Zero-Cycles

Take $k = n$, so that $\alpha \in A^n(X) = A_0(X)$ is a class of zero-cycles. Then $\mathrm{cl}(\alpha) \in H^{2n}(X;\mathbb{Z})$, and evaluation against the fundamental class is the degree: $\int_X \mathrm{cl}(\alpha) = \deg(\alpha)$. Since X is a connected smooth projective variety over $\mathbb{C}$, $X(\mathbb{C})$ is a compact connected oriented $2n$-manifold, so $\int_X$ is injective on $H^{2n}(X;\mathbb{Z})$; hence

$$\alpha \sim_{\mathrm{hom}} 0 \quad\Longleftrightarrow\quad \deg(\alpha) = 0$$

On a smooth projective curve C this says that $\mathcal{R}_{\mathrm{hom}}(C)$ meets $A^1(C) = A_0(C) = \mathrm{Pic}\,(C)$ (proposition 11.1.3) in the divisor classes of degree zero, that is in $\mathrm{Pic}^{\,0}(C)$.

Integral cohomology can carry torsion classes that no intersection number detects, so definition 15.3.1 needs one caveat attached to it before the comparisons below.

15.3.3 Warning: Integral versus Rational Coefficients Definition 15.3.1 takes $\mathbb{Z}$ coefficients, so a class whose image in $H^{2k}(X;\mathbb{Z})$ is a nonzero torsion element is not homologically trivial. The comparison with numerical equivalence below (theorem 15.3.11) is insensitive to this, but the converse comparison is not: theorem 15.3.9(4) will show that every torsion class of $A^*(X)$ is numerically trivial, whereas cl need not kill torsion: on an Enriques surface X the canonical class K_X is a nonzero 2-torsion element of $A^1(X)$ with $\mathrm{cl}(K_X) \neq 0$, which is what makes the last inclusion of theorem 15.3.11 strict for that X. The rational variant, $\alpha \sim_{\mathrm{hom},\mathbb{Q}} 0$ when $\mathrm{cl}(\alpha) = 0$ in $H^{2k}(X;\mathbb{Q})$, differs from definition 15.3.1 only on torsion classes, and it is the variant in which conjecture 15.3.14 is stated.

Rather than requiring a cycle class to vanish in some receiving group, numerical equivalence requires only that every number the intersection product can extract from it be zero. Since a class of complementary codimension multiplies α into $A^n(X)$, where the degree homomorphism of definition 10.2.4 is defined, those numbers are available without leaving the Chow ring.

Definition 15.3.4: Numerical Equivalence

Let X be a smooth projective variety of dimension n. A class $\alpha \in A^k(X)$ is *numerically equivalent to zero*, written $\alpha \sim_{\mathrm{num}} 0$, if

$$\deg\big(\alpha \cdot \beta\big) \;=\; 0 \qquad \text{for every } \beta \in A^{n-k}(X)$$

Two classes are numerically equivalent if their difference is. Write $\mathcal{R}_{\mathrm{num}}(X) \subseteq A^*(X)$ for the graded subgroup of numerically trivial classes and $A^*_{\mathrm{num}}(X) = A^*(X)/\mathcal{R}_{\mathrm{num}}(X)$; the group $A^k_{\mathrm{num}}(X)$ is also written $\mathrm{Num}^k(X)$.

The definition is exactly the statement that the pairing $A^k(X) \times A^{n-k}(X) \to \mathbb{Z}$, $(\alpha,\beta) \mapsto \deg(\alpha\cdot\beta)$, becomes nondegenerate on the left after passing to $A^*_{\mathrm{num}}(X)$. Numerical equivalence is thus the coarsest identification under which intersection numbers remain well defined, and proposition 15.3.10 will make this precise.

Example 15.3.5: The Two Rulings of a Quadric Surface

Let $S = \mathbb{P}^1 \times \mathbb{P}^1$, and let $f_1 = [\mathbb{P}^1 \times \{q\}]$ and $f_2 = [\{p\} \times \mathbb{P}^1]$ in $A^1(S) = A_1(S)$ be the classes of the two rulings (example 14.1.3). Both are flat pullbacks of point classes: writing $\mathrm{pr}_1, \mathrm{pr}_2 \colon S \to \mathbb{P}^1$ for the projections, which are flat by lemma 14.1.1, proposition 10.3.5 gives $f_1 = \mathrm{pr}_2^*[q]$ and $f_2 = \mathrm{pr}_1^*[p]$, the flat pullback of a fundamental cycle being the fundamental cycle of the preimage.
The self-intersections vanish. Choose $q' \neq q$ in $\mathbb{P}^1$. By example 14.2.3 any two closed points of $\mathbb{P}^1$ have the same class in $A_0(\mathbb{P}^1)$, so $f_1 = [\mathbb{P}^1 \times \{q'\}]$ as well. The subvarieties $\mathbb{P}^1 \times \{q\}$ and $\mathbb{P}^1 \times \{q'\}$ are disjoint, so the refined product $[\mathbb{P}^1 \times \{q\}] \cdot_S [\mathbb{P}^1 \times \{q'\}]$ of definition 14.1.10 lies in the Chow group of the empty scheme, which is zero; by proposition 14.1.11 the product in $A^*(S)$ is the pushforward of that class, so $f_1 \cdot f_1 = 0$, and symmetrically $f_2 \cdot f_2 = 0$.
The cross term is a point. Let $\iota \colon \{p\} \times \mathbb{P}^1 \hookrightarrow S$ be the inclusion, a morphism of smooth projective

varieties, so that $\iota_*[\{p\} \times \mathbb{P}^1] = f_2$. The projection formula theorem 14.2.10(2), with α the fundamental class of $\{p\} \times \mathbb{P}^1$, which is the unit of that Chow ring by theorem 14.2.7(4), and with $\beta = f_1$, gives

$$f_2 \cdot f_1 \;=\; \iota_*\big(\iota^* f_1\big)$$

and $\iota^* f_1 = \iota^* \mathrm{pr}_2^*[q] = (\mathrm{pr}_2 \circ \iota)^*[q]$ by theorem 14.2.10(4). Since $\mathrm{pr}_2 \circ \iota$ is the isomorphism $\{p\} \times \mathbb{P}^1 \to \mathbb{P}^1$, this is the class of the point (p, q), whence $f_1 \cdot f_2 = [(p, q)]$ and $\deg(f_1 \cdot f_2) = 1$. Consequently $\deg\big((af_1 + bf_2) \cdot f_2\big) = a$ and $\deg\big((af_1 + bf_2) \cdot f_1\big) = b$, so no nonzero integer combination of the two ruling classes is numerically equivalent to zero. On this surface the pairing already separates the classes it is fed.

Rational, algebraic, homological and numerical equivalence were each defined by a different mechanism, and nothing so far says they have anything in common beyond coarsening one another. What they share is the list of operations that descend to their quotients, and that list is short enough to be made a definition. It is the list section 15.4 will need, since a correspondence acts by a pullback, a product and a pushforward in succession.

Definition 15.3.6: Adequate Equivalence Relation

An *adequate equivalence relation* $\sim$ assigns to every smooth projective variety X a graded subgroup $\mathcal{R}_\sim(X) \subseteq A^*(X)$, the classes *$\sim$-equivalent to zero*, subject to three conditions. For all smooth projective varieties X and Y and every morphism $f\colon X \to Y$:

1. $\mathcal{R}_\sim(X)$ is an ideal of $A^*(X)$: if $\alpha \in \mathcal{R}_\sim(X)$ and $\gamma \in A^*(X)$ then $\alpha \cdot \gamma \in \mathcal{R}_\sim(X)$;
2. $f^*\mathcal{R}_\sim(Y) \subseteq \mathcal{R}_\sim(X)$;
3. $f_*\mathcal{R}_\sim(X) \subseteq \mathcal{R}_\sim(Y)$.

Write $\alpha \sim \beta$ for $\alpha - \beta \in \mathcal{R}_\sim(X)$ and $A^*_\sim(X) = A^*(X)/\mathcal{R}_\sim(X)$. The relation is *nondegenerate* if $\mathcal{R}_\sim(\operatorname{Spec}\mathbb{C}) = 0$.

Two remarks fix how the definition is read. Pushforward preserves dimension rather than codimension, so in (3) the grading is the one by dimension, $f_* A_k(X) \subseteq A_k(Y)$; a graded subgroup is graded for either index, the two being related by $A^p(X) = A_{\dim X - p}(X)$. And the conditions are imposed on $A^*(X)$, not on cycles, so rational equivalence is built into the definition: every adequate relation is coarser than rational equivalence, and $\mathcal{R}_{\mathrm{rat}}(X) = 0$ is the finest one. In this notation $\mathcal{R}_{\mathrm{alg}}(X) = \bigoplus_k A_k(X)_{\mathrm{alg}}$, the graded subgroup of algebraically trivial classes named degreewise in definition 15.1.7.

The three conditions are exactly what is needed for the quotient to retain the structure $A^*(X)$ has. Condition (1) makes $A^*_\sim(X)$ a graded ring; condition (2) makes $X \mapsto A^*_\sim(X)$ contravariant, with f^* a ring homomorphism because it is one on $A^*(X)$ by theorem 14.2.10(3); condition (3) gives f_*, and the projection formula $f_*(\alpha \cdot f^*\beta) = f_*\alpha \cdot \beta$ of theorem 14.2.10(2) descends because both sides do. Nondegeneracy says the relation does not identify a point with zero on $\operatorname{Spec}\mathbb{C}$, where $A^*(\operatorname{Spec}\mathbb{C}) = \mathbb{Z}$; exercise 15.3.1 (6) shows it is equivalent to the degree homomorphism descending to the quotient.

Example 15.3.7: The Two Extreme Relations

Two assignments satisfy definition 15.3.6 for trivial reasons, and they bound the range of possibilities. Taking $\mathcal{R}_\sim(X) = 0$ for every X gives rational equivalence: the three conditions are conditions on the zero subgroup, and $\mathcal{R}_\sim(\operatorname{Spec}\mathbb{C}) = 0$, so the relation is nondegenerate. Taking $\mathcal{R}_\sim(X) = A^*(X)$

for every X also satisfies the three conditions, since every operation lands in A^* of its target; here $A^*_\sim(X) = 0$ for all X, and $\mathcal{R}_\sim(\operatorname{Spec}\mathbb{C}) = \mathbb{Z} \neq 0$, so this relation is degenerate. Nondegeneracy is what rules out the second, and proposition 15.3.10 will show that the range it leaves is bounded above by numerical equivalence.

Verifying the conditions for algebraic equivalence needs a way to convert its defining families into pullbacks. The construction is the fibre inclusion of the parameter curve.

Lemma 15.3.8: Fibres of a Family as Pullbacks

Let X be a smooth projective variety, let T be a smooth connected curve, and set $P = T \times X$ with projections $p\colon P \to T$ and $q\colon P \to X$. For a closed point $t \in T$ let $i_t\colon X \to P$ be $x \mapsto (t, x)$, and let $t_0, t_1 \in T$ be closed points. Then:

1. i_t is a regular embedding of codimension 1 whose normal bundle is trivial, and its Gysin map agrees with the pullback i_t^* of definition 14.2.8;
2. if $V \subseteq P$ is a subvariety dominating T, then $i_t^*[V] = [V_t]$, the fundamental cycle of the scheme-theoretic fibre $V_t = V \cap (\{t\} \times X)$ read in X; hence $i_t^*[\Gamma] = \Gamma(t)$ for every cycle Γ on P all of whose components dominate T;
3. for every class $\xi \in A_*(P)$, the difference $i_{t_1}^*\xi - i_{t_0}^*\xi$ is algebraically equivalent to zero on X.

***Proof*:**

1. The projection q is the base change of $T \to \operatorname{Spec}\mathbb{C}$ along $X \to \operatorname{Spec}\mathbb{C}$, hence smooth of relative dimension 1, and i_t is a section of it. By lemma 14.2.4(1), i_t is a regular embedding of codimension 1 with normal bundle $i_t^*T_{P/X}$. The relative tangent bundle $T_{P/X}$ is p^*T_T, so the normal bundle is $(p \circ i_t)^*T_T$; the composite $p \circ i_t$ is the constant morphism $X \to T$ with image t, and the pullback of a line bundle along a morphism factoring through a closed point is trivial, being the pullback of a line bundle on $\operatorname{Spec}\mathbb{C}$. Thus the normal bundle is $\mathcal{O}_X$. Both X and P are smooth varieties, so theorem 14.2.12(3) identifies $i_t^!$ with i_t^*, and theorem 14.2.12(2) identifies $i_t^!$ with the Gysin map of the regular embedding.
2. The subscheme $\{t\} \times X = p^{-1}(t)$ has ideal sheaf generated locally by $p^\#\pi$, where π generates the maximal ideal of the regular one-dimensional local ring $\mathcal{O}_{T,t}$. Its restriction to V is nonzero: V dominates T, so V is not contained in $p^{-1}(t)$. As V is integral, a nonzero section of $\mathcal{O}_V$ is a nonzerodivisor, so the ideal of V_t in V is generated by a single nonzerodivisor and $V_t \hookrightarrow V$ is a regular embedding of codimension 1. Proposition 13.3.3, applied to the regular embedding i_t of codimension 1 and the subvariety V, therefore gives $i_t^![V] = \iota_*[V_t]$, which is $[V_t]$ under the isomorphism $\{t\} \times X \cong X$; by (1) the left side is $i_t^*[V]$. Extending linearly over the components of Γ gives the last assertion.
3. Represent ξ by a cycle $\sum_j n_j[V_j]$, which is possible because i_t^* is defined on $A_*(P)$ and the value does not depend on the representative. The image $p(V_j)$ is irreducible, being the continuous image of an irreducible space, and closed, because p is proper (X is projective, so p is the base change of a proper morphism); the irreducible closed subsets of the curve T are T itself and the closed points, so each V_j either dominates T or lies in a single fibre.

Let Γ be the part of the cycle whose components dominate T. By (2), $i_{t_1}^*[\Gamma] - i_{t_0}^*[\Gamma] = \Gamma(t_1) - \Gamma(t_0)$, which is algebraically equivalent to zero by the definition of algebraic equivalence recalled in section 15.1.

Let V be a component lying in a single fibre $p^{-1}(s)$. If $s \neq t$, then $V \cap (\{t\} \times X) = \emptyset$, and by corollary 13.3.12 the class $i_t^![V]$ is the image of a class on that intersection, hence zero. If $s = t$, write $\beta \in A_*(X)$ for the class of V read in $\{t\} \times X \cong X$, so that $[V] = i_{t*}\beta$; then part (1) and theorem 14.3.2(2) give

$$i_t^*[V] \;=\; i_t^!\big(i_{t*}\beta\big) \;=\; c_1(\mathcal{O}_X) \cap \beta \;=\; 0$$

the last equality because the constant section 1 of $\mathcal{O}_X$ has empty divisor, so the operator $c_1(\mathcal{O}_X) \cap -$ of definition 11.4.1 is zero. Every component lying in a fibre therefore contributes zero to both $i_{t_1}^*\xi$ and $i_{t_0}^*\xi$, and $i_{t_1}^*\xi - i_{t_0}^*\xi = \Gamma(t_1) - \Gamma(t_0)$, completing the proof.

The lemma says that algebraic triviality on X can be tested with an arbitrary Chow class on $T \times X$ rather than with a cycle whose components are constrained to dominate T. That freedom is what makes the next verification routine, since the operations of definition 15.3.6 act on classes and not on chosen representatives.

Theorem 15.3.9: The Four Relations Are Adequate

Each of the following is an adequate equivalence relation in the sense of definition 15.3.6, on the class of smooth projective varieties over $\mathbb{C}$, and each is nondegenerate:

1. rational equivalence, $\mathcal{R}_{\mathrm{rat}}(X) = 0$;
2. algebraic equivalence, $\mathcal{R}_{\mathrm{alg}}(X)$ as defined in section 15.1;
3. homological equivalence, $\mathcal{R}_{\mathrm{hom}}(X)$ of definition 15.3.1;
4. numerical equivalence, $\mathcal{R}_{\mathrm{num}}(X)$ of definition 15.3.4. Moreover $\mathcal{R}_{\mathrm{num}}(X)$ contains every torsion class of $A^*(X)$, and $A^*_{\mathrm{num}}(X)$ is torsion free.

***Proof*:**
A morphism $f\colon X \to Y$ of smooth projective varieties is proper: it factors as the graph $\gamma_f\colon X \to X \times Y$, a closed immersion by lemma 14.2.4(3), followed by the projection $\mathrm{pr}_Y\colon X \times Y \to Y$, which is proper because X is complete. Both f^* (definition 14.2.8) and f_* are therefore defined on all of $A^*(X)$ throughout, and theorem 14.2.10 applies to f without further hypothesis.

1. The subgroup is zero, so (1), (2) and (3) of definition 15.3.6 hold vacuously, and nondegeneracy is immediate. What the case records is that the three operations exist on $A^*(X)$ at all: the product is theorem 14.2.7, the pullback is theorem 14.2.10, and pushforward descends to rational equivalence by theorem 10.2.3.

2. Fix $\alpha \in \mathcal{R}_{\mathrm{alg}}(X)$ and a family exhibiting it: a smooth connected curve T, closed points $t_0, t_1 \in T$, and a cycle Γ on $P = T \times X$ with every component dominating T and $\alpha = \Gamma(t_1) - \Gamma(t_0)$. By lemma 15.3.8(2), $\alpha = i_{t_1}^*[\Gamma] - i_{t_0}^*[\Gamma]$. A general element of $\mathcal{R}_{\mathrm{alg}}(X)$ is a finite sum of such, and each condition below is additive, so it suffices to treat one family.

   Ideal. Let $\gamma \in A^*(X)$ and put $\xi = [\Gamma] \cdot q^*\gamma \in A_*(P)$, where $q\colon P \to X$ is the projection.

Since i_t^* is a ring homomorphism (theorem 14.2.10(3)) and $q \circ i_t = \mathrm{id}_X$, functoriality (theorem 14.2.10(4)) gives

$$i_t^*\xi \;=\; i_t^*[\Gamma] \cdot i_t^* q^*\gamma \;=\; \Gamma(t) \cdot \gamma$$

so $\alpha \cdot \gamma = i_{t_1}^*\xi - i_{t_0}^*\xi$, which is algebraically equivalent to zero by lemma 15.3.8(3).

Pullback. Let $g\colon X' \to X$ be a morphism of smooth projective varieties and let $G = \mathrm{id}_T \times g\colon T \times X' \to P$, a morphism of smooth varieties. Put $\xi = G^*[\Gamma]$. Writing i'_t for the fibre inclusion of $T \times X'$, the square identity $G \circ i'_t = i_t \circ g$ and theorem 14.2.10(4) give $(i'_t)^*\xi = g^* i_t^*[\Gamma] = g^*\Gamma(t)$, so $g^*\alpha = (i'_{t_1})^*\xi - (i'_{t_0})^*\xi$ is algebraically equivalent to zero by lemma 15.3.8(3).

Pushforward. Let $f\colon X \to Y$ be a morphism of smooth projective varieties and let $F = \mathrm{id}_T \times f\colon P \to T \times Y$, which is proper, being the base change of the proper f. Put $\xi = F_*[\Gamma]$. The preimage $F^{-1}(\{t\} \times Y)$ is $\{t\} \times X$, a regular embedding of codimension 1 in P by lemma 15.3.8(1), so proposition 14.2.6 identifies the refined Gysin map of i_t^Y along F with the Gysin map of i_t^X; theorem 13.3.11(1) for the proper F then gives

$$(i_t^Y)^*\big(F_*[\Gamma]\big) \;=\; f_*\big((i_t^X)^*[\Gamma]\big) \;=\; f_*\Gamma(t)$$

so $f_*\alpha = (i_{t_1}^Y)^*\xi - (i_{t_0}^Y)^*\xi$ is algebraically equivalent to zero by lemma 15.3.8(3).

Nondegeneracy: on $X = \operatorname{Spec}\mathbb{C}$ the product $T \times \operatorname{Spec}\mathbb{C}$ is T, a cycle all of whose components dominate T is a multiple $m[T]$, and its fibre cycle is m times the class of the point for every t, so $\Gamma(t_1) - \Gamma(t_0) = 0$ and $\mathcal{R}_{\mathrm{alg}}(\operatorname{Spec}\mathbb{C}) = 0$.

3. The kernel of a homomorphism of graded rings is a graded ideal, so $\mathcal{R}_{\mathrm{hom}}(X)$ satisfies condition (1). For (2) and (3), the cycle class map commutes with f^* for an arbitrary morphism by the granted input (15.2), and with f_* by theorem 15.2.9 (theorem 15.2.13 is the projection case only, which is not enough here), so $\mathrm{cl}(f^*\alpha) = f^*\mathrm{cl}(\alpha)$ vanishes when $\mathrm{cl}(\alpha)$ does, and likewise for f_*. Nondegeneracy: on $\operatorname{Spec}\mathbb{C}$ the map cl is the degree $A^0(\operatorname{Spec}\mathbb{C}) = \mathbb{Z} \to H^0(\mathrm{pt};\mathbb{Z}) = \mathbb{Z}$, which is injective.

4. Write $m = \dim X$ and let $\alpha \in \mathcal{R}_{\mathrm{num}}(X)$.

   Ideal. For $\gamma \in A^*(X)$ and $\beta \in A^*(X)$ of the codimension complementary to $\alpha \cdot \gamma$, associativity (theorem 14.2.7(3)) gives $\deg((\alpha \cdot \gamma) \cdot \beta) = \deg(\alpha \cdot (\gamma \cdot \beta))$, and $\gamma \cdot \beta$ has the codimension complementary to α, so the value is zero.

   Pullback. Let $f\colon X' \to X$ be a morphism of smooth projective varieties and $\beta \in A^*(X')$ of complementary codimension. Since $\deg = \int_{X'}$ agrees with $\int_X \circ f_*$ (definition 10.2.4), the projection formula theorem 14.2.10(2) gives

   $$\deg\big(f^*\alpha \cdot \beta\big) \;=\; \deg\big(f_*(f^*\alpha \cdot \beta)\big) \;=\; \deg\big(\alpha \cdot f_*\beta\big) \;=\; 0$$

   the last equality because $f_*\beta$ has the codimension complementary to α.

   Pushforward. Let $f\colon X \to Y$ and $\beta \in A^*(Y)$ of complementary codimension. The same two ingredients give

   $$\deg\big(f_*\alpha \cdot \beta\big) \;=\; \deg\big(f_*(\alpha \cdot f^*\beta)\big) \;=\; \deg\big(\alpha \cdot f^*\beta\big) \;=\; 0$$

   Nondegeneracy: on $\operatorname{Spec}\mathbb{C}$ a class is an integer a, and $\deg(a \cdot 1) = a$, so only $a = 0$ is numerically trivial.

For the last two assertions, let $\alpha \in A^*(X)$ satisfy $r\alpha = 0$ for some integer $r \geq 1$. For every β of complementary codimension, $r\deg(\alpha \cdot \beta) = \deg(r\alpha \cdot \beta) = 0$ in $\mathbb{Z}$, so $\deg(\alpha \cdot \beta) = 0$ and $\alpha \in \mathcal{R}_{\mathrm{num}}(X)$. The same computation applied to a class α with $r\alpha \in \mathcal{R}_{\mathrm{num}}(X)$ gives $\alpha \in \mathcal{R}_{\mathrm{num}}(X)$, so the quotient $A^*_{\mathrm{num}}(X)$ has no nonzero torsion, completing the proof.

Nondegeneracy is what pins numerical equivalence to the coarse end of the list: an adequate relation that keeps the degree of a zero-cycle cannot identify more than numerical equivalence does.

Proposition 15.3.10: Numerical Equivalence Is the Coarsest Nondegenerate Relation

Let $\sim$ be a nondegenerate adequate equivalence relation. Then $\mathcal{R}_\sim(X) \subseteq \mathcal{R}_{\mathrm{num}}(X)$ for every smooth projective variety X.

***Proof*:**
Let $\alpha \in \mathcal{R}_\sim(X)$ with X of dimension n, and let $\beta \in A^{n-k}(X)$ be of the codimension complementary to the codimension-k component of α; replacing α by that component is harmless because $\mathcal{R}_\sim(X)$ is graded. By condition (1) of definition 15.3.6, $\alpha \cdot \beta \in \mathcal{R}_\sim(X) \cap A^n(X)$. Let $\pi\colon X \to \operatorname{Spec}\mathbb{C}$ be the structure morphism, a morphism of smooth projective varieties. By condition (3), $\pi_*(\alpha \cdot \beta) \in \mathcal{R}_\sim(\operatorname{Spec}\mathbb{C})$, which is zero by nondegeneracy. Definition 10.2.4 identifies π_* on $A_0(X)$ with the degree, so $\deg(\alpha \cdot \beta) = 0$. As β was arbitrary, $\alpha \in \mathcal{R}_{\mathrm{num}}(X)$, as we sought to show.

With the two ends of the list identified, only the middle inclusion remains, and it is the one carrying geometric content: a family of cycles over a connected curve has a single cohomology class, because the two fibre inclusions are homotopic.

Theorem 15.3.11: The Tower of Adequate Equivalence Relations

Let X be a smooth projective variety over $\mathbb{C}$. Then

$$0 \;=\; \mathcal{R}_{\mathrm{rat}}(X) \;\subseteq\; \mathcal{R}_{\mathrm{alg}}(X) \;\subseteq\; \mathcal{R}_{\mathrm{hom}}(X) \;\subseteq\; \mathcal{R}_{\mathrm{num}}(X)$$

Equivalently, a class that is rationally trivial is algebraically trivial, one that is algebraically trivial is homologically trivial, and one that is homologically trivial is numerically trivial.

***Proof*:**
Rational implies algebraic. This is the statement that $\mathcal{R}_{\mathrm{alg}}(X)$ is a subgroup of $A^*(X)$ rather than of the group of cycles, which is theorem 15.1.6: a cycle rationally equivalent to zero is algebraically equivalent to zero, the family being parametrized by $\mathbb{P}^1$.

Algebraic implies homological. Let $\alpha \in \mathcal{R}_{\mathrm{alg}}(X)$, and fix a family exhibiting it: a smooth connected curve T, closed points $t_0, t_1 \in T$, and a cycle Γ on $T \times X$ with all components dominating T and $\alpha = \Gamma(t_1) - \Gamma(t_0)$. It suffices to treat one such family, since cl is additive.

Step 1: the parameter curve may be taken projective. By theorem 7.1.3 there are a smooth connected projective curve $\overline{T}$ and an open immersion $T \hookrightarrow \overline{T}$ with dense image, the base field $\mathbb{C}$ being perfect. Let $\overline{\Gamma}$ be the cycle on $\overline{T} \times X$ whose components are the closures of the components of Γ, with the same multiplicities. Each closure dominates $\overline{T}$, since it dominates the dense open

T. Moreover $\overline{V} \cap \big(T \times X\big) = V$ for each component V, closure and intersection with an open subscheme being inverse operations on closed subvarieties of that open, so the scheme-theoretic fibres over points of T agree and $\overline{\Gamma}(t_i) = \Gamma(t_i)$ for $i = 0, 1$. Replacing T by $\overline{T}$ and Γ by $\overline{\Gamma}$, assume T is a smooth connected projective curve.

Step 2: the fibre cycle as a pushforward. Write $P = T \times X$, with $p\colon P \to T$ and $q\colon P \to X$ the projections; both are flat by lemma 14.1.1, and q is proper because T is complete. Fix a closed point $t \in T$. By proposition 10.3.5 the flat pullback $p^*[t]$ is the fundamental cycle of $p^{-1}(t) = \{t\} \times X$, which is $i_{t*}[X]$. Applying the projection formula theorem 14.2.10(2) to the morphism i_t of smooth projective varieties, with $[X]$ in the first slot and $[\Gamma]$ in the second, and using that $[X]$ is the unit of $A^*(X)$ (theorem 14.2.7(4)),

$$i_{t*}\big(i_t^*[\Gamma]\big) \;=\; i_{t*}\big([X] \cdot i_t^*[\Gamma]\big) \;=\; i_{t*}[X] \cdot [\Gamma] \;=\; p^*[t] \cdot [\Gamma]$$

Since $q \circ i_t = \mathrm{id}_X$, applying q_* and lemma 15.3.8(2) gives

$$\Gamma(t) \;=\; i_t^*[\Gamma] \;=\; q_*\big([\Gamma] \cdot p^*[t]\big) \tag{15.3}$$

Step 3: the cohomology class does not depend on t. Apply cl to (15.3). The map cl carries the proper pushforward q_* to the umkehr map $q_!$ of definition 15.2.8 (theorem 15.2.9), it commutes with the flat pullback p^* (theorem 15.2.13), and it is a ring homomorphism (corollary 15.2.14), so

$$\mathrm{cl}\big(\Gamma(t)\big) \;=\; q_!\Big(\mathrm{cl}\big([\Gamma]\big) \cup p^*\mathrm{cl}\big([t]\big)\Big)$$

Now T is a smooth connected projective curve over $\mathbb{C}$, so $T(\mathbb{C})$ is a connected compact manifold, hence path connected; any two of its points therefore have the same class in $H_0(T;\mathbb{Z})$, and since cl of a point class is the Poincaré dual of that class (definition 15.2.3), $\mathrm{cl}([t_1]) = \mathrm{cl}([t_0])$ in $H^2(T;\mathbb{Z})$. Subtracting the two instances of the displayed identity and using additivity of $q_!$, p^* and the cup product,

$$\mathrm{cl}(\alpha) \;=\; q_!\Big(\mathrm{cl}\big([\Gamma]\big) \cup p^*\big(\mathrm{cl}([t_1]) - \mathrm{cl}([t_0])\big)\Big) \;=\; 0$$

so $\alpha \in \mathcal{R}_{\mathrm{hom}}(X)$.

Homological implies numerical. Homological equivalence is adequate and nondegenerate by theorem 15.3.9(3), so proposition 15.3.10 gives $\mathcal{R}_{\mathrm{hom}}(X) \subseteq \mathcal{R}_{\mathrm{num}}(X)$, completing the proof.

The last inclusion is also direct: if $\mathrm{cl}(\alpha) = 0$ and β has complementary codimension, then $\deg(\alpha \cdot \beta) = \int_X \mathrm{cl}(\alpha \cdot \beta) = \int_X \mathrm{cl}(\alpha) \cup \mathrm{cl}(\beta) = 0$. What proposition 15.3.10 adds is that no adequate relation whatever, not merely the three above it, sits below numerical equivalence while keeping degrees.

Each of the three inclusions is strict for some X, and none is strict for every X: on $\mathbb{P}^m$ all four relations coincide, as exercise 15.3.1 (1) asks the reader to check. The strictness of the first already occurs on a curve.

Example 15.3.12: Divisor Classes on an Elliptic Curve
Let (E, O) be an elliptic curve over $\mathbb{C}$ and let $P \in E$ be a closed point with $P \neq O$. In $A^1(E) = A_0(E)$ consider $\alpha = [P] - [O]$.
α is algebraically trivial. Take $T = E$ and $\Gamma = [\Delta]$, the class of the diagonal in $E \times E$, whose single component dominates the first factor. The scheme-theoretic fibre of Δ over a closed point t

is the reduced point (t,t), so $\Gamma(t) = [t]$ in $A_0(E)$, and $\Gamma(P) - \Gamma(O) = \alpha$.
α is not rationally trivial. By proposition 11.1.3 the group $A_0(E)$ is $\mathrm{Pic}\,(E)$, and theorem 7.6.3 says that $Q \mapsto [Q] - [O]$ is a bijection from the closed points of E onto $\mathrm{Pic}^{\,0}(E)$. In particular $[P] - [O] = 0$ would force $P = O$.
Hence $\mathcal{R}_{\mathrm{rat}}(E) \subsetneq \mathcal{R}_{\mathrm{alg}}(E)$, and the first inclusion of theorem 15.3.11 is strict. The three coarser relations, by contrast, agree here. Numerical triviality in $A^1(E) = A^n(E)$ with $n = 1$ tests α against $A^0(E) = \mathbb{Z}\,[E]$, and $\deg(\alpha \cdot [E]) = \deg(\alpha)$ since $[E]$ is the unit (theorem 14.2.7(4)), so $\mathcal{R}_{\mathrm{num}}(E) \cap A^1(E) = \mathrm{Pic}^{\,0}(E)$; the same group is $\mathcal{R}_{\mathrm{hom}}(E) \cap A^1(E)$ by example 15.3.2. The first paragraph puts every $[Q] - [O]$, hence all of $\mathrm{Pic}^{\,0}(E)$, into $\mathcal{R}_{\mathrm{alg}}(E)$, and theorem 15.3.11 confines it to $\mathrm{Pic}^{\,0}(E)$.

The second inclusion is strict on a general quintic threefold in $\mathbb{P}^4$, and the example is far less accessible: Griffiths produced there a difference of two lines that is homologically trivial but not algebraically trivial, the obstruction coming from the intermediate Jacobian rather than from any intersection number. The construction is not developed here; see [38, Ch. 19]. The third inclusion is strict on an Enriques surface X, for the reason recorded in box 15.3.3: the canonical class K_X is a nonzero 2-torsion element of $\mathrm{Pic}\,(X) = A^1(X)$ (proposition 11.1.3), so it is numerically trivial by theorem 15.3.9(4), while the kernel of cl on divisor classes is $\mathrm{Pic}^{\,0}(X)$, which vanishes because $H^1(X, \mathcal{O}_X) = 0$; hence $\mathrm{cl}(K_X) \neq 0$. The surface theory behind those two facts about K_X and $H^1(X, \mathcal{O}_X)$ is not developed here. Whether homological and numerical equivalence agree after tensoring with $\mathbb{Q}$ is open, and is the subject of conjecture 15.3.14.

Numerical equivalence collapses $A^*(X)$ far enough to be finitely generated, which neither rational nor algebraic equivalence achieves: $A^*(X)$ itself need not be finitely generated, and even $\mathrm{NS}^*(X) = A^*(X)/\sim_{\mathrm{alg}}$ is only known to be finitely generated in codimension one (section 15.1). Homological equivalence does achieve it, its quotient being a subgroup of the cohomology of a compact manifold, and the proof below extracts the numerical statement from that one.

Theorem 15.3.13: Finiteness of Numerical Equivalence

Let X be a smooth projective variety over $\mathbb{C}$. For each k the group $\mathrm{Num}^k(X) = A^k_{\mathrm{num}}(X)$ is a finitely generated free abelian group, of rank at most the rank of $H^{2k}(X;\mathbb{Z})$.

***Proof*:**
Freeness will follow from finite generation together with the absence of torsion, which is theorem 15.3.9(4).

For finite generation, theorem 15.3.11 gives $\mathcal{R}_{\mathrm{hom}}(X) \subseteq \mathcal{R}_{\mathrm{num}}(X)$, so the identity of $A^k(X)$ induces a surjection

$$A^k_{\mathrm{hom}}(X) \;\twoheadrightarrow\; A^k_{\mathrm{num}}(X)$$

By definition 15.3.1 the group $A^k_{\mathrm{hom}}(X)$ is the image of cl, hence a subgroup of $H^{2k}(X;\mathbb{Z})$. The space $X(\mathbb{C})$ is a compact manifold, and the singular cohomology of a compact manifold is a finitely generated abelian group in each degree; that topological input is not proved in this book (for the corresponding statement over an arbitrary base field, where a Weil cohomology theory replaces singular cohomology, see [38, Ch. 19]). A subgroup of a finitely generated abelian group is finitely generated, and a quotient of a finitely generated group is finitely generated, so $A^k_{\mathrm{num}}(X)$ is finitely generated, of rank at most that of $H^{2k}(X;\mathbb{Z})$. Being finitely generated and torsion free, it is free, as we sought to show.

The rank of $\mathrm{Num}^1(X)$ is the Picard number $\rho(X)$ met in section 15.1, and the theorem is the statement that every codimension has such a number. For $k = 1$ the finiteness is the theorem of the base, proved there by different means; for general k the argument above is the only one available, and it runs through cohomology rather than through the geometry of families.

Grothendieck's standard conjectures are a short list of statements about algebraic cycles which, if known, would give the theory of motives its expected structure; the one that concerns the tower directly is the following.

Conjecture 15.3.14: Homological and Numerical Equivalence Agree

Let X be a smooth projective variety over $\mathbb{C}$ and let $k \geq 0$. Then a class in $A^k(X) \otimes \mathbb{Q}$ is homologically equivalent to zero if and only if it is numerically equivalent to zero; that is,

$$\mathcal{R}_{\mathrm{hom}}(X) \otimes \mathbb{Q} \;=\; \mathcal{R}_{\mathrm{num}}(X) \otimes \mathbb{Q} \qquad \text{in } A^k(X) \otimes \mathbb{Q}$$

This is the standard conjecture usually labelled $D(X)$.

One inclusion is theorem 15.3.11, so the content is that a class pairing to zero against every algebraic cycle of complementary dimension already has vanishing cohomology class. The conjecture is known in codimensions 0, 1, 2, $n-1$ and n, and for every k when X is an abelian variety. For $k = 0$ and $k = n$ both subgroups are computed outright, integrally, with no rational coefficients needed: in codimension 0 they vanish, since exercise 15.3.1 (2) gives $\mathcal{R}_{\mathrm{num}}(X) \cap A^0(X) = 0$ and theorem 15.3.11 confines $\mathcal{R}_{\mathrm{hom}}(X) \cap A^0(X)$ inside it, while in codimension n both relations say that the degree vanishes, by example 15.3.2 together with definition 15.3.4. For $k = 1$ it holds as well, by the exponential sequence and GAGA: the first Chern class realizes $\mathrm{Pic}\,(X)$ modulo its connected component as a subgroup of $H^2(X;\mathbb{Z})$, and [38, p. 19.3.1] reads the statement off that. For $k = 2$ it is a theorem of Lieberman, who also settled every k for abelian varieties. See [38, p. 19.3.2]. For $k = n-1$ it follows from the case $k = 1$ together with the case $k = n-1$ of the Hodge conjecture in section 15.2, by which every class in $\mathrm{cl}(A^{n-1}(X) \otimes \mathbb{Q})$ is $\mathrm{cl}(h)^{n-2} \cup \mathrm{cl}(\beta)$ for some $\beta \in A^1(X) \otimes \mathbb{Q}$, where h is the class of a hyperplane section. If $\alpha \in A^{n-1}(X) \otimes \mathbb{Q}$ is numerically equivalent to zero, write $\mathrm{cl}(\alpha) = \mathrm{cl}(h)^{n-2} \cup \mathrm{cl}(\beta)$ in this way, and for an arbitrary $\gamma \in A^{n-1}(X) \otimes \mathbb{Q}$ write $\mathrm{cl}(\gamma) = \mathrm{cl}(h)^{n-2} \cup \mathrm{cl}(\delta)$. Then corollary 15.2.14 and corollary 15.2.10 give $\deg(\beta \cdot \gamma) = \deg(\alpha \cdot \delta) = 0$, so β is numerically equivalent to zero. The case $k = 1$ then gives $\mathrm{cl}(\beta) = 0$, and so $\mathrm{cl}(\alpha) = 0$. For $3 \leq k \leq n-2$ no case is known for arbitrary X. The conjecture does not stand alone: the standard conjecture $B(X)$, on the algebraicity of the inverse of the hard Lefschetz operator, implies $D(X)$ in characteristic zero, so a proof of B would settle the tower. And D is what would make homological equivalence independent of the cohomology theory used to define it, since numerical equivalence refers to no cohomology at all: the étale cycle class map named in section 15.2 defines a second homological equivalence, and D implies that it agrees with the one above.

Exercise 15.3.1

1. Let $X = \mathbb{P}^m$. Using example 14.2.3, which presents $A^*(\mathbb{P}^m)$ as $\mathbb{Z}[h]/(h^{m+1})$ with h^j the class of a linear subspace of codimension j and $\deg(h^m) = 1$, show that no nonzero class of $A^*(\mathbb{P}^m)$ is numerically equivalent to zero. Deduce that rational, algebraic, homological and numerical equivalence all coincide on $\mathbb{P}^m$.

2. Let X be a smooth projective variety of dimension n. Show that $\mathcal{R}_{\mathrm{num}}(X) \cap A^0(X) = 0$, using $A^0(X) = \mathbb{Z}\,[X]$ and the fact that $[X]$ is the unit of $A^*(X)$. Conclude that all four relations of

theorem 15.3.11 agree in codimension 0. Show also that $\mathcal{R}_{\mathrm{num}}(X) \cap A^n(X) = \ker(\deg)$, so that homological and numerical equivalence agree in codimension n as well by example 15.3.2, and explain why example 15.3.12 forbids adding rational equivalence to that agreement.

3. Let $\mathcal{T}(X) \subseteq A^*(X)$ be the subgroup of torsion classes. Show that $X \mapsto \mathcal{T}(X)$ satisfies the three conditions of definition 15.3.6 and is nondegenerate. Deduce from proposition 15.3.10 that every torsion class is numerically equivalent to zero, recovering part of theorem 15.3.9(4) without computing degrees.

4. Let $\sim$ and $\sim'$ be adequate equivalence relations. Show that $X \mapsto \mathcal{R}_{\sim}(X) \cap \mathcal{R}_{\sim'}(X)$ and $X \mapsto \mathcal{R}_{\sim}(X) + \mathcal{R}_{\sim'}(X)$ are both adequate. Which of the two is nondegenerate whenever $\sim$ is?

5. Let X be smooth projective of dimension n. Show that $(\alpha, \beta) \mapsto \deg(\alpha \cdot \beta)$ descends to a pairing
$$A^k_{\mathrm{num}}(X) \times A^{n-k}_{\mathrm{num}}(X) \longrightarrow \mathbb{Z}$$
and that this pairing is nondegenerate on both sides. Explain why the same statement for $A^k_{\mathrm{hom}}(X)$ would follow from conjecture 15.3.14 after tensoring with $\mathbb{Q}$, but is not available unconditionally.

6. Let $\sim$ be an adequate equivalence relation. Show that $\sim$ is nondegenerate if and only if, for every smooth projective X, the degree homomorphism $\deg\colon A^n(X) \to \mathbb{Z}$ vanishes on $\mathcal{R}_{\sim}(X) \cap A^n(X)$, where $n = \dim X$; that is, if and only if the degree descends to $A^*_{\sim}$.

7. Continue with $S = \mathbb{P}^1 \times \mathbb{P}^1$ and the classes f_1, f_2 of example 15.3.5. Show that a class of $A^2(S)$ is numerically equivalent to zero if and only if it has degree zero, and that cl is injective on the subgroup of $A^1(S)$ generated by f_1 and f_2. (For the second part, use theorem 15.3.11 rather than any computation in cohomology.)

8. Let X be smooth projective over $\mathbb{C}$ of dimension n and suppose $H^{2k}(X;\mathbb{Z})$ is torsion free. Show that $A^k_{\mathrm{hom}}(X)$ and $A^k_{\mathrm{num}}(X)$ are both finitely generated free abelian groups and that the surjection $A^k_{\mathrm{hom}}(X) \to A^k_{\mathrm{num}}(X)$ of theorem 15.3.13 is an isomorphism if and only if the two groups have the same rank.

15.4 Correspondences

A morphism $f\colon X \to Y$ moves cycles in both directions, forward by f_* and backward by f^*, and the datum determining it is a single cycle on the product: its graph. Conversely, an arbitrary cycle class on $X \times Y$ produces a homomorphism $A^*(X) \to A^*(Y)$, and the graph of f produces f_* while its transpose produces f^*. This section constructs those homomorphisms, shows that composing two of them is again given by a cycle on a product, and matches the construction against the cycle class map of section 15.2.

Throughout, X, Y, Z and W are smooth projective varieties over $\overline{k}$ of dimensions d_X, d_Y, d_Z and d_W; the base field is $\mathbb{C}$ exactly where the cycle class map appears, namely in proposition 15.4.12, corollary 15.4.13 and exercise 15.4.1 (5). Products of smooth projective varieties are again smooth projective varieties, as they were in the diagonal construction of theorem 14.1.6, so $A^*(X \times Y)$ is a ring graded by codimension (theorem 14.2.7) and $\dim(X \times Y) = d_X + d_Y$. Every projection from such a product onto a subproduct of its factors is flat, being a base change of a structure morphism

$V \to \operatorname{Spec} \overline{k}$, and is proper as soon as the factors it forgets are projective, again by base change; for a *smooth* morphism the pullback of definition 14.2.11 is the flat pullback of definition 10.3.3 (theorem 14.2.12(2)), so the two are written p^* without distinction below. Every morphism this section applies it to is a projection of a product of smooth varieties, hence smooth. (Flatness alone would not do: $\mathbb{A}^2 \to \mathbb{A}^1$, $(x, y) \mapsto xy$, is flat between smooth varieties and is not smooth.)

The grading is chosen so that the correspondences of degree 0 from X to Y are the classes of dimension d_Y on $X \times Y$, which is the dimension of the graph of a morphism $Y \to X$.

Definition 15.4.1: Correspondence

For $r \in \mathbb{Z}$, the group of *correspondences of degree r from X to Y* is

$$\operatorname{Corr}^r(X, Y) = A^{d_X + r}(X \times Y)$$

The *transpose* of $\alpha \in \operatorname{Corr}^r(X, Y)$ is ${}^t\alpha = \sigma_* \alpha$, where $\sigma \colon X \times Y \to Y \times X$ interchanges the two factors.

Since σ is an isomorphism it preserves codimension, so ${}^t\alpha$ lies in $A^{d_X+r}(Y \times X) = \operatorname{Corr}^{r+d_X-d_Y}(Y, X)$: transposition changes the degree unless X and Y have the same dimension. A correspondence acts on cycle classes by pulling back along the first projection, multiplying, and pushing forward along the second.

Proposition 15.4.2: Action of a Correspondence

Let $\alpha \in \operatorname{Corr}^r(X, Y)$, and let $\operatorname{pr}_1, \operatorname{pr}_2$ be the projections of $X \times Y$ onto X and Y. The assignment

$$\alpha_* \beta = \operatorname{pr}_{2*}\left(\alpha \cdot \operatorname{pr}_1^* \beta\right)$$

is defined for every $\beta \in A^*(X)$, carries $A^k(X)$ into $A^{k+r}(Y)$, and is additive in α and in β.

***Proof*:**
The projection pr_1 is flat of relative dimension d_Y, so pr_1^* carries $A_m(X)$ into $A_{m+d_Y}(X \times Y)$ (definition 10.3.3); in codimension this reads $A^k(X) \to A^k(X \times Y)$, since $\dim(X \times Y) = d_X + d_Y$. The product with $\alpha \in A^{d_X+r}(X \times Y)$ is defined because $X \times Y$ is smooth (theorem 14.2.7) and lies in $A^{k+d_X+r}(X \times Y)$, that is, in $A_{d_Y-k-r}(X \times Y)$. The projection pr_2 is proper, since X is projective, so pr_{2*} is defined and preserves dimension (definition 10.2.1), landing in $A_{d_Y-k-r}(Y) = A^{k+r}(Y)$. Additivity in β holds because pr_1^*, multiplication by α and pr_{2*} are each homomorphisms of groups, and additivity in α because multiplication in $A^*(X \times Y)$ is biadditive, as we sought to show.

The degree r is the amount by which the action raises codimension, so a correspondence of degree 0 preserves the codimension grading. On a product of two projective lines the group of degree 0 correspondences is free of rank two, and each of its elements can be evaluated on all of $A^*(\mathbb{P}^1)$.

Example 15.4.3: Correspondences from $\mathbb{P}^1$ to $\mathbb{P}^1$

Fix points $p, q \in \mathbb{P}^1$ and set $h_1 = \operatorname{pr}_1^*[p]$ and $h_2 = \operatorname{pr}_2^*[q]$ in $A^1(\mathbb{P}^1 \times \mathbb{P}^1)$. This ring was computed in example 15.3.5, where the same two classes appear as f_2 and f_1: the projective bundle formula

gives

$$A^0 = \mathbb{Z}\cdot[\mathbb{P}^1\times\mathbb{P}^1], \qquad A^1 = \mathbb{Z}h_1\oplus\mathbb{Z}h_2, \qquad A^2 = \mathbb{Z}\cdot[(p,q)],$$

the classes are independent of the chosen points, and the products are $h_1^2 = h_2^2 = 0$ with $h_1\cdot h_2 = [(p,q)]$. Nothing about that computation is repeated here; what this example adds is the action.

Now let $\alpha = ah_1 + bh_2$ be a correspondence of degree 0 from $\mathbb{P}^1$ to $\mathbb{P}^1$, so $\alpha\in A^1(\mathbb{P}^1\times\mathbb{P}^1) = \mathrm{Corr}^0(\mathbb{P}^1,\mathbb{P}^1)$. On $A^0(\mathbb{P}^1) = \mathbb{Z}\cdot[\mathbb{P}^1]$, the class $\mathrm{pr}_1^*[\mathbb{P}^1]$ is the unit of the ring, so $\alpha_*[\mathbb{P}^1] = \mathrm{pr}_{2*}(ah_1 + bh_2)$. Here pr_2 maps $\{p\}\times\mathbb{P}^1$ isomorphically onto $\mathbb{P}^1$ and contracts $\mathbb{P}^1\times\{q\}$ to the point q, so $\mathrm{pr}_{2*}h_1 = [\mathbb{P}^1]$ and $\mathrm{pr}_{2*}h_2 = 0$ by definition 10.2.1, giving $\alpha_*[\mathbb{P}^1] = a[\mathbb{P}^1]$. On $A^1(\mathbb{P}^1) = \mathbb{Z}\cdot[p]$, one has $\mathrm{pr}_1^*[p] = h_1$ and hence $\alpha\cdot h_1 = ah_1^2 + b\,h_1h_2 = b[(p,q)]$, so $\alpha_*[p] = b[q]$. Thus α acts as multiplication by a in codimension 0 and by b in codimension 1; in particular a correspondence of degree 0 from $\mathbb{P}^1$ to $\mathbb{P}^1$ is determined by its action.

Composing two such actions ought to be the action of a third correspondence, and the cycle producing it is manufactured on the triple product: pull the two correspondences back to $X\times Y\times Z$ from the first two and the last two factors, multiply, and push forward to $X\times Z$.

Definition 15.4.4: Composition of Correspondences

Let $\alpha\in\mathrm{Corr}^r(X,Y)$ and $\beta\in\mathrm{Corr}^s(Y,Z)$, and write p_{12},p_{23},p_{13} for the projections of $X\times Y\times Z$ onto the indicated pairs of factors. The *composition* of α and β is

$$\beta\circ\alpha = p_{13*}\big(p_{12}^*\alpha\cdot p_{23}^*\beta\big)$$

Proposition 15.4.5: Composition Computes the Composite Action

With α and β as in definition 15.4.4, the class $\beta\circ\alpha$ lies in $\mathrm{Corr}^{r+s}(X,Z)$, the composition is additive in α and in β, and

$$(\beta\circ\alpha)_* = \beta_*\circ\alpha_*\colon A^k(X)\to A^{k+r+s}(Z)$$

for every k.

***Proof*:**

The degree. The projections p_{12} and p_{23} are flat of relative dimensions d_Z and d_X, so they preserve codimension: $p_{12}^*\alpha\in A^{d_X+r}(X\times Y\times Z)$ and $p_{23}^*\beta\in A^{d_Y+s}(X\times Y\times Z)$. Their product lies in $A^{d_X+d_Y+r+s}$, that is, in A_{d_Z-r-s}. The projection p_{13} is proper because Y is projective, and p_{13*} preserves dimension, so $\beta\circ\alpha\in A_{d_Z-r-s}(X\times Z) = A^{d_X+r+s}(X\times Z) = \mathrm{Corr}^{r+s}(X,Z)$. Additivity in each argument is inherited from the biadditivity of the product and the additivity of p_{12}^*, p_{23}^* and p_{13*}.

Reducing both sides to the triple product. Write pr_i^{XY}, pr_i^{YZ}, pr_i^{XZ} for the projections of the three double products, and p_1,p_2,p_3 for the projections of $X\times Y\times Z$ onto single factors. Fix

$\zeta \in A^k(X)$. The square

$$\begin{array}{ccc} X \times Y \times Z & \xrightarrow{p_{23}} & Y \times Z \\ {\scriptstyle p_{12}}\downarrow & & \downarrow{\scriptstyle \mathrm{pr}_1^{YZ}} \\ X \times Y & \xrightarrow[\mathrm{pr}_2^{XY}]{} & Y \end{array}$$

is Cartesian, since $(X \times Y) \times_Y (Y \times Z) = X \times Y \times Z$; its lower map is proper (X is projective) and its right-hand map is flat. By the compatibility of proper pushforward with flat pullback in a fibre square (proposition 10.3.6),

$$\mathrm{pr}_1^{YZ*} \circ \mathrm{pr}_{2*}^{XY} = p_{23*} \circ p_{12}^*$$

Applying this to $\alpha \cdot \mathrm{pr}_1^{XY*}\zeta$ and using that p_{12}^* is a ring homomorphism with $\mathrm{pr}_1^{XY} \circ p_{12} = p_1$ (theorem 14.2.10) gives

$$\mathrm{pr}_1^{YZ*}(\alpha_*\zeta) = p_{23*}\big(p_{12}^*\alpha \cdot p_1^*\zeta\big)$$

Therefore

$$\beta_*(\alpha_*\zeta) = \mathrm{pr}_{2*}^{YZ}\Big(\beta \cdot p_{23*}\big(p_{12}^*\alpha \cdot p_1^*\zeta\big)\Big)$$

The morphism p_{23} is proper because X is projective, so the projection formula (theorem 14.2.10) moves β inside the pushforward as $p_{23}^*\beta$, and $\mathrm{pr}_2^{YZ} \circ p_{23} = p_3$ together with the functoriality of proper pushforward (definition 10.2.1) gives

$$\beta_*(\alpha_*\zeta) = p_{3*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta \cdot p_1^*\zeta\big)$$

The other side. Expanding the definition of the action of $\beta \circ \alpha$,

$$(\beta \circ \alpha)_*\zeta = \mathrm{pr}_{2*}^{XZ}\Big(p_{13*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta\big) \cdot \mathrm{pr}_1^{XZ*}\zeta\Big)$$

The morphism p_{13} is proper, so the projection formula moves $\mathrm{pr}_1^{XZ*}\zeta$ inside as $p_{13}^*\mathrm{pr}_1^{XZ*}\zeta = (\mathrm{pr}_1^{XZ} \circ p_{13})^*\zeta = p_1^*\zeta$. Since $\mathrm{pr}_2^{XZ} \circ p_{13} = p_3$, functoriality of proper pushforward gives

$$(\beta \circ \alpha)_*\zeta = p_{3*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta \cdot p_1^*\zeta\big)$$

which is the expression obtained for $\beta_*(\alpha_*\zeta)$, completing the proof.

Composition is therefore compatible with the action, but the action does not determine a correspondence, so associativity is not a consequence of the associativity of composing maps. It has to be proved on the product of all four varieties, where both bracketings collapse to the same expression.

Theorem 15.4.6: Associativity of Composition

Let $\alpha \in \mathrm{Corr}^r(W, X)$, $\beta \in \mathrm{Corr}^s(X, Y)$ and $\gamma \in \mathrm{Corr}^t(Y, Z)$. Then

$$(\gamma \circ \beta) \circ \alpha = \gamma \circ (\beta \circ \alpha)$$

in $\mathrm{Corr}^{r+s+t}(W, Z)$.

***Proof*:**
Write p_{ij} and p_{ijk} for the projections of $W \times X \times Y \times Z$ onto the indicated factors, numbering W, X, Y, Z as $1, 2, 3, 4$; write q_{ij} for the projections of $W \times X \times Y$, r_{ij} for those of $W \times Y \times Z$, s_{ij} for those of $X \times Y \times Z$, and t_{ij} for those of $W \times X \times Z$. Both sides are shown to equal

$$\Theta = p_{14*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta \cdot p_{34}^*\gamma\big)$$

The right-hand bracketing. The square

$$\begin{array}{ccc} W \times X \times Y \times Z & \xrightarrow{p_{134}} & W \times Y \times Z \\ {\scriptstyle p_{123}}\downarrow & & \downarrow{\scriptstyle r_{12}} \\ W \times X \times Y & \xrightarrow[q_{13}]{} & W \times Y \end{array}$$

is Cartesian, since $(W \times X \times Y) \times_{W\times Y} (W \times Y \times Z) = W \times X \times Y \times Z$. Its lower map q_{13} is proper because X is projective, and its right-hand map r_{12} is flat, so proposition 10.3.6 gives $r_{12}^* q_{13*} = p_{134*} p_{123}^*$. Since p_{123}^* is a ring homomorphism with $q_{12} \circ p_{123} = p_{12}$ and $q_{23} \circ p_{123} = p_{23}$ (theorem 14.2.10),

$$r_{12}^*(\beta \circ \alpha) = p_{134*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta\big)$$

Hence

$$\gamma \circ (\beta \circ \alpha) = r_{13*}\Big(p_{134*}\big(p_{12}^*\alpha \cdot p_{23}^*\beta\big) \cdot r_{23}^*\gamma\Big)$$

The morphism p_{134} is proper because X is projective, so the projection formula (theorem 14.2.10) moves $r_{23}^*\gamma$ inside the pushforward as $p_{134}^* r_{23}^*\gamma = (r_{23} \circ p_{134})^*\gamma = p_{34}^*\gamma$. Finally $r_{13} \circ p_{134} = p_{14}$, so functoriality of proper pushforward (definition 10.2.1) gives $\gamma \circ (\beta \circ \alpha) = \Theta$.

The left-hand bracketing. The square

$$\begin{array}{ccc} W \times X \times Y \times Z & \xrightarrow{p_{234}} & X \times Y \times Z \\ {\scriptstyle p_{124}}\downarrow & & \downarrow{\scriptstyle s_{13}} \\ W \times X \times Z & \xrightarrow[t_{23}]{} & X \times Z \end{array}$$

is Cartesian for the same reason, its lower map t_{23} is flat, and its right-hand map s_{13} is proper because Y is projective. By proposition 10.3.6, $t_{23}^* s_{13*} = p_{124*} p_{234}^*$, and since $s_{12} \circ p_{234} = p_{23}$ and $s_{23} \circ p_{234} = p_{34}$,

$$t_{23}^*(\gamma \circ \beta) = p_{124*}\big(p_{23}^*\beta \cdot p_{34}^*\gamma\big)$$

Therefore

$$(\gamma \circ \beta) \circ \alpha = t_{13*}\Big(t_{12}^*\alpha \cdot p_{124*}\big(p_{23}^*\beta \cdot p_{34}^*\gamma\big)\Big)$$

The morphism p_{124} is proper because Y is projective, so the projection formula moves $t_{12}^*\alpha$ inside as $p_{124}^* t_{12}^*\alpha = (t_{12} \circ p_{124})^*\alpha = p_{12}^*\alpha$, and $t_{13} \circ p_{124} = p_{14}$ gives $(\gamma \circ \beta) \circ \alpha = \Theta$. The two bracketings agree, as we sought to show.

Only three properties of the projections entered that argument: flat base change, the projection formula, and functoriality. The same three properties identify the correspondences attached to an

actual morphism.

Proposition 15.4.7: The Graph of a Morphism and its Transpose

Let $f\colon X \to Y$ be a morphism and let $\gamma_f = (\mathrm{id}_X, f)\colon X \to X \times Y$, a closed immersion with image the graph Γ_f. Then $[\Gamma_f] \in \mathrm{Corr}^{d_Y - d_X}(X, Y)$ and ${}^t[\Gamma_f] \in \mathrm{Corr}^0(Y, X)$, and for all $\beta \in A^*(X)$ and $\beta' \in A^*(Y)$,

$$[\Gamma_f]_*\beta = f_*\beta, \qquad {}^t[\Gamma_f]_*\beta' = f^*\beta'$$

***Proof*:**
The morphism γ_f is a section of $\mathrm{pr}_1\colon X \times Y \to X$, and a section of a morphism with separated target is a closed immersion, so Γ_f is a closed subvariety of $X \times Y$ isomorphic to X by γ_f. Hence $[\Gamma_f] = \gamma_{f*}[X]$ (definition 10.2.1), the extension of function fields being trivial, and $\dim \Gamma_f = d_X$, so $[\Gamma_f] \in A^{d_Y}(X \times Y) = \mathrm{Corr}^{d_Y - d_X}(X, Y)$. Transposing preserves codimension, so ${}^t[\Gamma_f] \in A^{d_Y}(Y \times X) = \mathrm{Corr}^0(Y, X)$.

The action of the graph. A closed immersion is proper, so the projection formula (theorem 14.2.10) applies to γ_f and gives, for $\beta \in A^*(X)$,

$$[\Gamma_f] \cdot \mathrm{pr}_1^*\beta = \gamma_{f*}\big([X] \cdot \gamma_f^*\mathrm{pr}_1^*\beta\big) = \gamma_{f*}\big((\mathrm{pr}_1 \circ \gamma_f)^*\beta\big) = \gamma_{f*}\beta$$

where $[X]$ was dropped because it is the unit of $A^*(X)$ (theorem 14.2.7) and $\mathrm{pr}_1 \circ \gamma_f = \mathrm{id}_X$. Pushing forward along pr_2 and using $\mathrm{pr}_2 \circ \gamma_f = f$ with the functoriality of proper pushforward gives $[\Gamma_f]_*\beta = f_*\beta$.

The action of the transpose. Let $\sigma\colon X \times Y \to Y \times X$ be the interchange, so ${}^t[\Gamma_f] = \sigma_*\gamma_{f*}[X] = \tilde{\gamma}_{f*}[X]$ with $\tilde{\gamma}_f = \sigma \circ \gamma_f = (f, \mathrm{id}_X)\colon X \to Y \times X$, again a closed immersion. Writing $\mathrm{pr}_1', \mathrm{pr}_2'$ for the projections of $Y \times X$, the same two steps give, for $\beta' \in A^*(Y)$,

$${}^t[\Gamma_f] \cdot \mathrm{pr}_1'^*\beta' = \tilde{\gamma}_{f*}\big((\mathrm{pr}_1' \circ \tilde{\gamma}_f)^*\beta'\big) = \tilde{\gamma}_{f*}(f^*\beta')$$

and then, since $\mathrm{pr}_2' \circ \tilde{\gamma}_f = \mathrm{id}_X$, ${}^t[\Gamma_f]_*\beta' = f^*\beta'$, completing the proof.

The graph therefore carries both directions of f: the class itself acts as the pushforward, its transpose as the pullback, and the degrees match, since f_* raises codimension by $d_Y - d_X$ while f^* preserves it. For a self-map of $\mathbb{P}^1$ the degree of the map determines the graph class.

Example 15.4.8: The Graph of a Self-Map of $\mathbb{P}^1$
Let $f\colon \mathbb{P}^1 \to \mathbb{P}^1$ be a nonconstant morphism, so that f is finite of some degree $d = [k(\mathbb{P}^1) : f^*k(\mathbb{P}^1)]$. Both source and target have dimension 1, so $[\Gamma_f] \in \mathrm{Corr}^0(\mathbb{P}^1, \mathbb{P}^1) = A^1(\mathbb{P}^1 \times \mathbb{P}^1)$, and by example 15.4.3 it can be written $[\Gamma_f] = ah_1 + bh_2$ with the action of a in codimension 0 and b in codimension 1. By proposition 15.4.7 that action is f_*. Now $f_*[\mathbb{P}^1] = d[\mathbb{P}^1]$ by definition 10.2.1, since f maps $\mathbb{P}^1$ onto $\mathbb{P}^1$ with function-field extension of degree d; and $f_*[x] = [f(x)]$ for a point x, since f restricts to an isomorphism $\{x\} \to \{f(x)\}$. Comparing with the action computed in

example 15.4.3 gives $a = d$ and $b = 1$, that is,

$$[\Gamma_f] = d\,h_1 + h_2$$

For $f = \mathrm{id}$ this reads $[\Delta_{\mathbb{P}^1}] = h_1 + h_2$, and the action is multiplication by 1 in both codimensions.

Graphs compose the way the morphisms do, and the diagonal is a unit for composition. Both are proved the same way: rewrite one of the two pulled-back classes as a pushforward from a copy of a smaller product, then follow where the remaining projections send that copy.

Proposition 15.4.9: Graphs and the Diagonal under Composition

Let $f\colon X \to Y$ and $g\colon Y \to Z$ be morphisms, and let $\Delta_X \subseteq X \times X$ be the diagonal.

1. $[\Gamma_g] \circ [\Gamma_f] = [\Gamma_{g\circ f}]$.
2. $\alpha \circ [\Delta_X] = \alpha$ and $[\Delta_Y] \circ \alpha = \alpha$ for every $\alpha \in \mathrm{Corr}^r(X, Y)$.

***Proof*:**

1. Let $u = \mathrm{id}_X \times \gamma_g\colon X \times Y \to X \times Y \times Z$, so $u(x, y) = (x, y, g(y))$, a closed immersion. The square

$$\begin{array}{ccc} X \times Y & \xrightarrow{\mathrm{pr}_2^{XY}} & Y \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle \gamma_g} \\ X \times Y \times Z & \xrightarrow[p_{23}]{} & Y \times Z \end{array}$$

   is Cartesian: a point of $(X \times Y \times Z) \times_{Y\times Z} Y$ is a triple (x, y, z) together with a point y' of Y satisfying $(y, z) = (y', g(y'))$, so $y' = y$ and $z = g(y)$. Its right-hand map γ_g is a closed immersion, hence proper, and its lower map p_{23} is flat, so proposition 10.3.6 gives $p_{23}^*\gamma_{g*} = u_*\mathrm{pr}_2^{XY*}$. Since $\mathrm{pr}_2^{XY*}[Y] = [X \times Y]$ (definition 10.3.3) and $[\Gamma_g] = \gamma_{g*}[Y]$,

$$p_{23}^*[\Gamma_g] = u_*[X \times Y]$$

   The morphism u is proper, so the projection formula (theorem 14.2.10) and $p_{12} \circ u = \mathrm{id}_{X\times Y}$ give

$$p_{12}^*[\Gamma_f] \cdot u_*[X \times Y] = u_*\big(u^* p_{12}^*[\Gamma_f] \cdot [X \times Y]\big) = u_*[\Gamma_f]$$

   Finally $p_{13} \circ u = \mathrm{id}_X \times g$, so by the functoriality of proper pushforward

$$[\Gamma_g] \circ [\Gamma_f] = (\mathrm{id}_X \times g)_*[\Gamma_f]$$

   The morphism $\mathrm{id}_X \times g$ carries Γ_f onto $\Gamma_{g\circ f}$, and it does so isomorphically, because on both graphs the first projection to X is an isomorphism and $\mathrm{id}_X \times g$ commutes with it. Hence the pushforward is $[\Gamma_{g\circ f}]$ by definition 10.2.1.

2. Let $\delta\colon X \to X \times X$ be the diagonal immersion, so $[\Delta_X] = \delta_*[X]$, and let $v = \delta \times \mathrm{id}_Y\colon X \times Y \to X \times X \times Y$, $v(x, y) = (x, x, y)$. The maps v and $\mathrm{pr}_1^{XY}\colon X \times Y \to X$ present $X \times Y$ as the fibre product $(X \times X \times Y) \times_{X\times X} X$ taken over p_{12} and δ, since a point of that fibre product is a triple (x_1, x_2, y) together with a point x satisfying

$(x_1, x_2) = (x, x)$. The immersion δ is proper and p_{12} is flat, so proposition 10.3.6 together with $\mathrm{pr}_1^{XY*}[X] = [X \times Y]$ gives $p_{12}^*[\Delta_X] = v_*[X \times Y]$, as in part (1). Since $p_{23} \circ v = \mathrm{id}_{X\times Y}$, the projection formula gives

$$p_{12}^*[\Delta_X] \cdot p_{23}^*\alpha = v_*\big(v^* p_{23}^*\alpha\big) = v_*\alpha$$

and since $p_{13} \circ v = \mathrm{id}_{X\times Y}$ as well, pushing forward gives $\alpha \circ [\Delta_X] = \alpha$. For the other identity, let $w = \mathrm{id}_X \times \delta_Y \colon X \times Y \to X \times Y \times Y$, $w(x, y) = (x, y, y)$, where $\delta_Y \colon Y \to Y \times Y$ is the diagonal. The maps w and pr_2^{XY} present $X \times Y$ as $(X \times Y \times Y) \times_{Y\times Y} Y$ over p_{23} and δ_Y, so the same argument gives $p_{23}^*[\Delta_Y] = w_*[X \times Y]$; then $p_{12} \circ w = p_{13} \circ w = \mathrm{id}_{X\times Y}$ turns the projection formula and the pushforward into $[\Delta_Y] \circ \alpha = \alpha$, completing the proof.

Transposition reverses composition, which is what makes the assignment $f \mapsto {}^t[\Gamma_f]$ contravariant.

Proposition 15.4.10: Transposition Reverses Composition

For $\alpha \in \mathrm{Corr}^r(X, Y)$ and $\beta \in \mathrm{Corr}^s(Y, Z)$,

$$^t(\beta \circ \alpha) = {}^t\alpha \circ {}^t\beta$$

***Proof*:**
Let $\tau \colon X \times Y \times Z \to Z \times Y \times X$ reverse the three factors, let q_{ij} be the projections of $Z \times Y \times X$, and let $\sigma_{XY}, \sigma_{YZ}, \sigma_{XZ}$ be the interchanges of the corresponding double products. Composing maps gives $q_{12} \circ \tau = \sigma_{YZ} \circ p_{23}$, $q_{23} \circ \tau = \sigma_{XY} \circ p_{12}$ and $q_{13} \circ \tau = \sigma_{XZ} \circ p_{13}$.

For an isomorphism h, the flat pullback h^* and the pushforward $(h^{-1})_*$ send the class of a subvariety V to the class of $h^{-1}(V)$ with multiplicity one (definition 10.3.3, definition 10.2.1), so $h^* = (h^{-1})_*$ and hence $h^*h_* = \mathrm{id}$ and $h_*h^* = \mathrm{id}$ by functoriality of proper pushforward. Applying this to σ_{YZ} and σ_{XY} and using functoriality of pullback,

$$\tau^* q_{12}^*({}^t\beta) = p_{23}^*\sigma_{YZ}^*\sigma_{YZ*}\beta = p_{23}^*\beta, \qquad \tau^* q_{23}^*({}^t\alpha) = p_{12}^*\alpha$$

Since τ^* is a ring homomorphism (theorem 14.2.10) and $\tau_*\tau^* = \mathrm{id}$,

$$q_{12}^*({}^t\beta) \cdot q_{23}^*({}^t\alpha) = \tau_*\big(p_{23}^*\beta \cdot p_{12}^*\alpha\big)$$

Pushing forward along q_{13} and using $q_{13} \circ \tau = \sigma_{XZ} \circ p_{13}$ with the functoriality of proper pushforward,

$$^t\alpha \circ {}^t\beta = q_{13*}\tau_*\big(p_{12}^*\alpha \cdot p_{23}^*\beta\big) = \sigma_{XZ*}\big(\beta \circ \alpha\big) = {}^t(\beta \circ \alpha)$$

as we sought to show.

Composition preserves degree 0, the transposed graphs have degree 0, and proposition 15.4.9 gives identities, so these correspondences form a category.

Corollary 15.4.11: The Category of Correspondences

There is a category $\mathcal{C}$ whose objects are the smooth projective varieties over $\overline{k}$, with $\mathrm{Hom}_{\mathcal{C}}(X,Y) = \mathrm{Corr}^0(X,Y)$, composition as in definition 15.4.4, and identity morphism $[\Delta_X]$ at X. The assignment sending X to itself and a morphism $f\colon X \to Y$ to ${}^t[\Gamma_f] \in \mathrm{Hom}_{\mathcal{C}}(Y,X)$ is a contravariant functor from smooth projective varieties to $\mathcal{C}$.

***Proof*:**

Composition carries $\mathrm{Corr}^0(X,Y) \times \mathrm{Corr}^0(Y,Z)$ into $\mathrm{Corr}^0(X,Z)$ by proposition 15.4.5, and is associative by theorem 15.4.6. The class $[\Delta_X]$ lies in $A^{d_X}(X \times X) = \mathrm{Corr}^0(X,X)$ and is a two-sided identity by proposition 15.4.9(2), so $\mathcal{C}$ is a category.

For the functor, proposition 15.4.7 places ${}^t[\Gamma_f]$ in $\mathrm{Corr}^0(Y,X) = \mathrm{Hom}_{\mathcal{C}}(Y,X)$. Given $f\colon X \to Y$ and $g\colon Y \to Z$, proposition 15.4.10 and proposition 15.4.9(1) give

$$ {}^t[\Gamma_{g\circ f}] = {}^t\big([\Gamma_g] \circ [\Gamma_f]\big) = {}^t[\Gamma_f] \circ {}^t[\Gamma_g] $$

and $\Gamma_{\mathrm{id}_X} = \Delta_X$ is carried to itself by the interchange of factors, so ${}^t[\Delta_X] = [\Delta_X]$ is the identity of X in $\mathcal{C}$, completing the proof.

Over $\mathbb{C}$ the construction is compatible with the cycle class map, because it is built from flat pullback, the intersection product and proper pushforward, and section 15.2 establishes compatibility with each of the three.

Proposition 15.4.12: Correspondences and the Cycle Class Map

Let X and Y be smooth projective varieties over $\mathbb{C}$ and $\alpha \in \mathrm{Corr}^r(X,Y)$. Define

$$ \mathrm{cl}(\alpha)_*\colon H^{2k}(X;\mathbb{Z}) \to H^{2(k+r)}(Y;\mathbb{Z}), \qquad u \mapsto \mathrm{pr}_{2!}\big(\mathrm{cl}(\alpha) \cup \mathrm{pr}_1^* u\big) $$

where $\mathrm{pr}_{2!}$ is the Gysin homomorphism through which section 15.2 states the compatibility of cl with proper pushforward, obtained from pushforward on homology by **??**. Then for every $\beta \in A^k(X)$,

$$ \mathrm{cl}\big(\alpha_*\beta\big) = \mathrm{cl}(\alpha)_*\mathrm{cl}(\beta) $$

***Proof*:**

The product $X \times Y$ is a smooth projective variety over $\mathbb{C}$, so cl is defined on $A^*(X \times Y)$ and is a ring homomorphism there (section 15.2). The projection pr_1 is flat, being a base change of $Y \to \mathrm{Spec}\,\mathbb{C}$, and pr_2 is proper, being a base change of the proper morphism $X \to \mathrm{Spec}\,\mathbb{C}$, so the compatibilities of cl with pullback along a projection and with proper pushforward established in section 15.2 apply to them. Reading the definition of $\alpha_*\beta$ through those three compatibilities in turn,

$$ \mathrm{cl}\big(\mathrm{pr}_{2*}(\alpha \cdot \mathrm{pr}_1^*\beta)\big) = \mathrm{pr}_{2!}\,\mathrm{cl}\big(\alpha \cdot \mathrm{pr}_1^*\beta\big) = \mathrm{pr}_{2!}\big(\mathrm{cl}(\alpha) \cup \mathrm{cl}(\mathrm{pr}_1^*\beta)\big) = \mathrm{pr}_{2!}\big(\mathrm{cl}(\alpha) \cup \mathrm{pr}_1^*\mathrm{cl}(\beta)\big) $$

and the right-hand side is $\mathrm{cl}(\alpha)_*\mathrm{cl}(\beta)$ by definition, completing the proof.

The degrees on the two sides agree: $\mathrm{cl}(\alpha)$ lies in $H^{2(d_X+r)}(X \times Y;\mathbb{Z})$ and $\mathrm{pr}_{2!}$ lowers cohomological

degree by $2d_X$, so $\mathrm{cl}(\alpha)_*$ raises it by $2r$, matching the shift of α_* by r in codimension. One consequence is that the action of a correspondence on classes modulo homological equivalence depends only on its cycle class.

Corollary 15.4.13: Correspondences Preserve Homological Equivalence

Let X and Y be smooth projective over $\mathbb{C}$ and $\alpha \in \mathrm{Corr}^r(X,Y)$. If $\beta \in A^k(X)$ is homologically equivalent to zero, then so is $\alpha_*\beta$. Consequently α_* descends to a homomorphism from $A^k(X)$ modulo homological equivalence to $A^{k+r}(Y)$ modulo homological equivalence.

***Proof*:**
Homological equivalence to zero means $\mathrm{cl}(\beta) = 0$ (section 15.3). By proposition 15.4.12, $\mathrm{cl}(\alpha_*\beta) = \mathrm{pr}_{2!}(\mathrm{cl}(\alpha) \cup \mathrm{pr}_1^* 0) = 0$, so $\alpha_*\beta$ is homologically equivalent to zero. Since α_* is additive (proposition 15.4.2), it therefore carries the subgroup of classes homologically equivalent to zero into the corresponding subgroup on Y and descends to the quotients, as we sought to show.

The proofs of theorem 15.4.6 and proposition 15.4.9 used only proper pushforward, pullback and the intersection product, and an adequate equivalence relation in the sense of section 15.3 is by definition compatible with all three. That definition is stated there over $\mathbb{C}$, with nondegeneracy read on $\operatorname{Spec}\mathbb{C}$. Read it here over $\overline{k}$, with nondegeneracy on $\operatorname{Spec}\overline{k}$, which affects none of the three compatibilities. Replacing $A^*(X \times Y)$ throughout by its quotient modulo such a relation therefore yields a category of correspondences for each relation in the tower of section 15.3, with the same objects, identities and composition. Formally adjoining an image for each idempotent $p \in \mathrm{Corr}^0(X,X)$, that is, each p with $p \circ p = p$, produces the category of pure motives attached to the relation: its objects are pairs consisting of a variety and such an idempotent, and a single variety typically decomposes into several of them.

Exercise 15.4.1

1. Let $\alpha \in \mathrm{Corr}^r(X,Y)$ for smooth projective varieties X and Y. Show that ${}^t\alpha$ lies in $\mathrm{Corr}^{r+d_X-d_Y}(Y,X)$, that ${}^t({}^t\alpha) = \alpha$, and hence that transposition is an isomorphism of groups $\mathrm{Corr}^r(X,Y) \to \mathrm{Corr}^{r+d_X-d_Y}(Y,X)$.

2. By example 15.4.3 a correspondence of degree 0 from $\mathbb{P}^1$ to $\mathbb{P}^1$ is determined by its action. Use this together with proposition 15.4.5 to show that

$$(a'h_1 + b'h_2) \circ (ah_1 + bh_2) = aa'\,h_1 + bb'\,h_2$$

   Conclude that $\mathrm{Corr}^0(\mathbb{P}^1,\mathbb{P}^1)$, with composition as multiplication, is isomorphic as a ring to $\mathbb{Z} \times \mathbb{Z}$.

3. Let X and Y be smooth projective, $\xi \in A^a(X)$ and $\eta \in A^b(Y)$, and set $\alpha = \mathrm{pr}_1^*\xi \cdot \mathrm{pr}_2^*\eta$. Show that $\alpha \in \mathrm{Corr}^{a+b-d_X}(X,Y)$ and that, for $\beta \in A^k(X)$,

$$\alpha_*\beta = \Big(\int_X \xi \cdot \beta\Big)\,\eta \quad \text{if } a+k = d_X, \qquad \alpha_*\beta = 0 \quad \text{otherwise}$$

   where $\int_X$ is the degree of a zero cycle (definition 10.2.4). (For the vanishing, treat $a+k > d_X$ and $a+k < d_X$ separately.)

4. Let X and Y be smooth projective and let $c\colon X \to Y$ be the constant morphism with image a point y_0. Show that $[\Gamma_c] = \mathrm{pr}_2^*[y_0]$, and compute the action of $[\Gamma_c]$ on $A^k(X)$ for every k.

5. Let X and Y be smooth projective over $\mathbb{C}$ and let $\alpha, \alpha' \in \mathrm{Corr}^r(X,Y)$ be homologically equivalent. Show that $\alpha_*\beta$ and $\alpha'_*\beta$ are homologically equivalent for every $\beta \in A^k(X)$, so that the induced map on classes modulo homological equivalence depends only on the class of α modulo homological equivalence.

6. Let X be a smooth projective variety. Show that composition makes $\mathrm{Corr}^0(X,X)$ an associative ring with identity $[\Delta_X]$, and that $\alpha \mapsto \alpha_*$ is a homomorphism of rings from $\mathrm{Corr}^0(X,X)$ to the ring of additive endomorphisms of $A^*(X)$ preserving the codimension grading.

7. Verify from example 15.4.8 that $[\Delta_{\mathbb{P}^1}] = h_1 + h_2$, and check using the composition formula of exercise 15.4.1 (2) that this class is idempotent. Which other classes in $\mathrm{Corr}^0(\mathbb{P}^1,\mathbb{P}^1)$ are idempotent?

15.5 Summary

This chapter is cited from outside for its relations rather than for its arguments, so the relations are collected here with what each one is and what it costs.

Relation	**Defined in**	$\alpha \sim 0$ **when**	**Status**
Rational	definition 10.1.3	$\alpha \in \mathrm{Rat}_k(X)$	finest; unconditional
Algebraic	definition 15.1.3	α is a $\mathbb{Z}$-combination of fibre differences	unconditional
Homological	definition 15.3.1	$\mathrm{cl}(\alpha) = 0$ in $H^{2*}(X;\mathbb{Z})$	needs (15.2)
Numerical	definition 15.3.4	$\deg(\alpha\cdot\beta) = 0$ for every β	coarsest nondegenerate

All four are adequate in the sense of definition 15.3.6 (theorem 15.3.9), and they nest,

$$\text{rat} \subseteq \text{alg} \subseteq \text{hom} \subseteq \text{num}$$

by theorem 15.3.11, with numerical equivalence the coarsest nondegenerate one (proposition 15.3.10) and $\mathrm{Num}^*(X)$ finitely generated (theorem 15.3.13).

The homological row carries conditions a citing book needs to know about, and so do the last *two* inclusions of the tower: theorem 15.3.11 Step 3 applies cl to a product and cites corollary 15.2.14, so the middle inclusion inherits the grant as well. Both rest on (15.2), the diagonal case of the pullback comparison, which is an input and not a theorem here (theorem 15.2.13 is proved for a projection only). That is one of five external inputs, listed in full in section 15.3. The other four are triangulability (theorem 15.2.2), the local specialization statement inside lemma 15.2.6, the identification of cl with c_1 on divisors, and finite generation of $H^*(X;\mathbb{Z})$. Each is stated where it is used.

Correspondences (definition 15.4.1) act on all four groups, compose by theorem 15.4.6, and are the device by which a morphism is replaced by its graph; that replacement is what chapter 16 uses to factor a proper morphism.

16

Riemann-Roch

Riemann-Roch computes a cohomological invariant from a geometric one. In its oldest form it says that for a divisor D on a curve of genus g the difference $\ell(D) - \ell(K - D)$ is $\deg D + 1 - g$: a count of sections, which is hard, expressed through a degree and a genus, which are not. Every later version keeps that shape. Something defined by cohomology on the left, something defined by intersection numbers on the right, and an equality that lets each be computed from the other.

Grothendieck's formulation makes the shape exact and, in doing so, changes what the theorem is about. It is not a statement about one variety but about a *morphism*: pushing a class forward in K-theory and then taking its Chern character differs from taking the Chern character first and pushing forward in the Chow ring, and the discrepancy is a universal correction, the Todd class of the relative tangent bundle. Set Y to a point and the classical statements fall out.

Section 16.1 builds the two power series the correction is made of. The Chern character converts the multiplicative bookkeeping of K-theory into the additive bookkeeping of the Chow ring, and the Todd class measures its failure to commute with pushforward. Section 16.2 proves the theorem for a proper morphism of smooth varieties by factoring it into a closed immersion and a projection, and states the extension to local complete intersection morphisms. Section 16.3 spends it: Hirzebruch-Riemann-Roch, then the curve and surface statements that [9] proved by hand, recovered here as instances.

16.1 The Chern Character and the Todd Class

Two power series in the Chern roots are what Riemann-Roch is written in, and both are produced by the calculus of proposition 12.2.22: substitute the roots, verify a symmetric-function identity, descend by injectivity. The first is the exponential.

Definition 16.1.1: The Chern Character

Let E be a vector bundle of rank r on an algebraic scheme X. The *Chern character* of E is the operator on $A_*(X)_{\mathbb{Q}}$ obtained from the symmetric power series

$$\mathrm{ch}(a_1,\dots,a_r)=\sum_{p=1}^{r}e^{a_p}=\sum_{p=1}^{r}\sum_{k\geq 0}\frac{a_p^k}{k!}$$

by proposition 12.2.22. It is written $\mathrm{ch}(E)$, and its component lowering dimension by k is written $\mathrm{ch}_k(E)$, so that $\mathrm{ch}(E)=\sum_{k\geq 0}\mathrm{ch}_k(E)$ with the sum finite by lemma 12.2.20.

The definition is stated through the roots for brevity, but no roots are used: what proposition 12.2.22 returns is a specific polynomial in $c_1(E),\dots,c_r(E)$ with rational coefficients, and the next proposition writes it out. In every positive degree that polynomial is the same for all ranks, once the convention $c_i(E)=0$ for $i>\mathrm{rank}E$ from section 12.2 applies; the rank enters only in degree zero, where the constant term is the rank itself. That is what allows bundles of different ranks to be compared in a single identity: the positive-degree components match term by term and the ranks do their own bookkeeping in degree zero.

Proposition 16.1.2: Components of the Chern Character

Let E be a vector bundle of rank r on X, and write $c_i=c_i(E)$. Then $\mathrm{ch}_k(E)=\frac{1}{k!}\,p_k$, where $p_0=r$ and the operators p_k are determined by Newton's recursion

$$p_k-c_1p_{k-1}+c_2p_{k-2}-\cdots+(-1)^{k-1}c_{k-1}p_1+(-1)^k k\,c_k=0\qquad(k\geq 1)\tag{16.1}$$

In particular

$$\mathrm{ch}(E)=r+c_1+\tfrac{1}{2}\big(c_1^2-2c_2\big)+\tfrac{1}{6}\big(c_1^3-3c_1c_2+3c_3\big)+\cdots$$

so $\mathrm{ch}_0(E)=\mathrm{rank}E$ and $\mathrm{ch}_1(E)=c_1(E)$. For a line bundle L, $\mathrm{ch}(L)=e^{c_1(L)}$.

***Proof*:**

Work first with formal symbols. In $\mathbb{Q}[a_1,\dots,a_r][[t]]$ put $E(t)=\prod_{p=1}^{r}(1+a_pt)=\sum_{j\geq 0}e_jt^j$, where $e_j=e_j(a)$ and $e_j=0$ for $j>r$. Each factor $1+a_pt$ has constant term 1, hence is invertible, and the product rule gives

$$E'(t)=\sum_{p=1}^{r}a_p\prod_{q\neq p}(1+a_qt)=E(t)\sum_{p=1}^{r}\frac{a_p}{1+a_pt}$$

Expanding $\frac{a_p}{1+a_pt}=\sum_{k\geq 1}(-1)^{k-1}a_p^kt^{k-1}$ and summing over p turns this into

$$E'(t)=E(t)\sum_{k\geq 1}(-1)^{k-1}p_kt^{k-1},\qquad p_k:=\sum_{p=1}^{r}a_p^k$$

Comparing coefficients of t^{k-1} on both sides gives $ke_k=\sum_{m=1}^{k}(-1)^{m-1}e_{k-m}\,p_m$, which on multiplying by $(-1)^{k-1}$ and transposing is exactly (16.1) with e_i in place of c_i. Solving the recursion in low degrees, $p_1=e_1$, then $p_2=e_1p_1-2e_2=e_1^2-2e_2$, then $p_3=e_1p_2-e_2p_1+3e_3=e_1^3-3e_1e_2+3e_3$.

The power sums determine the Chern character, since interchanging the two finite-in-each-degree summations gives

$$\sum_{p=1}^{r} e^{a_p} = \sum_{k\geq 0} \frac{1}{k!} \sum_{p=1}^{r} a_p^k = r + \sum_{k\geq 1} \frac{p_k}{k!}$$

Each p_k is symmetric, and (16.1) exhibits it as an isobaric polynomial of weight k in $e_1, \ldots, e_k$; by the uniqueness in [17, Symmetric Power Series in the Chern Roots] that polynomial is the one proposition 12.2.22 substitutes into. Substituting $c_i = c_i(E)$ therefore gives $\mathrm{ch}_k(E) = \frac{1}{k!} p_k$ with p_k satisfying (16.1), and the displayed expansion follows from the three computed cases. Finally $\mathrm{ch}_0(E) = p_0 = r$ and $\mathrm{ch}_1(E) = p_1 = c_1$. For $r = 1$ the series is e^{a_1} and $e_1 = a_1$, so $\widetilde{\mathrm{ch}}(y_1) = e^{y_1}$ and $\mathrm{ch}(L) = e^{c_1(L)} = \sum_{k\geq 0} c_1(L)^k / k!$, a finite sum by lemma 12.2.20, as we sought to show.

The denominators do not cancel. Already the factor $\frac{1}{2}$ in $\mathrm{ch}_2 = \frac{1}{2}(c_1^2 - 2c_2)$ survives on projective space, where $c_1^2 - 2c_2$ is an odd multiple of the point class for suitable bundles, so ch_2 is not the image of any operator on $A_*(X)$ with integer coefficients. The next example exhibits the smallest such case.

Example 16.1.3: The Chern Character of a Line Bundle on $\mathbb{P}^n$

Let $h = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$, so that $h^k \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}]$ for $0 \leq k \leq n$ by example 11.4.7, and $h^{n+1} = 0$ as an operator by lemma 12.2.20. For the line bundle $\mathcal{O}_{\mathbb{P}^n}(d)$ one has $c_1(\mathcal{O}_{\mathbb{P}^n}(d)) = d\,h$ by proposition 11.4.4(3), so

$$\mathrm{ch}\big(\mathcal{O}_{\mathbb{P}^n}(d)\big) = e^{dh} = 1 + dh + \frac{d^2}{2}h^2 + \cdots + \frac{d^n}{n!}h^n$$

the series terminating because $h^{n+1} = 0$. Capping with the fundamental class on $\mathbb{P}^2$,

$$\mathrm{ch}\big(\mathcal{O}_{\mathbb{P}^2}(d)\big) \cap [\mathbb{P}^2] = [\mathbb{P}^2] + d\,[\mathbb{P}^1] + \frac{d^2}{2}\,[\mathrm{pt}]$$

For odd d the last coefficient is not an integer, so this class lies in $A_0(\mathbb{P}^2)_{\mathbb{Q}}$ and in no subgroup coming from $A_0(\mathbb{P}^2)$. Rational coefficients are not a convenience here; without them the Chern character of $\mathcal{O}_{\mathbb{P}^2}(1)$ does not exist.

The point of the exponential is the identity $e^{a+b} = e^a e^b$, which converts both operations on bundles into operations on operators. Both of the proofs below compare two bundles at once, so they need a single splitting map that works for several bundles simultaneously.

Theorem 16.1.4: Additivity and Multiplicativity of the Chern Character

Let X be an algebraic scheme and let E, F be vector bundles on X.

1. If $0 \to E' \to E \to E'' \to 0$ is an exact sequence of vector bundles on X, then
$$\mathrm{ch}(E) = \mathrm{ch}(E') + \mathrm{ch}(E'')$$
as operators on $A_*(X)_{\mathbb{Q}}$. In particular $\mathrm{ch}(E \oplus F) = \mathrm{ch}(E) + \mathrm{ch}(F)$.
2. $\mathrm{ch}(E \otimes F) = \mathrm{ch}(E)\,\mathrm{ch}(F)$, the product on the right being composition of operators.

***Proof*:**
Write $r = \operatorname{rank} E$, $r' = \operatorname{rank} E'$, $r'' = \operatorname{rank} E''$ and $s = \operatorname{rank} F$; in part (1) the ranks satisfy $r = r' + r''$.

1. *Additivity.* By theorem 12.2.14 choose a flat proper $f\colon X' \to X$ with f^* injective that is a splitting map for both E' and E'', with Chern roots $a_1, \dots, a_{r'}$ and $b_1, \dots, b_{r''}$ respectively.

   The same f splits E. Pulling the exact sequence back gives $0 \to f^*E' \xrightarrow{\iota} f^*E \xrightarrow{\pi} f^*E'' \to 0$, again exact since pullback of vector bundles is exact. Let $0 = E'_0 \subset \cdots \subset E'_{r'} = f^*E'$ and $0 = E''_0 \subset \cdots \subset E''_{r''} = f^*E''$ be the two filtrations, with line-bundle quotients L_p and M_q, and define

   $$H_p = \iota(E'_p) \quad (0 \le p \le r'), \qquad H_{r'+q} = \pi^{-1}\big(E''_q\big) \quad (1 \le q \le r'')$$

   This is a filtration of f^*E by subbundles: the first stretch is the filtration of the subbundle f^*E', the second consists of preimages of subbundles under a surjection of bundles. Its successive quotients are $L_1, \dots, L_{r'}$ followed by $H_{r'+q}/H_{r'+q-1} \cong E''_q/E''_{q-1} = M_q$, the isomorphism holding because π carries $H_{r'+q}$ onto E''_q with kernel $f^*E' = H_{r'}$ contained in $H_{r'+q-1}$. So f is a splitting map for E with Chern roots $a_1, \dots, a_{r'}, b_1, \dots, b_{r''}$.

   Now apply proposition 12.2.22(4) three times. For every $\alpha \in A_*(X)_{\mathbb{Q}}$,

   $$f^*\big(\operatorname{ch}(E) \cap \alpha\big) = \Big(\sum_{p=1}^{r'} e^{a_p} + \sum_{q=1}^{r''} e^{b_q}\Big) \cap f^*\alpha = f^*\big(\operatorname{ch}(E') \cap \alpha\big) + f^*\big(\operatorname{ch}(E'') \cap \alpha\big)$$

   the first equality reading the roots of E off the spliced filtration and the second applying the proposition to E' and to E'' separately. Since f^* is injective on $A_*(X)_{\mathbb{Q}}$, this gives $\operatorname{ch}(E) \cap \alpha = \operatorname{ch}(E') \cap \alpha + \operatorname{ch}(E'') \cap \alpha$ for every α, which is the asserted identity of operators. The direct sum is the case of a split exact sequence.

2. *Multiplicativity.* First a statement about filtrations: if a bundle A has a filtration with line-bundle quotients $N_1, \dots, N_a$ and B one with quotients $P_1, \dots, P_b$, then $A \otimes B$ has a filtration with quotients the $N_i \otimes P_j$. Induct on a. For $a = 1$ the bundle $A = N_1$ is a line bundle, and tensoring the filtration B_j of B by it gives a filtration of $N_1 \otimes B$ with quotients $N_1 \otimes P_j$, since tensoring by a line bundle is exact and carries subbundles to subbundles. For $a > 1$, tensoring $0 \to A_{a-1} \to A \to N_a \to 0$ with the locally free B keeps it exact; the subbundle $A_{a-1} \otimes B$ has the required filtration by induction, and taking preimages of the filtration of $N_a \otimes B$ under the surjection $A \otimes B \to N_a \otimes B$ extends it, exactly as in part (1).

   By theorem 12.2.14 choose a flat proper $g\colon X'' \to X$ with g^* injective that is a splitting map for both E and F, with Chern roots $w_1, \dots, w_r$ and $u_1, \dots, u_s$. Applying the previous paragraph to $g^*E \otimes g^*F = g^*(E \otimes F)$ produces a filtration whose quotients are the rs tensor products of line bundles from the two filtrations, and the first Chern class of such a tensor product is $w_p + u_j$ by proposition 11.4.4(3). So g is a splitting map for $E \otimes F$ with Chern roots the operators $w_p + u_j$. By proposition 12.2.22(4) and the formal identity $e^{w+u} = e^w e^u$,

   $$g^*\big(\operatorname{ch}(E \otimes F) \cap \alpha\big) = \Big(\sum_{p,j} e^{w_p + u_j}\Big) \cap g^*\alpha = \Big(\sum_p e^{w_p}\Big)\Big(\sum_j e^{u_j}\Big) \cap g^*\alpha$$

and the right-hand side is $g^*\big(\mathrm{ch}(E)\,\mathrm{ch}(F)\cap\alpha\big)$, again by proposition 12.2.22(4) applied twice, the two operators commuting by proposition 12.2.22(1). Injectivity of g^* gives $\mathrm{ch}(E\otimes F)=\mathrm{ch}(E)\,\mathrm{ch}(F)$, completing the proof.

The theorem says that ch converts the two ways of building bundles into the two operations of a commutative ring: extensions become sums, tensor products become composites. That is the structure of the Grothendieck group of vector bundles, in which an exact sequence is declared to be a sum and the tensor product is the multiplication, and the Chern character is the map out of it that the Riemann-Roch theorem of theorem 16.2.2 computes with. A reader who has met Chern classes topologically [78] will recognize the axioms driving the argument, the Whitney formula and naturality being the same there; the topological Chern character satisfies the same two identities. The construction here is independent of that one, valid over any algebraically closed field and on singular schemes, and landing in rational Chow groups rather than in cohomology.

Additivity comes at a price. The total Chern class is multiplicative, so ch cannot also be, and the class that Riemann-Roch attaches to the tangent bundle, correcting the Chern character of a bundle to its Euler characteristic, has to be multiplicative. The Todd class is that multiplicative partner. The specific power series below is not derivable from anything in this chapter; it is the one that makes Riemann-Roch true, and the first evidence for it is the computation at the end of this section, where the top Todd component of the tangent bundle of $\mathbb{P}^n$ integrates to $1=\chi(\mathcal{O}_{\mathbb{P}^n})$.

Definition 16.1.5: The Todd Class

Write $Q(t)=\dfrac{t}{1-e^{-t}}\in\mathbb{Q}[[t]]$, which is a power series because $1-e^{-t}=t\big(1-\frac{t}{2}+\frac{t^2}{6}-\cdots\big)$ and the second factor has constant term 1, hence is invertible. For a vector bundle E of rank r on an algebraic scheme X, the *Todd class* of E is the operator on $A_*(X)_{\mathbb{Q}}$ obtained from the symmetric power series

$$\mathrm{td}(a_1,\dots,a_r)=\prod_{p=1}^{r}\frac{a_p}{1-e^{-a_p}}$$

by proposition 12.2.22, written $\mathrm{td}(E)$, with $\mathrm{td}_k(E)$ its component lowering dimension by k. When X is smooth, $\mathrm{td}(X)$ abbreviates $\mathrm{td}(T_X)$ for the tangent bundle T_X.

Proposition 16.1.6: Components of the Todd Class

Let E be a vector bundle on X and write $c_i=c_i(E)$. Then

$$\mathrm{td}(E)=1+\tfrac{1}{2}c_1+\tfrac{1}{12}\big(c_1^2+c_2\big)+\tfrac{1}{24}c_1c_2+\cdots$$

In particular $\mathrm{td}_0(E)=1$, so $\mathrm{td}(E)$ is an invertible operator on $A_*(X)_{\mathbb{Q}}$, and for a line bundle L,

$$\mathrm{td}(L)=Q\big(c_1(L)\big)=1+\tfrac{1}{2}c_1(L)+\tfrac{1}{12}c_1(L)^2+\cdots$$

***Proof*:**

Expand Q first. From $1-e^{-t}=t\big(1-\frac{t}{2}+\frac{t^2}{6}-\frac{t^3}{24}+\cdots\big)$ one gets $Q(t)=(1-u)^{-1}$ with $u=\frac{t}{2}-\frac{t^2}{6}+\frac{t^3}{24}-\cdots$, so $Q(t)=1+u+u^2+u^3+\cdots$. Collecting terms,

$$Q(t)=1+\tfrac{t}{2}+\Big(\tfrac{1}{4}-\tfrac{1}{6}\Big)t^2+\Big(\tfrac{1}{8}-\tfrac{1}{6}+\tfrac{1}{24}\Big)t^3+\cdots=1+\tfrac{t}{2}+\tfrac{t^2}{12}+0\cdot t^3+\cdots$$

Now write $q_1=\frac{1}{2}$, $q_2=\frac{1}{12}$, $q_3=0$ and expand $\prod_{p=1}^{r}\big(1+q_1a_p+q_2a_p^2+q_3a_p^3+\cdots\big)$ in degrees at most three, using the power sums $p_k=\sum_p a_p^k$ of proposition 16.1.2. In degree one the only contribution is $q_1p_1=\frac{1}{2}e_1$. In degree two the contributions are q_2p_2 from a single factor and $q_1^2e_2$ from two distinct factors, giving

$$\tfrac{1}{12}\big(e_1^2-2e_2\big)+\tfrac{1}{4}e_2=\tfrac{1}{12}\big(e_1^2+e_2\big)$$

In degree three the contributions are $q_3p_3=0$, then $q_1q_2\sum_{p\neq q}a_p^2a_q$ from two distinct factors, then $q_1^3e_3$ from three distinct factors. Since $\sum_{p\neq q}a_p^2a_q=p_1p_2-p_3=e_1e_2-3e_3$, the degree-three term is

$$\tfrac{1}{24}\big(e_1e_2-3e_3\big)+\tfrac{1}{8}e_3=\tfrac{1}{24}e_1e_2$$

Substituting $e_i=c_i(E)$ through proposition 12.2.22 gives the stated expansion. Invertibility follows from $\operatorname{td}(E)=\mathrm{id}+N$ with $N=\sum_{k\geq 1}\operatorname{td}_k(E)$ a sum of dimension-lowering operators, so $N^{\dim X+1}=0$ by lemma 12.2.20 and $\operatorname{td}(E)^{-1}=\sum_{k\geq 0}(-N)^k$ is a finite sum. For $r=1$ the series is $Q(a_1)$ with $e_1=a_1$, so $\operatorname{td}(L)=Q(c_1(L))$, as we sought to show.

The first component $\frac{1}{2}c_1$ already forces rational coefficients, exactly as ch_2 did, and the degree-three coefficient of Q vanishes because $Q(t)-\frac{t}{2}$ is even, so Q has no odd-degree terms beyond the first. The next example computes the class in the smallest case, where a single Chern class controls everything.

Example 16.1.7: The Todd Class of a Line Bundle on $\mathbb{P}^2$

With $h=c_1(\mathcal{O}_{\mathbb{P}^2}(1))$ as in example 16.1.3 and $h^3=0$, proposition 16.1.6 gives

$$\operatorname{td}\big(\mathcal{O}_{\mathbb{P}^2}(d)\big)=1+\frac{d}{2}h+\frac{d^2}{12}h^2$$

so that, capping with the fundamental class, $\operatorname{td}(\mathcal{O}_{\mathbb{P}^2}(d))\cap[\mathbb{P}^2]=[\mathbb{P}^2]+\frac{d}{2}[\mathbb{P}^1]+\frac{d^2}{12}[\mathrm{pt}]$. For $d=1$ the zero-dimensional component is $\frac{1}{12}[\mathrm{pt}]$, of degree $\frac{1}{12}$ under $\int_{\mathbb{P}^2}$. Individual Todd components carry denominators that no bundle removes; it is only the full expression appearing in Riemann-Roch, a Todd class multiplied by a Chern character, that is forced to have integral degree.

Proposition 16.1.8: Multiplicativity of the Todd Class

Let $0\to E'\to E\to E''\to 0$ be an exact sequence of vector bundles on an algebraic scheme X. Then

$$\operatorname{td}(E)=\operatorname{td}(E')\operatorname{td}(E'')$$

as operators on $A_*(X)_{\mathbb{Q}}$. In particular $\operatorname{td}(E\oplus F)=\operatorname{td}(E)\operatorname{td}(F)$, and $\operatorname{td}(E\oplus\mathcal{O}_X^{\oplus m})=\operatorname{td}(E)$.

***Proof*:**
Choose, by theorem 12.2.14, a flat proper $f\colon X' \to X$ with f^* injective splitting both E' and E'', with roots $a_1, \dots, a_{r'}$ and $b_1, \dots, b_{r''}$. Part (1) of the proof of theorem 16.1.4 shows that f then splits E, with roots the union of the two lists. Applying proposition 12.2.22(4) three times, to E, to E' and to E'', and using the factorization of the defining product over the union of the two lists,

$$f^*\big(\mathrm{td}(E)\cap\alpha\big) = \Big(\prod_p Q(a_p)\prod_q Q(b_q)\Big)\cap f^*\alpha = f^*\big(\mathrm{td}(E')\,\mathrm{td}(E'')\cap\alpha\big)$$

for every $\alpha \in A_*(X)_{\mathbb{Q}}$, the two operators on the right commuting by proposition 12.2.22(1). Injectivity of f^* gives $\mathrm{td}(E) = \mathrm{td}(E')\mathrm{td}(E'')$. The direct sum is the split case, and a trivial bundle contributes $Q(0)^m = 1$ because $c_1(\mathcal{O}_X) = 0$ by example 11.4.3, completing the proof.

Additivity of ch and multiplicativity of td are what make both computable: any bundle presented by an exact sequence with known ends has both classes determined. The tangent bundle of projective space is presented in exactly that way, and the computation below is the one Riemann-Roch is checked against.

Example 16.1.9: The Tangent Bundle of $\mathbb{P}^n$
Example 12.2.17 has already imported the Euler sequence from theorem 5.5.19, dualized it to

$$0 \longrightarrow \mathcal{O}_{\mathbb{P}^n} \longrightarrow \mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)} \longrightarrow T_{\mathbb{P}^n} \longrightarrow 0$$

and read off $c(T_{\mathbb{P}^n}) = (\mathrm{id}+H)^{n+1}$. What is new here is the Chern character and Todd class the same sequence yields. Here $\mathbb{P}^n$ is projective n-space with its standard twisting sheaf, so the convention of box 9.0.2 does not intervene and no further dualization is needed. Write $h = c_1(\mathcal{O}_{\mathbb{P}^n}(1))$.

The Chern character. By theorem 16.1.4(1), $\mathrm{ch}(\mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)}) = \mathrm{ch}(\mathcal{O}_{\mathbb{P}^n}) + \mathrm{ch}(T_{\mathbb{P}^n})$, and the left side is $(n+1)e^h$ while $\mathrm{ch}(\mathcal{O}_{\mathbb{P}^n}) = 1$. Hence

$$\mathrm{ch}(T_{\mathbb{P}^n}) = (n+1)e^h - 1$$

The Todd class. Proposition 16.1.8 applied to the same sequence gives $\mathrm{td}(\mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)}) = \mathrm{td}(\mathcal{O}_{\mathbb{P}^n})\,\mathrm{td}(T_{\mathbb{P}^n})$, and the trivial bundle has $\mathrm{td}(\mathcal{O}_{\mathbb{P}^n}) = 1$, so

$$\mathrm{td}(T_{\mathbb{P}^n}) = \mathrm{td}\big(\mathcal{O}_{\mathbb{P}^n}(1)^{\oplus(n+1)}\big) = Q(h)^{\,n+1}$$

with Q the series of definition 16.1.5. Both classes are computed from the single operator h, whose powers are known: $h^k \cap [\mathbb{P}^n] = [\mathbb{P}^{n-k}]$ and $h^{n+1} = 0$.

The case $n = 1$. Here $h^2 = 0$, so $\mathrm{ch}(T_{\mathbb{P}^1}) = 2(1+h) - 1 = 1 + 2h$ and $\mathrm{td}(T_{\mathbb{P}^1}) = (1+\frac{h}{2})^2 = 1 + h$. The first agrees with the identification $T_{\mathbb{P}^1} \cong \mathcal{O}_{\mathbb{P}^1}(2)$, whose Chern character is $e^{2h} = 1 + 2h$ by example 16.1.3. The dimension-lowering component of $\mathrm{td}(T_{\mathbb{P}^1})$ caps to $h \cap [\mathbb{P}^1] = [\mathrm{pt}]$, of degree $\int_{\mathbb{P}^1}[\mathrm{pt}] = 1$.

The case $n = 2$. Here $h^3 = 0$ and

$$\mathrm{ch}(T_{\mathbb{P}^2}) = 3\Big(1 + h + \tfrac{h^2}{2}\Big) - 1 = 2 + 3h + \tfrac{3}{2}h^2$$

which cross-checks against proposition 16.1.2: the Whitney formula applied to the Euler sequence gives $c(T_{\mathbb{P}^2}) = (1+h)^3 = 1 + 3h + 3h^2$, so $c_1 = 3h$ and $c_2 = 3h^2$, and then $\mathrm{ch}_0 = 2 = \mathrm{rank} T_{\mathbb{P}^2}$,

$\mathrm{ch}_1 = c_1 = 3h$, and $\mathrm{ch}_2 = \frac{1}{2}(c_1^2 - 2c_2) = \frac{1}{2}(9h^2 - 6h^2) = \frac{3}{2}h^2$. For the Todd class,

$$\mathrm{td}(T_{\mathbb{P}^2}) = \left(1 + \tfrac{h}{2} + \tfrac{h^2}{12}\right)^3 = 1 + \tfrac{3}{2}h + \left(3 \cdot \tfrac{1}{12} + 3 \cdot \tfrac{1}{4}\right)h^2 = 1 + \tfrac{3}{2}h + h^2$$

agreeing with $\mathrm{td}_2 = \frac{1}{12}(c_1^2 + c_2) = \frac{1}{12}(9+3)h^2 = h^2$ from proposition 16.1.6. Capping with the fundamental class,

$$\mathrm{ch}(T_{\mathbb{P}^2}) \cap [\mathbb{P}^2] = 2[\mathbb{P}^2] + 3[\mathbb{P}^1] + \tfrac{3}{2}[\mathrm{pt}], \qquad \mathrm{td}(T_{\mathbb{P}^2}) \cap [\mathbb{P}^2] = [\mathbb{P}^2] + \tfrac{3}{2}[\mathbb{P}^1] + [\mathrm{pt}]$$

in $A_*(\mathbb{P}^2)_{\mathbb{Q}}$.

The check. In both cases the zero-dimensional component of $\mathrm{td}(T_{\mathbb{P}^n}) \cap [\mathbb{P}^n]$ has degree 1 under $\int_{\mathbb{P}^n}$, and $\chi(\mathcal{O}_{\mathbb{P}^n}) = 1$ by theorem 6.3.1. The agreement of these two numbers is the simplest instance of theorem 16.3.1, which computes, for a vector bundle E on a smooth projective X, the integer $\chi(E) = \int_X \mathrm{ch}(E)\,\mathrm{td}(X) \cap [X]$; and it is the reason $t/(1-e^{-t})$, rather than some other multiplicative series, is the one attached to the tangent bundle.

16.1.10 Remark: Operators and Ring Elements Both classes have been defined as operators on $A_*(X)_{\mathbb{Q}}$, and every identity above is an identity of operators, composition serving as multiplication. The reason is generality: this section is stated for an arbitrary algebraic scheme X, and $A_*(X)$ carries no product. For smooth X a product is available, and has been since theorem 14.2.7 in chapter 14. Capping with the fundamental class turns each of these operators into a class, and $\mathrm{ch}(E)$ and $\mathrm{td}(E)$ are then elements of the graded ring $A^*(X)_{\mathbb{Q}}$. No statement in this section changes under that reading: an identity of operators on $A_*(X)_{\mathbb{Q}}$ specializes to an identity of classes by applying it to $[X]$.

So far ch and td are operators attached to a *bundle*. Riemann-Roch needs them attached to a class in K-theory, because the pushforward it compares against lives there and not on bundles: a proper morphism sends a coherent sheaf to an alternating sum of higher direct images, which is a K-theory class and nothing smaller. The passage loses nothing, and the reason is theorem 16.1.4.

Proposition 16.1.11: The Chern Character on K-Theory

Let X be an algebraic scheme. The assignment $E \mapsto \mathrm{ch}(E)$ descends to a homomorphism

$$\mathrm{ch}\colon K^\circ(X) \longrightarrow \mathrm{End}\left(A_*(X)_{\mathbb{Q}}\right)$$

from the Grothendieck group of vector bundles ([10, K_0 of a Scheme]), and it carries the product of $K^\circ(X)$ to composition of operators. If X is a smooth variety, then under proposition 14.3.13 the image lies in $A^*(X)_{\mathbb{Q}}$ and

$$\mathrm{ch}\colon K^\circ(X) \longrightarrow A^*(X)_{\mathbb{Q}}$$

is a homomorphism of rings.

***Proof*:**
$K^\circ(X)$ is the free abelian group on isomorphism classes of vector bundles modulo the relations $[E] = [E'] + [E'']$ for every short exact sequence $0 \to E' \to E \to E'' \to 0$ ([10, K_0 of a Scheme]). Theorem 16.1.4(1) says exactly that ch respects those relations, so it factors through the quotient; the resulting map is a homomorphism of groups because $\mathrm{ch}(E \oplus F) = \mathrm{ch}(E) + \mathrm{ch}(F)$. Multiplicativity is theorem 16.1.4(2), and the product on $K^\circ(X)$ is induced by tensor product ([10, Ring and Module Structures]), so ch is multiplicative. For X smooth, proposition 14.3.13 identifies the operator $\mathrm{ch}(\alpha)$ with multiplication by $\mathrm{ch}(\alpha) \cap [X]$, and both structures match, as we sought to show.

On a smooth variety the distinction between bundles and coherent sheaves also disappears, which is what lets the right-hand side of Riemann-Roch be written at all.

Corollary 16.1.12: The Chern Character of a Coherent Sheaf

Let X be a smooth separated variety. Then $K^\circ(X) \to K_\circ(X)$ is an isomorphism ([10, The Duality Map]), so every coherent sheaf $\mathscr{F}$ has a well-defined Chern character

$$\mathrm{ch}(\mathscr{F}) \;=\; \sum_i (-1)^i \mathrm{ch}(E_i) \;\in\; A^*(X)_{\mathbb{Q}}$$

computed from any finite locally free resolution $E_\bullet \to \mathscr{F}$, and independent of it.

***Proof*:**
A smooth variety is regular, so the duality map is an isomorphism with the stated inverse, and ch of the resulting class is computed by proposition 16.1.11. Independence of the resolution is independence of the class in $K^\circ(X)$, which the cited isomorphism gives.

Exercise 16.1.1

1. Let $h = c_1(\mathcal{O}_{\mathbb{P}^2}(1))$ and let $L = \mathcal{O}_{\mathbb{P}^2}(d)$. Compute $\mathrm{ch}(L) \cap [\mathbb{P}^2]$ and $\mathrm{td}(L) \cap [\mathbb{P}^2]$ in $A_*(\mathbb{P}^2)_{\mathbb{Q}}$, and compute the degree $\int_{\mathbb{P}^2}$ of the zero-dimensional component of $\mathrm{ch}(L)\,\mathrm{td}(T_{\mathbb{P}^2}) \cap [\mathbb{P}^2]$. Determine for which d this last number is an integer.

2. Show that $\mathrm{ch}_k(E^\vee) = (-1)^k \mathrm{ch}_k(E)$ for every vector bundle E and every k. (Dualize a filtration by subbundles and use proposition 11.4.4(3).) Deduce that $\mathrm{ch}(E \otimes E^\vee)$ has $\mathrm{ch}_1 = 0$ for every E.

3. Let E have rank r and let $\det E = \Lambda^r E$. Show that $c_1(\det E) = c_1(E)$ and hence $\mathrm{ch}(\det E) = e^{c_1(E)}$. (Use that the top exterior power of a filtered bundle is the tensor product of the line-bundle quotients.)

4. Compute $\mathrm{ch}(T_{\mathbb{P}^3})$ and $\mathrm{td}(T_{\mathbb{P}^3})$ as polynomials in $h = c_1(\mathcal{O}_{\mathbb{P}^3}(1))$, and verify that $\int_{\mathbb{P}^3}$ of the zero-dimensional component of $\mathrm{td}(T_{\mathbb{P}^3}) \cap [\mathbb{P}^3]$ equals 1. Check the degree-two and degree-three Todd components against proposition 16.1.6 using $c(T_{\mathbb{P}^3}) = (1+h)^4$.

5. Let S be a smooth projective surface and E a vector bundle of rank r on S. Write out the zero-dimensional component of $\mathrm{ch}(E)\,\mathrm{td}(T_S) \cap [S]$ in terms of $c_1(E), c_2(E), c_1(T_S), c_2(T_S)$, and specialize to $E = \mathcal{O}_S$ and to E a line bundle.

6. Show that $\mathrm{ch}(E \oplus \mathcal{O}_X^{\oplus m}) = \mathrm{ch}(E) + m$ and $\mathrm{td}(E \oplus \mathcal{O}_X^{\oplus m}) = \mathrm{td}(E)$, and explain why no bundle of positive rank can have $\mathrm{ch}(E) = 0$.

16.2 Grothendieck-Riemann-Roch

This section defines the Todd class of the relative tangent bundle of a morphism, proves Riemann-Roch for a proper morphism of smooth quasi-projective varieties, and states the extension to local complete intersection morphisms.

Two conventions apply throughout. First, every variety appearing is smooth and quasi-projective over $\overline{k}$, hence regular and separated of finite Krull dimension. So $K^\circ = K_\circ$ on it by corollary 16.1.12, and the pushforward $f_*[\mathscr{F}] = \sum_i (-1)^i [R^i f_* \mathscr{F}]$ of [10, Proper Pushforward] transports along that identification to a homomorphism $f_* \colon K^\circ(X) \to K^\circ(Y)$ for every proper $f \colon X \to Y$. Second, since the varieties are smooth, proposition 14.3.13 and box 16.1.10 identify each of the operators $\mathrm{ch}(\alpha)$ and $\mathrm{td}(E)$ with the class it produces from the fundamental class, and all products below are taken in the graded ring $A^*(X)_{\mathbb{Q}}$ of theorem 14.2.7.

Definition 16.2.1: The Todd Class of a Morphism

Let $f \colon X \to Y$ be a morphism of smooth varieties, with tangent bundles T_X and T_Y (definition 5.5.28). The *relative tangent class* of f is

$$T_f \;=\; [T_X] - [f^* T_Y] \;\in\; K^\circ(X)$$

and the *Todd class of* f is

$$\mathrm{td}(T_f) \;=\; \mathrm{td}(T_X)\,\mathrm{td}(f^* T_Y)^{-1} \;\in\; A^*(X)_{\mathbb{Q}}$$

The second formula is forced by the first once td is known to be defined on K-theory. The group $K^\circ(X)$ is the free abelian group on isomorphism classes of vector bundles modulo the relation $[E] = [E'] + [E'']$ for each exact sequence $0 \to E' \to E \to E'' \to 0$ ([10, K_0 of a Scheme]). The assignment $E \mapsto \mathrm{td}(E)$ takes values in the units of $A^*(X)_{\mathbb{Q}}$, since $\mathrm{td}_0(E) = 1$ by proposition 16.1.6, and converts those relations into products by proposition 16.1.8. So it extends uniquely to a homomorphism from the additive group $K^\circ(X)$ to the multiplicative group of units of $A^*(X)_{\mathbb{Q}}$, and $\mathrm{td}(T_f)$ is the value of that homomorphism at T_f. In particular $\mathrm{td}(T_f)$ depends only on the class T_f, not on any presentation of it.

Three cases fix what the definition computes. If $Y = \operatorname{Spec} \overline{k}$ then $T_Y = 0$ and $\mathrm{td}(T_f) = \mathrm{td}(T_X)$, so the relative class is the absolute one. If $i \colon X \to Y$ is a closed immersion of smooth varieties with normal bundle N, then dualizing the conormal sequence of theorem 5.5.27 gives the exact sequence $0 \to T_X \to i^* T_Y \to N \to 0$, so $\mathrm{td}(i^* T_Y) = \mathrm{td}(T_X)\mathrm{td}(N)$ by proposition 16.1.8 and

$$T_i \;=\; -[N], \qquad \mathrm{td}(T_i) \;=\; \mathrm{td}(N)^{-1}$$

Finally let $p \colon Y \times \mathbb{P}^m \to Y$ be the projection, with ρ the projection to $\mathbb{P}^m$. Over an affine open $\operatorname{Spec} R \subseteq Y$ and an affine open $\operatorname{Spec} S \subseteq \mathbb{P}^m$, a $\overline{k}$-derivation of $R \otimes_{\overline{k}} S$ is determined by, and can be prescribed arbitrarily on, the two factors separately, so $\Omega_{R \otimes S} \cong (\Omega_R \otimes S) \oplus (R \otimes \Omega_S)$. These isomorphisms are compatible on overlaps and glue, giving $T_{Y \times \mathbb{P}^m} = p^* T_Y \oplus \rho^* T_{\mathbb{P}^m}$. Hence $T_p = [\rho^* T_{\mathbb{P}^m}]$, and writing $\zeta = c_1(\rho^* \mathcal{O}_{\mathbb{P}^m}(1))$ and $Q(t) = t/(1 - e^{-t})$ as in definition 16.1.5, pulling

the Euler sequence on $\mathbb{P}^m$ back along the flat ρ gives

$$0 \to \mathcal{O}_P \to \rho^*\mathcal{O}(1)^{\oplus(m+1)} \to \rho^* T_{\mathbb{P}^m} \to 0$$

on P, so proposition 16.1.8 applied there gives

$$\operatorname{td}(T_p) \;=\; Q(\zeta)^{\,m+1}$$

Proper pushforward commutes with any operator built as a polynomial in the Chern classes of bundles on the target and pulled back to the source. This is used repeatedly below, so it is isolated first. Let $g\colon X' \to X$ be a proper morphism, let $G_1, \dots, G_t$ be vector bundles on X, and let Θ be an operator on $A_*(X)_{\mathbb{Q}}$ whose component in each degree is a fixed polynomial with rational coefficients in the Chern classes $c_l(G_r)$. Write $g^*\Theta$ for the operator on $A_*(X')_{\mathbb{Q}}$ given by the same polynomials in the $c_l(g^*G_r)$. Then

$$g_*\big((g^*\Theta)\cap\gamma\big) \;=\; \Theta \cap g_*\gamma \qquad \text{for all } \gamma \in A_*(X')_{\mathbb{Q}} \tag{16.2}$$

Each monomial in the $c_l(g^*G_r)$ is a composite of Chern class operators of pullback bundles, and proposition 12.2.10(2) moves them across g_* one factor at a time. Summing over the monomials of a fixed degree and then over degrees, both sums being finite on a given class by lemma 12.2.20(1), gives (16.2). Every operator used below is of this kind: proposition 12.2.22(1) exhibits $\operatorname{ch}(G)$ and $\operatorname{td}(G)$ in each degree as such a polynomial, the same applies to $\operatorname{td}(G)^{-1}$ because the reciprocal series $\prod_p (1-e^{-a_p})/a_p$ is again symmetric with constant term 1, and ch of a difference $[G_1]-[G_2]$ is the corresponding difference.

What Riemann-Roch asserts is that a single correction of this kind repairs the failure of ch to commute with pushforward, and that the correction is the Todd class of the tangent bundle at each end.

Theorem 16.2.2: Grothendieck-Riemann-Roch

Let $f\colon X \to Y$ be a proper morphism of smooth quasi-projective varieties over $\overline{k}$. Then for every $\alpha \in K^\circ(X)$,

$$\operatorname{ch}\big(f_*\alpha\big)\operatorname{td}(T_Y) \;=\; f_*\big(\operatorname{ch}(\alpha)\operatorname{td}(T_X)\big)$$

in $A^*(Y)_{\mathbb{Q}}$, the pushforward on the left being that of [10, Proper Pushforward] and the one on the right the proper pushforward of cycle classes of definition 10.2.1.
Equivalently, writing $\tau_X(\alpha) = \operatorname{ch}(\alpha)\operatorname{td}(T_X)\cap[X]$ for the *Riemann-Roch map* of a smooth variety, the square

$$\begin{array}{ccc} K^\circ(X) & \xrightarrow{\tau_X} & A_*(X)_{\mathbb{Q}} \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle f_*} \\ K^\circ(Y) & \xrightarrow[\tau_Y]{} & A_*(Y)_{\mathbb{Q}} \end{array}$$

commutes: τ intertwines proper pushforward of K-classes with proper pushforward of cycle classes. The Todd factor is what makes it commute, and without it the square already fails for $X = \mathbb{P}^1$ over a point.

Both sides are homomorphisms $K^\circ(X) \to A^*(Y)_{\mathbb{Q}}$, and neither is a ring homomorphism, so the content is an equality of two additive maps and nothing more can be extracted by multiplying the identity by itself. Taking $Y = \operatorname{Spec}\overline{k}$ turns the left side into the Euler characteristic $\chi(X,\alpha) =$

$\sum_i (-1)^i \dim_{\overline{k}} H^i(X,\alpha)$ and the right side into the degree of a zero-cycle, which is the form section 16.3 works with. The smallest instance is $X=\mathbb{P}^1$ with $\alpha=[\mathcal{O}_{\mathbb{P}^1}(n)]$: the left side is $\chi(\mathbb{P}^1,\mathcal{O}(n))=n+1$, and the right side is the degree of the zero-dimensional part of $(1+nh)(1+h)\cap[\mathbb{P}^1]$ with $h=c_1(\mathcal{O}_{\mathbb{P}^1}(1))$, using $\mathrm{td}(T_{\mathbb{P}^1})=1+h$ from example 16.1.9, which is $n+1$ as well. Without the Todd factor the right side would be n, so the correction is not optional even in dimension one.

Rewriting the identity as $\mathrm{ch}(f_*\alpha)=f_*\big(\mathrm{ch}(\alpha)\mathrm{td}(T_f)\big)$ is legitimate and is how the theorem is usually quoted: by proposition 16.1.8 and (16.2),

$$f_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_f)\big)\,\mathrm{td}(T_Y)=f_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_X)\,\mathrm{td}(f^*T_Y)^{-1}\,\mathrm{td}(f^*T_Y)\big)=f_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_X)\big)$$

and $\mathrm{td}(T_Y)$ is invertible by proposition 16.1.6, so the two forms are equivalent.

The proof factors the morphism, and the square of theorem 16.2.2 is what makes that legitimate. The Riemann-Roch map lands in $A_*(X)_{\mathbb{Q}}$, the theorem reads $\tau_Y(f_*\alpha)=f_*\tau_X(\alpha)$, and in this form it is stable under composition: if it holds for $f\colon X\to Y$ and $g\colon Y\to Z$ then $\tau_Z((gf)_*\alpha)=\tau_Z(g_*f_*\alpha)=g_*\tau_Y(f_*\alpha)=g_*f_*\tau_X(\alpha)=(gf)_*\tau_X(\alpha)$, using functoriality of pushforward in K-theory ([10, Proper Pushforward]) and on Chow groups (theorem 10.2.3). A proper morphism from a quasi-projective source factors as a closed immersion followed by a projection $Y\times\mathbb{P}^m\to Y$, so two cases suffice, and they are the next two lemmas.

The projection is the case where the theorem becomes a computation on $\mathbb{P}^m$ and nothing else. The reduction to that computation rests on the description of $K^\circ(Y\times\mathbb{P}^m)$ by twisted pullbacks, which is K-theory rather than intersection theory and is cited from [10].

Lemma 16.2.3: Riemann-Roch for a Projection

Let Y be a smooth quasi-projective variety, $P=Y\times\mathbb{P}^m$ and $p\colon P\to Y$ the projection. Then for every $\alpha\in K^\circ(P)$,

$$\mathrm{ch}\big(p_*\alpha\big)\,\mathrm{td}(T_Y)\;=\;p_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_P)\big)$$

in $A^*(Y)_{\mathbb{Q}}$.

***Proof*:**

Write $\rho\colon P\to\mathbb{P}^m$ for the second projection and $\zeta=c_1(\rho^*\mathcal{O}_{\mathbb{P}^m}(1))\in A^1(P)$.

Step 1: reduction to twisted pullbacks. Both sides are additive in α, so it suffices to treat α in a generating set of the group $K^\circ(P)$. The generators used are the classes

$$p^*\beta\cdot\rho^*\big[\mathcal{O}_{\mathbb{P}^m}(n)\big],\qquad \beta\in K^\circ(Y),\ n\in\mathbb{Z}$$

These generate $K^\circ(Y\times\mathbb{P}^m)$: by [10, K_0 of a Relative Projective Space] the group $K^\circ(Y\times\mathbb{P}^m)$ is free over $K^\circ(Y)$ on $1,t,\dots,t^m$ for $t=[\rho^*\mathcal{O}(-1)]$, and t is a unit there, so the classes above already exhaust it. The hypotheses of that theorem hold: Y is a smooth quasi-projective variety, hence regular, Noetherian, separated, and of finite Krull dimension.

Step 2: the left-hand side. Fix β and n and put $\alpha=p^*\beta\cdot\rho^*[\mathcal{O}(n)]$. The projection formula in K-theory ([10, Projection Formula]) gives $p_*\alpha=\beta\cdot p_*\rho^*[\mathcal{O}(n)]$, so the remaining task is to identify $p_*\rho^*[\mathcal{O}(n)]$. Over an affine open $U=\operatorname{Spec}R\subseteq Y$ one has $p^{-1}(U)=\mathbb{P}^m_R$ and $\rho^*\mathcal{O}(n)$ restricts to $\mathcal{O}_{\mathbb{P}^m_R}(n)$, so theorem 6.3.1, whose statement requires $m\geq 1$, computes (for $m=0$ the projection is the identity and the lemma is immediate) $H^i\big(p^{-1}(U),\rho^*\mathcal{O}(n)\big)$ as a free R-module:

the degree-n part of $R[x_0,\dots,x_m]$ for $i=0$, the degree-n part of $(x_0\cdots x_m)^{-1}R[x_0^{-1},\dots,x_m^{-1}]$ for $i=m$, and zero otherwise. These modules are compatible with restriction to smaller affines and have R-rank equal to the $\overline{k}$-dimension of the corresponding space for $R=\overline{k}$, so the sheaves $R^ip_*\rho^*\mathcal{O}(n)$, being the sheafifications of $U\mapsto H^i(p^{-1}(U),-)$, are free of rank $h^i(\mathbb{P}^m,\mathcal{O}_{\mathbb{P}^m}(n))$. Counting monomials in the two displayed modules gives

$$\chi\big(\mathbb{P}^m,\mathcal{O}_{\mathbb{P}^m}(n)\big) \;=\; \binom{n+m}{m} \;:=\; \frac{(n+1)(n+2)\cdots(n+m)}{m!}$$

for every $n\in\mathbb{Z}$. For $n\geq 0$ only H^0 survives, of dimension the number of monomials of degree n in $m+1$ variables, which is the displayed product. For $-m\leq n\leq -1$ both displayed modules vanish, and the displayed product has the factor $n+j=0$ with $j=-n$. For $n\leq -m-1$ only H^m survives, of dimension the number of tuples $(a_0,\dots,a_m)$ of integers $a_l\geq 1$ with $\sum_l a_l=-n$, that is $\binom{-n-1}{m}$, so that $\chi=(-1)^m\binom{-n-1}{m}$. Writing $n=-m-1-s$ with $s\geq 0$ turns the displayed product into $(-1)^m\binom{m+s}{m}$, the same number. Hence $p_*\rho^*[\mathcal{O}(n)]=\binom{n+m}{m}[\mathcal{O}_Y]$ and

$$\mathrm{ch}\big(p_*\alpha\big)\,\mathrm{td}(T_Y) \;=\; \binom{n+m}{m}\,\mathrm{ch}(\beta)\,\mathrm{td}(T_Y)$$

Step 3: the right-hand side. By proposition 16.1.11 and the computation of T_P preceding theorem 16.2.2,

$$\mathrm{ch}(\alpha)\,\mathrm{td}(T_P) \;=\; \Big(\mathrm{ch}(p^*\beta)\,\mathrm{td}(p^*T_Y)\Big)\cdot\Big(e^{n\zeta}\,Q(\zeta)^{m+1}\Big)$$

where $\mathrm{ch}(\rho^*\mathcal{O}(n))=e^{n\zeta}$ because $c_1(\rho^*\mathcal{O}(n))=n\zeta$ by proposition 11.4.4(3) and (4), and $\mathrm{td}(\rho^*T_{\mathbb{P}^m})=Q(\zeta)^{m+1}$ as computed there. The first bracket is a polynomial in Chern classes of bundles pulled back from Y, so (16.2) applies to the proper morphism p and gives

$$p_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_P)\big) \;=\; \mathrm{ch}(\beta)\,\mathrm{td}(T_Y)\cdot p_*\Big(e^{n\zeta}Q(\zeta)^{m+1}\cap[P]\Big)$$

Expand $e^{n\zeta}Q(\zeta)^{m+1}=\sum_{k\geq 0}\lambda_k\zeta^k$ with $\lambda_k\in\mathbb{Q}$. The bundle $\mathcal{O}_Y^{\oplus(m+1)}$ has $\mathbb{P}(\mathcal{O}_Y^{\oplus(m+1)})=P$ with tautological class ζ and Segre classes $s_0=1$, $s_i=0$ for $i\neq 0$ (example 12.1.7), so definition 12.1.3 with $r=m$ and $[P]=p^*[Y]$ (proposition 10.3.5(2)) gives $p_*(\zeta^k\cap[P])=s_{k-m}(\mathcal{O}_Y^{\oplus(m+1)})\cap[Y]$, which is $[Y]$ for $k=m$ and zero otherwise. Hence

$$p_*\big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_P)\big) \;=\; \lambda_m\,\mathrm{ch}(\beta)\,\mathrm{td}(T_Y),\qquad \lambda_m=\big[\zeta^m\big]\Big(e^{n\zeta}Q(\zeta)^{m+1}\Big)$$

Step 4: the coefficient. Comparing Steps 2 and 3, the lemma is the numerical identity

$$\big[\zeta^m\big]\Big(e^{n\zeta}\,Q(\zeta)^{m+1}\Big) \;=\; \binom{n+m}{m} \tag{16.3}$$

for all $m\geq 0$ and $n\in\mathbb{Z}$. Work in the field $\mathbb{Q}((\zeta))$ of formal Laurent series and write $\mathrm{res}(g\,d\zeta)$ for the coefficient of ζ^{-1} in g. If $\varphi\in\mathbb{Q}[[\zeta]]$ has $\varphi(0)=0$ and $\varphi'(0)\neq 0$, then substituting φ for u carries $\mathbb{Q}((u))$ into $\mathbb{Q}((\zeta))$ and

$$\mathrm{res}\,\big(G(\varphi)\,\varphi'\,d\zeta\big) \;=\; \mathrm{res}\,\big(G\,du\big)\qquad\text{for all } G\in\mathbb{Q}((u))$$

By linearity it is enough to check $G = u^k$. For $k \neq -1$ one has $\varphi^k\varphi' = \frac{1}{k+1}\big(\varphi^{k+1}\big)'$, and the derivative of a formal Laurent series has no term in ζ^{-1}, so both sides are zero. For $k = -1$, writing $\varphi = \zeta\psi$ with $\psi(0) \neq 0$ gives $\varphi'/\varphi = \zeta^{-1} + \psi'/\psi$ with $\psi'/\psi \in \mathbb{Q}[[\zeta]]$, so both sides are 1.

Now $e^{n\zeta}Q(\zeta)^{m+1} = \zeta^{m+1}g(\zeta)$ with $g(\zeta) = e^{n\zeta}(1-e^{-\zeta})^{-(m+1)}$, so the coefficient of ζ^m on the left of (16.3) is $\operatorname{res}(g\,d\zeta)$. Put $u = \varphi(\zeta) = 1 - e^{-\zeta}$, which lies in $\zeta + \zeta^2\mathbb{Q}[[\zeta]]$ and so satisfies the hypothesis, and note $\varphi' = e^{-\zeta} = 1 - u$ and $e^{n\zeta} = (1-u)^{-n}$. Then $g = G(\varphi)\varphi'$ with $G(u) = (1-u)^{-n-1}u^{-m-1}$, whence

$$\operatorname{res}(g\,d\zeta) \;=\; \operatorname{res}\big((1-u)^{-n-1}u^{-m-1}\,du\big) \;=\; \big[u^m\big](1-u)^{-n-1}$$

Finally, differentiating m times at $u = 0$,

$$\big[u^m\big](1-u)^{-n-1} \;=\; \frac{1}{m!}\,(n+1)(n+2)\cdots(n+m) \;=\; \binom{n+m}{m}$$

which is (16.3), as we sought to show.

The identity (16.3) is the reason the series $t/(1-e^{-t})$ appears in the theorem rather than some other multiplicative series: it is exactly the substitution $u = 1 - e^{-\zeta}$ that turns the coefficient extraction into the binomial coefficient counting monomials on $\mathbb{P}^m$. Setting $n = 0$ recovers the check made at the end of section 16.1, that the top Todd component of $T_{\mathbb{P}^m}$ has degree $1 = \chi(\mathcal{O}_{\mathbb{P}^m})$.

The closed immersion is the other case, and it is where the Todd class enters through a resolution rather than through a coefficient. The case of the zero section of a vector bundle is proved first, and the transfer to a general closed immersion is made by resolving on the deformation space of chapter 13 and restricting the resolution to its two fibres.

Lemma 16.2.4: Riemann-Roch for a Closed Immersion

Let $i\colon X \to Y$ be a closed immersion of smooth quasi-projective varieties. Then for every $\alpha \in K^\circ(X)$,

$$\operatorname{ch}\big(i_*\alpha\big)\operatorname{td}(T_Y) \;=\; i_*\big(\operatorname{ch}(\alpha)\operatorname{td}(T_X)\big)$$

in $A^*(Y)_{\mathbb{Q}}$.

***Proof*:**

Step 1: reduction to the normal bundle. Let $d = \dim Y - \dim X$. By theorem 5.5.27 the ideal sheaf $\mathcal{I}$ of X is locally generated by d elements and $\mathcal{I}/\mathcal{I}^2$ is locally free of rank d. That ideal has height d at every point of X, since X has pure codimension d in the variety Y (theorem 2.6.12). The local rings of Y are regular, hence Cohen-Macaulay, their depth equalling their dimension by [25, Global Dimension of a Regular Local Ring]; and d elements generating an ideal of height d in such a ring form a regular sequence ([25, Height-Many Elements in a Cohen-Macaulay Ring Form a Regular Sequence]), so i is a regular embedding of codimension d (definition 5.1.45) with normal bundle $N = (\mathcal{I}/\mathcal{I}^2)^\vee$. Dualizing the conormal sequence of the same theorem gives $0 \to T_X \to i^*T_Y \to N \to 0$, so $\operatorname{td}(i^*T_Y) = \operatorname{td}(T_X)\operatorname{td}(N)$ by proposition 16.1.8, and therefore

$$i_*\big(\operatorname{ch}(\alpha)\operatorname{td}(T_X)\big) = i_*\Big(\operatorname{ch}(\alpha)\operatorname{td}(N)^{-1}\operatorname{td}(i^*T_Y)\Big) = \operatorname{td}(T_Y)\cdot i_*\Big(\operatorname{ch}(\alpha)\operatorname{td}(N)^{-1}\Big)$$

the second equality by (16.2) applied to the proper morphism i and the bundle T_Y on Y. Since

$\mathrm{td}(T_Y)$ is invertible (proposition 16.1.6), the lemma is equivalent to

$$\mathrm{ch}\big(i_*\alpha\big) \;=\; i_*\Big(\mathrm{ch}(\alpha)\,\mathrm{td}(N)^{-1}\Big) \tag{16.4}$$

Step 2: the zero section, inside the projective completion. Let E be a vector bundle of rank d on a smooth variety X and set

$$P \;=\; \mathbb{P}(E\oplus 1), \qquad \varrho\colon P\to X,$$

the projective completion of definition 12.3.3, a smooth X-scheme, proper over X, containing the total space of E as a dense open. Let $\mathcal{Q}$ be the universal quotient bundle on P, of rank d, and let $f\colon X\to P$ be the zero section of E read inside P. It is a section of ϱ, which is a projective bundle and so smooth of relative dimension d; so f is a regular embedding of codimension d (proposition 5.1.48). Its normal bundle is $f^*\mathcal{Q}$: the conormal sheaf $\mathcal{I}/\mathcal{I}^2$ depends only on a neighbourhood of $f(X)$ in the ambient, the total space of E is such a neighbourhood, being an open subscheme of P containing $f(X)$, and the normal bundle of a zero section is the bundle itself, which is the computation at (13.6). And $f^*\mathcal{Q}=E$, because along the zero section the tautological subbundle of $\varrho^*(E\oplus 1)$ is the trivial summand, whose quotient is E. So $N_f=E$ and this step proves (16.4) for f. It is stated on P rather than on the total space E deliberately: Step 3 below uses it on the projective completion, and restriction $A_*(P)\to A_*(E)$ is only surjective (theorem 10.4.1), so an identity proved on E need not transfer back.

Write $\sigma\in\Gamma(P,\mathcal{Q})$ for the section obtained by projecting the trivial summand of $\varrho^*(E\oplus 1)$ onto $\mathcal{Q}$. Its zero scheme is exactly the zero section: at a point of P the fibre of $\mathcal{Q}$ is the quotient of $E\oplus 1$ by the line the point names, and the image of $(0,1)$ vanishes there precisely when that line is the trivial summand, which is the zero section of E. The comparison is scheme-theoretic, not merely pointwise: on the chart of $P|_U$ used below, where the trivial coordinate is invertible, σ becomes the tuple of affine coordinates, which cuts out the zero section with multiplicity one; on the complementary charts σ is nowhere zero. So $Z(\sigma)=f(X)$, of pure codimension d in P.

First a resolution. Contraction against σ makes

$$0\longrightarrow \Lambda^d\mathcal{Q}^\vee\longrightarrow\cdots\longrightarrow\Lambda^1\mathcal{Q}^\vee\longrightarrow\mathcal{O}_P\longrightarrow f_*\mathcal{O}_X\longrightarrow 0$$

a complex, and it is exact. Exactness is local, and over an affine open $U=\operatorname{Spec}A\subseteq X$ trivializing E the section σ is, on the chart of $P|_U=U\times\mathbb{P}^d$ where the trivial coordinate is invertible, the tuple $(t_1,\dots,t_d)$ of affine coordinates on that chart, so the displayed complex becomes the Koszul complex of that tuple ([17, Koszul Complex]); on the complementary charts σ is nowhere vanishing, so contraction against it is a homotopy equivalence and the complex is exact there as well. On the first chart $t_1,\dots,t_d$ is a regular sequence, t_j being a nonzerodivisor on $A[t_1,\dots,t_d]/(t_1,\dots,t_{j-1})=A[t_j,\dots,t_d]$, with quotient $A=f_*\mathcal{O}_X$, so [17, Exactness of the Koszul Complex] applies. A closed immersion has exact pushforward on quasi-coherent sheaves, being extension by zero on the underlying space, so $R^qf_*\mathcal{O}_X=0$ for $q>0$ and the K-theoretic pushforward of [10, Proper Pushforward] is the single class $[f_*\mathcal{O}_X]$, which is a class in $K^\circ(P)$ under the duality identification of [10, The Duality Map], available because P is smooth and separated. Taking the alternating sum of the classes of the terms,

$$\big[f_*\mathcal{O}_X\big] \;=\; \sum_{j=0}^{d}(-1)^j\big[\Lambda^j\mathcal{Q}^\vee\big] \qquad \text{in } K^\circ(P) \tag{16.5}$$

Next the Chern character of that alternating sum. Let G be a vector bundle of rank d on an algebraic scheme W. The claim is

$$\sum_{j=0}^{d}(-1)^j \mathrm{ch}\big(\Lambda^j G^\vee\big) \;=\; c_d(G)\,\mathrm{td}(G)^{-1} \tag{16.6}$$

as operators on $A_*(W)_{\mathbb{Q}}$. Choose by theorem 12.2.14 a splitting map $g\colon W' \to W$ for G, with g^*G filtered by subbundles with line-bundle quotients $L_1, \dots, L_d$ and $a_p = c_1(L_p)$. Dualizing that filtration term by term gives a filtration of $(g^*G)^\vee$ by subbundles with line-bundle quotients $L_1^\vee, \dots, L_d^\vee$ in the reverse order, dualization preserving exactness because a short exact sequence of vector bundles is locally split. If a bundle H sits in an exact sequence $0 \to M \to H \to H' \to 0$ with M a line bundle, then for each j the sequence

$$0 \longrightarrow M \otimes \Lambda^{j-1}H' \longrightarrow \Lambda^j H \longrightarrow \Lambda^j H' \longrightarrow 0$$

is exact: the right-hand map is Λ^j of $H \to H'$, the left-hand one sends $m \otimes \omega$ to $m \wedge \widetilde{\omega}$ for any lift $\widetilde{\omega}$ of ω to $\Lambda^{j-1}H$, which is well defined because two lifts differ by a section of $M \otimes \Lambda^{j-2}H$ and $\Lambda^2 M = 0$, and exactness is a local statement, checked where the sequence splits. Iterating this along the filtration of $(g^*G)^\vee$ shows that $\Lambda^j(g^*G)^\vee = g^*\Lambda^j G^\vee$ is filtered by subbundles whose line-bundle quotients are the $\bigotimes_{p\in S} L_p^\vee$ with $S \subseteq \{1,\dots,d\}$ of size j. By proposition 11.4.4(3) their first Chern classes are the $-\sum_{p\in S} a_p$. So g is a splitting map for $\Lambda^j G^\vee$ with those Chern roots, and proposition 12.2.22(4) gives, for every $\gamma \in A_*(W)_{\mathbb{Q}}$,

$$g^*\Big(\sum_j (-1)^j \mathrm{ch}(\Lambda^j G^\vee)\cap\gamma\Big) = \Big(\sum_j (-1)^j \sum_{|S|=j} e^{-\sum_{p\in S} a_p}\Big)\cap g^*\gamma = \Big(\prod_{p=1}^{d}\big(1-e^{-a_p}\big)\Big)\cap g^*\gamma$$

the last equality being the expansion of the product. The same proposition applied to $c_d(G)$ and to the symmetric series $\prod_p (1-e^{-a_p})/a_p$ defining $\mathrm{td}(G)^{-1}$ gives $g^*\big(c_d(G)\mathrm{td}(G)^{-1}\cap\gamma\big) = \prod_p a_p \prod_p \frac{1-e^{-a_p}}{a_p}\cap g^*\gamma$, which is the same operator. Injectivity of g^* yields (16.6).

Now combine. Applying ch to (16.5) and using (16.6) for $G = \mathcal{Q}$,

$$\mathrm{ch}\big(f_*[\mathcal{O}_X]\big) \;=\; c_d(\mathcal{Q})\,\mathrm{td}(\mathcal{Q})^{-1}$$

For a general $\alpha \in K^\circ(X)$ one has $\alpha = f^*\varrho^*\alpha$, since $\varrho f = \mathrm{id}_X$, so the projection formula in K-theory ([10, Projection Formula]) gives $f_*\alpha = \varrho^*\alpha \cdot f_*[\mathcal{O}_X]$ and hence, ch being multiplicative (proposition 16.1.11),

$$\mathrm{ch}\big(f_*\alpha\big) \;=\; \mathrm{ch}(\varrho^*\alpha)\,c_d(\mathcal{Q})\,\mathrm{td}(\mathcal{Q})^{-1}$$

On the other side, $f^*(\varrho^*\alpha) = \alpha$ and $f^*\mathcal{Q} = E$, so (16.2) applied to the proper morphism f and the classes $\varrho^*\alpha$ and $\mathcal{Q}$ on P gives

$$f_*\Big(\mathrm{ch}(\alpha)\,\mathrm{td}(E)^{-1}\cap[X]\Big) = \mathrm{ch}(\varrho^*\alpha)\,\mathrm{td}(\mathcal{Q})^{-1}\cap f_*[X]$$

and $f_*[X] = c_d(\mathcal{Q})\cap[P]$ by lemma 14.3.14, applied to the bundle $\mathcal{Q}$ on the smooth variety P and its section σ, whose zero scheme is $f(X)$ of pure codimension d. The two displayed right-hand sides agree, which is (16.4) for f.

Step 3: from the zero section to a general closed immersion. Both sides are additive in α and

$K^\circ(X)$ is generated by classes of vector bundles, so we may take $\alpha = [E]$. The transfer is made by resolving on the deformation space and restricting the resolution to its two fibres.

Let $M = M_X Y$ be the deformation space of definition 13.1.1, the blow-up of $Y \times \mathbb{P}^1$ along $X \times \{\infty\}$, with blow-down p and projection $\pi\colon M \to \mathbb{P}^1$. Four properties of it are used, and each is recorded before it is needed.

(a) M is a nonsingular quasi-projective variety. The centre $X \times \{\infty\}$ is a nonsingular closed subvariety of the nonsingular variety $Y \times \mathbb{P}^1$, so [9, Blow-up Along a Nonsingular Centre] makes M a nonsingular variety of dimension $\dim Y + 1$, with p projective and birational. It is quasi-projective: p is projective, so M is a closed subscheme of $Y \times \mathbb{P}^1 \times \mathbb{P}^r$; writing Y as an open subscheme of a projective variety $\overline{Y}$, iterating the Segre embedding of [9, Products of Projective Varieties] makes $\overline{Y} \times \mathbb{P}^1 \times \mathbb{P}^r$ projective, so the open subscheme $Y \times \mathbb{P}^1 \times \mathbb{P}^r$ is quasi-projective and so is its closed subscheme M. By [9, Quasi-Projective Schemes Carry an Ample Sheaf] it therefore carries an ample invertible sheaf.

(b) M is flat over $\mathbb{P}^1$. Each of the two standard charts of $\mathbb{P}^1$ has coordinate ring $\overline{k}[u]$, a principal ideal domain, over which a module is flat exactly when it is torsion-free. An affine chart of M over such a chart is a domain by (a) into which $\overline{k}[u]$ injects, π being dominant, so it is torsion-free and hence flat. Consequently every locally free sheaf on M is flat over $\mathbb{P}^1$. Record also, for use in the conclusion, that the composite $q\colon M \to Y \times \mathbb{P}^1 \to Y$ is proper, both factors being so.

(c) The constant subscheme is closed in M. Apply lemma 13.2.6 to the closed immersion $i\colon X \to Y$ with $Z = X$. Here $i^{-1}(X) = X$, so the centre is $X \times \{\infty\}$ inside $X \times \mathbb{P}^1$, an effective Cartier divisor; blowing up an invertible ideal changes nothing, by the universal property proposition 8.4.2(4) applied to the identity, so $M_X X = X \times \mathbb{P}^1$. The deleted piece $\mathrm{Bl}_X X$ is empty, the Rees algebra of the zero ideal being $\mathcal{O}_X$ in degree zero and nothing above, so $M_X^\circ X = X \times \mathbb{P}^1$ too. The lemma produces $F\colon X \times \mathbb{P}^1 \to M$ over $i \times \mathrm{id}_{\mathbb{P}^1}$ with $F^{-1}(M_X^\circ Y) = M_X^\circ X = X \times \mathbb{P}^1$, and by (2) of that lemma F is proper because i is; so F has closed image and lands in the open subscheme $M_X^\circ Y$.

It agrees with the closed immersion of theorem 13.1.5(4). Both morphisms are defined on $X \times \mathbb{P}^1$, which is reduced, both land in the separated M, and over $\mathbb{A}^1$ both restrict to $i \times \mathrm{id}$: for F this is lemma 13.2.6(1), and for the immersion of theorem 13.1.5(4) it is that part's own description of its restriction over $\mathbb{A}^1$. Two morphisms from a reduced scheme to a separated scheme that agree on a dense open of the source are equal, and $X \times \mathbb{A}^1$ is dense in $X \times \mathbb{P}^1$. Hence F is a closed immersion onto its image in $M_X^\circ Y$, and a closed immersion into an open subscheme whose image is closed in the ambient is a closed immersion into the ambient. Put $\bar{E} = \mathrm{pr}_X^* E$, so $F_* \bar{E}$ is coherent on M and flat over $\mathbb{P}^1$, being pulled back from X along a projection and pushed forward along a closed immersion over $\mathbb{P}^1$.

(d) The fibre at infinity. Let $\operatorname{Spec} A \subseteq Y$ be an affine open meeting X in the ideal I, and let $U \subseteq \mathbb{P}^1$ be the chart around ∞ with coordinate u. Write $B = A[u]$, so the ideal of the centre is $J = IB + uB$. Because B is free over A on the powers of u, an element of IB divisible by u lies in uIB, whence $IB \cap uB = uIB \subseteq J^2$; comparing u-degrees in $J^2 = I^2B + uIB + u^2B$ likewise gives $J^2 \cap IB = I^2B + uIB$ and $J^2 \cap uB = uIB + u^2B$. So the conormal module splits,

$$J/J^2 \;=\; IB/(I^2B + uIB) \;\oplus\; uB/(uIB + u^2B) \;=\; I/I^2 \;\oplus\; A/I,$$

and these identifications agree on overlaps: the decomposition of the ideal sheaf of the centre into the two pulled-back factors is global, and the splitting is read off from it by the same formula on every chart. The centre is a nonsingular closed subvariety of the nonsingular $Y \times \mathbb{P}^1$, hence regularly embedded, of codimension $d+1$ and with normal bundle $N \oplus 1$ by the computation just

made; so lemma 14.3.5(1) identifies the exceptional divisor of M with $\mathbb{P}(N \oplus 1)$, the projective completion of definition 12.3.3, exactly the ambient of Step 2 for the bundle N. The fibre M_∞ is the pullback of the Cartier divisor $Y \times \{\infty\}$, hence the total transform, so

$$[M_\infty] \;=\; \big[\mathbb{P}(N \oplus 1)\big] \;+\; \big[\mathrm{Bl}_X Y\big] \tag{16.7}$$

both multiplicities being one. The computation is chart by chart. Shrink $\operatorname{Spec} A$ so that I is generated by a regular sequence $b_1, \dots, b_d$, available from Step 1; then J is generated by $b_1, \dots, b_d, u$ and the blow-up is covered by the charts on which $J\mathcal{O}_M$ is generated by one of them. On the chart where the generator is u, every b_i becomes u times a regular function, so the pullback of $\{u = 0\}$ is cut out by u alone: the exceptional divisor occurs with multiplicity one and the strict transform does not meet this chart. On the chart where the generator is b_j, one has $u = b_j u'$ with b_j a local equation for the exceptional divisor and u' a regular function. The exceptional coefficient is already known to be one from the u-chart, which is the complement of $\mathbb{P}(N)$ in the exceptional divisor and so meets the generic point of the irreducible $\mathbb{P}(N \oplus 1)$, so u' carries no exceptional component and cuts out exactly the closure of the locus where u vanishes and the b_i do not, which is the strict transform. It occurs to the first power because p is an isomorphism away from the centre (proposition 8.4.2(2)), in particular at the generic point of that closure, where $Y \times \{\infty\}$ is reduced. So as effective Cartier divisors on M,

$$p^*\big(Y \times \{\infty\}\big) \;=\; \mathbb{P}(N \oplus 1) \;+\; \widetilde{Y_\infty},$$

$\widetilde{Y_\infty}$ denoting the strict transform, and (16.7) is the associated identity of cycles. The strict transform is the deleted piece $\mathrm{Bl}_X Y$ of lemma 13.1.2(2): both are the closure in M of $p^{-1}\big((Y \setminus X) \times \{\infty\}\big)$, and the lemma's final clause makes it closed in M. Because the exceptional multiplicity is one, the closed subschemes M_∞ and $\mathbb{P}(N \oplus 1)$ agree on the open set $M \setminus \mathrm{Bl}_X Y$, which is the fact used below.

Restricting the resolution. By (a) the variety M is regular of finite dimension and carries an ample invertible sheaf, so [9, Finite Locally Free Resolutions on a Regular Scheme] gives a finite resolution $G_\bullet \to F_*\bar{E}$ by locally free sheaves on M. Since M, every G_i and $F_*\bar{E}$ are flat over $\mathbb{P}^1$ by (b) and (c), [25, Restriction of a Resolution to a Fibre] keeps $G_\bullet$ a resolution after restriction to any fibre of π. Over a point of $\mathbb{A}^1$ the fibre is Y: the deleted piece $\mathrm{Bl}_X Y$ lies over $Y \times \{\infty\}$ by lemma 13.1.2(2), so M and $M_X^\circ Y$ agree over $\mathbb{A}^1$, where theorem 13.1.5(1) identifies the family with $Y \times \mathbb{A}^1$; and F restricts there to i by lemma 13.2.6(1). A closed immersion is affine, and pushforward along an affine morphism commutes with arbitrary base change; F lies over $\mathbb{P}^1$, so $F^{-1}(M_t) = X \times \{t\}$ scheme-theoretically and $F_*\bar{E}|_Y = i_*E$. Hence $G_\bullet|_Y$ resolves i_*E.

Restricting further to a *component* of M_∞ is not covered by that statement, and one observation settles both components. Write $\bar{f}\colon X \to \mathbb{P}(N \oplus 1)$ for the zero section and $S \subseteq M_\infty$ for the support of $F_*\bar{E}|_{M_\infty}$. By (c) and theorem 13.1.5(4) that support is the vertex of $C_X Y$, which is N by proposition 12.3.11, applicable since $d \geq 1$ (for $d = 0$ the immersion i is an isomorphism and the lemma is trivial); the vertex of a vector bundle regarded as a cone is its zero section (example 12.3.2(1)), so $S = \bar{f}(X)$, disjoint from $\mathrm{Bl}_X Y$. As over $\mathbb{A}^1$, base change along the affine morphism F identifies $F_*\bar{E}|_{M_\infty}$ with the pushforward of E along the restriction of F over ∞, which by theorem 13.1.5(4) is $\bar{f}$. On the open set $M_\infty \setminus S$ the complex $G_\bullet|_{M_\infty}$ is an exact complex of vector bundles, hence locally split exact, hence stays exact under pullback along any morphism into $M_\infty \setminus S$. Since $\mathrm{Bl}_X Y \subseteq M_\infty \setminus S$, the restriction $G_\bullet|_{\mathrm{Bl}_X Y}$ is acyclic. For the other component, cover $\mathbb{P}(N \oplus 1)$ by the two opens $\mathbb{P}(N \oplus 1) \setminus S$, where the same splitness argument applies and $\bar{f}_*E$ vanishes, and $M_\infty \setminus \mathrm{Bl}_X Y$, which contains S, is open in M_∞ and coincides with

the corresponding open subscheme of $\mathbb{P}(N \oplus 1)$ by the divisor identity of (d); there $G_\bullet$ restricts to a resolution of $F_*\bar{E}$ already. Exactness being local, the restriction $G_\bullet|_{\mathbb{P}(N\oplus 1)}$ resolves $\bar{f}_*E$, which is Step 2's situation for the bundle N.

Conclusion. Write $\mathrm{ch}(G_\bullet) = \sum_i (-1)^i \mathrm{ch}(G_i)$ and let $j_0 \colon Y \hookrightarrow M$, $k \colon \mathbb{P}(N \oplus 1) \hookrightarrow M$ and $l \colon \mathrm{Bl}_X Y \hookrightarrow M$ be the inclusions of (16.7) and of the fibre over 0. Both fibres are Cartier divisors whose associated line bundle is $\pi^*\mathcal{O}_{\mathbb{P}^1}(1)$, so $M_0 \cdot [M] = M_\infty \cdot [M]$ in $A_*(M)$ by proposition 11.4.2; neither contains M, so definition 11.2.1(1) evaluates both sides as the associated cycles and gives $[M_0] = [M_\infty]$. Applying (16.2) to each inclusion,

$$j_{0*}\Big(\mathrm{ch}\big(i_*E\big) \cap [Y]\Big) \;=\; \mathrm{ch}(G_\bullet) \cap [M_0] \;=\; \mathrm{ch}(G_\bullet) \cap [M_\infty] \;=\; k_*\Big(\mathrm{ch}\big(\bar{f}_*E\big) \cap [\mathbb{P}(N \oplus 1)]\Big)$$

the $\mathrm{Bl}_X Y$ term vanishing because an acyclic bounded complex of vector bundles is locally split exact, so its syzygies are locally free and its alternating sum is zero already in $K^\circ(\mathrm{Bl}_X Y)$, hence so is its Chern character. Step 2 evaluates the right-hand side as $k_*\bar{f}_*\big(\mathrm{ch}(E)\mathrm{td}(N)^{-1} \cap [X]\big)$.

Now apply q_*, legitimate because q is proper by (b). On the left $q \circ j_0 = \mathrm{id}_Y$; on the right $q \circ k \circ \bar{f} = i$, by construction of the deformation. Hence

$$\mathrm{ch}\big(i_*E\big) \;=\; i_*\Big(\mathrm{ch}(E)\,\mathrm{td}(N)^{-1}\Big)$$

which is (16.4) for i, as we sought to show.

***Proof of theorem 16.2.2*:**
Step 1: the factorization. Since X is quasi-projective there is a locally closed immersion $j \colon X \to \mathbb{P}^m$ for some m. Put $P = Y \times \mathbb{P}^m$, let $p \colon P \to Y$ be the projection and set $i = (f, j) \colon X \to P$, so that $f = p \circ i$. The morphism i is the composite of the graph $X \to Y \times X$ of f, which is a closed immersion because Y is separated, with $\mathrm{id}_Y \times j$, which is an immersion because immersions are stable under base change, so i is an immersion. It is proper: it factors as $X \to X \times_Y P \to P$, where the first map is the graph of i over Y, a closed immersion because p is separated, and the second is the base change of the proper morphism f. A proper morphism has closed image, and an immersion whose image is closed is a closed immersion, so i is a closed immersion. Finally P is smooth and quasi-projective, being a product of such varieties.

Step 2: composing the two cases. With $\tau_X(\alpha) = \mathrm{ch}(\alpha)\mathrm{td}(T_X) \cap [X]$ as above, lemma 16.2.4 applied to i gives $\tau_P(i_*\alpha) = i_*\tau_X(\alpha)$, and lemma 16.2.3 applied to p and to the class $i_*\alpha \in K^\circ(P)$ gives $\tau_Y(p_*i_*\alpha) = p_*\tau_P(i_*\alpha)$. Both lemmas apply because X, P and Y are smooth and quasi-projective. Combining them,

$$\tau_Y\big(f_*\alpha\big) = \tau_Y\big(p_*i_*\alpha\big) = p_*\tau_P\big(i_*\alpha\big) = p_*i_*\tau_X(\alpha) = f_*\tau_X(\alpha)$$

where the first and last equalities use $f_* = p_* \circ i_*$, in K-theory by [10, Proper Pushforward] and on Chow groups by theorem 10.2.3. The first and last terms of this chain are the two sides of the asserted identity, as we sought to show.

The two cases contribute differently. In the projection case the Todd class is a power series whose m-th coefficient is forced by (16.3). In the closed immersion case it is the Chern character of a Koszul complex, appearing because a sheaf supported on a subvariety is resolved on the ambient one by

exterior powers of the conormal bundle. The factorization argument shows that these two are the only inputs, everything else being the behaviour of τ under composition.

The example below runs the theorem end to end for $Y = \operatorname{Spec}\overline{k}$, where the closed immersion of Step 1 is an isomorphism and the whole content is lemma 16.2.3 over a point. It is checked against a cohomology computation that does not use the theorem.

Example 16.2.5: The Euler Characteristic of $\mathcal{O}_{\mathbb{P}^m}(n)$

Let $f\colon \mathbb{P}^m \to \operatorname{Spec}\overline{k}$ be the structure morphism and $\alpha = [\mathcal{O}_{\mathbb{P}^m}(n)]$. Write $h = c_1(\mathcal{O}_{\mathbb{P}^m}(1))$, so that $h^m \cap [\mathbb{P}^m]$ is the class of a point and $h^{m+1} = 0$ (example 16.1.3).

The left-hand side of theorem 16.2.2 is a number. Since $A^*(\operatorname{Spec}\overline{k})_{\mathbb{Q}} = \mathbb{Q}$ and $T_{\operatorname{Spec}\overline{k}} = 0$, it is $\operatorname{ch}(f_*\alpha) = \chi(\mathbb{P}^m, \mathcal{O}(n))$, the alternating sum of the dimensions of the cohomology groups.

The right-hand side is the degree of a zero-cycle: by definition 10.2.4, f_* of a class in $A_*(\mathbb{P}^m)_{\mathbb{Q}}$ is the degree of its zero-dimensional part, so the right-hand side is

$$\int_{\mathbb{P}^m} \operatorname{ch}\big(\mathcal{O}(n)\big)\,\operatorname{td}(T_{\mathbb{P}^m}) \cap [\mathbb{P}^m] \;=\; \big[h^m\big]\Big(e^{nh}\,Q(h)^{m+1}\Big)$$

using $\operatorname{ch}(\mathcal{O}(n)) = e^{nh}$ and $\operatorname{td}(T_{\mathbb{P}^m}) = Q(h)^{m+1}$ from example 16.1.9, and $\int_{\mathbb{P}^m} h^m \cap [\mathbb{P}^m] = 1$.

For $m = 2$ the two sides read as follows. From example 16.1.9, $\operatorname{td}(T_{\mathbb{P}^2}) = 1 + \frac{3}{2}h + h^2$, and $\operatorname{ch}(\mathcal{O}(n)) = 1 + nh + \frac{n^2}{2}h^2$, so the coefficient of h^2 in the product is

$$\frac{n^2}{2} + \frac{3n}{2} + 1 \;=\; \frac{(n+1)(n+2)}{2}$$

which is $\dim_{\overline{k}}$ of the space of degree-n forms in three variables for $n \geq 0$, that is $\chi(\mathbb{P}^2, \mathcal{O}(n))$. For $m = 3$, with $\operatorname{td}(T_{\mathbb{P}^3}) = 1 + 2h + \frac{11}{6}h^2 + h^3$ and $\operatorname{ch}(\mathcal{O}(n)) = 1 + nh + \frac{n^2}{2}h^2 + \frac{n^3}{6}h^3$, the coefficient of h^3 is

$$\frac{n^3}{6} + \frac{n^2}{2}\cdot 2 + n\cdot\frac{11}{6} + 1 \;=\; \frac{n^3 + 6n^2 + 11n + 6}{6} \;=\; \frac{(n+1)(n+2)(n+3)}{6}$$

again $\chi(\mathbb{P}^3, \mathcal{O}(n))$. Both agree with (16.3), which Step 4 of lemma 16.2.3 proved for all m and n at once. Neither factor has integral coefficients on its own, the Todd coefficients $\frac{3}{2}$ and $\frac{11}{6}$ and the Chern character coefficients $\frac{n^2}{2}$ and $\frac{n^3}{6}$ all being fractions. Only the product has integral degree.

Smoothness of X enters the statement of the theorem in three places: through $\operatorname{td}(T_X)$, through the identification $K^\circ(X) = K_\circ(X)$ that makes $f_*\alpha$ meaningful for $\alpha \in K^\circ(X)$, and through the ring $A^*(X)_{\mathbb{Q}}$ in which the product $\operatorname{ch}(\alpha)\operatorname{td}(T_X)$ is formed. The corollary below drops it, and has to replace all three: $\operatorname{td}(T_X)$ by $\operatorname{td}(T_f)$, the ring product by a cap against $[X]$, and the identification by the map $K^\circ(X) \to K_\circ(X)$. A local complete intersection morphism carries a virtual relative tangent class even when its source is singular, built from a factorization rather than from a tangent bundle, and the theorem holds in that generality.

Corollary 16.2.6: Riemann-Roch for a Local Complete Intersection Morphism

Let Y be a smooth quasi-projective variety, X a variety, and $f\colon X \to Y$ a proper local complete intersection morphism (definition 5.1.50) admitting on all of X a factorization $f = p \circ i$ with $i\colon X \to P$ a regular embedding with normal bundle N_i and $p\colon P \to Y$ smooth, as in definition 14.2.11. Set

$$T_f \;=\; \big[i^*T_{P/Y}\big] - \big[N_i\big] \;\in\; K^\circ(X)$$

Then for every $\alpha \in K^\circ(X)$,

$$\mathrm{ch}\big(f_*\alpha\big) \cap [Y] \;=\; f_*\Big(\mathrm{ch}(\alpha)\,\mathrm{td}(T_f) \cap [X]\Big) \qquad \text{in } A_*(Y)_{\mathbb{Q}}$$

where $f_*\alpha$ means the image of α under

$$K^\circ(X) \longrightarrow K_\circ(X) \xrightarrow{f_*} K_\circ(Y) = K^\circ(Y)$$

the last identification being corollary 16.1.12 applied to the smooth Y. The standing convention of this section identifies K° with $K_\circ$ on the source as well, but X is not assumed smooth here, so that identification is unavailable and the composite above is what the symbol denotes. When X is smooth, T_f agrees with the relative tangent class of definition 16.2.1 and the identity is theorem 16.2.2.

***Proof Cited*:**
The proof is not given here. An l.c.i. morphism need not have smooth source, so the argument of theorem 16.2.2 does not apply: what replaces it is a Riemann-Roch transformation defined on the K-theory of coherent sheaves on a possibly singular X, which this book does not construct. That transformation is built, and the theorem in this generality proved, in [38, the Grothendieck-Riemann-Roch theorem]. The case of a proper morphism of smooth varieties, theorem 16.2.2, is proved above. The present extension is stated only.

The comparison in the last sentence is a computation and is given. If X is smooth, then $0 \to T_X \to i^*T_P \to N_i \to 0$ is exact by theorem 5.5.27, and $0 \to T_{P/Y} \to T_P \to p^*T_Y \to 0$ is exact because p is smooth. Pulling the second back along i and subtracting in $K^\circ(X)$,

$$\big[i^*T_{P/Y}\big] - \big[N_i\big] = \Big(\big[i^*T_P\big] - \big[f^*T_Y\big]\Big) - \Big(\big[i^*T_P\big] - \big[T_X\big]\Big) = \big[T_X\big] - \big[f^*T_Y\big]$$

which is T_f as defined in definition 16.2.1. The displayed identity then becomes $\mathrm{ch}(f_*\alpha) = f_*\big(\mathrm{ch}(\alpha)\mathrm{td}(T_X)\mathrm{td}(f^*T_Y)^{-1}\big)$, which multiplied by $\mathrm{td}(T_Y)$ and rearranged by (16.2) is the statement of theorem 16.2.2, completing the comparison.

The class T_f is what replaces the tangent bundle of the source. Only the difference $[i^*T_{P/Y}] - [N_i]$ enters the identity, never either term on its own, and this is the same shape as definition 14.2.11: the Gysin pullback $f^! = i^! \circ p^*$ is also assembled from a factorization, and by theorem 14.2.12(1) neither it nor the virtual relative dimension, which is the rank of T_f, depends on which factorization is chosen. Independence of the *class* T_f, which is what $\mathrm{td}(T_f)$ and hence the right-hand side above depend on, is a stronger statement and is not proved here. The corollary is read as asserting its identity for whichever factorization has been fixed. See [38, B.7.6].

Exercise 16.2.1

1. Let $f\colon X \to Y$ and $g\colon Y \to Z$ be morphisms of smooth varieties. Show that $T_{g\circ f} = T_f + f^*T_g$ in $K^\circ(X)$, where f^* is pullback of bundles extended to K-theory, and deduce that $\operatorname{td}(T_{g\circ f}) = \operatorname{td}(T_f)\operatorname{td}(f^*T_g)$.

2. Compute the coefficient of h^4 in $Q(h)^5$, where $Q(t) = t/(1-e^{-t})$ and $h = c_1(\mathcal{O}_{\mathbb{P}^4}(1))$, using $Q(t) = 1 + \frac{t}{2} + \frac{t^2}{12} + 0\cdot t^3 - \frac{t^4}{720} + \cdots$. Check the answer against (16.3) with $n = 0$, and say what the check asserts about $\chi(\mathcal{O}_{\mathbb{P}^4})$.

3. Fix $m \geq 1$. Show that $[\zeta^m]\big(e^{n\zeta}Q(\zeta)^{m+1}\big) = 0$ for every integer n with $-m \leq n \leq -1$, and identify the cohomological statement this corresponds to under lemma 16.2.3.

4. Use theorem 16.2.2 for $\mathbb{P}^m \to \operatorname{Spec}\overline{k}$ and the classes computed in example 16.1.9 to evaluate $\chi(\mathbb{P}^2, T_{\mathbb{P}^2})$ and $\chi(\mathbb{P}^3, T_{\mathbb{P}^3})$. Verify both against the Euler sequence, which expresses $T_{\mathbb{P}^m}$ through $\mathcal{O}(1)^{\oplus(m+1)}$ and $\mathcal{O}$.

5. Specialize the Koszul resolution in Step 2 of lemma 16.2.4 to a line bundle L on a smooth variety X, with $\pi\colon L \to X$ the total space and s the zero section. Write down the resulting two-term resolution of $s_*\mathcal{O}_X$, compute $\operatorname{ch}(s_*[\mathcal{O}_X])$ from it, and check directly that the answer equals $c_1(\pi^*L)\operatorname{td}(\pi^*L)^{-1}$.

6. Let $C \subseteq \mathbb{P}^2$ be a smooth plane curve of degree e with inclusion i, so that C is the zero scheme of a section of $\mathcal{O}_{\mathbb{P}^2}(e)$ and its normal bundle is $N = \mathcal{O}_{\mathbb{P}^2}(e)|_C$. Compute $\operatorname{ch}(i_*[\mathcal{O}_C]) \in A^*(\mathbb{P}^2)_{\mathbb{Q}}$ from the exact sequence $0 \to \mathcal{O}_{\mathbb{P}^2}(-e) \to \mathcal{O}_{\mathbb{P}^2} \to i_*\mathcal{O}_C \to 0$, compute $i_*\big(\operatorname{td}(N)^{-1} \cap [C]\big)$ using proposition 12.2.10(2), and check that the two agree as (16.4) predicts.

7. Let $i\colon X \to Y$ be a closed immersion of smooth quasi-projective varieties of codimension d and let $\alpha \in K^\circ(X)$. Using lemma 16.2.4 in the form (16.4), show that $\operatorname{ch}_k(i_*\alpha) = 0$ for $k < d$ and that $\operatorname{ch}_d(i_*\alpha) = \operatorname{rk}(\alpha)\, i_*[X]$.

8. For $f\colon \mathbb{P}^1 \to \operatorname{Spec}\overline{k}$ and $\alpha = [\mathcal{O}_{\mathbb{P}^1}(n)]$, compute $\chi(\mathbb{P}^1, \mathcal{O}(n))$, the degree $\int_{\mathbb{P}^1}\operatorname{ch}(\mathcal{O}(n)) \cap [\mathbb{P}^1]$, and the degree $\int_{\mathbb{P}^1}\operatorname{ch}(\mathcal{O}(n))\operatorname{td}(T_{\mathbb{P}^1}) \cap [\mathbb{P}^1]$. Deduce that ch does not commute with proper pushforward, and that the discrepancy in this case is exactly one.

16.3 Consequences

Setting $Y = \operatorname{Spec}\overline{k}$ in theorem 16.2.2 leaves a statement about a single variety rather than about a morphism: the pushforward in K-theory becomes an alternating sum of dimensions of cohomology groups, and the pushforward on Chow groups becomes the degree of a zero-cycle. What survives is a formula for the Euler characteristic of a coherent sheaf in terms of Chern classes. This section proves that formula and then derives the classical curve and surface statements from the cases $\dim X = 1$ and $\dim X = 2$.

Throughout, X is a smooth projective variety of dimension n over $\overline{k}$, and $T_X = (\Omega^1_{X/\overline{k}})^\vee$ is its tangent bundle, locally free of rank n because X is smooth (definition 5.5.28). On a smooth variety the Chern character and the Todd class take values in the Chow ring: the operator $\operatorname{ch}(\alpha)$ is multiplication by an element of $A^*(X)_{\mathbb{Q}}$ and $\operatorname{ch}\colon K^\circ(X) \to A^*(X)_{\mathbb{Q}}$ is a ring homomorphism (proposition 16.1.11), so both are written as elements from here on. For $\beta \in A^*(X)_{\mathbb{Q}}$ the symbol β_p denotes the component in $A^p(X)_{\mathbb{Q}} = A_{n-p}(X)_{\mathbb{Q}}$, and $\deg\colon A_0(X)_{\mathbb{Q}} \to \mathbb{Q}$ is the $\mathbb{Q}$-linear extension of the degree of a zero-cycle

(definition 10.2.4).

The invariant on the cohomological side is the Euler characteristic

$$\chi(X, \mathscr{F}) \;=\; \sum_{i\geq 0} (-1)^i \dim_{\overline{k}} H^i(X, \mathscr{F})$$

of a coherent sheaf $\mathscr{F}$, a sum in which every dimension is finite (corollary 6.6.7) and all but finitely many vanish, $H^i(X, \mathscr{F})$ being zero above the dimension of a Noetherian space (theorem 6.2.5). That is the alternating sum defining the K-theoretic pushforward along the structure morphism ([10, Proper Pushforward]), so Grothendieck-Riemann-Roch for that morphism already has χ on its left side. Extracting the formula is then a matter of computing what K-theory, the Chow ring and the Todd class do on a point.

Theorem 16.3.1: Hirzebruch-Riemann-Roch

Let X be a smooth projective variety of dimension n over $\overline{k}$ and let $\mathscr{F}$ be a coherent sheaf on X. Then

$$\chi(X, \mathscr{F}) \;=\; \deg\big(\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X)\big)_n$$

the degree of the component of $\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X)$ in $A^n(X)_{\mathbb{Q}} = A_0(X)_{\mathbb{Q}}$.

***Proof*:**

Step 1: Grothendieck-Riemann-Roch for the structure morphism. Write $P = \operatorname{Spec}\overline{k}$ and let $f\colon X \to P$ be the structure morphism. Then P is a smooth variety of dimension zero, X is a smooth variety, and X is projective over $\overline{k}$, so X is quasi-projective and f is proper. Being smooth over $\overline{k}$, X is regular; being projective, it is of finite dimension and carries an ample invertible sheaf, and P is quasi-projective too. So every coherent sheaf on X admits a finite locally free resolution ([9, Finite Locally Free Resolutions on a Regular Scheme]); on the point P the same holds trivially, every module over a field being free. That resolution property is the hypothesis of [10, The Duality Map], so $K^\circ \to K_\circ$ is an isomorphism on each; in particular $\mathscr{F}$ determines a class $\alpha \in K^\circ(X)$ whose Chern character is $\mathrm{ch}(\mathscr{F})$ (corollary 16.1.12). Applying theorem 16.2.2 to f and α gives

$$\mathrm{ch}(f_*\alpha)\,\mathrm{td}(T_P) \;=\; f_*\big(\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X)\big)$$

in $A^*(P)_{\mathbb{Q}}$.

Step 2: the Chow ring of a point, and $\mathrm{td}(T_P) = 1$. The scheme P is a single point, whose only subvariety is P itself, so $A_0(P) = Z_0(P) = \mathbb{Z}\,[P]$ and $A_k(P) = 0$ for $k \neq 0$ (definition 10.2.4). Hence $A^*(P)_{\mathbb{Q}} = A^0(P)_{\mathbb{Q}} = \mathbb{Q}$, the class $[P]$ corresponding to 1. Every Todd class has $\mathrm{td}_0 = 1$ (proposition 16.1.6), and its components in positive codimension lie in $A^{>0}(P)_{\mathbb{Q}} = 0$, so $\mathrm{td}(T_P) = 1$ and the left side of the displayed identity is $\mathrm{ch}(f_*\alpha)$.

Step 3: the left side is $\chi(X, \mathscr{F})$. A coherent sheaf on P is a finite-dimensional $\overline{k}$-vector space V, and $V \cong \overline{k}^{\dim V}$, so $[V] = (\dim V)\,[\overline{k}]$ in $K_\circ(P)$; conversely $\dim_{\overline{k}}$ is additive on short exact sequences of vector spaces, so it descends to a homomorphism $K_\circ(P) \to \mathbb{Z}$ inverse to $m \mapsto m\,[\overline{k}]$. Thus $\dim_{\overline{k}}$ identifies $K_\circ(P)$, and with it $K^\circ(P)$, with $\mathbb{Z}$. Proper pushforward in K-theory is $f_*[\mathscr{F}] = \sum_i (-1)^i [R^i f_* \mathscr{F}]$ ([10, Proper Pushforward]), and $R^i f_* \mathscr{F}$ is the sheaf on P attached

to the vector space $H^i(X,\mathscr{F})$, since R^if_* is the sheaf associated to $U\mapsto H^i(f^{-1}U,\mathscr{F})$ and P has exactly one nonempty open set. Therefore $\dim_{\overline{k}} f_*\alpha=\chi(X,\mathscr{F})$. Finally $\mathrm{ch}_0(E)=\mathrm{rk}E$ (proposition 16.1.2) while ch_k lands in $A^k(P)_{\mathbb{Q}}=0$ for $k>0$, so $\mathrm{ch}\colon K^\circ(P)\to A^*(P)_{\mathbb{Q}}=\mathbb{Q}$ is exactly the map $\dim_{\overline{k}}$, giving $\mathrm{ch}(f_*\alpha)=\chi(X,\mathscr{F})$.

Step 4: the right side is a degree. Proper pushforward of cycles preserves dimension (definition 10.2.1), so f_* annihilates $A_k(X)_{\mathbb{Q}}$ for $k>0$ because $A_k(P)_{\mathbb{Q}}=0$ there, and on $A_0(X)_{\mathbb{Q}}$ it is deg (definition 10.2.4). Writing $\beta=\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X)$, the component β_p lies in $A_{n-p}(X)_{\mathbb{Q}}$, so only β_n contributes and $f_*\beta=\deg(\beta_n)$. Combining this with Step 3 and Step 2 gives $\chi(X,\mathscr{F})=\deg(\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X))_n$, as we sought to show.

The left side of the formula is built from the cohomology of $\mathscr{F}$, and the right side is a polynomial in the Chern classes of $\mathscr{F}$ and of T_X evaluated on the fundamental class. Two consequences follow. First, $\chi(X,\mathscr{F})$ depends on $\mathscr{F}$ only through its Chern character, so two coherent sheaves with the same Chern character have the same Euler characteristic however different their individual cohomology groups. Second, only the top component of the product contributes, so on an n-dimensional X the Chern classes c_i with $i>n$ never enter, and the formula is a finite computation with $n+1$ terms. What the theorem does not do is compute the individual dimensions $h^i(X,\mathscr{F})$; separating them out of the alternating sum requires vanishing theorems, which are not part of this book.

In dimension one only two terms survive, and the identity they produce is the theorem for curves. Recall that the genus of a smooth projective curve C over $\overline{k}$ is $g=\dim_{\overline{k}}H^1(C,\mathcal{O}_C)$; Serre duality identifies this with $\dim_{\overline{k}}H^0(C,\omega_C)$ (corollary 6.5.10), which is the other standard normalization. For a line bundle L on C the class $c_1(L)$ lies in $A^1(C)=A_0(C)$, and $\deg L$ means $\deg c_1(L)$; when $L\cong\mathcal{O}_C(D)$ this is the degree of the divisor D, since $c_1(L)\cap[C]=D\cdot[C]=[D]$ (definition 11.4.1).

Corollary 16.3.2: Riemann-Roch for Curves

Let C be a smooth projective curve of genus g over $\overline{k}$, with canonical bundle $\omega_C=\Omega^1_{C/\overline{k}}=T_C^\vee$ and canonical class $K_C=c_1(\omega_C)\in A^1(C)$. Then:

1. $\deg K_C=2g-2$;
2. $\chi(C,L)=\deg L+1-g$ for every line bundle L on C.

***Proof*:**
Since $\dim C=1$, $A^p(C)=A_{1-p}(C)=0$ for $p\geq 2$. A line bundle has the single Chern root $c_1(L)$, so $\mathrm{ch}(L)=e^{c_1(L)}=1+c_1(L)$ in $A^*(C)_{\mathbb{Q}}$ (proposition 16.1.2), the terms $c_1(L)^k/k!$ with $k\geq 2$ lying in $A^{\geq 2}(C)_{\mathbb{Q}}=0$; for the same reason $\mathrm{td}(T_C)=1+\frac{1}{2}c_1(T_C)$ (proposition 16.1.6). Multiplying and taking the component in $A^1(C)_{\mathbb{Q}}$,

$$\big(\mathrm{ch}(L)\,\mathrm{td}(T_C)\big)_1 \;=\; c_1(L)+\tfrac{1}{2}c_1(T_C)$$

so theorem 16.3.1 with $n=1$ gives $\chi(C,L)=\deg L+\frac{1}{2}\deg c_1(T_C)$ for every L.

1. Take $L=\mathcal{O}_C=\mathcal{O}_C(0)$, whose first Chern class is the operator attached to the zero divisor and so vanishes (definition 11.4.1), giving $\deg L=0$. The displayed formula then reads $\chi(C,\mathcal{O}_C)=\frac{1}{2}\deg c_1(T_C)$. On the other hand $H^0(C,\mathcal{O}_C)=\overline{k}$ by theorem 3.5.33, whose hypotheses a smooth projective curve over an algebraically closed field meets, being

reduced and connected. Hence $\chi(C,\mathcal{O}_C) = 1-g$ and $\deg c_1(T_C) = 2-2g$. Since $\omega_C = T_C^\vee$ gives $K_C = -c_1(T_C)$ (proposition 11.4.4(3)), $\deg K_C = 2g-2$.

2. Substituting $\frac{1}{2}\deg c_1(T_C) = 1-g$ from (1) into the displayed formula gives $\chi(C,L) = \deg L + 1 - g$, as we sought to show.

This is the statement theorem 6.7.12 proves cohomologically, in a different notation. There the theorem reads $h^0(C,\mathcal{O}_C(D)) - h^0(C,\mathcal{O}_C(K-D)) = \deg D + 1 - g$ for a divisor D and a canonical divisor K. Serre duality gives $H^1(C,L) \cong H^0(C,\omega_C \otimes L^\vee)^*$ (corollary 6.5.10), and $\omega_C \otimes L^\vee \cong \mathcal{O}_C(K-D)$ for $L = \mathcal{O}_C(D)$, so the left side there is $h^0(C,L) - h^1(C,L) = \chi(C,L)$ and the two statements agree term by term. The difference is in what each proof uses: the cohomological argument is internal to the curve, whereas corollary 16.3.2 is the one-dimensional case of a formula holding in every dimension, and the genus enters it only as $\frac{1}{2}\deg c_1(T_C)$.

Dimension two brings in the second Todd component, which involves c_2. Stating the result in the classical shape needs the translation between the tangent bundle and the canonical class. For a vector bundle E of rank r,

$$c_1(\det E) = c_1(E), \qquad c_1(E^\vee) = -c_1(E)$$

The second is the case $i=1$ of corollary 12.2.16, and the first follows from the splitting principle in the same way: on a flat $\pi\colon X' \to X$ with π^* injective and π^*E filtered with line-bundle quotients $L_1,\dots,L_r$ one has $\det \pi^*E \cong L_1 \otimes \cdots \otimes L_r$, the determinant being multiplicative on short exact sequences, so proposition 11.4.4(3) and the filtered-bundle formula (lemma 12.2.11) give $c_1(\det \pi^*E) = \sum_i c_1(L_i) = c_1(\pi^*E)$. Pullback commutes with det, being a tensor functor and so compatible with exterior powers, and it commutes with c_1 by proposition 12.2.10(3), π being flat. Applied to $\Omega^1_{S/\overline{k}} = T_S^\vee$ on a smooth projective surface S, they give the canonical class

$$K_S \;=\; c_1(\omega_S) \;=\; -c_1(T_S), \qquad \omega_S = \det \Omega^1_{S/\overline{k}}$$

Following the standard surface notation, juxtaposition denotes the product in $A^*(S)$ and a dot between two classes in $A^1(S)$ denotes the degree of their product, $\alpha\cdot\beta = \deg(\alpha\beta) \in \mathbb{Z}$; thus $K_S^2 = K_S \cdot K_S$ is an integer, and for line bundles L, M the number $L\cdot M$ means $c_1(L)\cdot c_1(M)$.

Corollary 16.3.3: Noether's Formula

Let S be a smooth projective surface over $\overline{k}$, and write $c_2(S) = \deg c_2(T_S)$. Then

$$\chi(S,\mathcal{O}_S) \;=\; \frac{1}{12}\big(K_S^2 + c_2(S)\big)$$

***Proof*:**
The structure sheaf is a line bundle with $c_1(\mathcal{O}_S) = 0$ (definition 11.4.1, taking the divisor to be 0), so $\operatorname{ch}(\mathcal{O}_S) = e^0 = 1$ and $\operatorname{ch}(\mathcal{O}_S)\operatorname{td}(T_S) = \operatorname{td}(T_S)$. By proposition 16.1.6 the component of $\operatorname{td}(T_S)$ in $A^2(S)_{\mathbb{Q}}$ is $\frac{1}{12}\big(c_1(T_S)^2 + c_2(T_S)\big)$, so theorem 16.3.1 with $n=2$ gives

$$\chi(S,\mathcal{O}_S) \;=\; \frac{1}{12}\deg\big(c_1(T_S)^2 + c_2(T_S)\big)$$

Now $c_1(T_S) = -K_S$, so $c_1(T_S)^2 = K_S K_S$ and $\deg c_1(T_S)^2 = K_S\cdot K_S = K_S^2$, while $\deg c_2(T_S) = c_2(S)$ by definition. Hence $\chi(S,\mathcal{O}_S) = \frac{1}{12}(K_S^2 + c_2(S))$, completing the proof.

The left side is a sum of three dimensions of cohomology groups and the right side is a pair of intersection numbers, so the formula constrains which pairs $(K_S^2, c_2(S))$ can occur: their sum is divisible by 12 for every smooth projective surface. Over $\mathbb{C}$ the number $c_2(S)$ is the topological Euler characteristic of $S(\mathbb{C})$, which is the form in which theorem 8.3.3 is stated there; the identification of the degree of the top Chern class with that Euler characteristic is a topological input, and it is not proved in this book. The version above is the algebraic one and needs no base change to $\mathbb{C}$: $c_2(S)$ is a degree of a zero-cycle over any algebraically closed $\overline{k}$.

Riemann-Roch for a general line bundle on a surface follows by the same computation with $\mathrm{ch}(L)$ in place of 1.

Example 16.3.4: Riemann-Roch for a Line Bundle on a Surface

Let S be a smooth projective surface and L a line bundle on S, and abbreviate $\ell = c_1(L)$. As in corollary 16.3.2, L has the single Chern root ℓ, so $\mathrm{ch}(L) = e^{\ell} = 1 + \ell + \frac{1}{2}\ell^2$, the terms of codimension at least 3 vanishing because $A^p(S) = 0$ for $p \geq 3$. By proposition 16.1.6 the Todd class has $\mathrm{td}_1(T_S) = \frac{1}{2}c_1(T_S) = -\frac{1}{2}K_S$, so the component of the product in $A^2(S)_{\mathbb{Q}}$ is

$$\big(\mathrm{ch}(L)\,\mathrm{td}(T_S)\big)_2 \;=\; \tfrac{1}{2}\ell^2 - \tfrac{1}{2}\ell K_S + \mathrm{td}_2(T_S)$$

the three summands coming from $\mathrm{ch}_2(L)\mathrm{td}_0$, $\mathrm{ch}_1(L)\mathrm{td}_1$ and $\mathrm{ch}_0(L)\mathrm{td}_2$. The proof of corollary 16.3.3 computed $\deg \mathrm{td}_2(T_S) = \frac{1}{12}(K_S^2 + c_2(S))$, which that corollary identifies with $\chi(S, \mathcal{O}_S)$, so taking degrees and applying theorem 16.3.1 on the left gives

$$\chi(S, L) \;=\; \chi(S, \mathcal{O}_S) + \tfrac{1}{2}\, L \cdot (L - K_S)$$

where $L \cdot (L - K_S)$ abbreviates $\deg\big(\ell(\ell - K_S)\big) = L \cdot L - L \cdot K_S$.

Take $S = \mathbb{P}^2$ and $h = c_1(\mathcal{O}_{\mathbb{P}^2}(1))$, so that h^2 is the class of a point and $\deg h^2 = 1$ (example 16.1.3). The Euler sequence computation recorded in example 16.1.9 gives

$$c(T_{\mathbb{P}^2}) \;=\; (1+h)^3 \;=\; 1 + 3h + 3h^2$$

so $c_1(T_{\mathbb{P}^2}) = 3h$, $K_{\mathbb{P}^2} = -3h$ and $c_2(T_{\mathbb{P}^2}) = 3h^2$. Hence $K_{\mathbb{P}^2}^2 = \deg(9h^2) = 9$ and $c_2(\mathbb{P}^2) = \deg(3h^2) = 3$, and corollary 16.3.3 gives $\chi(\mathbb{P}^2, \mathcal{O}_{\mathbb{P}^2}) = \frac{1}{12}(9+3) = 1$. For $L = \mathcal{O}_{\mathbb{P}^2}(d)$ one has $c_1(L) = d\,h$ (example 16.1.3), so $L \cdot L = d^2$ and $L \cdot K_{\mathbb{P}^2} = -3d$, and the formula above reads

$$\chi\big(\mathbb{P}^2, \mathcal{O}_{\mathbb{P}^2}(d)\big) \;=\; 1 + \tfrac{1}{2}\big(d^2 + 3d\big) \;=\; \tfrac{1}{2}(d+1)(d+2)$$

For $d \geq 0$ this is $\binom{d+2}{2}$, the number of monomials of degree d in three variables, matching (16.3) at $m = 2$, whose values for $m = 2$ and $m = 3$ are computed in example 16.2.5. Both sides of that comparison are Riemann-Roch computations, so it checks the arithmetic rather than giving a second proof.

The surface formula shows that $\chi(S, L)$ depends on L only through the two intersection numbers $L \cdot L$ and $L \cdot K_S$, so two line bundles agreeing in both have the same Euler characteristic. It also constrains those numbers: $\chi(S, L)$ and $\chi(S, \mathcal{O}_S)$ are integers, so $L \cdot (L - K_S)$ is even for every line bundle on every smooth projective surface.

16.3.5 Note: Singular Riemann-Roch Every statement in this section assumes X smooth, and the assumption is used twice: to have a tangent bundle whose Todd class can be formed, and to have $K^\circ(X) = K_\circ(X)$ so that a coherent sheaf has a Chern character. On a singular X neither is available, and $\mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X)$ has no meaning. Baum, Fulton and MacPherson replace the product by a single homomorphism $\tau_X : K_\circ(X) \to A_*(X)_{\mathbb{Q}}$, defined for every quasi-projective scheme X over a field and covariant for proper morphisms in the sense that $\tau_Y \circ f_* = f_* \circ \tau_X$; when X is smooth, $\tau_X([\mathscr{F}]) = \mathrm{ch}(\mathscr{F})\,\mathrm{td}(T_X) \cap [X]$, so that naturality specializes to theorem 16.2.2. The class $\tau_X([\mathcal{O}_X])$ plays the role of the Todd class of a singular variety, its top-dimensional component being $[X]$, and for X proper the degree of $\tau_X([\mathscr{F}])$ is $\chi(X, \mathscr{F})$. The construction rests on localized Chern characters and on MacPherson's graph construction, neither of which is developed here; see [38].

Exercise 16.3.1

1. Let C be a smooth projective curve of genus g over $\overline{k}$ and let E be a vector bundle of rank r on C, with $\deg E = \deg c_1(E)$. Show that

$$\chi(C, E) \;=\; \deg E + r(1-g)$$

and conclude that $\chi(C, E)$ depends on E only through its rank and degree. (Compute $\mathrm{ch}(E)$ in $A^*(C)_{\mathbb{Q}}$ using proposition 16.1.2, and use corollary 16.3.2(1) together with $K_C = -c_1(T_C)$, so that $\deg c_1(T_C) = 2 - 2g$.)

2. Let S be a smooth projective surface and let $C \subseteq S$ be a smooth curve of genus g, regarded as an effective divisor with associated line bundle $\mathcal{O}_S(C)$ and class $c_1(\mathcal{O}_S(C)) \in A^1(S)$. Using the exact sequence

$$0 \longrightarrow \mathcal{O}_S(-C) \longrightarrow \mathcal{O}_S \longrightarrow \mathcal{O}_C \longrightarrow 0$$

the additivity of χ on short exact sequences of coherent sheaves (proposition 6.7.2), the equality $\chi(S, \mathcal{O}_C) = \chi(C, \mathcal{O}_C)$ for a closed immersion, cohomology being unchanged by pushforward along one, together with $\chi(C, \mathcal{O}_C) = 1 - g$ from corollary 16.3.2(2) and $c_1(\mathcal{O}_S(-C)) = -c_1(\mathcal{O}_S(C))$ from proposition 11.4.4(3), and example 16.3.4, prove the adjunction formula

$$2g - 2 \;=\; C \cdot (C + K_S)$$

This is theorem 8.2.8, proved there from the conormal sequence; what the exercise adds is that Riemann-Roch reaches it by a different route, the genus entering only through $\chi(C, \mathcal{O}_C) = 1 - g$.

3. Let $C \subseteq \mathbb{P}^2$ be a smooth plane curve of degree d, so that $\mathcal{O}_{\mathbb{P}^2}(C) \cong \mathcal{O}_{\mathbb{P}^2}(d)$. Using exercise 16.3.1 (2) and the Chern data of $T_{\mathbb{P}^2}$ computed in example 16.3.4, show that the genus of C is $g = \frac{1}{2}(d-1)(d-2)$. Check the answer for $d = 1, 2, 3$ against the genera of a line, a smooth conic and a smooth plane cubic. The formula is classical, and [9] reaches it both from adjunction and from the Hilbert polynomial; the point here is that it needs nothing once the previous question is done.

4. Let $S = \mathbb{P}^1 \times \mathbb{P}^1$ with projections p_1, p_2, and let $f_i = c_1(p_i^* \mathcal{O}_{\mathbb{P}^1}(1)) \in A^1(S)$, Show first that $f_i^2 = 0$, pulling back $h^2 = 0$ from $\mathbb{P}^1$ along the flat p_i (proposition 12.2.10(3)), and that $f_1 f_2$ is the class of a point, so $\deg(f_1 f_2) = 1$. Then, using $T_S \cong p_1^* T_{\mathbb{P}^1} \oplus p_2^* T_{\mathbb{P}^1}$, the value $c(T_{\mathbb{P}^1}) = 1 + 2h$ from example 16.1.9, the Whitney formula (theorem 12.2.15) and flat pullback

again, compute K_S^2 and $c_2(S)$, and deduce $\chi(S, \mathcal{O}_S) = 1$ from corollary 16.3.3. Then show that the line bundle L with $c_1(L) = af_1 + bf_2$ has $\chi(S, L) = (a+1)(b+1)$.

5. Let S be a smooth projective surface and L a line bundle on S. Show from example 16.3.4 that
$$\chi\big(S, \omega_S \otimes L^\vee\big) \;=\; \chi(S, L)$$
and explain why Serre duality (corollary 6.5.10) predicts this equality. (Use proposition 11.4.4(3) to compute $c_1(\omega_S \otimes L^\vee)$.)

6. Let S be a smooth projective surface. The text asserts the first two statements below; give the arguments.

   1. Deduce from corollary 16.3.3 that $K_S^2 + c_2(S)$ is divisible by 12.
   2. Deduce from example 16.3.4 that $L \cdot (L - K_S)$ is even for every line bundle L on S.
   3. Verify both statements for $S = \mathbb{P}^2$ and $L = \mathcal{O}_{\mathbb{P}^2}(d)$.

17

Enumerative Geometry and Degeneracy Loci

Enumerative geometry asks how many geometric objects satisfy a list of conditions, and it is the oldest motivation for everything in this book. How many lines meet four given lines in space; how many conics are tangent to five given conics; how many lines lie on a smooth cubic surface. The nineteenth century answered such questions by a principle of conservation of number, moving the given data into special position, counting there, and asserting that the count was unchanged. The arguments were right often enough to build a subject and wrong often enough to discredit it, and Hilbert's fifteenth problem asked for the foundation that would separate the two.

The Chow ring is that foundation, and this chapter spends it. A counting problem becomes a product of classes in the Chow ring of a parameter space, and the answer is the degree of that product. What the classical arguments could not give, and what chapter 14 now does, is the guarantee that the product is well defined and independent of the position of the data.

Two parameter spaces carry almost all of the classical problems, and section 17.1 builds the first. The Grassmannian of r-planes has a cell decomposition whose closures, the Schubert varieties, give a free basis of its Chow ring; the multiplication in that basis is Schubert calculus, and section 17.2 makes it explicit enough to compute with. Section 17.3 then treats the general mechanism behind such counts: a condition on a map of bundles cuts out a locus whose class is a determinant in the Chern classes, the Thom–Porteous formula, of which the rectangular Schubert classes are the case of a Grassmannian. Section 17.4 returns to the classical questions and answers them, including the twenty-seven lines that [30, The Twenty-Seven Lines] found by hand.

A word on what is not here. The five-conic problem is famous partly because the naive parameter space gives the wrong answer, and the repair is a better parameter space rather than a better count. That repair is the beginning of moduli theory, and the chapter says where it goes without building it.

17.1 The Chow Ring of the Grassmannian

Fix an n-dimensional vector space V over $\overline{k}$ and an integer r with $0 < r < n$. This section decomposes $\mathrm{Gr}(r,n)$ into affine cells indexed by the partitions fitting in an $r \times (n-r)$ box, produces from that decomposition a free basis of $A^*(\mathrm{Gr}(r,n))$, and identifies the one-row basis elements with the Chern classes of the tautological quotient bundle.

The Grassmannian $\mathrm{Gr}(r,n)$ parametrizes the r-dimensional subspaces $W \subseteq V$. It is an irreducible projective variety of dimension $r(n-r)$, embedded in $\mathbb{P}(\Lambda^r V)$ by the Plücker map [30, Plücker Embedding], [30, The Grassmannian Is a Projective Variety]. Its construction [30, Grassmannian] provides affine charts, one family for each basis of V: given a basis $e_1, \dots, e_n$ of V and an r-element subset $a = \{a_1 < \cdots < a_r\} \subseteq \{1, \dots, n\}$, put $E_a = \langle e_j \,|\, j \notin a \rangle$ and

$$U_a = \{W \in \mathrm{Gr}(r,n) \,|\, W \oplus E_a = V\}$$

an open subset of $\mathrm{Gr}(r,n)$. Every $W \in U_a$ has a unique basis $w_1, \dots, w_r$ of the form $w_i = e_{a_i} + \sum_{j \notin a} c_{ij} e_j$, and $(c_{ij})_{i \le r,\, j \notin a}$ identifies U_a with $\mathbb{A}^{r(n-r)}$. For a fixed basis the $\binom{n}{r}$ charts U_a cover $\mathrm{Gr}(r,n)$, so $\mathrm{Gr}(r,n)$ is smooth of dimension $r(n-r)$. Write $N = r(n-r)$ for the dimension, $\mathcal{O} = \mathcal{O}_{\mathrm{Gr}(r,n)}$, and let

$$0 \to S \to V \otimes \mathcal{O} \to Q \to 0$$

be the tautological sequence, in which the fibre of S at W is W itself and Q has rank $n-r$ (theorem 5.3.56).

Since $\mathrm{Gr}(r,n)$ is smooth, theorem 14.2.7 and proposition 14.3.13 give the intersection product on $A^*(\mathrm{Gr}(r,n)) = \bigoplus_p A^p(\mathrm{Gr}(r,n))$ with $A^p = A_{N-p}$, and Chern classes may be treated as ring elements: $c_i(E)$ denotes $c_i(E) \cap [\mathrm{Gr}(r,n)] \in A^i(\mathrm{Gr}(r,n))$, and capping a class with $c_i(E)$ is multiplication by that element.

A subvariety of $\mathrm{Gr}(r,n)$ can be cut out by conditions on how W meets a fixed collection of subspaces of V. Taking that collection to be a complete flag and prescribing the pattern of intersection dimensions produces a locally closed subset that is an affine space, and letting the pattern vary covers the whole Grassmannian exactly once.

Definition 17.1.1: Schubert Cell and Schubert Variety

A *complete flag* in V is a chain of subspaces $F_\bullet\colon 0 = F_0 \subset F_1 \subset \cdots \subset F_n = V$ with $\dim F_j = j$. A partition $\lambda = (\lambda_1 \ge \lambda_2 \ge \cdots \ge \lambda_r \ge 0)$ *lies in the* $r \times (n-r)$ *box* if $\lambda_1 \le n-r$; its size is $|\lambda| = \lambda_1 + \cdots + \lambda_r$, and for such a λ set

$$a_i(\lambda) = n - r + i - \lambda_i, \qquad i = 1, \dots, r$$

Given a complete flag $F_\bullet$ and a partition λ in the box, the *Schubert cell* is

$$\Omega_\lambda^\circ(F_\bullet) = \left\{ W \in \mathrm{Gr}(r,n) \;\middle|\; \begin{array}{l} \dim\left(W \cap F_{a_i(\lambda)}\right) = i \text{ and} \\ \dim\left(W \cap F_{a_i(\lambda)-1}\right) = i-1 \text{ for } i = 1, \dots, r \end{array} \right\}$$

and the *Schubert variety* $\Omega_\lambda(F_\bullet)$ is its closure in $\mathrm{Gr}(r,n)$.

Because λ is weakly decreasing, $a_i(\lambda) - a_{i-1}(\lambda) = 1 + \lambda_{i-1} - \lambda_i \ge 1$, and $\lambda_1 \le n-r$ forces $a_1(\lambda) \ge 1$ while $\lambda_r \ge 0$ forces $a_r(\lambda) \le n$; so $1 \le a_1(\lambda) < a_2(\lambda) < \cdots < a_r(\lambda) \le n$. The defining conditions

say that the function $j \mapsto \dim(W \cap F_j)$, which climbs from 0 to r in steps of 0 or 1, takes its steps exactly at $a_1(\lambda), \dots, a_r(\lambda)$.

For $r = 2$ and $n = 4$ the box is 2×2 and the point of $\mathrm{Gr}(2,4)$ is a line in $\mathbb{P}^3 = \mathbb{P}(V)$. The partition $\lambda = (1,0)$ has $a(\lambda) = (2,4)$, so its cell consists of the W with $\dim(W \cap F_1) = 0$, $\dim(W \cap F_2) = 1$ and $\dim(W \cap F_3) = 1$: the lines that meet the line $\mathbb{P}(F_2)$ in exactly one point, miss the point $\mathbb{P}(F_1)$, and are not contained in the plane $\mathbb{P}(F_3)$. The partition $(2,2)$ has $a(\lambda) = (1,2)$ and its cell is the single point $W = F_2$. The remaining four partitions in the box are $(0,0)$, $(2,0)$, $(1,1)$ and $(2,1)$, and example 17.1.6 works out the whole list with its geometry.

Three properties of these sets carry the rest of the section: each cell is an affine space of dimension $r(n-r) - |\lambda|$, the cells cover $\mathrm{Gr}(r,n)$ without overlap, and the closure of a cell is again cut out by intersection conditions, namely the inequalities obtained by relaxing the equalities in definition 17.1.1.

Proposition 17.1.2: Structure of the Schubert Cells

Let $F_\bullet$ be a complete flag and λ a partition in the $r \times (n-r)$ box, and abbreviate $a_i = a_i(\lambda)$ and $a = \{a_1, \dots, a_r\}$.

1. $\Omega^\circ_\lambda(F_\bullet)$ is a locally closed subvariety of $\mathrm{Gr}(r,n)$ isomorphic to $\mathbb{A}^{N-|\lambda|}$. More precisely, let $e_1, \dots, e_n$ be a basis of V *adapted* to the flag, meaning that $F_j = \langle e_1, \dots, e_j \rangle$ for every j, and let U_a be the chart of that basis attached to a. Then $\Omega^\circ_\lambda(F_\bullet) \subseteq U_a$ and
$$\Omega^\circ_\lambda(F_\bullet) = \{W \in U_a \big| c_{ij} = 0 \text{ for } j > a_i\}$$
the coordinate subspace on the coordinates c_{ij} with $j < a_i$, $j \notin a$.
2. $\mathrm{Gr}(r,n)$ is the disjoint union of the cells $\Omega^\circ_\mu(F_\bullet)$ over the partitions μ in the box.
3. Writing $\lambda \subseteq \mu$ for $\lambda_i \le \mu_i$ for all i,
$$\Omega_\lambda(F_\bullet) = \big\{W \in \mathrm{Gr}(r,n) \big| \dim(W \cap F_{a_i}) \ge i \text{ for } i = 1, \dots, r\big\} = \bigsqcup_{\mu \supseteq \lambda} \Omega^\circ_\mu(F_\bullet)$$
It is an irreducible closed subvariety of codimension $|\lambda|$, and $\Omega^\circ_\lambda(F_\bullet)$ is open and dense in it.

***Proof*:**
Fix a basis $e_1, \dots, e_n$ of V adapted to the flag, that is with $F_j = \langle e_1, \dots, e_j \rangle$ for every j; such a basis exists, since choosing $e_j \in F_j \setminus F_{j-1}$ for each j makes $\langle e_1, \dots, e_j \rangle$ a j-dimensional subspace of F_j. All charts below are the charts of this basis, and adaptedness is the only property of it that the argument uses, so the description in (1) holds for every adapted basis.

For $W \in \mathrm{Gr}(r,n)$ let $J(W) = \{j \big| \dim(W \cap F_j) > \dim(W \cap F_{j-1})\}$. Since $\dim(W \cap F_j)$ increases from 0 at $j = 0$ to r at $j = n$ and each step raises it by at most 1 (the quotient $(W \cap F_j)/(W \cap F_{j-1})$ injects into F_j/F_{j-1}, which is one-dimensional), $J(W)$ has exactly r elements and $\dim(W \cap F_j) = \#\{c \in J(W) \big| c \le j\}$ for every j. Comparing with definition 17.1.1, $W \in \Omega^\circ_\lambda(F_\bullet)$ if and only if $J(W) = \{a_1, \dots, a_r\}$. Moreover $\lambda \mapsto (a_1(\lambda), \dots, a_r(\lambda))$ is a bijection from the partitions in the box to the r-element subsets of $\{1, \dots, n\}$: it lands there by the monotonicity computed after definition 17.1.1, and $\lambda_i = n - r + i - a_i$ recovers λ from a strictly increasing sequence $1 \le a_1 < \cdots < a_r \le n$, the resulting λ being weakly decreasing with

$\lambda_1 \le n-r$ and $\lambda_r \ge 0$ precisely because $a_i - a_{i-1} \ge 1$, $a_1 \ge 1$ and $a_r \le n$.

1. Work in the chart U_a of the adapted basis just fixed; since $F_{a_i} = \langle e_1, \dots, e_{a_i}\rangle$ and $F_{a_i-1} = \langle e_1, \dots, e_{a_i-1}\rangle$, a vector of F_{a_i} lies outside F_{a_i-1} exactly when its e_{a_i}-coordinate is nonzero. If $W \in \Omega^\circ_\lambda(F_\bullet)$, choose for each i a vector $w_i \in (W \cap F_{a_i}) \setminus F_{a_i-1}$, scale it so that its e_{a_i}-coordinate is 1, and subtract from it the multiples $c\,w_k$ $(k<i)$ that clear its e_{a_k}-coordinates; the resulting vectors satisfy

$$w_i = e_{a_i} + \sum_{j<a_i,\ j\notin a} c_{ij} e_j$$

and are a basis of W, having distinct top indices $a_1 < \cdots < a_r$. In particular $W \oplus E_a = V$, so $W \in U_a$ and (w_i) is the basis of W attached to the chart, whose coordinates satisfy $c_{ij} = 0$ for $j > a_i$. Conversely, if $W \in U_a$ has chart coordinates with $c_{ij} = 0$ for $j > a_i$, then its chart basis has top indices $a_1 < \cdots < a_r$, so any nonzero combination $\sum_i \alpha_i w_i$ has top index $\max\{a_i \big| \alpha_i \neq 0\}$; hence $\dim(W \cap F_j) = \#\{i \big| a_i \le j\}$ and $J(W) = a$. Thus $\Omega^\circ_\lambda(F_\bullet)$ is the closed subvariety of $U_a \cong \mathbb{A}^{r(n-r)}$ cut out by the vanishing of the coordinates c_{ij} with $j > a_i$, that is, a coordinate subspace with coordinates c_{ij} for $j < a_i$, $j \notin a$. Their number is $\sum_{i=1}^r \big((a_i-1)-(i-1)\big) = \sum_{i=1}^r (n-r-\lambda_i) = N - |\lambda|$, so $\Omega^\circ_\lambda(F_\bullet) \cong \mathbb{A}^{N-|\lambda|}$, locally closed in $\mathrm{Gr}(r,n)$ as a closed subvariety of an open one.

2. Every W has a jump set $J(W)$ of size r, and by the bijection above $J(W) = a(\mu)$ for exactly one partition μ in the box; by the first paragraph this says that W lies in $\Omega^\circ_\mu(F_\bullet)$ and in no other cell.

3. Write $\Sigma_\lambda = \{W \big| \dim(W \cap F_{a_i}) \ge i \text{ for all } i\}$. It is closed: in a chart U_b the composite $W \to V \to V/F_{a_i}$ is given, in the chart basis of W and a basis of V/F_{a_i}, by a matrix whose entries are the chart coordinates or constants, and $\dim(W \cap F_{a_i}) \ge i$ says that this matrix has rank at most $r-i$, which is the vanishing of its $(r-i+1)\times(r-i+1)$ minors. Next, $\Sigma_\lambda = \bigsqcup_{\mu\supseteq\lambda} \Omega^\circ_\mu(F_\bullet)$: by (2) it suffices to see, for $W \in \Omega^\circ_\mu(F_\bullet)$, that $W \in \Sigma_\lambda$ if and only if $\mu \supseteq \lambda$; and indeed $\dim(W \cap F_{a_i(\lambda)}) = \#\{k \big| a_k(\mu) \le a_i(\lambda)\}$, which is $\ge i$ if and only if $a_i(\mu) \le a_i(\lambda)$ (the $a_k(\mu)$ being increasing), if and only if $\mu_i \ge \lambda_i$.

   It remains to prove $\Sigma_\lambda = \overline{\Omega^\circ_\lambda(F_\bullet)}$. The inclusion $\supseteq$ holds because Σ_λ is closed and contains the cell. For $\subseteq$, take $\mu \supseteq \lambda$ in the box; by induction on $|\mu| - |\lambda|$ it suffices to treat the case where μ is obtained from λ by adding one box, since if $\mu \supsetneq \lambda$ and k is the largest index with $\mu_k > \lambda_k$, then $\mu_{k+1} = \lambda_{k+1} \le \lambda_k \le \mu_k - 1$ (with $\mu_{r+1} = 0$), so removing one box from row k of μ leaves a partition in the box still containing λ. So let $\mu_k = \lambda_k + 1$ and $\mu_i = \lambda_i$ for $i \neq k$, and let $W \in \Omega^\circ_\mu(F_\bullet)$ have a basis $w_1, \dots, w_r$ with w_i of top index $a_i(\mu)$, as in (1). Here $a_i(\mu) = a_i(\lambda)$ for $i \neq k$ and $a_k(\mu) = a_k(\lambda) - 1$. For $t \in \mathbb{A}^1$ set

$$W_t = \langle w_1, \dots, w_{k-1},\ t\,e_{a_k(\lambda)} + w_k,\ w_{k+1}, \dots, w_r\rangle$$

   For every t the listed vectors are independent: for $t \neq 0$ their top indices are $a_1(\lambda), \dots, a_r(\lambda)$, which are distinct, and for $t = 0$ they are the w_i. Hence $t \mapsto W_t$ is a morphism $\mathbb{A}^1 \to \mathrm{Gr}(r,n)$, its Plücker coordinates being the $r \times r$ minors of a matrix with entries linear in t, not all vanishing for any t. By the criterion in (1), $W_t \in \Omega^\circ_\lambda(F_\bullet)$ for $t \neq 0$, while $W_0 = W$. The preimage of the closed set $\overline{\Omega^\circ_\lambda(F_\bullet)}$ under this morphism is closed in $\mathbb{A}^1$ and contains the dense subset $\mathbb{A}^1 \setminus \{0\}$, so it is all of $\mathbb{A}^1$ and $W = W_0 \in \overline{\Omega^\circ_\lambda(F_\bullet)}$.

Finally, $\Omega_\lambda(F_\bullet)$ is the closure of the irreducible set $\Omega^\circ_\lambda(F_\bullet) \cong \mathbb{A}^{N-|\lambda|}$, hence irreducible of dimension $N-|\lambda|$, that is, of codimension $|\lambda|$; the cell is dense in it by construction, and open in it because its complement $\bigsqcup_{\mu \supsetneq \lambda} \Omega^\circ_\mu(F_\bullet)$ is the union of the closed sets Σ_μ over the partitions μ obtained from λ by adding a single box, as we sought to show.

The proposition converts a question about $\mathrm{Gr}(r,n)$ into a question about partitions. Each Schubert variety is the closure of one cell, indexed by a partition whose size is its codimension, and the containment order on partitions is the containment order on Schubert varieties. At the two ends of that order, $\lambda = (0,\dots,0)$ gives the open cell and $\Omega_\lambda = \mathrm{Gr}(r,n)$, while the full box $\lambda = (n-r,\dots,n-r)$ has $a_i(\lambda) = i$ and gives the single point $W = F_r$.

Proposition 17.1.3: Duality of Schubert Classes

Call two complete flags $F_\bullet$ and $G_\bullet$ *transverse* if $F_a \cap G_b = 0$ whenever $a+b \le n$. For a partition λ in the $r \times (n-r)$ box let

$$\lambda^\vee = (n-r-\lambda_r,\ n-r-\lambda_{r-1},\ \dots,\ n-r-\lambda_1)$$

the *complementary partition*, again in the box, with $|\lambda| + |\lambda^\vee| = N$ and $(\lambda^\vee)^\vee = \lambda$. Let $F_\bullet, G_\bullet$ be transverse and let λ, μ be partitions in the box with $|\lambda| + |\mu| \ge N$. Then $\Omega_\lambda(F_\bullet) \cap \Omega_\mu(G_\bullet)$ is empty unless $|\lambda| + |\mu| = N$ and $\mu = \lambda^\vee$, in which case it is a single reduced point at which both Schubert varieties are smooth with complementary tangent spaces. Consequently, for $|\lambda| + |\mu| = N$,

$$\deg\left([\Omega_\lambda(F_\bullet)] \cdot [\Omega_\mu(G_\bullet)]\right) = \begin{cases} 1 & \mu = \lambda^\vee \\ 0 & \mu \ne \lambda^\vee \end{cases}$$

***Proof*:**

Step 1: an adapted basis. For each i the space $F_i \cap G_{n-i+1}$ is one-dimensional: it is nonzero because $\dim F_i + \dim G_{n-i+1} = n+1$, and it meets the hyperplane G_{n-i} of G_{n-i+1} in $F_i \cap G_{n-i} = 0$, so it has dimension at most 1. Choose a generator e_i. If $\sum_{k \le i} \alpha_k e_k = 0$ with some $\alpha_k \ne 0$ and k_0 is the largest index with $\alpha_{k_0} \ne 0$, then $e_{k_0} \in \langle e_1,\dots,e_{k_0-1}\rangle \subseteq F_{k_0-1}$ while $e_{k_0} \in G_{n-k_0+1}$, and $F_{k_0-1} \cap G_{n-k_0+1} = 0$ forces $e_{k_0} = 0$, a contradiction. So $e_1,\dots,e_n$ is a basis, $F_j = \langle e_1,\dots,e_j\rangle$ by dimension count, and $G_j \supseteq \langle e_{n-j+1},\dots,e_n\rangle$ with equality for the same reason.

Step 2: the partitions must be complementary. Let $W \in \Omega_\lambda(F_\bullet) \cap \Omega_\mu(G_\bullet)$. Put $A_i = F_{a_i(\lambda)}$ and $B_i = G_{a_i(\mu)}$, so that by proposition 17.1.2(3) $\dim(W \cap A_i) \ge i$ and $\dim(W \cap B_i) \ge i$ for all i. Fix i and apply this to A_i and B_{r+1-i}: inside the r-dimensional space W the subspaces $W \cap A_i$ and $W \cap B_{r+1-i}$ have dimensions summing to at least $r+1$, so they meet nontrivially, whence $A_i \cap B_{r+1-i} \ne 0$. By Step 1, $F_c \cap G_d = 0$ as soon as $c+d \le n$, so

$$a_i(\lambda) + a_{r+1-i}(\mu) \ge n+1$$

which upon substituting $a_i(\lambda) = n-r+i-\lambda_i$ and $a_{r+1-i}(\mu) = n+1-i-\mu_{r+1-i}$ reads $\lambda_i + \mu_{r+1-i} \le n-r$. Summing over i gives $|\lambda| + |\mu| \le N$. So the intersection is empty when $|\lambda| + |\mu| > N$; and when $|\lambda| + |\mu| = N$ all r of the inequalities are equalities, $\mu_{r+1-i} = n-r-\lambda_i$ for every i, which is $\mu = \lambda^\vee$.

Step 3: the intersection is one point. Assume $\mu = \lambda^\vee$ and write $a_i = a_i(\lambda)$. Then $a_i + a_{r+1-i}(\mu) =$

$n+1$, so with the basis of Step 1, $A_i \cap B_{r+1-i} = \langle e_1, \dots, e_{a_i}\rangle \cap \langle e_{a_i}, \dots, e_n\rangle = \langle e_{a_i}\rangle$. The argument of Step 2 produced a nonzero vector of W inside $A_i \cap B_{r+1-i}$, so $e_{a_i} \in W$ for every i; as the a_i are distinct, W is the single subspace $W_\lambda := \langle e_{a_1}, \dots, e_{a_r}\rangle$. Conversely W_λ does lie in both Schubert varieties, since $\dim(W_\lambda \cap F_j) = \#\{i \big| a_i \le j\}$ shows $W_\lambda \in \Omega^\circ_\lambda(F_\bullet)$, and the computation of Step 4 below identifies W_λ as a point of $\Omega^\circ_{\lambda^\vee}(G_\bullet)$ as well.

Step 4: transversality at that point. Work in the chart U_a of the basis $e_\bullet$ of Step 1, with $a = \{a_1, \dots, a_r\}$; that basis is adapted to $F_\bullet$, and the chart contains W_λ, the origin of its coordinates c_{ij}. By proposition 17.1.2(1),

$$\Omega^\circ_\lambda(F_\bullet) \cap U_a = \{c_{ij} = 0 \text{ for } j > a_i\}$$

Reindex by the basis $f_j = e_{n+1-j}$, for which $G_b = \langle f_1, \dots, f_b\rangle$. The subset of $\{1, \dots, n\}$ attached to W_λ in the f-basis is $a' = \{n+1-a_i\}$, that is, $a'_k = n+1-a_{r+1-k}$, and $n+1-a_{r+1-k} = k + \lambda_{r+1-k} = a_k(\lambda^\vee)$; so $W_\lambda \in \Omega^\circ_{\lambda^\vee}(G_\bullet)$, completing Step 3, and $U_{a'} = U_a$ because $\langle f_j \big| j \notin a'\rangle = \langle e_m \big| m \notin a\rangle$. The chart bases match up as $w'_k = w_{r+1-k}$, so $c'_{kj} = c_{r+1-k,\, n+1-j}$, and proposition 17.1.2(1), applied to $\lambda^\vee$ and $G_\bullet$ in the f-basis, which is adapted to $G_\bullet$, gives

$$\Omega^\circ_{\lambda^\vee}(G_\bullet) \cap U_a = \{c_{ij} = 0 \text{ for } j < a_i\}$$

The two cells are therefore complementary coordinate subspaces of $U_a \cong \mathbb{A}^N$, meeting exactly at the origin and with tangent spaces there intersecting in 0. Each cell is open in its Schubert variety (proposition 17.1.2(3)), so $\Omega_\lambda(F_\bullet)$ and $\Omega_{\lambda^\vee}(G_\bullet)$ are smooth at W_λ with complementary tangent spaces, and their codimensions $|\lambda|$ and $|\lambda^\vee|$ sum to N. Proposition 14.3.12 now gives $\deg([\Omega_\lambda(F_\bullet)] \cdot [\Omega_{\lambda^\vee}(G_\bullet)]) = 1$, while for $\mu \neq \lambda^\vee$ with $|\lambda| + |\mu| = N$ the intersection is empty and the product vanishes, completing the proof.

Taking the degree of the product with $[\Omega_{\lambda^\vee}(G_\bullet)]$ therefore extracts the coefficient of $[\Omega_\lambda(F_\bullet)]$ from a class, one coefficient at a time, and this is what turns the cell decomposition into a basis. Generation comes from the cells and the localization sequence; independence comes from the pairing just computed; and the same pairing shows that the class of a Schubert variety does not depend on the flag used to define it, so the notation σ_λ below is unambiguous.

Theorem 17.1.4: The Chow Ring of the Grassmannian

For a partition λ in the $r \times (n-r)$ box, the class $[\Omega_\lambda(F_\bullet)] \in A^{|\lambda|}(\mathrm{Gr}(r,n))$ is independent of the complete flag $F_\bullet$; write σ_λ for it, the *Schubert class* of λ. For each p the group $A^p(\mathrm{Gr}(r,n))$ is free abelian with basis $\{\sigma_\lambda \big| |\lambda| = p\}$, so $A^*(\mathrm{Gr}(r,n))$ is free abelian of total rank $\binom{n}{r}$. Moreover $\sigma_{(0,\dots,0)} = 1$, the class $\sigma_{(n-r,\dots,n-r)}$ is the class of a point, and $\deg\colon A^N(\mathrm{Gr}(r,n)) \to \mathbb{Z}$ is an isomorphism.

***Proof*:**
Fix a complete flag $F_\bullet$ and abbreviate $\Omega_\mu = \Omega_\mu(F_\bullet)$, $\Omega^\circ_\mu = \Omega^\circ_\mu(F_\bullet)$.

Step 1: the classes $[\Omega_\mu]$ *generate.* For $0 \le p \le N+1$ set $Y_p = \bigcup_{|\mu|=p} \Omega_\mu$, a closed subset by

proposition 17.1.2(3), with $Y_0 = \mathrm{Gr}(r,n)$ and $Y_{N+1} = \emptyset$. By proposition 17.1.2(2) and (3),

$$Y_p = \bigsqcup_{|\nu| \geq p} \Omega_\nu^\circ$$

since Ω_μ is the union of the cells indexed by partitions containing μ, and conversely every ν with $|\nu| \geq p$ contains a partition of size exactly p (remove boxes one at a time from the last nonempty row). In particular $Y_{p+1} \subseteq Y_p$ and $Y_p \setminus Y_{p+1} = \bigsqcup_{|\mu|=p} \Omega_\mu^\circ$, a disjoint union of copies of $\mathbb{A}^{N-p}$ by proposition 17.1.2(1). A cycle on a disjoint union is the sum of its restrictions, so $A_k(Y_p \setminus Y_{p+1})$ is 0 for $k \neq N-p$ and is free on the classes $[\Omega_\mu^\circ]$, $|\mu| = p$, for $k = N-p$ (proposition 10.5.1).

Claim: $A_k(Y_p)$ is generated by the classes $[\Omega_\mu]$ with $|\mu| = N-k$ and $|\mu| \geq p$, an empty list (so that $A_k(Y_p) = 0$) when $N-k < p$. This holds for $p = N+1$. Assume it for $p+1$ and apply the localization sequence (theorem 10.4.1)

$$A_k(Y_{p+1}) \to A_k(Y_p) \to A_k(Y_p \setminus Y_{p+1}) \to 0$$

in which the first map is pushforward along a closed immersion and the second is restriction of cycles. If $k \neq N-p$ the third group vanishes, so $A_k(Y_p)$ is the image of $A_k(Y_{p+1})$, which by induction is generated by the $[\Omega_\mu]$ with $|\mu| = N-k \geq p+1$, and these classes push forward to the classes of the same subvarieties. If $k = N-p$, then $N-k = p < p+1$, so $A_k(Y_{p+1}) = 0$ by induction and the restriction map is an isomorphism; each generator $[\Omega_\mu^\circ]$ with $|\mu| = p$ is the restriction of $[\Omega_\mu]$, because $\Omega_\mu \setminus Y_{p+1} = \Omega_\mu^\circ$ by the displayed description of Y_{p+1} together with proposition 17.1.2(3). This proves the claim, and $p = 0$ gives that $A_k(\mathrm{Gr}(r,n))$ is generated by the classes $[\Omega_\mu]$ with $|\mu| = N-k$.

Step 2: they are independent. A flag transverse to a given flag $F_\bullet$ exists: build $G_\bullet$ by choosing $u_k \notin F_{n-k} + G_{k-1}$ and setting $G_k = G_{k-1} + \langle u_k \rangle$, which is possible since $\dim(F_{n-k} + G_{k-1}) \leq n-1$; then $G_k \cap F_{n-k} = 0$, for if $g + \alpha u_k \in F_{n-k}$ with $g \in G_{k-1}$ then $\alpha \neq 0$ would put $u_k \in F_{n-k} + G_{k-1}$, while $\alpha = 0$ gives $g \in G_{k-1} \cap F_{n-k} \subseteq G_{k-1} \cap F_{n-k+1} = 0$ by induction. Fix such a $G_\bullet$ and suppose $\sum_{|\lambda|=p} c_\lambda [\Omega_\lambda] = 0$ in $A^p(\mathrm{Gr}(r,n))$. Multiplying by $[\Omega_{\lambda_0^\vee}(G_\bullet)]$ for a partition λ_0 of size p and taking degrees, proposition 17.1.3 leaves the single term c_{λ_0}, so every coefficient vanishes. With Step 1 this shows that $A^p(\mathrm{Gr}(r,n)) = A_{N-p}(\mathrm{Gr}(r,n))$ is free with basis $\{[\Omega_\lambda(F_\bullet)] \,|\, |\lambda| = p\}$.

Step 3: independence of the flag. Let $F_\bullet$ and $F'_\bullet$ be complete flags. A flag $G_\bullet$ transverse to both exists by the construction of Step 2, run with $u_k \notin (F_{n-k} + G_{k-1}) \cup (F'_{n-k} + G_{k-1})$: a vector space is never the union of two proper subspaces, since for $u \in A \setminus B$ and $v \in B \setminus A$ the vector $u+v$ lies in neither. By Step 2 applied to $F'_\bullet$, write $[\Omega_\lambda(F_\bullet)] = \sum_{|\mu|=|\lambda|} c_\mu [\Omega_\mu(F'_\bullet)]$. Multiplying by $[\Omega_\nu(G_\bullet)]$ with $|\nu| = N - |\lambda|$ and taking degrees, proposition 17.1.3 gives $\delta_{\nu,\lambda^\vee} = c_{\nu^\vee}$ on the two sides. As $\nu \mapsto \nu^\vee$ is a bijection of the partitions of size $N-|\lambda|$ onto those of size $|\lambda|$, with $\nu = \lambda^\vee$ exactly when $\nu^\vee = \lambda$, this says $c_\mu = \delta_{\mu\lambda}$, that is, $[\Omega_\lambda(F_\bullet)] = [\Omega_\lambda(F'_\bullet)]$.

Step 4: the remaining assertions. The partitions in the box biject with the r-element subsets of $\{1,\dots,n\}$ (proof of proposition 17.1.2), so the total rank is $\binom{n}{r}$. For $\lambda = (0,\dots,0)$ the Schubert variety is $\mathrm{Gr}(r,n)$ itself, whose class is the identity of $A^*(\mathrm{Gr}(r,n))$, and for $\lambda = (n-r,\dots,n-r)$ it is a single point. Hence $A^N(\mathrm{Gr}(r,n))$ is free of rank one on the class of a point, whose degree is 1 (definition 10.2.4), so deg is an isomorphism onto $\mathbb{Z}$, completing the proof.

The Chow ring of $\mathrm{Gr}(r,n)$ is thus free of rank $\binom{n}{r}$ on classes indexed by combinatorial data, graded so that σ_λ sits in codimension $|\lambda|$, and equipped with a perfect pairing $A^p \times A^{N-p} \to \mathbb{Z}$ whose matrix in the Schubert bases is a permutation matrix. An enumerative problem posed as an intersection of Schubert conditions is therefore a finite computation as soon as the products $\sigma_\lambda \cdot \sigma_\mu$ are known in the basis. The next proposition gives the first family of such products indirectly, by identifying the classes of the one-row partitions with Chern classes, which are already subject to the Whitney formula.

Write $\sigma_m = \sigma_{(m,0,\dots,0)}$ for $0 \le m \le n-r$; these are the *special* Schubert classes. Only the first of the defining conditions is a restriction: for $\lambda = (m,0,\dots,0)$ and $i \ge 2$ one has $a_i(\lambda) = n-r+i$ and $\dim(W \cap F_{n-r+i}) \ge r + (n-r+i) - n = i$ automatically, so proposition 17.1.2(3) gives

$$\Omega_{(m)}(F_\bullet) = \{W \,\big|\, W \cap F_{n-r+1-m} \neq 0\}$$

a condition on a single subspace of V.

Proposition 17.1.5: Special Schubert Classes as Chern Classes

In $A^*(\mathrm{Gr}(r,n))$ the tautological sub-bundle and quotient bundle satisfy $c(S)\,c(Q) = 1$, and

$$c_m(Q) = \sigma_m \qquad \text{for } 0 \le m \le n-r$$

so that $c(Q) = 1 + \sigma_1 + \cdots + \sigma_{n-r}$ and $c(S) = (1 + \sigma_1 + \cdots + \sigma_{n-r})^{-1}$.

***Proof*:**

Step 1: the two total Chern classes are inverse. The trivial bundle $V \otimes \mathcal{O}$ has $c_i(V \otimes \mathcal{O}) = 0$ for $i > 0$ (example 12.2.12), so the Whitney formula (theorem 12.2.15) applied to the tautological sequence gives $c(S)\,c(Q) = c(V \otimes \mathcal{O}) = 1$.

Step 2: a resolution of the special Schubert variety. Let $\pi\colon \mathbb{P}(S) \to \mathrm{Gr}(r,n)$ be the bundle of lines in S (box 12.2.5; definition 5.3.51 uses the quotient convention, so the import dualizes, box 9.0.2), whose points are the pairs $(W,[v])$ with $0 \neq v \in W$, and let $\mathcal{O}_{\mathbb{P}(S)}(-1) \subseteq \pi^*S$ be the tautological sub-line-bundle (proposition 5.3.53); put $\xi = c_1(\mathcal{O}_{\mathbb{P}(S)}(1))$. Composing $S \hookrightarrow V \otimes \mathcal{O}$ with the tautological inclusion gives a morphism

$$q\colon \mathbb{P}(S) \to \mathbb{P}(V), \qquad (W,[v]) \mapsto [v]$$

with $q^*\mathcal{O}_{\mathbb{P}(V)}(-1) = \mathcal{O}_{\mathbb{P}(S)}(-1)$, both being the line $\langle v\rangle$; hence $\xi = q^*h$ for $h = c_1(\mathcal{O}_{\mathbb{P}(V)}(1))$. The map q is flat: fixing $\psi \in V^\vee$ and writing $V' = \ker\psi$, every $[v]$ with $\psi(v) \neq 0$ has the normalized representative $v/\psi(v)$, which depends algebraically on $[v]$ and splits $V = \langle v\rangle \oplus V'$, so that $W \mapsto W/\langle v\rangle \subseteq V/\langle v\rangle \cong V'$ identifies $q^{-1}(\{\psi \neq 0\})$ with $\{\psi \neq 0\} \times \mathrm{Gr}(r-1,V')$ over $\{\psi \neq 0\}$.

For a nonzero subspace $L \subseteq V$ set $\Sigma_L = q^{-1}(\mathbb{P}(L)) = \{(W,[v]) \,\big|\, v \in L \cap W\}$. By the local description just given it is a Zariski-locally trivial bundle over $\mathbb{P}(L)$ with fibre $\mathrm{Gr}(r-1,n-1)$, hence an irreducible variety of dimension $(\dim L - 1) + (r-1)(n-r)$, and $q^*[\mathbb{P}(L)] = [\Sigma_L]$ by flat pullback of cycles (definition 10.3.3). Furthermore $[\mathbb{P}(L)] = h^{n-\dim L} \cap [\mathbb{P}(V)]$: for a hyperplane $L' \subset L$, choose $\psi \in V^\vee$ with $\ker\psi \cap L = L'$; then ψ is a section of $\mathcal{O}_{\mathbb{P}(V)}(1)$ whose restriction to $\mathbb{P}(L)$ is a section whose divisor of zeros is $\mathbb{P}(L')$ with multiplicity one, since in each standard affine chart of $\mathbb{P}(L)$ it is a nonzero linear polynomial and so generates a prime ideal, so $h \cap [\mathbb{P}(L)] = [\mathbb{P}(L')]$ by the construction of the first Chern class operator (definition 11.4.1),

and $[\mathbb{P}(V)] = h^0 \cap [\mathbb{P}(V)]$ starts the induction (theorem 10.5.2). Since Chern class operators commute with flat pullback (proposition 12.2.10) and $q^*[\mathbb{P}(V)] = [\mathbb{P}(S)]$,

$$\xi^{\,n-\dim L} \cap [\mathbb{P}(S)] = q^*\big(h^{\,n-\dim L} \cap [\mathbb{P}(V)]\big) = [\Sigma_L] \tag{17.1}$$

Step 3: pushing forward. Fix $0 \le m \le n-r$, put $\ell = n-r+1-m$ and $L = F_\ell$ for a complete flag $F_\bullet$, so that $n - \dim L = r-1+m$ and, by the description of $\Omega_{(m)}(F_\bullet)$ preceding this proposition, $\pi(\Sigma_L) = \Omega_{(m)}(F_\bullet)$. The map π is proper, so $\pi|_{\Sigma_L}$ is proper; the two varieties have the same dimension, namely $(\ell-1)+(r-1)(n-r) = N-m$; and over a point W of the dense open cell $\Omega^\circ_{(m)}(F_\bullet)$, where $\dim(W \cap F_\ell) = 1$, the fibre is the reduced point $\mathbb{P}(W \cap F_\ell)$, of length one. Hence $\pi|_{\Sigma_L}$ is birational onto its image and

$$\pi_*[\Sigma_L] = [\Omega_{(m)}(F_\bullet)] = \sigma_m$$

by definition 10.2.1 and theorem 17.1.4. Combining with (17.1), $\sigma_m = \pi_*\big(\xi^{\,r-1+m} \cap [\mathbb{P}(S)]\big)$ for $0 \le m \le n-r$.

Step 4: identifying the pushforwards. For $j \in \mathbb{Z}$ set $p_j = \pi_*\big(\xi^{\,r-1+j} \cap [\mathbb{P}(S)]\big)$, with $p_j = 0$ for $j < 0$: indeed for $0 \le k < r-1$ the class $\xi^k \cap [\mathbb{P}(S)]$ has dimension $\dim \mathbb{P}(S) - k = N+r-1-k > N$, and $A_d(\mathrm{Gr}(r,n)) = 0$ for $d > N$. Step 3 gives $p_m = \sigma_m$ for $0 \le m \le n-r$, and in particular $p_0 = \sigma_0 = 1$. Being a projective bundle over a smooth variety, $\mathbb{P}(S)$ is itself smooth, so theorem 14.2.7 gives its Chow ring as well. The tautological sequence on $\mathbb{P}(S)$ reads $0 \to \mathcal{O}_{\mathbb{P}(S)}(-1) \to \pi^*S \to Q' \to 0$ with Q' of rank $r-1$, so by theorem 12.2.15 and $c(\mathcal{O}_{\mathbb{P}(S)}(-1)) = 1-\xi$ (proposition 11.4.4),

$$c(Q') = \pi^*c(S) \cdot (1-\xi)^{-1} = \pi^*c(S) \cdot (1+\xi+\xi^2+\cdots)$$

the inverse making sense because ξ is nilpotent in $A^*(\mathbb{P}(S))$. The rank of Q' is $r-1$, so $c_r(Q') = 0$ (theorem 12.2.9), which is the relation

$$\sum_{i=0}^{r} \pi^*c_i(S) \cdot \xi^{\,r-i} = 0$$

Multiplying it by $\xi^{\,j-1}$ for $j \ge 1$, capping with $[\mathbb{P}(S)]$ and pushing forward by π, the projection formula (proposition 12.2.10) gives

$$0 = \sum_{i=0}^{r} c_i(S) \cdot \pi_*\big(\xi^{\,r-i+j-1} \cap [\mathbb{P}(S)]\big) = \sum_{i=0}^{r} c_i(S) \cdot p_{j-i}$$

since $r-i+j-1 = r-1+(j-i)$. Together with $p_0 = 1$ these relations say that the class $p = \sum_{j \ge 0} p_j$ satisfies $c(S) \cdot p = 1$, and $c(S)$ is invertible in $A^*(\mathrm{Gr}(r,n))$ because it is 1 plus a nilpotent class. Step 1 gives $c(S) \cdot c(Q) = 1$ as well, so $p = c(Q)$ and $p_m = c_m(Q)$ for every m. With Step 3, $\sigma_m = c_m(Q)$ for $0 \le m \le n-r$, and since $c_m(Q) = 0$ for $m > n-r$ the total class is $c(Q) = 1 + \sigma_1 + \cdots + \sigma_{n-r}$, completing the proof.

The single-condition Schubert classes are therefore characteristic classes of the tautological bundles, and as such they obey the Whitney formula: $c(S)c(Q) = 1$ is a family of relations among Schubert

classes, and it determines all of them once the products of the special classes with arbitrary Schubert classes are known. In $\mathrm{Gr}(2,4)$ the whole ring already follows from what has been proved.

Example 17.1.6: Lines in Projective Three-Space
Take $r=2$ and $n=4$, so that $N=4$ and a point of $\mathrm{Gr}(2,4)$ is a line in $\mathbb{P}^3=\mathbb{P}(V)$. The 2×2 box holds six partitions, and proposition 17.1.2(3) turns each into an incidence condition on a line $\mathbb{P}(W)\subseteq\mathbb{P}^3$ relative to the flag $\mathbb{P}(F_1)\subset\mathbb{P}(F_2)\subset\mathbb{P}(F_3)$, a point on a line in a plane.

1. $\lambda=(0,0)$: $\Omega_\lambda=\mathrm{Gr}(2,4)$, and $\sigma_{(0,0)}=1$.
2. $\lambda=(1,0)$, $a=(2,4)$: the conditions are $\dim(W\cap F_2)\geq 1$ and $\dim(W\cap F_4)\geq 2$, the second vacuous, so this is the locus of lines meeting $\mathbb{P}(F_2)$; codimension 1.
3. $\lambda=(2,0)$, $a=(1,4)$: the conditions reduce to $F_1\subseteq W$, the lines through the point $\mathbb{P}(F_1)$; codimension 2.
4. $\lambda=(1,1)$, $a=(2,3)$: the conditions are $\dim(W\cap F_2)\geq 1$ and $\dim(W\cap F_3)\geq 2$, the second of which says $W\subseteq F_3$ and implies the first: the lines inside the plane $\mathbb{P}(F_3)$; codimension 2.
5. $\lambda=(2,1)$, $a=(1,3)$: the conditions are $F_1\subseteq W\subseteq F_3$, the pencil of lines through $\mathbb{P}(F_1)$ inside $\mathbb{P}(F_3)$, a copy of $\mathbb{P}^1$; codimension 3.
6. $\lambda=(2,2)$, $a=(1,2)$: the conditions force $W=F_2$, the single line $\mathbb{P}(F_2)$; codimension 4.

By theorem 17.1.4 the Chow ring is free of rank $6=\binom{4}{2}$ on these classes, with $A^0=\mathbb{Z}$, $A^1=\mathbb{Z}\sigma_1$, $A^2=\mathbb{Z}\sigma_2\oplus\mathbb{Z}\sigma_{1,1}$, $A^3=\mathbb{Z}\sigma_{2,1}$ and $A^4=\mathbb{Z}\sigma_{2,2}$. Complementation acts by $(0,0)^\vee=(2,2)$, $(1,0)^\vee=(2,1)$, $(2,0)^\vee=(2,0)$ and $(1,1)^\vee=(1,1)$, so proposition 17.1.3 gives $\deg(\sigma_1\sigma_{2,1})=1$, $\deg(\sigma_2^2)=\deg(\sigma_{1,1}^2)=1$ and $\deg(\sigma_2\sigma_{1,1})=0$. Since A^4 is free on the class of a point, this already determines $\sigma_2^2=\sigma_{1,1}^2=\sigma_{2,2}$ and $\sigma_2\sigma_{1,1}=0$.

The product $\sigma_1^2=a\,\sigma_2+b\,\sigma_{1,1}$ is fixed by the two numbers $a=\deg(\sigma_1^2\sigma_2)$ and $b=\deg(\sigma_1^2\sigma_{1,1})$, again by proposition 17.1.3. For the first, choose F_2 and G_2 with $V=F_2\oplus G_2$, bases $F_2=\langle u_0,u_1\rangle$ and $G_2=\langle v_0,v_1\rangle$, and the point $p=[u_0+v_0]$. The loci $\{W'\big|W'\cap F_2\neq 0\}$, $\{W'\big|W'\cap G_2\neq 0\}$ and $\{W'\big|u_0+v_0\in W'\}$ are Schubert varieties for complete flags through F_2, through G_2 and through $\langle u_0+v_0\rangle$, so by theorem 17.1.4 their classes are σ_1, σ_1 and σ_2. A line $\mathbb{P}(W)$ meeting $\mathbb{P}(F_2)$ and $\mathbb{P}(G_2)$ and passing through p has $\dim(W\cap F_2)=1$, since $\dim(W\cap F_2)=2$ would give $W=F_2$ and then $v_0\in F_2\cap G_2=0$, because $u_0+v_0\in F_2$; writing $W\cap F_2=\langle u\rangle$ and $W\cap G_2=\langle v\rangle$, these are independent and $W=\langle u,v\rangle$. Expanding $u_0+v_0=xu+yv$ and comparing components in $V=F_2\oplus G_2$ gives $xu=u_0$ and $yv=v_0$, so $W=\langle u_0,v_0\rangle$ is the unique solution. At that point, use the chart attached to the basis u_0,u_1,v_0,v_1 and the index set picking out u_0 and v_0: it identifies the subspaces complementary to $E=\langle u_1,v_1\rangle$ with $\mathrm{Hom}(W,E)$, a homomorphism φ corresponding to its graph $W_\varphi=\langle u_0+\varphi(u_0),\,v_0+\varphi(v_0)\rangle$ and W itself to $\varphi=0$. Write $\varphi(u_0)=\alpha u_1+\beta v_1$ and $\varphi(v_0)=\gamma u_1+\delta v_1$. In this chart each of the three conditions is a system of linear equations in $\alpha,\beta,\gamma,\delta$. A combination $s(u_0+\varphi(u_0))+t(v_0+\varphi(v_0))$ lies in $F_2=\langle u_0,u_1\rangle$ exactly when $t=0$ and $s\beta=0$, so $W_\varphi\cap F_2\neq 0$ if and only if $\beta=0$; exchanging the roles of the u and v vectors gives $W_\varphi\cap G_2\neq 0$ if and only if $\gamma=0$; and u_0+v_0 lies in W_φ only for $s=t=1$, hence exactly when $\alpha+\gamma=0$ and $\beta+\delta=0$. The three loci are therefore linear subspaces of the chart, so they are smooth at W and equal to their own tangent spaces there, and the equations $\beta=0$, $\gamma=0$ and $\alpha+\gamma=\beta+\delta=0$ have only the solution $\varphi=0$, so the three tangent spaces meet in zero. As the three codimensions $1+1+2$ sum to 4, the transversality proposition 14.3.12 gives $a=1$.

For the second, keep F_2 and G_2 and choose the plane $F_3' = \langle u_0, v_0, u_1 + v_1\rangle$, which meets F_2 in $\langle u_0\rangle$ and G_2 in $\langle v_0\rangle$. If $W \subseteq F_3'$ meets both F_2 and G_2, then $W \cap F_2 \subseteq F_3' \cap F_2 = \langle u_0\rangle$ and likewise $W \cap G_2 = \langle v_0\rangle$, so again $W = \langle u_0, v_0\rangle$ is the unique solution, and $\{W' \big| W' \subseteq F_3'\}$ is a Schubert variety for a complete flag through F_3', of class $\sigma_{1,1}$. In the chart above, $W_\varphi \subseteq F_3'$ if and only if $\varphi(u_0), \varphi(v_0) \in F_3' \cap E = \langle u_1 + v_1\rangle$, that is $\alpha = \beta$ and $\gamma = \delta$, a linear subspace again; intersecting it with $\beta = 0$ and $\gamma = 0$ leaves only $\varphi = 0$, and the codimensions $1 + 1 + 2$ again sum to 4, so $b = 1$ and

$$\sigma_1^2 = \sigma_2 + \sigma_{1,1}$$

The relation says that the lines meeting two general lines of $\mathbb{P}^3$ break, as a class, into the lines through a point and the lines in a plane. Finally proposition 17.1.5 reads $c(Q) = 1 + \sigma_1 + \sigma_2$ here, so $c(S) = (1 + \sigma_1 + \sigma_2)^{-1} = 1 - \sigma_1 + (\sigma_1^2 - \sigma_2) - \cdots = 1 - \sigma_1 + \sigma_{1,1} - \cdots$, whose terms in codimensions 3 and 4 vanish because S has rank 2.

Exercise 17.1.1

1. Show that $\lambda \mapsto (a_1(\lambda), \ldots, a_r(\lambda))$ is a bijection from the partitions in the $r \times (n-r)$ box onto the strictly increasing sequences $1 \le a_1 < \cdots < a_r \le n$, with inverse $\lambda_i = n - r + i - a_i$. Deduce that the number of partitions in the box is $\binom{n}{r}$, and check directly that for $r = 2$, $n = 5$ the ranks of $A^p(\mathrm{Gr}(2,5))$ for $p = 0, \ldots, 6$ are $1, 1, 2, 2, 2, 1, 1$.

2. Take $r = 1$, so that $\mathrm{Gr}(1,n) = \mathbb{P}(V) = \mathbb{P}^{n-1}$ and the box is $1 \times (n-1)$. Show that the Schubert cells for a complete flag $F_\bullet$ are the sets $\mathbb{P}(F_{n-m}) \setminus \mathbb{P}(F_{n-m-1})$ for $0 \le m \le n-1$, that $\Omega_{(m)}(F_\bullet) = \mathbb{P}(F_{n-m})$, and that theorem 17.1.4 recovers theorem 10.5.2. Then verify proposition 17.1.5 in this case by computing $c(Q) = c(S)^{-1}$ from $S = \mathcal{O}_{\mathbb{P}(V)}(-1)$ and comparing with the classes of the linear subspaces.

3. Show that $\Omega_{(n-r,0,\ldots,0)}(F_\bullet) = \{W \big| F_1 \subseteq W\}$ and that $\Omega_{(1,1,\ldots,1)}(F_\bullet) = \{W \big| W \subseteq F_{n-1}\}$, and identify the two with $\mathrm{Gr}(r-1, n-1)$ and $\mathrm{Gr}(r, n-1)$ respectively. Check that their codimensions in $\mathrm{Gr}(r,n)$ are $n-r$ and r, in agreement with proposition 17.1.2(3).

4. Show that the pairing $A^p(\mathrm{Gr}(r,n)) \times A^{N-p}(\mathrm{Gr}(r,n)) \to \mathbb{Z}$ sending (α, β) to $\deg(\alpha \cdot \beta)$ is a perfect pairing of free abelian groups, in the sense that its matrix in the Schubert bases is invertible over $\mathbb{Z}$. Deduce that A^p and A^{N-p} have the same rank, and that a class $\alpha \in A^p$ is determined by the integers $\deg(\alpha \cdot \sigma_\mu)$ with $|\mu| = N - p$.

5. For two partitions λ, μ in the box let $\nu_i = \max(\lambda_i, \mu_i)$. Show that ν is again a partition in the box and that, for a single flag $F_\bullet$,

$$\Omega_\lambda(F_\bullet) \cap \Omega_\mu(F_\bullet) = \Omega_\nu(F_\bullet)$$

   Explain why this does not compute $\sigma_\lambda \cdot \sigma_\mu$, by comparing the codimension of Ω_ν with $|\lambda| + |\mu|$ in the case $\lambda = \mu = (1, 0, \ldots, 0)$.

6. Let λ be a partition in the box and let $i\colon \Omega_\lambda(F_\bullet) \hookrightarrow \mathrm{Gr}(r,n)$ be the inclusion. Show that $A_*(\Omega_\lambda(F_\bullet))$ is free abelian with basis the classes $[\Omega_\mu(F_\bullet)]$ for $\mu \supseteq \lambda$. (For generation, repeat Step 1 of the proof of theorem 17.1.4 with the stratification of Ω_λ by the cells it contains; for independence, push forward to $\mathrm{Gr}(r,n)$.)

7. On $\mathrm{Gr}(2,4)$, use example 17.1.6 to show that $c(S) = 1 - \sigma_1 + \sigma_{1,1}$. Deduce from the vanishing

of $c_3(S)$ and $c_4(S)$ the two relations

$$\sigma_1\sigma_{1,1} = \sigma_1\sigma_2, \qquad \sigma_2\sigma_{1,1} = 0$$

and check the second against proposition 17.1.3.

8. Let $F_\bullet$ be a complete flag in a four-dimensional V and consider $\Omega_{(1,0)}(F_\bullet) \subseteq \mathrm{Gr}(2,4)$. In the chart U_a with $a = \{1,2\}$ for a basis with $F_2 = \langle e_1, e_2\rangle$, show that $\Omega_{(1,0)}(F_\bullet) \cap U_a$ is the affine quadric $\{c_{13}c_{24} - c_{14}c_{23} = 0\}$, and conclude that $\Omega_{(1,0)}(F_\bullet)$ is singular at the point $W = F_2$. Which point of which Schubert cell is $W = F_2$, and how does the answer square with proposition 17.1.2(1)?

17.2 Schubert Calculus

Section 17.1 produced the additive structure of $A^*(\mathrm{Gr}(r,n))$ and a pairing recovering the coefficients of a class in the Schubert basis, but nothing so far computes a product of two Schubert classes, and every enumerative count is such a product. This section gives the multiplication table in three forms: Pieri's rule, which multiplies an arbitrary Schubert class by a special one; Giambelli's formula, which writes every Schubert class as a determinant in the special classes; and the presentation of $A^*(\mathrm{Gr}(r,n))$ by generators and relations that the two together force. The four lines problem is settled on the way.

Throughout, V is a fixed vector space of dimension n over $\overline{k}$, and $\mathrm{Gr}(r,n)$ parametrizes its r-dimensional subspaces W. *The box* is the set of partitions $\lambda = (\lambda_1 \geq \cdots \geq \lambda_r \geq 0)$ with $\lambda_1 \leq n-r$; these index the Schubert classes $\sigma_\lambda = [\Omega_\lambda(F_\bullet)]$ of theorem 17.1.4, where by proposition 17.1.2(3)

$$\Omega_\lambda(F_\bullet) \;=\; \left\{ W \in \mathrm{Gr}(r,n) \;\middle|\; \dim(W \cap F_{n-r+i-\lambda_i}) \geq i \;\text{ for } i = 1,\ldots,r \right\}$$

and $\Omega^\circ_\lambda(F_\bullet)$ is its open cell, on which each of these dimensions equals i and, in addition, $\dim(W \cap F_{n-r+i-\lambda_i-1}) = i-1$; equivalently, the function $j \mapsto \dim(W \cap F_j)$ takes its r jumps exactly at the indices $n-r+i-\lambda_i$. Write $\lambda \subseteq \mu$ for $\lambda_i \leq \mu_i$ for all i, $|\lambda| = \sum_i \lambda_i$, and $\lambda^\vee = (n-r-\lambda_r, \ldots, n-r-\lambda_1)$ for the complementary partition, so that $(\lambda^\vee)^\vee = \lambda$ and $|\lambda| + |\lambda^\vee| = r(n-r)$. Two conventions make every formula below uniform: σ_j denotes $\sigma_{(j)}$ for $1 \leq j \leq n-r$, with $\sigma_0 = [\mathrm{Gr}(r,n)]$ the unit of the ring and $\sigma_j = 0$ for $j < 0$ and for $j > n-r$; and $\sigma_\lambda = 0$ for any partition λ outside the box, that is, one with $\lambda_1 > n-r$ or with more than r nonzero parts.

The special classes have a description free of flags. For $1 \leq m \leq n-r$ put $a = n-r+1-m$ and, for a subspace $A \subseteq V$ of dimension a,

$$\Sigma_A \;=\; \{\, W \in \mathrm{Gr}(r,n) \,\big|\, W \cap A \neq 0 \,\}$$

Any complete flag $F_\bullet$ with $F_a = A$ has $\Omega_{(m)}(F_\bullet) = \Sigma_A$: the condition indexed by $i = 1$ is $\dim(W \cap A) \geq 1$, and the conditions indexed by $i \geq 2$ read $\dim(W \cap F_{n-r+i}) \geq i$, which every W satisfies because $\dim(W \cap F_j) \geq r + j - n$. Hence

$$\sigma_m \;=\; [\Sigma_A] \qquad \text{for every } A \text{ with } \dim A = n-r+1-m \tag{17.2}$$

and the class does not depend on which A is chosen, since σ_m does not depend on the flag.

Multiplying by σ_m adds m boxes to a Young diagram, and the rule says exactly which ways of adding them are allowed. Call μ obtained from λ by adding a *horizontal m-strip* if $\lambda \subseteq \mu$, $|\mu| = |\lambda| + m$,

and no two of the added boxes lie in the same column; in inequalities this is the interlacing condition

$$\mu_1 \;\geq\; \lambda_1 \;\geq\; \mu_2 \;\geq\; \lambda_2 \;\geq\; \cdots \;\geq\; \mu_r \;\geq\; \lambda_r$$

since $\mu_{i+1} \leq \lambda_i$ says precisely that row $i+1$ of μ stops before row i of λ ends, which is what forbids two added boxes in one column.

Theorem 17.2.1: Pieri's Formula

Let λ be a partition in the box and $m \geq 1$. Then in $A^*(\mathrm{Gr}(r,n))$

$$\sigma_\lambda \cdot \sigma_m \;=\; \sum_\mu \sigma_\mu$$

the sum being over the partitions μ in the box obtained from λ by adding a horizontal m-strip, that is, those μ with $|\mu| = |\lambda| + m$ and $\mu_1 \geq \lambda_1 \geq \mu_2 \geq \cdots \geq \mu_r \geq \lambda_r$.

***Proof*:**
For $m > n-r$ both sides vanish: the left side because $\sigma_m = 0$, and the right side because a horizontal m-strip occupies at least m columns, so every μ in the sum has $\mu_1 \geq m > n-r$ and lies outside the box. Assume therefore $1 \leq m \leq n-r$ and set $a = n-r+1-m$.

Step 1: the local form of a rank condition. Fix $W_0 \in \mathrm{Gr}(r,n)$ and a complement C, so $V = W_0 \oplus C$. The set $U_C = \{W \,\big|\, W \cap C = 0\}$ is open in $\mathrm{Gr}(r,n)$ and

$$\mathrm{Hom}(W_0, C) \longrightarrow U_C, \qquad \varphi \longmapsto \Gamma_\varphi = \{\, w + \varphi(w) \,\big|\, w \in W_0 \,\}$$

is an isomorphism of varieties carrying 0 to W_0; this is the standard affine chart of the Grassmannian, [30, Grassmannian]. Identify $T_{W_0}\,\mathrm{Gr}(r,n)$ with $\mathrm{Hom}(W_0, C)$, and C with V/W_0, through it.

Let $B \subseteq V$ be a subspace with $\dim(W_0 \cap B) = c$ exactly, let $\rho\colon V \to V/B$ be the quotient map, and let $M(\varphi) = \rho \circ (\mathrm{id}_{W_0} + \varphi)$, a linear map $W_0 \to V/B$ depending affinely on φ. Since $w + \varphi(w) \in B$ if and only if $M(\varphi)(w) = 0$, the locus $\{W \,\big|\, \dim(W \cap B) \geq c\}$ meets U_C in $\{\varphi \,\big|\, \mathrm{rk} M(\varphi) \leq r - c\}$. Split $W_0 = K' \oplus K$ with $K = W_0 \cap B$, and $V/B = M(0)(W_0) \oplus T$; in the resulting blocks

$$M(\varphi) \;=\; \begin{pmatrix} P(\varphi) & Q(\varphi) \\ R(\varphi) & S(\varphi) \end{pmatrix}, \qquad P(0) \text{ invertible}, \quad Q(0) = R(0) = S(0) = 0$$

because $M(0)$ kills K and maps K' isomorphically onto $M(0)(W_0)$. For φ near 0 the block $P(\varphi)$ is invertible, and the row and column operations

$$\begin{pmatrix} I & 0 \\ -RP^{-1} & I \end{pmatrix} M \begin{pmatrix} I & -P^{-1}Q \\ 0 & I \end{pmatrix} \;=\; \begin{pmatrix} P & 0 \\ 0 & S - RP^{-1}Q \end{pmatrix}$$

show that $\mathrm{rk} M(\varphi) \leq r - c$ if and only if $S(\varphi) - R(\varphi)P(\varphi)^{-1}Q(\varphi) = 0$. These are $c \cdot \dim T$ regular functions near $\varphi = 0$; as Q and R vanish at $\varphi = 0$ and depend affinely on φ, the term $RP^{-1}Q$ vanishes to order two, so the differential at $\varphi = 0$ of the system is $\varphi \mapsto S'(\varphi)$, the composite

$$\mathrm{Hom}(W_0, C) \longrightarrow \mathrm{Hom}(K, T), \qquad \varphi \longmapsto \big(K \xrightarrow{\varphi} C \xrightarrow{\rho} V/B \longrightarrow T\big)$$

Restriction $\mathrm{Hom}(W_0, C) \to \mathrm{Hom}(K, C)$ is surjective, and $C \to T$ is surjective because $V = W_0 + C$ while W_0 maps into $M(0)(W_0)$, which dies in T; so the differential is surjective. Consequently the locus $\{\dim(W \cap B) \geq c\}$ is smooth at W_0 of codimension $c \cdot \dim T$, with tangent space the kernel of that differential, namely

$$T_{W_0}\{\dim(W \cap B) \geq c\} \;=\; \left\{ \varphi \in \mathrm{Hom}(W_0, V/W_0) \;\middle|\; \varphi(W_0 \cap B) \subseteq (W_0 + B)/W_0 \right\} \tag{17.3}$$

Any closed subscheme of $\mathrm{Gr}(r, n)$ contained in this locus and passing through W_0 has its tangent space at W_0 contained in the right-hand side of (17.3).

Step 2: reduction to a triple intersection number. By theorem 17.1.4 write $\sigma_\lambda \cdot \sigma_m = \sum_\mu c_\mu \sigma_\mu$ over the partitions μ in the box with $|\mu| = |\lambda| + m$. Pairing with a complementary class and using proposition 17.1.3 in the form $\deg(\sigma_\theta \cdot \sigma_{\mu^\vee}) = \delta_{\theta\mu}$,

$$c_\mu \;=\; \deg\left(\sigma_\lambda \cdot \sigma_m \cdot \sigma_{\mu^\vee}\right) \tag{17.4}$$

so the theorem is the assertion that this triple intersection number is 1 when μ/λ is a horizontal m-strip and 0 otherwise.

Fix a basis $e_1, \ldots, e_n$ of V and the two opposite flags $F_i = \langle e_1, \ldots, e_i \rangle$ and $G_i = \langle e_{n-i+1}, \ldots, e_n \rangle$, and abbreviate $G'_l = \langle e_l, \ldots, e_n \rangle = G_{n-l+1}$. Represent the three classes by $\Omega_\lambda(F_\bullet)$, by $\Omega_{\mu^\vee}(G_\bullet)$, and by Σ_A as in (17.2), with A to be chosen. Put

$$j_i \;=\; n - r + i - \lambda_i, \qquad l_i \;=\; n - r + i - \mu_i, \qquad E_i \;=\; \langle e_{l_i}, \ldots, e_{j_i} \rangle$$

so that $j_1 < \cdots < j_r$ and $l_1 < \cdots < l_r$, all lying in $[1, n]$. Rewriting the conditions cutting out $\Omega_{\mu^\vee}(G_\bullet)$ in terms of the index $i' = r + 1 - i$, using $(\mu^\vee)_i = (n - r) - \mu_{r+1-i}$, they read $\dim(W \cap G'_{l_{i'}}) \geq r + 1 - i'$. So

$$Y \;:=\; \Omega_\lambda(F_\bullet) \cap \Omega_{\mu^\vee}(G_\bullet) \;=\; \left\{ W \;\middle|\; \dim(W \cap F_{j_i}) \geq i \;\text{ and }\; \dim(W \cap G'_{l_i}) \geq r + 1 - i \;\text{ for all } i \right\} \tag{17.5}$$

Step 3: the geometry of Y. For any $W \in Y$ and any i, the two subspaces $W \cap F_{j_i}$ and $W \cap G'_{l_i}$ of W have dimensions at least i and $r + 1 - i$, so they meet in a subspace of dimension at least 1; as $F_{j_i} \cap G'_{l_i} = \langle e_{l_i}, \ldots, e_{j_i} \rangle$ when $l_i \leq j_i$ and 0 otherwise, this gives two consequences.

First, if $\mu \not\supseteq \lambda$, say $\mu_i < \lambda_i$, then $l_i > j_i$ and the intersection $F_{j_i} \cap G'_{l_i}$ is zero, so $Y = \emptyset$. The refined product of definition 14.1.10 then lies in $A_*(Y) = 0$, and proposition 14.1.11 gives $\sigma_\lambda \cdot \sigma_{\mu^\vee} = 0$, whence $c_\mu = 0$ by (17.4). Assume from now on $\lambda \subseteq \mu$, so $l_i \leq j_i$ and $E_i \neq 0$ for every i; then $W \cap E_i \neq 0$ for every $W \in Y$ and every i.

Second, let $P = E_1 + \cdots + E_r$, spanned by the e_s with s in the union $T = \bigcup_i [l_i, j_i]$. Every $W \in Y$ satisfies $W \subseteq P$. To see this, let $g \in [1, n] \setminus T$ be a gap. For each i exactly one of $j_i < g$ and $l_i > g$ holds; write α and β for the number of indices of each kind, so $\alpha + \beta = r$. The indices with $j_i < g$ are $1, \ldots, \alpha$ and the indices with $l_i > g$ are $r - \beta + 1, \ldots, r$, since $j_\bullet$ and $l_\bullet$ increase. Taking $i = \alpha$ in the first family of conditions of (17.5) gives $\dim(W \cap F_{g-1}) \geq \alpha$, since $F_{j_\alpha} \subseteq F_{g-1}$, and taking $i = r - \beta + 1$ in the second gives $\dim(W \cap G'_{g+1}) \geq \beta$, since $G'_{l_{r-\beta+1}} \subseteq G'_{g+1}$; both bounds are vacuous when the count in question is zero. These two subspaces of W intersect in $W \cap F_{g-1} \cap G'_{g+1} = 0$ and their dimensions sum to at least $r = \dim W$, so

$$W \;=\; (W \cap F_{g-1}) \oplus (W \cap G'_{g+1}) \;\subseteq\; \langle e_s \,|\, s \neq g \rangle$$

As g was an arbitrary gap, $W \subseteq P$.

The intervals $[l_i, j_i]$ have lengths $j_i - l_i + 1 = \mu_i - \lambda_i + 1$, summing to $m+r$, and consecutive ones are disjoint exactly when $j_i < l_{i+1}$, that is when $\mu_{i+1} \leq \lambda_i$. So the intervals are pairwise disjoint precisely when μ/λ is a horizontal m-strip, in which case $\dim P = m+r$ and $P = E_1 \oplus \cdots \oplus E_r$; otherwise $\dim P \leq m+r-1$.

In the horizontal-strip case Y is exactly the set of W of the form $\langle w_1, \ldots, w_r \rangle$ with $0 \neq w_i \in E_i$. One inclusion holds because such a W has $w_1, \ldots, w_i \in F_{j_i}$ and $w_i, \ldots, w_r \in G'_{l_i}$, the w's being independent as the E_i are spanned by disjoint sets of basis vectors. Conversely for $W \in Y$ choose $0 \neq w_i \in W \cap E_i$; these are independent, hence a basis of W. The resulting bijection is the morphism

$$\mathbb{P}(E_1) \times \cdots \times \mathbb{P}(E_r) \longrightarrow \mathrm{Gr}(r,n) \subseteq \mathbb{P}(\textstyle\bigwedge^r V), \qquad (\langle w_1 \rangle, \ldots, \langle w_r \rangle) \longmapsto [w_1 \wedge \cdots \wedge w_r]$$

which is the Segre embedding followed by the linear map $E_1 \otimes \cdots \otimes E_r \to \bigwedge^r V$ sending $e_{s_1} \otimes \cdots \otimes e_{s_r} \mapsto e_{s_1} \wedge \cdots \wedge e_{s_r}$; distinct basis tensors of the source go to distinct nonzero basis vectors of the target because the intervals are disjoint, so that linear map is injective and the composite is a closed immersion. Thus $Y \cong \mathbb{P}(E_1) \times \cdots \times \mathbb{P}(E_r)$ is a smooth irreducible variety of dimension $\sum_i (\mu_i - \lambda_i) = m$.

Step 4: choosing A. Call $A \in \mathrm{Gr}(a,n)$ *admissible* if, for every one of the finitely many partitions μ in the box with $|\mu| = |\lambda| + m$ and $\lambda \subseteq \mu$, writing P_μ and E_i^μ for the subspaces just constructed: A meets no one of the subspaces

$$P_\mu \text{ (when } \mu/\lambda \text{ is not a horizontal strip)}, \qquad P_\mu \cap \{x_{l_i} = 0\}, \qquad P_\mu \cap \{x_{j_i} = 0\}$$

nontrivially, and $\dim(A \cap P_\mu) \leq 1$ for the remaining μ. Each listed subspace has dimension at most $m+r-1$, and $a + (m+r-1) = n$, so for each of them the set of A meeting it nontrivially is a proper closed subset of $\mathrm{Gr}(a,n)$: closed because it is cut out by a rank condition, and proper because a basis of the subspace extends to a basis of V whose remaining a vectors span a complementary A. Likewise $\{A \,|\, \dim(A \cap P_\mu) \geq 2\}$ is a proper closed subset. Finitely many conditions are imposed, so an admissible A exists; fix one.

Let $\mu \supseteq \lambda$ with μ/λ not a horizontal strip. Then $A \cap P_\mu = 0$, so $Y \cap \Sigma_A = \emptyset$ because every $W \in Y$ lies in P_μ. By definition 14.1.10 the refined product of $[\Omega_\lambda(F_\bullet)]$ and $[\Omega_{\mu^\vee}(G_\bullet)]$ is a class $\gamma \in A_m(Y)$ whose image in $A_m(\mathrm{Gr}(r,n))$ is $\sigma_\lambda \cdot \sigma_{\mu^\vee}$ (proposition 14.1.11); applying the same two results to γ and $[\Sigma_A]$, the product $(\sigma_\lambda \cdot \sigma_{\mu^\vee}) \cdot \sigma_m$ is the image of a class in $A_0(Y \cap \Sigma_A) = 0$. Hence $c_\mu = 0$ by (17.4).

Step 5: the horizontal-strip case. Let μ/λ be a horizontal m-strip, so $P = \bigoplus_i E_i$ has dimension $m+r$ and $\dim(A \cap P) = 1$, admissibility giving both ≤ 1 and, since $a + \dim P = n+1$, also ≥ 1. Write $A \cap P = \langle v \rangle$ and $v = v_1 + \cdots + v_r$ with $v_i \in E_i$. Admissibility says v has nonzero coefficient on e_{l_i} and on e_{j_i} for every i; in particular every $v_i \neq 0$. Set $W_0 = \langle v_1, \ldots, v_r \rangle \in Y$.

First, $\sigma_\lambda \cdot \sigma_{\mu^\vee} = [Y]$. The two Schubert varieties have dimensions $r(n-r) - |\lambda|$ and $r(n-r) - |\mu^\vee| = |\mu|$, whose sum minus $r(n-r)$ is $m = \dim Y$, and Y is irreducible, so proposition 14.3.11 applies once a suitable point is exhibited. Take W_0. Its intersections with the flag $F_\bullet$ are governed by the largest index s with e_s occurring in a given vector: that index is j_i for v_i, and distinct v_i involve disjoint sets of basis vectors, so $\dim(W_0 \cap F_p) = \#\{i \,|\, j_i \leq p\}$ for every p. That function jumps exactly at $j_1, \ldots, j_r$, which are the indices $n - r + i - \lambda_i$ attached to λ; symmetrically

the smallest occurring index of v_i is l_i, so $\dim(W_0 \cap G_q) = \#\{i \,|\, l_i \geq n-q+1\}$ for every q, jumping exactly at the indices $n+1-l_i$, which are those attached to $\mu^\vee$. Both jump patterns are the ones prescribed by definition 17.1.1, so W_0 lies in both open cells, where the Schubert varieties are smooth by proposition 17.1.2. For the tangent spaces, $W_0 \cap F_{j_i} = \langle v_1, \ldots, v_i \rangle$ and $W_0 \cap G'_{l_i} = \langle v_i, \ldots, v_r \rangle$, so (17.3) applied to each rank condition bounds

$$T_{W_0}\Omega_\lambda(F_\bullet) \cap T_{W_0}\Omega_{\mu^\vee}(G_\bullet) \;\subseteq\; \left\{ \varphi \;\middle|\; \varphi(v_i) \in \left[(F_{j_i} + W_0) \cap (G'_{l_i} + W_0)\right]/W_0 \;\text{ for all } i \right\}$$

the condition indexed by k constraining φ on $\langle v_1, \ldots, v_k \rangle$ and on $\langle v_k, \ldots, v_r \rangle$ respectively, so that the vector v_i is constrained by the conditions with $k \geq i$ in the first family and $k \leq i$ in the second, of which the binding ones are $k = i$ in both, the spaces F_{j_k} increasing and the spaces G'_{l_k} decreasing with k. Now $\dim(F_{j_i}+W_0) = j_i + r - i$ and $\dim(G'_{l_i}+W_0) = (n-l_i+1)+r-(r+1-i) = n - l_i + i$, while $F_{j_i} + G'_{l_i} = V$ because $l_i \leq j_i$; so the two sum to V and their intersection has dimension $(j_i + r - i) + (n - l_i + i) - n = j_i - l_i + r$. That is the dimension of $E_i + W_0$, which is contained in it, so the two agree and the displayed bound reads $\varphi(v_i) \in (E_i + W_0)/W_0$ for all i. Since $v_1, \ldots, v_r$ is a basis of W_0 and $\dim(E_i + W_0)/W_0 = j_i - l_i$, that space of φ has dimension $\sum_i (j_i - l_i) = m$. Proposition 14.3.11 applies and gives $\sigma_\lambda \cdot \sigma_{\mu^\vee} = [Y]$; incidentally the bound is an equality on $T_{W_0}Y$, which has dimension m and is contained in it, so

$$T_{W_0}Y \;=\; \left\{ \varphi \;\middle|\; \varphi(v_i) \in (E_i + W_0)/W_0 \;\text{ for all } i \right\} \tag{17.6}$$

Second, $\deg([Y] \cdot \sigma_m) = 1$. Set-theoretically $Y \cap \Sigma_A$ is the single point W_0: any $W \in Y$ meeting A meets $P \cap A = \langle v \rangle$, hence contains v, and writing $W = \langle w_1, \ldots, w_r \rangle$ with $w_i \in E_i$ and comparing E_i-components of $v \in W$ forces $\langle w_i \rangle = \langle v_i \rangle$ for every i, so $W = W_0$. Both Y and Σ_A are smooth at W_0, the former being a product of projective spaces and the latter by Step 1 applied to $B = A$ and $c = 1$, which is legitimate because $\dim(W_0 \cap A) = 1$; the same step gives $T_{W_0}\Sigma_A = \{\varphi \,|\, \varphi(v) \in (A + W_0)/W_0\}$. Let φ lie in both tangent spaces and write $\varphi(v_i) = u_i \bmod W_0$ with $u_i \in E_i$, which (17.6) permits. Then $\varphi(v) = \sum_i u_i \bmod W_0$ lies in $(A + W_0)/W_0$, so $\sum_i u_i \in P \cap (A + W_0)$. That intersection is W_0: if $p = \alpha + w$ with $p \in P$, $\alpha \in A$ and $w \in W_0 \subseteq P$, then $\alpha = p - w \in A \cap P = \langle v \rangle \subseteq W_0$, so $p \in W_0$. Hence $\sum_i u_i \in W_0 = \bigoplus_i \langle v_i \rangle$, and comparing components in $P = \bigoplus_i E_i$ gives $u_i \in \langle v_i \rangle$, that is $\varphi = 0$. So the tangent spaces meet in 0, which is the expected dimension $\dim Y + \dim \Sigma_A - r(n-r) = 0$, and proposition 14.3.11 applied to Y and Σ_A gives $[Y] \cdot [\Sigma_A] = [\{W_0\}]$, a reduced point, of degree 1 by definition 10.2.4.

Combining the two, $c_\mu = \deg(\sigma_\lambda \cdot \sigma_{\mu^\vee} \cdot \sigma_m) = \deg([Y] \cdot [\Sigma_A]) = 1$. With Steps 3 and 4 this evaluates every coefficient in (17.4), as we sought to show.

The rule is an algorithm: every product of special classes can be expanded by applying it repeatedly, and theorem 17.2.4 will show that this exhausts the ring. The combinatorial side deserves one remark. The box constrains the answer twice, once by discarding μ with more than r rows and once by discarding μ with $\mu_1 > n - r$; both discards are invisible in the interlacing inequalities and are what make the ring finite rather than a ring of symmetric functions.

The conventions fixed above extend the formula to every partition, which is what the inductions below use. If λ lies outside the box then so does every $\mu \supseteq \lambda$, and both sides of Pieri's formula vanish. If λ lies in the box but $m > n - r$, the left side vanishes and every μ occurring on the right has $\mu_1 \geq m > n - r$, so the right side vanishes too. And for $m = 0$ the only horizontal 0-strip is the

empty one, so the formula reads $\sigma_\lambda \cdot \sigma_0 = \sigma_\lambda$. Hence for all partitions λ and all $m \geq 0$,

$$\sigma_\lambda \cdot \sigma_m \;=\; \sum_{\mu} \sigma_\mu \tag{17.7}$$

summed over all partitions μ obtained from λ by adding a horizontal m-strip, with $\sigma_\theta = 0$ for θ outside the box.

Example 17.2.2: Lines Meeting Four General Lines in $\mathbb{P}^3$

Take $r = 2$ and $n = 4$, so $\mathrm{Gr}(2,4)$ parametrizes the lines of $\mathbb{P}^3$ and has dimension four, with box the 2×2 square. Here $\sigma_1 = [\Sigma_A]$ with $\dim A = 2$ by (17.2): the condition $W \cap A \neq 0$ says that the line of $\mathbb{P}^3$ determined by W meets the line determined by A. So $\deg(\sigma_1^4)$ is the intersection number attached to the classical problem of lines meeting four given lines.

The computation. Pieri's formula gives, in the 2×2 box,

$$\sigma_1^2 \;=\; \sigma_2 + \sigma_{1,1}$$

since one box may be added to the single box of (1) either beside it or below it. Multiplying again, $\sigma_2 \cdot \sigma_1 = \sigma_{2,1}$, the partition (3) falling outside the box, and $\sigma_{1,1} \cdot \sigma_1 = \sigma_{2,1}$, the partition $(1,1,1)$ having three rows; hence

$$\sigma_1^3 \;=\; 2\,\sigma_{2,1}, \qquad \sigma_1^4 \;=\; 2\,\sigma_{2,1} \cdot \sigma_1 \;=\; 2\,\sigma_{2,2}$$

because the only box addable to $(2,1)$ inside the square is the one completing it. Now $\sigma_{2,2}$ is the class of a point, $(2,2)$ being the full box, so $\deg(\sigma_1^4) = 2$. Duality gives the same answer from the second line: $\deg(\sigma_1^4) = \deg\big((\sigma_2 + \sigma_{1,1})^2\big) = \deg(\sigma_2^2) + 2\deg(\sigma_2\sigma_{1,1}) + \deg(\sigma_{1,1}^2) = 1 + 0 + 1$, using proposition 17.1.3 and $(2)^\vee = (2)$, $(1,1)^\vee = (1,1)$.

The geometry. Let $L_1, \ldots, L_4 \subseteq \mathbb{P}^3$ be four general lines. The first three are pairwise skew and lie on a unique smooth quadric surface Q, which they meet as three members of one of its two rulings; a line meets all three exactly when it belongs to the other ruling. The fourth line meets Q in two distinct points, and through each point passes exactly one line of the second ruling. So exactly two lines meet all four, and the number two is attained by two distinct honest solutions rather than by one solution counted twice.

Example 17.2.3: Incidence Counts for Lines in $\mathbb{P}^4$

Take $r = 2$ and $n = 5$, so $\mathrm{Gr}(2,5)$ parametrizes the lines of $\mathbb{P}^4$, has dimension six, and has the 2×3 rectangle as its box. By (17.2), $\sigma_1 = [\Sigma_A]$ with $\dim A = 3$: the lines meeting a fixed plane of $\mathbb{P}^4$. Likewise $\sigma_2 = [\Sigma_A]$ with $\dim A = 2$: the lines meeting a fixed line.

Repeated application of theorem 17.2.1 inside the 2×3 box gives

$$\begin{aligned}
\sigma_1^2 &= \sigma_2 + \sigma_{1,1} \\
\sigma_1^3 &= (\sigma_3 + \sigma_{2,1}) + \sigma_{2,1} \;=\; \sigma_3 + 2\,\sigma_{2,1} \\
\sigma_1^4 &= \sigma_{3,1} + 2(\sigma_{3,1} + \sigma_{2,2}) \;=\; 3\,\sigma_{3,1} + 2\,\sigma_{2,2} \\
\sigma_1^5 &= 3\,\sigma_{3,2} + 2\,\sigma_{3,2} \;=\; 5\,\sigma_{3,2} \\
\sigma_1^6 &= 5\,\sigma_{3,3}
\end{aligned}$$

where at each stage the partitions with a first part exceeding 3 or with three rows are discarded. For instance $\sigma_{2,1} \cdot \sigma_1 = \sigma_{3,1} + \sigma_{2,2}$, the third candidate $(2,1,1)$ having three rows. Since $\sigma_{3,3}$ is

the point class, $\deg(\sigma_1^6) = 5$: five lines of $\mathbb{P}^4$ meet six general planes.
The same table answers a mixed problem. From $\sigma_1^4 = 3\sigma_{3,1}+2\sigma_{2,2}$ and $(3,1)^\vee = (2)$, $(2,2)^\vee = (1,1)$,

$$\deg\left(\sigma_2 \cdot \sigma_1^4\right) \;=\; 3\deg(\sigma_2 \cdot \sigma_{3,1}) + 2\deg(\sigma_2 \cdot \sigma_{2,2}) \;=\; 3$$

by proposition 17.1.3: three lines of $\mathbb{P}^4$ meet four general planes and one general line.
The first number has a second reading. For $\dim A = n - r$ the condition $W \cap A \neq 0$ is equivalent to $W + A \neq V$, hence to the vanishing of $w_1 \wedge \cdots \wedge w_r \wedge a_1 \wedge \cdots \wedge a_{n-r} \in \bigwedge^n V \cong \overline{k}$, which is a linear condition on the Plücker coordinates of W. So σ_1 is the hyperplane class of the Plücker embedding ([30, Plücker Embedding]), and $\deg(\sigma_1^{r(n-r)})$ is the degree of $\mathrm{Gr}(r,n)$ in the projective space it embeds into: $\mathrm{Gr}(2,4) \subseteq \mathbb{P}^5$ has degree 2 and $\mathrm{Gr}(2,5) \subseteq \mathbb{P}^9$ has degree 5.
These numbers are intersection numbers. That a general choice of the incidence data makes the intersection transverse, so that the number counts distinct solutions, is a separate assertion; it was verified by hand for four lines in example 17.2.2, and in general it rests on a transversality theorem for the transitive action of $\mathrm{GL}(V)$ on $\mathrm{Gr}(r,n)$, which this book does not prove (see [38]).

Pieri's formula computes with one special factor at a time, which is enough to multiply out any polynomial in the special classes but says nothing about a product such as $\sigma_{2,1} \cdot \sigma_{2,1}$. Giambelli's formula removes the gap by expressing every Schubert class as a polynomial in the special ones, after which every product is computable by iterated Pieri. The polynomial is a determinant, and the determinant is the one that computes a Schur polynomial from the complete homogeneous symmetric polynomials.

Theorem 17.2.4: Giambelli's Formula

Let λ be a partition with at most ℓ nonzero parts. Then

$$\det\left(\sigma_{\lambda_p+q-p}\right)_{1\le p,q\le \ell} \;=\; \sigma_\lambda$$

in $A^*(\mathrm{Gr}(r,n))$: the determinant equals the Schubert class σ_λ when λ lies in the box, and vanishes otherwise. In particular the value of the determinant does not depend on the choice of $\ell \ge \ell(\lambda)$, and the special classes $\sigma_1, \ldots, \sigma_{n-r}$ generate $A^*(\mathrm{Gr}(r,n))$ as a ring.

***Proof*:**
Write $D_\ell(\lambda)$ for the determinant, entries being read with the conventions $\sigma_0 = 1$ and $\sigma_j = 0$ for $j < 0$ or $j > n - r$. Independence of ℓ is immediate: a row indexed by $p > \ell(\lambda)$ has entries σ_{q-p}, which vanish for $q < p$ and equal 1 for $q = p$, so expanding along the last row of an $\ell \times \ell$ determinant with $\ell > \ell(\lambda)$ returns the $(\ell-1) \times (\ell-1)$ one. The proof of the identity is by induction on ℓ, the case $\ell = 0$ being the empty determinant $1 = \sigma_\emptyset$.

Step 1: expansion along the first column. Let λ have at most $\ell \ge 1$ parts. The entry in position $(p,1)$ is $\sigma_{\lambda_p - p+1}$, and deleting row p and column 1 leaves the matrix with entries σ_{λ_i+q-i} for $i \neq p$ and $q \ge 2$. Re-indexing rows by $i' \in \{1, \ldots, \ell-1\}$ and columns by $q' = q - 1$, the entry becomes $\sigma_{(\lambda_{i'}+1)+q'-i'}$ for $i' < p$ and $\sigma_{\lambda_{i'+1}+q'-i'}$ for $i' \ge p$. So that minor is $D_{\ell-1}(\beta(p))$ for the sequence

$$\beta(p) \;=\; (\lambda_1 + 1, \ldots, \lambda_{p-1} + 1, \lambda_{p+1}, \ldots, \lambda_\ell)$$

which is a partition with $\ell - 1$ parts, being weakly decreasing at the junction because $\lambda_{p-1} + 1 >$

$\lambda_{p-1} \geq \lambda_{p+1}$. Laplace expansion and the inductive hypothesis give

$$D_\ell(\lambda) \;=\; \sum_{p=1}^{\ell} (-1)^{p-1}\, \sigma_{\lambda_p - p + 1}\, \sigma_{\beta(p)}$$

and (17.7) expands each summand as a sum of Schubert classes. Writing T_p for the set of partitions μ with at most ℓ parts obtained from $\beta(p)$ by adding a horizontal strip of size $\lambda_p - p + 1$, and noting that every such μ has $|\mu| = |\beta(p)| + \lambda_p - p + 1 = |\lambda|$,

$$D_\ell(\lambda) \;=\; \sum_{\mu} c_\mu \sigma_\mu, \qquad c_\mu = \sum_{p\,:\,\mu \in T_p} (-1)^{p-1}$$

the outer sum running over partitions μ of $|\lambda|$ with at most ℓ parts. It remains to prove that $c_\mu = \delta_{\mu\lambda}$.

Step 2: the membership conditions. Interlacing for the pair $\beta(p) \subseteq \mu$ says $\mu_i \geq \beta(p)_i \geq \mu_{i+1}$ for $1 \leq i \leq \ell - 1$. Substituting the entries of $\beta(p)$, and pairing each inequality with the index at which it constrains μ, the condition $\mu \in T_p$ is the conjunction of $|\mu| = |\lambda|$ with

$$\begin{aligned} &\text{(A) } \mu_i \geq \lambda_i + 1 \ (i < p); && \text{(B) } \mu_q \leq \lambda_{q-1} + 1 \ (2 \leq q \leq p);\\ &\text{(C) } \mu_i \geq \lambda_{i+1} \ (p \leq i \leq \ell - 1); && \text{(D) } \mu_q \leq \lambda_q \ (q > p) \end{aligned}$$

Let $S = \{i \in [1,\ell] \,\big|\, \mu_i > \lambda_i\}$. Conditions (A) and (D) force $[1, p-1] \subseteq S \subseteq [1, p]$, so T_p can contain μ only if S is an initial segment $[1, \alpha]$ and $p \in \{\alpha, \alpha + 1\}$.

If $\mu = \lambda$ then $S = \emptyset$, so only $p = 1$ can contribute; and $\lambda \in T_1$, since (A) and (B) are vacuous, (D) holds with equality, and (C) is $\lambda_i \geq \lambda_{i+1}$. Hence $c_\lambda = 1$.

If $\mu \neq \lambda$ then $S \neq \emptyset$, because $|\mu| = |\lambda|$ forbids $\mu_i \leq \lambda_i$ for all i unless $\mu = \lambda$; and $S \neq [1, \ell]$ for the same reason. So either S is not an initial segment, in which case no p contributes and $c_\mu = 0$, or $S = [1, \alpha]$ with $1 \leq \alpha \leq \ell - 1$ and only $p = \alpha$ and $p = \alpha + 1$ can contribute. For those two values, (A) and (D) hold automatically by the definition of S, and the remaining conditions differ in exactly two inequalities: $p = \alpha$ additionally requires (C) at $i = \alpha$, namely $\mu_\alpha \geq \lambda_{\alpha+1}$, and $p = \alpha + 1$ additionally requires (B) at $q = \alpha + 1$, namely $\mu_{\alpha+1} \leq \lambda_\alpha + 1$. Both hold automatically: $\mu_\alpha \geq \lambda_\alpha + 1 > \lambda_{\alpha+1}$ because $\alpha \in S$, and $\mu_{\alpha+1} \leq \lambda_{\alpha+1} \leq \lambda_\alpha + 1$ because $\alpha + 1 \notin S$. So μ belongs to T_α if and only if it belongs to $T_{\alpha+1}$, and the two contributions $(-1)^{\alpha-1}$ and $(-1)^\alpha$ cancel, giving $c_\mu = 0$.

Hence $D_\ell(\lambda) = \sigma_\lambda$. For the last assertion, the formula writes each σ_λ as a polynomial with integer coefficients in $\sigma_1, \ldots, \sigma_{n-r}$, and the classes σ_λ with λ in the box span $A^*(\mathrm{Gr}(r,n))$ by theorem 17.1.4, completing the proof.

The determinant is the Jacobi-Trudi determinant. In the ring Λ_d of symmetric polynomials in d variables over $\mathbb{Z}$, the Schur polynomial s_λ satisfies the two Jacobi-Trudi formulas [17, Jacobi–Trudi Formulas]

$$s_\lambda \;=\; \det\left(h_{\lambda_p + q - p}\right)_{1 \leq p,q \leq \ell(\lambda)}, \qquad s_\lambda \;=\; \det\left(e_{\lambda'_p + q - p}\right)_{1 \leq p,q \leq \lambda_1}$$

where h_j and e_j are the complete homogeneous and elementary symmetric polynomials and λ' is the conjugate partition. Both hold in Λ_d for every partition, by specialization from the ring of symmetric functions in infinitely many variables, where $e_j = 0$ for $j > d$. Also $s_\lambda = 0$ in Λ_d whenever

$\ell(\lambda) > d$. Theorem 17.2.4 says that the assignment $h_j \mapsto \sigma_j$ turns the first of these into the Schubert basis, truncated by the box. The truncation is what the next result makes precise: the relations of $A^*(\mathrm{Gr}(r,n))$ are exactly the vanishing of the Schur classes that fall out of the box.

Corollary 17.2.5: Presentation of the Chow Ring of the Grassmannian

Let $d = n - r$ and let $R = \mathbb{Z}[t_1, \dots, t_d]$ be graded by $\deg t_i = i$. Put $t_0 = 1$, $t_i = 0$ for $i < 0$ and for $i > d$, and

$$Y_j \;=\; \det\left(t_{1+q-p}\right)_{1\le p,q\le j} \;\in\; R$$

Then $t_i \mapsto \sigma_i$ induces an isomorphism of graded rings

$$R/(Y_{r+1}, Y_{r+2}, \dots, Y_n) \;\xrightarrow{\sim}\; A^*(\mathrm{Gr}(r,n))$$

***Proof*:**
Write $\varphi\colon R \to A^*(\mathrm{Gr}(r,n))$ for the graded ring homomorphism with $\varphi(t_i) = \sigma_i$, which exists and is unique because R is a polynomial ring. For a partition λ put $S_\lambda = \det(t_{\lambda_p+q-p})_{1\le p,q\le \ell(\lambda)}$, so that $Y_j = S_{(1^j)}$ and, by theorem 17.2.4, $\varphi(S_\lambda) = \sigma_\lambda$, this being 0 exactly when λ is outside the box.

Step 1: a symmetric-function model for R. The elementary symmetric polynomials $e_1, \dots, e_d$ generate Λ_d over $\mathbb{Z}$: [17, Schur Polynomials Are a Basis] gives a $\mathbb{Z}$-basis of Λ_d by Schur polynomials, and [17, Jacobi–Trudi Formulas] writes each Schur polynomial as an integer determinant in the e_i. The coefficient ring matters here, since Λ_d is taken over $\mathbb{Z}$ and the $\mathbb{Q}$-coefficient statements do not give $\mathbb{Z}$-generation. So $\psi\colon R \to \Lambda_d$ with $\psi(t_i) = e_i$ is a graded surjection.

It is an isomorphism by a rank count. This is equivalent to algebraic independence of the e_i over $\mathbb{Z}$, which the count establishes. Both R and Λ_d are free $\mathbb{Z}$-modules in each degree N: $\mathrm{rk} R_N$ is the number of partitions of N with all parts at most d, and $\mathrm{rk}(\Lambda_d)_N$ is the number of partitions of N with at most d parts. Conjugation $\lambda \mapsto \lambda'$ matches the two sets, so the ranks agree and a graded surjection of free $\mathbb{Z}$-modules of equal finite rank in each degree is an isomorphism. For a partition λ with $\lambda_1 \le d$ the second Jacobi-Trudi formula applied to λ', whose conjugate is λ and whose first part is $\ell(\lambda)$, gives $\psi(S_\lambda) = s_{\lambda'}$; in particular $\psi(Y_j) = s_{(j)} = h_j$. Since the s_μ with $\ell(\mu) \le d$ form a $\mathbb{Z}$-basis of Λ_d [17, Schur Polynomials Are a Basis], and $\lambda \mapsto \lambda'$ is a bijection between the partitions with $\lambda_1 \le d$ and those with $\ell(\mu) \le d$, the elements S_λ with $\lambda_1 \le d$ form a $\mathbb{Z}$-basis of R.

Step 2: the kernel. On that basis, $\varphi(S_\lambda) = \sigma_\lambda$ is nonzero exactly when λ lies in the box, that is when $\ell(\lambda) \le r$, the constraint $\lambda_1 \le d$ being already imposed; and distinct such λ give distinct basis elements σ_λ of $A^*(\mathrm{Gr}(r,n))$. Hence φ is surjective and

$$\ker\varphi \;=\; \bigoplus_{\lambda_1\le d,\ \ell(\lambda)>r} \mathbb{Z}\, S_\lambda$$

This kernel is the ideal generated by the Y_j with $j > r$. One containment holds because $Y_j = S_{(1^j)}$ has $\ell = j > r$, so lies in $\ker\varphi$, and $\ker\varphi$ is an ideal. For the other, let $\lambda_1 \le d$ and $\ell(\lambda) > r$. Applying ψ and the first Jacobi-Trudi formula to λ', which has $\ell(\lambda') = \lambda_1 \le d$ parts and first

part $\lambda'_1 = \ell(\lambda)$,

$$\psi(S_\lambda) \;=\; s_{\lambda'} \;=\; \det\left(h_{\lambda'_p+q-p}\right)_{1\le p,q\le\lambda_1}$$

whose first row consists of the entries $h_{\lambda'_1+q-1}$ with indices at least $\lambda'_1 = \ell(\lambda) > r$. Expanding along that row exhibits $s_{\lambda'}$ in the ideal generated by the h_j with $j > r$, so S_λ lies in the ideal generated by the Y_j with $j > r$.

Step 3: finitely many relations suffice. Expand Y_j along its first row. Its entries are t_q for $q = 1, \dots, j$, and the minor obtained by deleting row 1 and column q is block lower triangular: its entries t_{1+c-p} vanish for $c < p-1$, so the rows $2, \dots, q$ meet the columns $1, \dots, q-1$ in a lower triangular block with 1's on the diagonal $c = p-1$ and the rows $q+1, \dots, j$ vanish on those columns, while the rows and columns from $q+1$ to j form the matrix of Y_{j-q}. Hence

$$Y_j \;=\; \sum_{q=1}^{j} (-1)^{q-1}\, t_q\, Y_{j-q} \;=\; \sum_{q=1}^{d} (-1)^{q-1}\, t_q\, Y_{j-q}$$

the second equality because $t_q = 0$ for $q > d$. For $j > n$ every index appearing on the right satisfies $j - q \ge j - d > n - d = r$, so induction on j puts every Y_j with $j > n$ in the ideal generated by $Y_{r+1}, \dots, Y_n$. Therefore $\ker\varphi = (Y_{r+1}, \dots, Y_n)$ and φ induces the stated isomorphism, completing the proof.

The presentation identifies the relations with a statement about the tautological bundles. Since $\sigma_j = c_j(Q)$ and $c(S)c(Q) = 1$ by proposition 17.1.5, the class $(-1)^j Y_j$ evaluated at $t_i = \sigma_i$ is the degree j part of the inverse of the total Chern class of Q, that is $c_j(S)$; and S has rank r, so $c_j(S) = 0$ for $j > r$. The relations of corollary 17.2.5 are exactly these vanishings, and the content of the corollary is that they are the only ones. Two rank counts confirm the shape of the answer: the presentation has $n-r$ generators and $n-r$ relations, and the quotient is free of rank $\binom{n}{r}$, the number of partitions in the box.

Exercise 17.2.1

1. Let λ be a partition in the box. Using theorem 17.2.1, show that

$$\sigma_\lambda \cdot \sigma_{n-r} \;=\; \begin{cases} \sigma_{(n-r,\,\lambda_1,\dots,\lambda_{r-1})} & \text{if } \lambda_r = 0 \\ 0 & \text{if } \lambda_r > 0 \end{cases}$$

   (Compare the sizes of $\mu_2 + \cdots + \mu_r$ and $\lambda_1 + \cdots + \lambda_{r-1}$ for any μ occurring in the sum.)

2. Take $r = 1$, so that $\mathrm{Gr}(1, n) = \mathbb{P}^{n-1}$. Show that in the presentation of corollary 17.2.5 the relations $Y_2 = \cdots = Y_{n-1} = 0$ force $t_j = t_1^j$ for $j \le n-1$, and that Y_n then becomes $(-1)^n t_1^n$; conclude that the presentation reads $\mathbb{Z}[\sigma_1]/(\sigma_1^n)$ and identify σ_1 with the hyperplane class of theorem 10.5.2.

3. With R, t_i and Y_j as in corollary 17.2.5, prove that in $R[[u]]$

$$\Big(\sum_{i\ge 0} t_i u^i\Big)^{-1} \;=\; \sum_{j\ge 0} (-1)^j Y_j u^j$$

   using the recursion established in the proof of that corollary. Deduce, from $\sigma_j = c_j(Q)$ and

$c(S)c(Q) = 1$ (proposition 17.1.5), that the relations of the presentation are the vanishing of $c_j(S)$ for $j > r$.

4. In $\mathrm{Gr}(2,4)$ compute $\deg(\sigma_2^2)$, $\deg(\sigma_2 \cdot \sigma_{1,1})$ and $\deg(\sigma_{1,1}^2)$, using theorem 17.2.1 where one factor is special and proposition 17.1.3 otherwise. Then interpret each number, using (17.2) to see that σ_2 is the class of the lines through a fixed point of $\mathbb{P}^3$, and proposition 17.1.2(3) to see that the conditions defining $\Omega_{(1,1)}(F_\bullet)$ amount to $W \subseteq F_3$, so that $\sigma_{1,1}$ is the class of the lines contained in a fixed plane.

5. Verify theorem 17.2.4 in $\mathrm{Gr}(2,4)$ by computing the determinants for $\lambda = (1,1)$, $(2,1)$ and $(2,2)$, and check each answer against the products computed in example 17.2.2.

6. Write out the presentation of corollary 17.2.5 for $\mathrm{Gr}(2,4)$, computing Y_3 and Y_4 explicitly as polynomials in σ_1, σ_2. Then verify directly, degree by degree, that the quotient ring is free of rank 6, and that the images of 1, σ_1, σ_1^2, σ_2, $\sigma_1\sigma_2$, σ_2^2 span it.

7. In $\mathrm{Gr}(2,5)$ compute σ_2^2 by theorem 17.2.1 and then $\deg(\sigma_2^2 \cdot \sigma_1^2)$, using the expansion of σ_1^2 from example 17.2.3 together with proposition 17.1.3. State the enumerative problem in $\mathbb{P}^4$ whose intersection number this is.

8. Let λ and μ be partitions in the box with $\lambda_i + \mu_{r+1-i} > n - r$ for some i. Adapting Step 3 of the proof of theorem 17.2.1, show that $\Omega_\lambda(F_\bullet) \cap \Omega_\mu(G_\bullet) = \emptyset$ for opposite flags $F_\bullet$ and $G_\bullet$, and deduce that $\sigma_\lambda \cdot \sigma_\mu = 0$. Check that for $|\lambda| + |\mu| = r(n-r)$ this recovers the vanishing half of proposition 17.1.3.

17.3 Degeneracy Loci

The Schubert conditions of section 17.1 constrain a subspace to meet the members of a fixed flag in prescribed dimensions. Read through the tautological subbundle, each such condition says that a map of vector bundles drops rank. This section treats that phenomenon in general: for an arbitrary map $\varphi\colon E \to F$ of vector bundles on a smooth variety, the locus where $\mathrm{rk}\varphi \le k$ carries a class which is a determinant in the Chern classes of E and F, provided the locus has the codimension one expects. Schubert classes of rectangular shape return at the end of the section as the case of the tautological map on a Grassmannian.

A rank condition is a condition on minors, and minors generate an ideal, so the locus where the rank drops is a subscheme and not merely a subset. Fixing that scheme structure first is what makes the class of the locus well defined.

Definition 17.3.1: Degeneracy Locus

Let X be a scheme, let $\varphi\colon E \to F$ be a morphism of vector bundles of ranks e and f on X, and let $k \ge 0$ be an integer. The *k-th degeneracy locus* $D_k(\varphi)$ is the closed subscheme of X whose ideal sheaf is generated, over any open set on which E and F are trivialized, by the $(k+1) \times (k+1)$ minors of the $f \times e$ matrix of regular functions representing φ in those trivializations. Its underlying set is $\{x \in X \,|\, \mathrm{rk}\varphi(x) \le k\}$, and by convention $D_{-1}(\varphi) = \emptyset$. The integer $(e-k)(f-k)$ is the *expected codimension* of $D_k(\varphi)$.

The definition is independent of the trivializations. Changing them replaces the matrix A by PAQ

with P and Q invertible matrices of regular functions. Each row of PA is a linear combination of rows of A, so by multilinearity in the rows every $(k+1)$-minor of PA is a linear combination of $(k+1)$-minors of A; the same argument in the columns handles the right factor. Hence the ideal of $(k+1)$-minors of PAQ is contained in that of A, and applying the argument to $P^{-1}(PAQ)Q^{-1}$ gives the reverse containment. The two ideals agree, so the local definitions glue.

The name "expected codimension" is justified by the universal case, where the rank condition is imposed on the space of all matrices at once.

Example 17.3.2: The Generic Determinantal Variety

Let $\mathbb{A}^{ef}$ be the space of $f \times e$ matrices over $\overline{k}$, let φ be the tautological matrix (its entries are the coordinate functions), and write $M_k = D_k(\varphi)$. Fix $0 \le k < \min(e, f)$ and let $U \subseteq \mathbb{A}^{ef}$ be the open set where the upper left $k \times k$ block A_{11} is invertible. Writing

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}$$

in blocks of sizes k and $e-k$ down the columns and k and $f-k$ down the rows, the identity

$$\begin{pmatrix} I & 0 \\ -A_{21}A_{11}^{-1} & I \end{pmatrix} A \begin{pmatrix} I & -A_{11}^{-1}A_{12} \\ 0 & I \end{pmatrix} = \begin{pmatrix} A_{11} & 0 \\ 0 & \beta \end{pmatrix}, \qquad \beta := A_{22} - A_{21}A_{11}^{-1}A_{12} \tag{17.8}$$

holds on U, with both outer matrices invertible over $\mathcal{O}(U)$. By the invariance proved above, the ideal of $(k+1)$-minors of A on U equals that of the block diagonal matrix on the right. A $(k+1)$-minor of the latter is a product of a minor of A_{11} with a minor of β of positive size, hence lies in the ideal generated by the entries of β; conversely $\det(A_{11})\,\beta_{ij}$ is such a minor and $\det(A_{11})$ is a unit on U. So $M_k \cap U$ is the zero scheme of the $(e-k)(f-k)$ entries of β.

The map $(A_{11}, A_{12}, A_{21}, A_{22}) \mapsto (A_{11}, A_{12}, A_{21}, \beta)$ is an automorphism of U, being a morphism with an inverse of the same shape. Under it $M_k \cap U$ becomes the product of $\{A_{11}$ invertible$\}$ with the affine spaces of A_{12} and A_{21} and the origin in the β coordinates, so $M_k \cap U$ is smooth and irreducible of dimension

$$k^2 + k(e-k) + k(f-k) = ef - (e-k)(f-k)$$

Every matrix of rank exactly k has some invertible $k \times k$ submatrix, and permuting rows and columns is an automorphism of $\mathbb{A}^{ef}$ carrying M_k to itself, so the locus of matrices of rank exactly k is covered by copies of $M_k \cap U$ and is smooth of that dimension. A matrix A of rank $j < k$ is the limit as $t \to 0$ of $A + tC$, where C kills a chosen complement W of $\ker A$ and maps a $(k-j)$-dimensional subspace of $\ker A$ isomorphically onto a complement of the image of A; for $t \neq 0$ that sum has rank k. Hence M_k is the closure of the rank-k locus, irreducible of codimension exactly $(e-k)(f-k)$ in $\mathbb{A}^{ef}$.

The Schur complement in (17.8) is a local statement about matrices, so it globalizes to bundles at once. The next lemma is what every later argument in this section uses: near a point where the rank is exactly k, a degeneracy locus is the zero scheme of a section of a bundle of rank equal to its expected codimension.

Lemma 17.3.3: Local Form at a Point of Exact Rank

Let $\varphi\colon E \to F$ be as in definition 17.3.1 and let $x \in X$ satisfy $\mathrm{rk}\varphi(x) = k$. There is an open neighbourhood U of x, direct sum decompositions $E|_U = E_1 \oplus E_2$ and $F|_U = F_1 \oplus F_2$ with $\mathrm{rk}E_1 = \mathrm{rk}F_1 = k$, and an identification $F_1 \cong E_1$, under which

$$\varphi|_U = \begin{pmatrix} \mathrm{id}_{E_1} & 0 \\ 0 & \beta \end{pmatrix}, \qquad \beta \in \Gamma(U, \mathrm{Hom}(E_2, F_2)), \quad \beta(x) = 0$$

Consequently $D_k(\varphi) \cap U$ is the zero scheme of β, a section of a bundle of rank $(e-k)(f-k)$, and $\ker\varphi$ restricted to $D_k(\varphi) \cap U$ is the subbundle E_2.

***Proof*:**
Choose trivializations of E and F near x and let A be the resulting matrix. Since $\mathrm{rk}A(x) = k$, some $k \times k$ minor of $A(x)$ is nonzero; after permuting the frames we may assume it is the upper left one, and $\det A_{11}$ is then invertible on an open $U \ni x$. On U the two outer matrices in (17.8) have entries in $\mathcal{O}(U)$ and are invertible there, so they are automorphisms of $F|_U$ and $E|_U$; in the new frames φ is the block diagonal matrix with blocks A_{11} and β. Absorbing A_{11} into the frame of the first summand of $F|_U$ makes the first block the identity. Since $\mathrm{rk}\varphi(x) = k$ and the first block already has rank k at x, the second block satisfies $\beta(x) = 0$.

The computation of the ideal of $(k+1)$-minors carried out in example 17.3.2 applies verbatim to the block diagonal form, giving that $D_k(\varphi) \cap U$ is the zero scheme of the entries of β, that is, of the section β of $\mathrm{Hom}(E_2, F_2)$, a bundle of rank $(e-k)(f-k)$. On that zero scheme φ restricts to $\mathrm{id}_{E_1} \oplus 0$, whose kernel is E_2, completing the proof.

The formula to be proved expresses the class of $D_k(\varphi)$ through the Chern classes of E and F combined in one formal expression, which the following notation records.

Definition 17.3.4: Chern Classes of a Difference

Let X be a smooth variety and let E and F be vector bundles on X, either of which may be the zero bundle, with total Chern class 1 in that case. In the ring $A^*(X)$ of theorem 14.2.7 the total Chern class $c(E) = 1 + c_1(E) + \cdots$ is a unit, since $A^i(X) = 0$ for $i > \dim X$ makes $\sum_{j\geq 0}(1 - c(E))^j$ a finite sum inverting it. Set

$$c(F - E) := c(F)\, c(E)^{-1} \in A^*(X)$$

and write $c_i(F - E)$ for its component in $A^i(X)$, so that $c_0(F - E) = 1$ and $c_i(F - E) = 0$ for $i < 0$.

Two consequences of the definition are used constantly. First, $c(F - E)$ is multiplicative in the evident sense: $c((F \oplus F') - E) = c(F - E)c(F')$ by theorem 12.2.15. Second, the components of $c(-E) = c(E)^{-1}$ satisfy

$$\sum_{i=0}^{j} c_i(E)\, c_{j-i}(-E) = 0 \qquad (j \geq 1) \tag{17.9}$$

which is the degree j component of $c(E)c(-E) = 1$.

Theorem 17.3.5: Thom-Porteous Formula

Let X be a smooth variety, let $\varphi\colon E \to F$ be a morphism of vector bundles of ranks e and f, and let $0 \le k < \min(e, f)$. Assume

1. $D_k(\varphi)$ is empty or of pure codimension $(e-k)(f-k)$ in X; and
2. $D_{k-1}(\varphi)$ is empty or of codimension greater than $(e-k)(f-k)$.

Then, in $A^{(e-k)(f-k)}(X)$,

$$[D_k(\varphi)] = \det\left(c_{f-k+j-i}(F-E)\right)_{1\le i,j\le e-k}$$

where $[D_k(\varphi)]$ is the class of the fundamental cycle of the determinantal scheme (definition 10.1.2), each component counted with the length of the local ring of $D_k(\varphi)$ at its generic point.

Hypothesis (2) holds whenever $D_{k-1}(\varphi)$ has its own expected codimension, since $(e-k+1)(f-k+1) > (e-k)(f-k)$; in the applications below both hypotheses are verified directly. Fulton proves the formula assuming only (1), but must construct a class supported on $D_k(\varphi)$ before comparing it with the fundamental cycle ([38, Chapter 14]).

The determinant is an $(e-k)\times(e-k)$ matrix whose entries increase along rows, and each of its terms $\prod_i c_{f-k+\sigma(i)-i}(F-E)$ has total degree $(e-k)(f-k)$, so the right-hand side does live in the codimension the left-hand side occupies. The class of the locus depends on φ only through the bundles: any two maps $E \to F$ whose degeneracy loci have the expected codimension produce the same class. The answer is a Schur-type determinant in the classes $c_i(F-E)$, the same shape of expression as Giambelli's formula in theorem 17.2.4; corollary 17.3.7 shows the two agree where they overlap.

The proof replaces the rank condition, which is not linear, by a linear condition on a larger space: instead of asking that $\ker\varphi(x)$ have dimension at least $e-k$, one records a flag of subspaces of E_x of dimension $e-k$ inside the kernel. The locus of such records is the zero scheme of a section of a bundle, and its class is a top Chern class. Two ingredients are needed: the identification of the class of a zero scheme, and the computation of the pushforward from the flag bundle back to X.

The space on which the rank condition becomes linear is the bundle of flags of subbundles of E, built by iterating the projective bundle construction.

Definition 12.2.13 already builds this tower: $\mathrm{Fl}_m(E)$ is the m-step flag bundle of E, with tautological subbundles $S_1 \subset \cdots \subset S_m \subseteq q^*E$ and line quotients $\Lambda_i = S_i/S_{i-1}$. Write $\eta_i = c_1(\Lambda_i^\vee)$ and $S = S_m$, of rank m. One point of the construction bears repeating because getting it wrong negates every odd Chern class below: $\mathbb{P}(E^{(i-1)})$ is the bundle of *lines*, so importing a formula from definition 5.3.51, which uses the quotient convention, requires dualizing (box 9.0.2).

A point of Y_i over $y \in Y_{i-1}$ is a line in $E_y^{(i-1)} = E_x/(S_{i-1})_y$, that is a subspace S_i of E_x of dimension i containing S_{i-1}; inductively, a point of $\mathrm{Fl}_m(E)$ over $x \in X$ is a flag $S_1 \subset \cdots \subset S_m \subseteq E_x$ with $\dim S_i = i$, which is the description used below. If X is a smooth variety then so is $\mathrm{Fl}_m(E)$: each step is locally $U \times \mathbb{P}^{e-i}$ over a trivializing open U, hence smooth, and irreducible because any two such opens have preimages meeting over the intersection of two dense open subsets of an irreducible base. Its dimension is $\dim X + \sum_{i=1}^{m}(e-i)$.

Lemma 17.3.6: Pushforward from the Flag Bundle

Let X be a smooth variety, let E and F be bundles of ranks e and f, let $1 \le m \le e$, and let $q\colon Y = \mathrm{Fl}_m(E) \to X$ with tautological subbundle $S \subseteq q^*E$ of rank m. Put $\ell = f - e + m$ and

$$\gamma_m = \prod_{i=1}^{m-1} \eta_i^{m-i}$$

(an empty product, equal to 1, when $m = 1$). Then

$$q_*\Big(\gamma_m \cdot c_{mf}\big(S^\vee \otimes q^*F\big)\Big) = \det\big(c_{\ell+j-i}(F-E)\big)_{1\le i,j\le m}$$

***Proof*:**

Both sides lie in $A^{m\ell}(X)$: the class pushed forward has degree $mf + \binom{m}{2}$ and q has relative dimension $me - \binom{m+1}{2}$, and $mf + \binom{m}{2} - me + \binom{m+1}{2} = mf - me + m^2 = m\ell$, while each term of the determinant has degree $m\ell$. The proof is by induction on m, and the first three steps record what the projective bundle $\mathbb{P}(E)$ contributes at each stage of the tower. Throughout, $p\colon \mathbb{P}(E) \to X$ is the first step, $\Lambda = \Lambda_1$ and $\eta = \eta_1$.

Step 1: twisting by a line bundle. For a bundle F of rank f and a line bundle L on any smooth variety,

$$c_f(L \otimes F) = \sum_{i=0}^{f} c_i(F)\, c_1(L)^{f-i} \tag{17.10}$$

By theorem 12.2.14 it suffices to prove this after pulling back to a variety on which F has a filtration with line bundle quotients $L_1, \dots, L_f$ and on which pullback of Chern classes is injective. There $c_f(L \otimes F) = \prod_{i=1}^{f}(c_1(L) + c_1(L_i))$ by theorem 12.2.15, and expanding the product and collecting the elementary symmetric functions of the $c_1(L_i)$, which are the $c_i(F)$, gives (17.10).

Step 2: the tautological relation. The inclusion $\Lambda \subseteq p^*E$ is a nowhere-vanishing section of $\Lambda^\vee \otimes p^*E$, so that bundle contains a trivial line subbundle with locally free quotient W of rank $e-1$; by theorem 12.2.15 its total Chern class equals $c(W)$, whose component in degree e vanishes because W has rank $e-1$ (theorem 12.2.9). Applying (17.10) with $L = \Lambda^\vee$ and $F = p^*E$,

$$\sum_{i=0}^{e} c_i(E)\, \eta^{e-i} = 0 \tag{17.11}$$

where the Chern classes of E are written for their pullbacks.

Step 3: pushforward of powers of η. The class $p_*(\eta^j)$ lies in $A^{j-e+1}(X)$, hence vanishes for $j < e-1$. For $j = e-1$ it lies in $A^0(X) = \mathbb{Z}[X]$ and may be computed after restricting to an open U trivializing E, since p_* commutes with flat pullback (proposition 10.3.6) and $A^0(X) \to A^0(U)$ is an isomorphism. Over such a U one has $\mathbb{P}(E)|_U \cong U \times \mathbb{P}^{e-1}$ with η the pullback of the hyperplane class, and $\eta^{e-1} \cap [U \times \mathbb{P}^{e-1}]$ is the flat pullback of $\eta^{e-1} \cap [\mathbb{P}^{e-1}] = [\text{point}]$

(theorem 10.5.2, proposition 12.2.10), namely $[U \times \text{point}]$, which p maps isomorphically onto U. Hence $p_*(\eta^{e-1}) = 1$. For $j \geq 1$, multiplying (17.11) by η^{j-1} and pushing forward gives

$$p_*(\eta^{e-1+j}) = -\sum_{i=1}^{e} c_i(E)\, p_*(\eta^{e-1+j-i})$$

by the projection formula (proposition 12.2.10(2)), which is the recursion (17.9) for the components of $c(-E)$ with the same initial value. Therefore $p_*(\eta^{e-1+j}) = c_j(-E)$ for all $j \geq 0$. Combining this with (17.10) and the projection formula, for every $a \geq 0$,

$$p_*\Big(\eta^a\, c_f(\Lambda^\vee \otimes p^*F)\Big) = \sum_{i=0}^{f} c_i(F)\, p_*(\eta^{a+f-i}) = \sum_{i=0}^{f} c_i(F)\, c_{a+f-i-e+1}(-E) = c_{a+f-e+1}(F-E) \tag{17.12}$$

the last equality being the degree $a+f-e+1$ component of $c(F-E) = c(F)c(-E)$.

Step 4: the base case. For $m = 1$ one has $Y = \mathbb{P}(E)$, $S = \Lambda$, $\gamma_1 = 1$ and $\ell = f - e + 1$, so (17.12) with $a = 0$ gives $q_*(c_f(\Lambda^\vee \otimes q^*F)) = c_\ell(F-E)$, which is the asserted 1×1 determinant.

Step 5: the inductive step. Let $m \geq 2$ and assume the statement for $m-1$ over every smooth base. By construction $\mathrm{Fl}_m(E) = \mathrm{Fl}_{m-1}(E^{(1)})$ over the base $\mathbb{P}(E)$, where $E^{(1)} = p^*E/\Lambda$ has rank $e-1$; write $b\colon Y \to \mathbb{P}(E)$ for that flag bundle, so $q = p \circ b$, and let $S' \subseteq b^*E^{(1)}$ be its tautological subbundle of rank $m-1$. Under the identification of points as flags, $S' = S/\Lambda$, and the classes $\eta_2, \dots, \eta_{m-1}$ of Y over $\mathbb{P}(E)$ are those of the smaller tower, so

$$\gamma_m = \eta^{\,m-1} \cdot \gamma'_{m-1}, \qquad \gamma'_{m-1} = \prod_{i=1}^{m-2} \eta_{i+1}^{\,m-1-i}$$

The exact sequence $0 \to \Lambda \to S \to S' \to 0$ dualizes and tensors with q^*F to an exact sequence with sub $S'^\vee \otimes q^*F$ and quotient $\Lambda^\vee \otimes q^*F$, so theorem 12.2.15 gives

$$c_{mf}(S^\vee \otimes q^*F) = c_{(m-1)f}\big(S'^\vee \otimes b^*(p^*F)\big) \cdot c_f(\Lambda^\vee \otimes q^*F)$$

The second factor and η^{m-1} are pulled back from $\mathbb{P}(E)$, so by the projection formula and the inductive hypothesis applied over the smooth variety $\mathbb{P}(E)$ to the bundles $E^{(1)}$ and p^*F, whose associated integer is $f-(e-1)+(m-1) = \ell$,

$$q_*\Big(\gamma_m\, c_{mf}(S^\vee \otimes q^*F)\Big) = p_*\Big(\eta^{\,m-1}\, c_f(\Lambda^\vee \otimes p^*F) \cdot \det\big(c'_{\ell+j-i}\big)_{1\leq i,j\leq m-1}\Big)$$

where $c' = c(p^*F - E^{(1)})$. From $c(E^{(1)}) = c(p^*E)c(\Lambda)^{-1}$ and $c(\Lambda) = 1-\eta$ one gets $c' = c(F-E)(1-\eta)$, that is

$$c'_r = c_r - \eta\, c_{r-1}, \qquad c_r := c_r(F-E) \tag{17.13}$$

Step 6: the determinant expansion. Let M be the $m \times m$ matrix with $M_{ij} = c_{\ell+j-i}$, and let $M^{(1,t)}$ denote the matrix obtained from M by deleting the first row and the t-th column. Let R be the $(m-1) \times m$ matrix consisting of the last $m-1$ rows of M, so $R_{ij} = c_{\ell+j-i-1}$, and let N be the $(m-1)\times(m-1)$ matrix with entries $c'_{\ell+j-i}$. By (17.13) the j-th column of N is

$R_{\bullet,j+1} - \eta R_{\bullet,j}$. Expanding $\det N$ by multilinearity in the columns produces one term for each subset $T \subseteq \{1,\dots,m-1\}$ of columns at which the second alternative is taken, with coefficient $(-\eta)^{|T|}$ and columns $R_{\bullet,j}$ for $j \in T$ and $R_{\bullet,j+1}$ for $j \notin T$. If some $j \in T$ has $j \geq 2$ and $j-1 \notin T$ then the column $R_{\bullet,j}$ occurs twice, once from $j \in T$ and once as $R_{\bullet,(j-1)+1}$ from $j-1 \notin T$, and the term vanishes. The subsets with no such j are exactly the sets $T = \{1,\dots,t\}$ for $0 \leq t \leq m-1$, the empty set being the case $t = 0$, so only those contribute; for those the columns are $R_{\bullet,1},\dots,R_{\bullet,t},R_{\bullet,t+2},\dots,R_{\bullet,m}$ in increasing order, whose determinant is $\det M^{(1,t+1)}$. Hence

$$\det\left(c'_{\ell+j-i}\right)_{1\leq i,j\leq m-1} = \sum_{t\geq 0}(-\eta)^t \det M^{(1,t+1)} \tag{17.14}$$

Step 7: assembly. Substituting (17.14) into the expression of Step 5, moving the classes $\det M^{(1,t+1)}$ (which are pulled back from X) out by the projection formula, and evaluating each remaining pushforward by (17.12) with $a = m-1+t$, which returns $c_{\ell+t}$ because $(m-1+t)+f-e+1 = \ell+t$,

$$q_*\Big(\gamma_m\, c_{mf}(S^\vee \otimes q^*F)\Big) = \sum_{t\geq 0}(-1)^t\, c_{\ell+t} \det M^{(1,t+1)}$$

The right-hand side is the Laplace expansion of $\det M$ along its first row, whose entries are $M_{1,t+1} = c_{\ell+t}$ with cofactor sign $(-1)^{1+(t+1)} = (-1)^t$. So the pushforward equals $\det M$, completing the induction and the proof.

***Proof of theorem 17.3.5*:**
Write $m = e-k \geq 1$ and $\nu = f-k \geq 1$, so the expected codimension is $m\nu$ and the asserted determinant is the one produced by lemma 17.3.6, whose integer $\ell = f-e+m$ equals ν.

Step 1: the resolution. Let $q\colon Y = \mathrm{Fl}_m(E) \to X$ with tautological subbundle $S \subseteq q^*E$, and let

$$\Psi\colon S \hookrightarrow q^*E \xrightarrow{q^*\varphi} q^*F$$

regarded as a section of $G := S^\vee \otimes q^*F$, a bundle of rank mf. Write $Z = Z(\Psi)$ for its zero scheme: a point of Y lies in Z exactly when the flag it records has its top member inside $\ker\varphi$.

Step 2: the resolution over the locus of rank at least k. Put $X^\circ = X \setminus D_{k-1}(\varphi)$, an open subvariety, nonempty because hypothesis (2) makes $D_{k-1}(\varphi)$ of positive codimension. Write $Y^\circ = q^{-1}(X^\circ)$, $D^\circ = D_k(\varphi)\cap X^\circ$ and $Z^\circ = Z \cap Y^\circ$. Cover X° by open sets of two kinds: those meeting $D_k(\varphi)$ not at all, over which Z is empty, and neighbourhoods U of points of exact rank k, on which lemma 17.3.3 puts φ in the block form $\mathrm{id}_{E_1} \oplus \beta$. On such a U, a point of Z is a flag whose top member S satisfies $\varphi(S) = 0$; since the first block is the identity, the composite $S \to E|_U \to E_1$ vanishes, so $S \subseteq E_2$, and the induced map $S \to E_2$ of bundles of rank m is injective on fibres, hence an isomorphism. Thus $S = E_2$ on $Z \cap q^{-1}(U)$, the remaining data is a complete flag inside E_2, and the equations that survive are the entries of β, which cut out $D_k(\varphi)\cap U$. So

$$Z \cap q^{-1}(U) \cong \big(D_k(\varphi)\cap U\big) \times_U \mathrm{Fl}_m(E_2)$$

as schemes. Globally over X° this says $Z^\circ \cong \mathrm{Fl}_m(K)$, where $K = \ker(\varphi)|_{D^\circ}$ is locally free of rank m by lemma 17.3.3, and $\mathrm{Fl}_m(K)$ is the bundle of complete flags in K.

Step 3: purity. By hypothesis (1) the scheme D° is empty or of pure dimension $\dim X - m\nu$, so by Step 2, Z° is empty or of pure dimension $\dim X - m\nu + \binom{m}{2}$, the second summand being the dimension of a complete flag variety in m variables. Since $\dim Y = \dim X + \sum_{i=1}^{m}(e-i) = \dim X + me - \binom{m+1}{2}$, the codimension of Z° in Y° is

$$me - \binom{m+1}{2} + m\nu - \binom{m}{2} = me + m\nu - m^2 = m(k+\nu) = mf$$

using $e - m = k$ and $k + \nu = f$. So Z° is empty or of pure codimension mf, the rank of G.

Step 4: the two pushforwards. Lemma 14.3.14, applied on the smooth variety Y° to the section Ψ of G, gives $[Z^\circ] = c_{mf}(G) \cap [Y^\circ]$ in $A_{\dim Y - mf}(Y^\circ)$. Multiply by γ_m and push forward by q. On the right, lemma 17.3.6 applied over the smooth variety X° evaluates the result as the determinant $\Delta := \det(c_{\nu+j-i}(F-E))_{1\le i,j\le m}$ restricted to X°, Chern classes being compatible with restriction to an open subset (proposition 12.2.10). On the left, use Step 2: the morphism $Z^\circ \to D^\circ$ is the flag bundle of K, which is locally a product, so the multiplicity of each component of Z° in its fundamental cycle equals that of the component of D° below it, and γ_m restricts on Z° to the corresponding product of the classes η_i for the tower $\mathrm{Fl}_m(K) \to D^\circ$. That tower has $m-1$ nontrivial steps, the i-th being a projective bundle of a rank-$(m-i+1)$ bundle, and γ_m contributes $\eta_i^{(m-i+1)-1}$ at that step; pushing down one step at a time with the projection formula and $p_*(\eta^{r-1}) = 1$ from Step 3 of the proof of lemma 17.3.6 yields

$$q_*\big(\gamma_m \cap [Z^\circ]\big) = [D^\circ]$$

Hence $[D^\circ] = \Delta \cap [X^\circ]$ in $A_{\dim X - m\nu}(X^\circ)$.

Step 5: from X° to X. Set $d = \dim X - m\nu$. Restriction to the open subvariety X° carries $[D_k(\varphi)]$ to $[D^\circ]$ and $\Delta \cap [X]$ to $\Delta \cap [X^\circ]$, so the difference of the two classes on X lies in the kernel of $A_d(X) \to A_d(X^\circ)$, which by theorem 10.4.1 is the image of $A_d(D_{k-1}(\varphi))$. Hypothesis (2) makes $\dim D_{k-1}(\varphi) < d$, and a scheme carries no cycles of dimension exceeding its own, so that group vanishes. Therefore $[D_k(\varphi)] = \Delta \cap [X]$, completing the proof.

The formula returns familiar statements in its two extreme cases. For $e = 1$ and $k = 0$ the map φ is a section of $E^\vee \otimes F$ and the determinant is the single class $c_f(F-E)$, which is $c_f(E^\vee \otimes F)$; this is lemma 14.3.14 again. For $e = f$ and $k = e-1$ it reads $[D_{e-1}(\varphi)] = c_1(F) - c_1(E)$, the class of the divisor cut by $\det\varphi$, a section of $\mathrm{Hom}(\det E, \det F)$.

The case that connects this section to section 17.1 is the tautological map on a Grassmannian, where a single rank condition cuts out a Schubert variety of rectangular shape.

Corollary 17.3.7: Rectangular Schubert Classes as Determinants

Let $1 \le a \le r$ and $1 \le b \le n-r$, and let $\lambda = (b^a)$ be the partition with a parts equal to b, a rectangle inside the $r \times (n-r)$ box. On $\mathrm{Gr}(r,n)$,

$$\sigma_\lambda = \det\left(\sigma_{b+j-i}\right)_{1\le i,j\le a}$$

where $\sigma_j = c_j(Q)$ are the special Schubert classes and $\sigma_j = 0$ for $j < 0$.

***Proof*:**
Fix the complete flag $F_\bullet$ of definition 17.1.1 in the n-dimensional space V, put $t = n - r + a - b$, and let

$$\varphi\colon S \longrightarrow (V/F_t) \otimes \mathcal{O}$$

be the tautological subbundle followed by the quotient map, a morphism of bundles of ranks $e = r$ and $f = n - t = r - a + b$. For a point W of $\mathrm{Gr}(r, n)$ the fibre $\varphi(W)$ is the composite $W \subseteq V \to V/F_t$, whose kernel is $W \cap F_t$. Set $k = r - a$, so that $e - k = a$ and $f - k = b$, and the expected codimension is $ab = |\lambda|$.

Step 1: the support is the Schubert variety. A point W lies in $D_k(\varphi)$ exactly when $\dim(W \cap F_t) \geq a$. That single condition implies the others defining $\Omega_\lambda(F_\bullet)$: for $i < a$ the flag index attached to $\lambda_i = b$ is $n - r + i - b = t - (a - i)$, and lowering a flag index by one lowers the dimension of the intersection by at most one, so $\dim(W \cap F_{t-(a-i)}) \geq a - (a - i) = i$. Conversely the condition at $i = a$ is one of the defining conditions. Hence $D_k(\varphi)$ and $D_{k-1}(\varphi)$ have supports $\Omega_{(b^a)}(F_\bullet)$ and $\Omega_{((b+1)^{a+1})}(F_\bullet)$ respectively, the latter being empty when $((b+1)^{a+1})$ leaves the box. By proposition 17.1.2 these have codimensions ab and $(a+1)(b+1)$, and each is irreducible; so hypothesis (1) of theorem 17.3.5 holds once the codimension statement is known for the scheme, which it is since a scheme and its support have the same dimension, and hypothesis (2) holds because $(a+1)(b+1) > ab$.

Step 2: the determinantal scheme is generically reduced. Let W_0 be a point of the open cell $\Omega^\circ_\lambda(F_\bullet)$, so $K_0 = W_0 \cap F_t$ has dimension exactly a. Choose a complement U_0 of W_0 in V and a splitting $W_0 = K_0 \oplus K_0'$. The subspaces W with $W \cap U_0 = 0$ are exactly the graphs $W_u = \{w + u(w) \big| w \in W_0\}$ for $u \in \mathrm{Hom}(W_0, U_0)$, and $u \mapsto W_u$ is a bijection onto an open neighbourhood of W_0; identifying W_u with W_0 by $w \mapsto w + u(w)$, the map φ becomes $\varphi_u(w) = \overline{w + u(w)} \in V/F_t$, whose entries are affine functions of u. Decompose $V/F_t = \varphi_0(K_0') \oplus C$ with $\dim C = f - k = b$. In the resulting block form of φ_u, the $K_0' \to \varphi_0(K_0')$ block is invertible near $u = 0$ and depends only on $u|_{K_0'}$; the $K_0' \to C$ block vanishes at $u = 0$ and depends only on $u|_{K_0'}$; the $K_0 \to \varphi_0(K_0')$ block is linear in $u|_{K_0}$; and the $K_0 \to C$ block is the linear map $u|_{K_0}$ followed by the projection $U_0 \to V/(F_t + W_0) \cong C$. By (17.8) the ideal of $D_k(\varphi)$ near W_0 is generated by the entries of the Schur complement, which by the shape just listed is of the form $\beta(u) = \Phi_{u|_{K_0'}}(u|_{K_0})$ with Φ_{u_2} linear in the first argument and regular in u_2. At $u = 0$ the map Φ_0 is the restriction-then-project map $\mathrm{Hom}(W_0, U_0) \to \mathrm{Hom}(K_0, V/(F_t + W_0))$, which is surjective because $U_0 + W_0 = V$ forces $U_0 \to V/(F_t + W_0)$ to be surjective; surjectivity of a matrix of regular functions is an open condition, so Φ_{u_2} stays surjective for u_2 near 0. Its kernel is then a subbundle, and choosing a local trivialization splitting it makes the entries of β into ab of the coordinates. Hence $D_k(\varphi)$ is smooth of codimension ab near W_0, in particular reduced there, and its fundamental cycle is $[\Omega_\lambda(F_\bullet)] = \sigma_\lambda$.

Step 3: the Chern classes. The target of φ is a trivial bundle, so its total Chern class is 1 (example 12.2.12), and $c(S)c(Q) = 1$ by proposition 17.1.5, the tautological sequence being the one recalled in theorem 5.3.56. Hence

$$c\big((V/F_t) \otimes \mathcal{O} - S\big) = c(S)^{-1} = c(Q)$$

so c_j of the difference is σ_j. Theorem 17.3.5 with $e - k = a$ and $f - k = b$ now reads $\sigma_\lambda = \det(\sigma_{b+j-i})_{1 \leq i,j \leq a}$, as we sought to show.

The corollary is Giambelli's formula (theorem 17.2.4) for rectangular λ, obtained without Pieri's formula and without the symmetric function identity that section 17.2 used: the determinant appears here as the shape of the Thom-Porteous class rather than as a Jacobi-Trudi expansion. A Schubert variety attached to a non-rectangular partition is cut out by more than one rank condition, and one bundle map does not see it; the determinantal formula for several conditions at once is the Kempf-Laksov formula, of which theorem 17.3.5 is the one-condition case.

Away from Grassmannians the formula computes degrees of classically studied curves and surfaces from the shape of the matrix defining them.

Example 17.3.8: The Twisted Cubic as a Degeneracy Locus
On $X = \mathbb{P}^3$ with homogeneous coordinates $x_0, \dots, x_3$, let

$$\varphi\colon \mathcal{O}^{\oplus 2} \longrightarrow \mathcal{O}(1)^{\oplus 3}, \qquad \varphi = \begin{pmatrix} x_0 & x_1 \\ x_1 & x_2 \\ x_2 & x_3 \end{pmatrix}$$

so $e = 2$, $f = 3$ and the interesting locus is $D_1(\varphi)$, of expected codimension $(2-1)(3-1) = 2$: a curve. Its ideal is generated by the three 2×2 minors $x_0x_2 - x_1^2$, $x_0x_3 - x_1x_2$, $x_1x_3 - x_2^2$. A point of D_1 is one where the two columns are proportional; parametrizing the proportionality by $(1 : s)$ or $(s : 1)$ shows the support of D_1 is the image C of $\mathbb{P}^1 \to \mathbb{P}^3$, $(u : v) \mapsto (u^3 : u^2v : uv^2 : v^3)$, the twisted cubic. In particular D_1 has pure codimension 2, and $D_0(\varphi)$, where all six entries vanish, is empty. Both hypotheses of theorem 17.3.5 hold.

With h the hyperplane class, $c(E) = 1$ and $c(F) = (1+h)^3$, so $c(F-E) = 1 + 3h + 3h^2 + h^3$. Here $e - k = 1$ and $f - k = 2$, so the determinant is the single entry

$$[D_1(\varphi)] = c_2(F - E) = 3h^2$$

Independently, $A^2(\mathbb{P}^3)$ is generated by the class of a line (theorem 10.5.2), and a curve of degree d has class dh^2; the twisted cubic meets the plane $\{a_0x_0 + \cdots + a_3x_3 = 0\}$ where $a_0u^3 + a_1u^2v + a_2uv^2 + a_3v^3 = 0$, which for a general plane has three distinct roots in $\mathbb{P}^1$, so $\deg C = 3$ and $[C] = 3h^2$. The two computations agree, and since $[D_1(\varphi)] = \mu[C]$ for the multiplicity μ of D_1 along C, comparing them gives $\mu = 1$: the ideal of 2×2 minors above defines the twisted cubic with its reduced structure.

Exercise 17.3.1

1. Let $\varphi\colon \mathcal{O}_{\mathbb{P}^2}^{\oplus 2} \to \mathcal{O}_{\mathbb{P}^2}(1)^{\oplus 2}$ be given by a 2×2 matrix of linear forms whose determinant is not identically zero and whose four entries have no common zero. Show that $D_1(\varphi)$ satisfies the hypotheses of theorem 17.3.5, compute its class by the formula, and check the answer against the description of $D_1(\varphi)$ as the zero divisor of $\det \varphi$.

2. Fix $n \geq 2$ and let $\varphi\colon \mathcal{O}_{\mathbb{P}^n}^{\oplus 2} \to \mathcal{O}_{\mathbb{P}^n}(1)^{\oplus n}$ have i-th row $(x_{i-1} \;\; x_i)$ for $1 \leq i \leq n$. Show that $D_1(\varphi)$ is the rational normal curve of degree n, that $D_0(\varphi)$ is empty, and that theorem 17.3.5 assigns $D_1(\varphi)$ the class nh^{n-1}. Verify the degree independently from the parametrization $(u : v) \mapsto (u^n : u^{n-1}v : \cdots : v^n)$.

3. Let F be a vector bundle of rank f on a smooth variety X and let $\psi \in \Gamma(X, F)$ have zero

scheme of pure codimension f. Deduce from theorem 17.3.5, applied to $\varphi\colon \mathcal{O} \to F$, that $[Z(\psi)] = c_f(F)$, and identify which hypothesis of the theorem is discharged by the convention $D_{-1}(\varphi) = \emptyset$.

4. Let $\varphi\colon E \to F$ be a morphism of bundles of ranks e and f on a smooth variety. Show that $D_k(\varphi^\vee) = D_k(\varphi)$ as subschemes, where $\varphi^\vee\colon F^\vee \to E^\vee$. Then check, for $e = 2$, $f = 3$ and $k = 1$, that the two determinants theorem 17.3.5 produces from φ and from $\varphi^\vee$ agree, using $c_i(E^\vee) = (-1)^i c_i(E)$.

5. In $A^*(\mathrm{Gr}(2,5))$ use corollary 17.3.7 to express $\sigma_{2,2}$ as a polynomial in the special classes, and confirm the answer by expanding the two products that occur with Pieri's formula (theorem 17.2.1).

6. Let X be a smooth projective surface and $\varphi\colon E \to F$ a morphism of rank-2 bundles whose determinant $\det\varphi$ is a nonzero section of $\mathrm{Hom}(\det E, \det F)$ and whose vanishing locus $D_0(\varphi)$ is finite. Show that $D_1(\varphi)$ is the zero divisor of $\det\varphi$, that the hypotheses of theorem 17.3.5 hold, and that the formula returns $c_1(F) - c_1(E)$ in both descriptions.

7. Let $E = \mathcal{O} \oplus \mathcal{O}(1)$ on $\mathbb{P}^1$ and let $p\colon \mathbb{P}(E) \to \mathbb{P}^1$ with $\eta = c_1(\mathcal{O}_{\mathbb{P}(E)}(1))$. Using the tautological relation (17.11), compute $p_*(\eta^2)$ and compare it with the component $c_1(-E)$ of $c(E)^{-1}$.

17.4 Classical Enumerative Problems

Two counts are carried out here with the classes of sections 17.1 to 17.3. The first is the number of lines on a smooth cubic surface in $\mathbb{P}^3$: lines in $\mathbb{P}^3$ are parametrized by $\mathrm{Gr}(2,4)$, the condition of lying on a fixed cubic surface is the vanishing of a section of a rank-four bundle on that Grassmannian, and the count is the degree of the top Chern class of the bundle, once the section is known to vanish at finitely many points and to vanish at each of them simply. The second is the five-conic problem, where the same procedure on the space $\mathbb{P}^5$ of plane conics returns the wrong number. Between the two counts, the classical principle of conservation of number is stated precisely enough to identify which of its hypotheses fails.

Fix a four-dimensional vector space V over $\overline{k}$ and write $\mathbb{P}^3 = \mathbb{P}(V)$. A line in $\mathbb{P}^3$ is $\mathbb{P}(W)$ for a unique two-dimensional subspace $W \subseteq V$, so $\mathrm{Gr}(2,4)$ is the parameter space of lines in $\mathbb{P}^3$, of dimension 4. Let $S \subseteq V \otimes \mathcal{O}$ be the tautological subbundle, whose fibre at $[W]$ is W, and let Q be the tautological quotient, so that

$$0 \to S \to V \otimes \mathcal{O} \to Q \to 0$$

is exact (theorem 5.3.56).

A cubic form $F \in \mathrm{Sym}^3 V^\vee$ restricts on each two-plane to $F|_W \in \mathrm{Sym}^3 W^\vee$, and $\mathbb{P}(W)$ is contained in the surface defined by F precisely when $F|_W = 0$. These restrictions are the values of a single global section. Dualizing the tautological inclusion gives a surjection $V^\vee \otimes \mathcal{O} \to S^\vee$, hence a surjection $\mathrm{Sym}^3 V^\vee \otimes \mathcal{O} \to \mathrm{Sym}^3 S^\vee$; the image of the constant section F of the trivial bundle $\mathrm{Sym}^3 V^\vee \otimes \mathcal{O}$ is a global section σ_F of $\mathrm{Sym}^3 S^\vee$ with $\sigma_F([W]) = F|_W$. A rank-two bundle has Sym^3 of rank 4, since locally Sym^3 of a free module on u, v is free on u^3, u^2v, uv^2, v^3. So $\mathrm{Sym}^3 S^\vee$ has rank $4 = \dim \mathrm{Gr}(2,4)$, and the zero scheme of σ_F has expected dimension zero.

Theorem 17.4.1: The Twenty-Seven Lines on a Smooth Cubic Surface

Let $F \in \mathrm{Sym}^3 V^\vee$ be a nonzero cubic form and let $X \subseteq \mathbb{P}^3$ be the cubic surface it defines. Assume X is smooth, so that the four partial derivatives F_0, F_1, F_2, F_3 of F have no common zero on X (proposition 2.7.7). Then X contains exactly 27 lines.

***Proof*:**

Step 1: the zero scheme parametrizes the lines on X. Write Z for the zero scheme of σ_F, that is, the degeneracy locus $D_0(\sigma_F)$ of the bundle map $\sigma_F \colon \mathcal{O} \to \mathrm{Sym}^3 S^\vee$, whose determinantal structure is cut by the 1×1 minors, namely by the components of σ_F in any local trivialization. A point $[W] \in \mathrm{Gr}(2,4)$ lies in Z if and only if $F|_W = 0$, if and only if $\mathbb{P}(W) \subseteq X$. So the closed points of Z are the lines on X, each occurring once. What remains is to show that Z is finite, that it is reduced, and that its degree is 27.

Step 2: $\deg c_4(\mathrm{Sym}^3 S^\vee) = 27$. By section 17.1, the open Schubert cells $\Omega^\circ_{(0,\dots,0)}(F_\bullet) = \{W' \big| W' \cap F_2 = 0\}$ cover $\mathrm{Gr}(2,4)$ by copies of $\mathbb{A}^4$ (proposition 17.1.2), so $\mathrm{Gr}(2,4)$ is smooth and $A^*(\mathrm{Gr}(2,4))$ is a graded ring (theorem 14.2.7), in which the Chern classes may be multiplied.

By the splitting principle (theorem 12.2.14) there is a morphism $f \colon Y \to \mathrm{Gr}(2,4)$ with f^* injective on Chow groups and with f^*S carrying a line subbundle L whose quotient $M = f^*S/L$ is a line bundle. Set $x = c_1(L)$ and $y = c_1(M)$, so that $c(f^*S) = (1+x)(1+y)$ by the Whitney formula (theorem 12.2.15). Dualizing gives $0 \to M^\vee \to f^*S^\vee \to L^\vee \to 0$, and $c_1(L^\vee) = -x$, $c_1(M^\vee) = -y$, because $L \otimes L^\vee \cong \mathcal{O}$ and the first Chern class is additive on tensor products of line bundles and vanishes on $\mathcal{O}$ (proposition 11.4.4). Write $E = f^*S^\vee$, with line subbundle $M^\vee$ and quotient $L^\vee$.

The bundle $\mathrm{Sym}^3 E$ carries the filtration $\mathrm{Sym}^3 E = G^0 \supseteq G^1 \supseteq G^2 \supseteq G^3 \supseteq 0$, where G^j is the image of $(M^\vee)^{\otimes j} \otimes \mathrm{Sym}^{3-j} E \to \mathrm{Sym}^3 E$. Locally, if u spans $M^\vee$ and u, v span E, then G^j is spanned by the monomials in u, v of degree 3 with at least j factors of u, so G^j/G^{j+1} is a line bundle with generator the image of $u^j v^{3-j}$, that is, $G^j/G^{j+1} \cong (M^\vee)^{\otimes j} \otimes (L^\vee)^{\otimes(3-j)}$. Its first Chern class is $-jy - (3-j)x$. Applying theorem 12.2.15 to the three short exact sequences $0 \to G^{j+1} \to G^j \to G^j/G^{j+1} \to 0$ gives

$$c(\mathrm{Sym}^3 E) = (1-3x)(1-2x-y)(1-x-2y)(1-3y)$$

so that

$$c_4(\mathrm{Sym}^3 E) = 3x(2x+y)(x+2y)3y = 9xy\,(2x^2+5xy+2y^2)$$

Writing $e_1 = x+y = c_1(f^*S)$ and $e_2 = xy = c_2(f^*S)$ and substituting $2x^2+5xy+2y^2 = 2e_1^2+e_2$ gives $c_4(\mathrm{Sym}^3 E) = 9e_2(2e_1^2+e_2)$. Both sides are pullbacks along f, and f^* is injective, so

$$c_4(\mathrm{Sym}^3 S^\vee) = 9c_2(S)\big(2c_1(S)^2 + c_2(S)\big)$$

in $A^*(\mathrm{Gr}(2,4))$.

Now express $c_1(S)$ and $c_2(S)$ in the Schubert basis. By proposition 17.1.5, $c(S)c(Q) = 1$ with $c(Q) = 1+\sigma_1+\sigma_2$, and $c_i(S) = 0$ for $i > 2$ (theorem 12.2.9); comparing terms in degrees 1 and 2 gives $c_1(S) = -\sigma_1$ and $c_2(S) = \sigma_1^2 - \sigma_2$, which is $\sigma_{1,1}$ by the relation $\sigma_1^2 = \sigma_2 + \sigma_{1,1}$ of example 17.1.6. Therefore

$$c_4(\mathrm{Sym}^3 S^\vee) = 9\sigma_{1,1}(2\sigma_1^2 + \sigma_{1,1}) = 18\sigma_1^2\sigma_{1,1} + 9\sigma_{1,1}^2$$

The two degrees are read from Schubert duality (proposition 17.1.3): in the 2×2 box the complement of $\lambda = (2,0)$ is $(2,0)$ and the complement of $\lambda = (1,1)$ is $(1,1)$, so $\deg(\sigma_2\sigma_{1,1}) = 0$ and $\deg(\sigma_{1,1}^2) = 1$. Since $\sigma_1^2\sigma_{1,1} = \sigma_2\sigma_{1,1} + \sigma_{1,1}^2$, this gives $\deg(\sigma_1^2\sigma_{1,1}) = 1$, and hence

$$\deg c_4(\mathrm{Sym}^3 S^\vee) = 18 + 9 = 27$$

Step 3: Z is nonempty. Suppose σ_F vanished nowhere. Fix a point p and a local frame of $\mathrm{Sym}^3 S^\vee$ near p; since $\sigma_F(p) \neq 0$ in the fibre at p, one may complete $\sigma_F(p)$ to a basis of that fibre and lift the remaining basis vectors to local sections s_2, s_3, s_4. By Nakayama's lemma σ_F, s_2, s_3, s_4 generate $\mathrm{Sym}^3 S^\vee$ near p, and a surjection of free modules of equal rank is an isomorphism, so $\mathrm{Sym}^3 S^\vee \cong \mathcal{O}\sigma_F \oplus \mathcal{O}^3$ near p. Hence $\mathcal{O} \to \mathrm{Sym}^3 S^\vee$ is a subbundle inclusion with locally free quotient G of rank 3, and theorem 12.2.15 gives $c(\mathrm{Sym}^3 S^\vee) = c(\mathcal{O})c(G) = c(G)$. But $c_4(G) = 0$ because G has rank 3 (theorem 12.2.9), contradicting $\deg c_4(\mathrm{Sym}^3 S^\vee) = 27$ of Step 2. So σ_F vanishes somewhere: X contains at least one line.

Step 4: σ_F vanishes simply at each of its zeros. Let $[W] \in Z$, so that $\ell = \mathbb{P}(W) \subseteq X$. Choose a basis e_0, e_1, e_2, e_3 of V with $W = \langle e_0, e_1\rangle$ and let $U_0 = \{W' \big| W' \cap \langle e_2, e_3\rangle = 0\}$, the open Schubert cell containing $[W]$ from Step 2. Each $W' \in U_0$ is the row space of a unique matrix

$$\begin{pmatrix} 1 & 0 & a_0 & a_1 \\ 0 & 1 & b_0 & b_1 \end{pmatrix}$$

which identifies U_0 with $\mathbb{A}^4$ with coordinates (a_0, a_1, b_0, b_1) and $[W]$ with the origin. Over U_0 the bundle S is framed by $u = e_0 + a_0 e_2 + a_1 e_3$ and $v = e_1 + b_0 e_2 + b_1 e_3$, so $\mathrm{Sym}^3 S^\vee$ is framed by the monomials of degree 3 in the dual frame, and the section σ_F has as its four components the coefficients c_0, c_1, c_2, c_3 of the binary cubic

$$\Psi(a, b; s, t) = F(su + tv) = F(s,\ t,\ sa_0 + tb_0,\ sa_1 + tb_1)$$

in s^3, s^2t, st^2, t^3. Thus $Z \cap U_0$ is the closed subscheme of $\mathbb{A}^4$ defined by c_0, c_1, c_2, c_3.

Differentiating Ψ and evaluating at the origin, where the last two arguments of F vanish, gives

$$\left.\frac{\partial \Psi}{\partial a_j}\right|_0 = s\, G_{2+j}(s,t), \qquad \left.\frac{\partial \Psi}{\partial b_j}\right|_0 = t\, G_{2+j}(s,t), \qquad j = 0, 1$$

where $G_m(s,t) = F_m(s,t,0,0)$ is the restriction of the m-th partial derivative of F to ℓ, a binary quadratic. So the differential of (c_0, c_1, c_2, c_3) at the origin, viewed as a linear map from $\mathbb{A}^4$ to the space of binary cubics, is

$$(\alpha_0, \alpha_1, \beta_0, \beta_1) \longmapsto s(\alpha_0 G_2 + \alpha_1 G_3) + t(\beta_0 G_2 + \beta_1 G_3)$$

The two quadratics G_2, G_3 have no common zero. Indeed F vanishes identically on W, so $F(s,t,0,0) = 0$ in $\overline{k}[s,t]$; differentiating this identity with respect to s and to t gives $G_0 = G_1 = 0$. At a point $p \in \ell$ the gradient of F is therefore $(0, 0, G_2(p), G_3(p))$, and it is nonzero because X is smooth, so G_2 and G_3 do not both vanish at p.

Suppose now that $(\alpha_0, \alpha_1, \beta_0, \beta_1)$ lies in the kernel of the differential. Put $P = \alpha_0 G_2 + \alpha_1 G_3$ and $R = \beta_0 G_2 + \beta_1 G_3$, so that $sP = -tR$ in the unique factorization domain $\overline{k}[s,t]$. Then s divides R, say $R = sR_1$ with R_1 linear, and cancelling s gives $P = -tR_1$. Two cases arise.

If $R_1 = 0$ then $P = R = 0$. The quadratics G_2, G_3 are linearly independent: a relation $\alpha_0 G_2 + \alpha_1 G_3 = 0$ with, say, $\alpha_0 \neq 0$ makes G_2 a multiple of G_3, so every zero of G_3 is a zero of G_2, and G_3 has a zero in $\mathbb{P}^1$ unless $G_3 = 0$, in which case $G_2 = 0$ as well; either way G_2 and G_3 acquire a common zero, which they do not have. Hence $\alpha_0 = \alpha_1 = \beta_0 = \beta_1 = 0$.

If $R_1 \neq 0$, set $D = \alpha_0\beta_1 - \alpha_1\beta_0$. Eliminating G_3 from the two equations $P = -tR_1$ and $R = sR_1$ gives $\beta_1 P - \alpha_1 R = D\,G_2$, that is, $D\,G_2 = -(\alpha_1 s + \beta_1 t)R_1$; eliminating G_2 gives $\beta_0 P - \alpha_0 R = -D\,G_3$, that is, $D\,G_3 = (\alpha_0 s + \beta_0 t)R_1$. If $D \neq 0$ then the nonconstant form R_1 divides both G_2 and G_3, so they share a zero, which is excluded. If $D = 0$ then $(\alpha_1 s + \beta_1 t)R_1 = 0$ and $(\alpha_0 s + \beta_0 t)R_1 = 0$; since $R_1 \neq 0$ and $\overline{k}[s,t]$ is a domain, all four coefficients vanish, whence $P = 0 = -tR_1$ and $R_1 = 0$, contrary to assumption.

So the kernel is zero, and the differential is an isomorphism of four-dimensional spaces. Consequently the images of c_0, c_1, c_2, c_3 in $\mathfrak{m}/\mathfrak{m}^2$ are a basis, where $\mathfrak{m}$ is the maximal ideal of the local ring $\mathcal{O}_{\mathrm{Gr}(2,4),[W]}$; by Nakayama's lemma they generate $\mathfrak{m}$, and the local ring of Z at $[W]$ is $\mathcal{O}_{\mathrm{Gr}(2,4),[W]}/(c_0, c_1, c_2, c_3) = \mathcal{O}_{\mathrm{Gr}(2,4),[W]}/\mathfrak{m} = \overline{k}$. So $[W]$ is an isolated point of Z and Z is reduced there.

Step 5: the count. By Step 4 every point of Z is isolated, so Z is a zero-dimensional closed subscheme of the projective variety $\mathrm{Gr}(2,4)$, hence finite, and it is reduced, so its fundamental cycle is $[Z] = \sum_{p \in Z} [p]$ (definition 10.1.2). By Step 3 it is nonempty, so its codimension is 4, which is the expected codimension $(e-k)(f-k) = (1-0)(4-0)$ of the locus $D_0(\sigma_F)$ for $\sigma_F \colon \mathcal{O} \to \mathrm{Sym}^3 S^\vee$. The Thom-Porteous formula (theorem 17.3.5) applies and its determinant is 1×1:

$$[Z] = c_4(\mathrm{Sym}^3 S^\vee - \mathcal{O}) \cap [\mathrm{Gr}(2,4)] = c_4(\mathrm{Sym}^3 S^\vee) \cap [\mathrm{Gr}(2,4)]$$

the second equality because $c(\mathrm{Sym}^3 S^\vee - \mathcal{O}) = c(\mathrm{Sym}^3 S^\vee)/c(\mathcal{O}) = c(\mathrm{Sym}^3 S^\vee)$. Taking degrees (definition 10.2.4), the number of points of Z is $\deg c_4(\mathrm{Sym}^3 S^\vee) = 27$ by Step 2, and by Step 1 those points are the lines on X, as we sought to show.

The count holds for every smooth cubic surface, not merely for a general one: Step 4 verifies the simplicity of each zero using only the smoothness of X along the line in question. Nothing in the argument exhibits a line, and Step 3 shows that the nonvanishing of the Chern number is itself what forbids the empty answer. The configuration of the 27 lines, their 45 triples of coplanar lines and the incidence graph they form, is classical.

Smoothness is used twice and cannot be dropped. A cubic cone contains a one-parameter family of lines, so its zero scheme is a curve rather than 27 points, while $\deg c_4(\mathrm{Sym}^3 S^\vee)$ is still 27; the class is unchanged and it is the geometric hypothesis that has failed. This is the situation the classical enumerative tradition had no way to control.

17.4.2 Conservation of Number The principle of conservation of number asserted that the number of solutions of an enumerative problem is unchanged when the data imposing the conditions are varied continuously, provided the number of solutions remains finite. It was used to compute a count in a convenient special position and transport the answer back to the general position.

The proviso fails in two ways. A position can make the solution set infinite: the five tangency conditions of example 17.4.4 all contain the same surface of double lines, whatever the five conics are, so there is no position in which those conditions meet in a finite set. And a position can make a solution appear with multiplicity greater than one, so that the number of points drops while the number counted with multiplicity does not.

What takes its place is the pair of facts used in theorem 17.4.1. The locus imposed by a condition is a cycle class on a parameter space, and its class is independent of the datum imposing it: $[T_C] = 6h$ for every smooth conic C (proposition 17.4.3). The product of such classes is defined whether or not the loci meet properly (theorem 14.2.7), so no special position is needed to form it, and rational equivalence (definition 10.1.4) is what makes the product depend on the classes alone. The degree of the product is the number of solutions exactly when the solution set is finite and each solution occurs with multiplicity one, which is what Steps 4 and 5 of theorem 17.4.1 establish for the cubic surface. When a component of excess dimension occurs instead, theorem 14.3.9 is what accounts for its contribution to the same degree.

The conic problems are where the second failure mode occurs, and they need one computation: the class of a single tangency condition. Plane conics are parametrized by $\mathbb{P}^5 = \mathbb{P}(W)$, where $W = \operatorname{Sym}^2 V_3^\vee$ is the six-dimensional space of quadratic forms on a three-dimensional vector space V_3, and $\mathbb{P}^2 = \mathbb{P}(V_3)$; write h for the hyperplane class of $\mathbb{P}^5$. Two loci in $\mathbb{P}^5$ matter: the tangency locus of a fixed smooth conic, and the surface

$$\mathcal{V} = \{[\ell^2] \big| \ell \in V_3^\vee \setminus \{0\}\} \subseteq \mathbb{P}^5$$

of double lines. The following computes the first and shows that it contains the second. The computation assumes $\operatorname{char} \overline{k} = 0$.[1]

[1]What fails in characteristic two is the symmetric-matrix criterion of Step 1 below, not the normal form. The polar form of a ternary quadratic form is alternating in characteristic two, hence degenerate in odd dimension, so no invertible symmetric A represents a smooth conic; indeed $x^{\mathsf{T}}Ax$ with A symmetric is there a sum of squares of the coordinates and cannot produce the monomial x_0x_2 at all. The conic $\{x_0x_2 = x_1^2\}$ is itself smooth in every characteristic, being the image of $[s : t] \mapsto [s^2 : st : t^2]$, and it remains the normal form for a smooth plane conic; what would need another proof is the passage from smoothness to that normal form. Characteristic zero is used a second time in Step 2, for the separability of the field extension induced by a dominant morphism.

Proposition 17.4.3: The Tangency Condition Is a Sextic Hypersurface

Assume $\operatorname{char} \overline{k} = 0$. Let $C \subseteq \mathbb{P}^2$ be a smooth conic, defined by $q_C \in W$, and fix an isomorphism $\nu\colon \mathbb{P}^1 \to C$. Let $T_C \subseteq \mathbb{P}^5$ be the closure of the set of $[q]$ with q not proportional to q_C for which the degree-four divisor $\operatorname{div}(\nu^* q)$ on $\mathbb{P}^1$ is non-reduced. Since ν identifies $\operatorname{div}(\nu^* q)$ with the intersection divisor of C and the conic $\{q = 0\}$, a repeated point of that divisor is a point at which the two curves meet with intersection multiplicity at least two; so T_C is the locus of conics tangent to C. The locus T_C is an irreducible hypersurface with

$$[T_C] = 6h$$

and T_C contains the surface $\mathcal{V}$ of double lines.

***Proof*:**

Step 1: normal form and restriction to C. Writing $q_C(x) = x^{\mathsf{T}} A x$ with A symmetric, a singular point of C is a nonzero x with $Ax = 0$ and $q_C(x) = 0$; the first condition implies the second, so C is smooth exactly when A is invertible. Over an algebraically closed field of characteristic other than two any two invertible symmetric matrices of the same size are congruent, so after a linear change of coordinates $q_C = x_0 x_2 - x_1^2$ and $\nu[s : t] = [s^2 : st : t^2]$. Restriction along ν is the linear map

$$\rho\colon W \to U, \qquad \rho(q)(s,t) = q(s^2, st, t^2)$$

where U is the five-dimensional space of binary quartics. It is surjective, since the six monomials $x_0^2, x_0x_1, x_0x_2, x_1^2, x_1x_2, x_2^2$ go to $s^4, s^3t, s^2t^2, s^2t^2, st^3, t^4$, which span U; so its kernel is one-dimensional, and it contains q_C, so it is spanned by q_C.

Step 2: the discriminant hypersurface in $\mathbb{P}(U) = \mathbb{P}^4$. Let $\Delta \subseteq \mathbb{P}^4$ be the set of $[f]$ such that f has a repeated root. A binary quartic has a repeated root exactly when it is divisible by the square of a linear form, so Δ is the image of

$$\Phi\colon \mathbb{P}^1 \times \mathbb{P}^2 \to \mathbb{P}^4, \qquad ([p],[g]) \mapsto [\ell_p^2 g]$$

where $\mathbb{P}^2 = \mathbb{P}(U_2)$ is the space of binary quadratics g and $\ell_p = p_1 s - p_0 t$ is the linear form vanishing at $p = [p_0 : p_1]$. The five coefficients of $\ell_p^2 g$ are bihomogeneous of bidegree $(2,1)$ in the coordinates of p and of g, and they do not vanish simultaneously, since $\ell_p^2 g \neq 0$. Hence Φ is a morphism and $\Phi^* \mathcal{O}_{\mathbb{P}^4}(1) \cong \mathcal{O}_{\mathbb{P}^1}(2) \boxtimes \mathcal{O}_{\mathbb{P}^2}(1)$, so that

$$\Phi^* h_4 = 2\theta + \eta$$

where h_4 is the hyperplane class of $\mathbb{P}^4$, θ the pullback of the class of a point of $\mathbb{P}^1$ and η the pullback of the hyperplane class of $\mathbb{P}^2$; the identification of c_1 of a tensor product with the sum is proposition 11.4.4.

The map Φ is injective over the quartics with exactly one repeated root, that root having multiplicity two: for such an f, the form ℓ is determined up to scalar as the linear form vanishing at the double root and then $g = f/\ell^2$. Such f exist, for instance $s^2t(s+t)$. Since $\mathbb{P}^1 \times \mathbb{P}^2$ is complete, the image Δ is closed, and it is irreducible as the image of an irreducible variety. In characteristic zero the function field extension induced by a dominant morphism is separable, so

a morphism injective over a nonempty open subset of its image has degree one over that image and is birational onto it; hence Δ has dimension 3 and $\Phi_*[\mathbb{P}^1 \times \mathbb{P}^2] = [\Delta]$ (definition 10.2.1).

Step 3: the degree of Δ. Since $\mathbb{P}^1 \times \mathbb{P}^2 = \mathbb{P}(\mathcal{O}^{\oplus 3})$ over $\mathbb{P}^1$, the projective bundle formula (theorem 12.1.9) makes $A^*(\mathbb{P}^1 \times \mathbb{P}^2)$ free over $A^*(\mathbb{P}^1)$ on $1, \eta, \eta^2$ with $\eta^3 = 0$, the Chern classes of a trivial bundle being zero, while $\theta^2 = 0$ in $A^*(\mathbb{P}^1)$ (theorem 10.5.2) and $\theta\eta^2$ is the class of a point. Hence

$$(2\theta + \eta)^3 = \eta^3 + 6\theta\eta^2 + 12\theta^2\eta + 8\theta^3 = 6\theta\eta^2$$

By the projection formula (proposition 12.2.10) applied to Φ,

$$\deg\left(h_4^3 \cap [\Delta]\right) = \deg\left(h_4^3 \cap \Phi_*[\mathbb{P}^1 \times \mathbb{P}^2]\right) = \deg\left((\Phi^* h_4)^3 \cap [\mathbb{P}^1 \times \mathbb{P}^2]\right) = 6$$

Since $A_3(\mathbb{P}^4)$ is generated by the class of a hyperplane (theorem 10.5.2), on which h_4^3 has degree 1, this says $[\Delta]$ is 6 times that class. Writing Δ as the zero locus of an irreducible form G of degree m, the rational function G/y_0^m on $\mathbb{P}^4$ has divisor $\Delta - m\{y_0 = 0\}$, so $[\Delta]$ is m times the hyperplane class and $m = 6$.

Step 4: from Δ *to* T_C. Choose coordinates $y_0, \dots, y_5$ on $\mathbb{P}^5$ so that y_5 is the coordinate of q_C and $y_0, \dots, y_4$ are pulled back along ρ from coordinates on $\mathbb{P}(U)$; this is possible by Step 1. For $[q] \neq [q_C]$ the divisor $\operatorname{div}(\nu^* q)$ is non-reduced exactly when $[\rho(q)] \in \Delta$, that is, when $G(y_0, \dots, y_4) = 0$. Hence T_C is the zero locus in $\mathbb{P}^5$ of $G(y_0, \dots, y_4)$, an irreducible form of degree 6 in six variables, and the divisor computation of Step 3, run on $\mathbb{P}^5$, gives $[T_C] = 6h$.

Step 5: the double lines. Let $\ell \in V_3^\vee$ be nonzero. The line $\{\ell = 0\}$ does not contain the irreducible conic C, so $\nu^*\ell$ is a nonzero binary quadratic and $\nu^*(\ell^2) = (\nu^*\ell)^2$ is a nonzero binary quartic every root of which is repeated. Also $[\ell^2] \neq [q_C]$, since q_C is irreducible and ℓ^2 is not. So $[\ell^2] \in T_C$, and as ℓ varies $\mathcal{V} \subseteq T_C$, completing the proof.

The proposition gives the invariance of the class and the containment $\mathcal{V} \subseteq T_C$. The class $6h$ is the same for every smooth conic C, which is the invariance the classical principle wanted, and it is here a theorem about classes rather than an assumption about counts. The containment $\mathcal{V} \subseteq T_C$ is the obstruction: the double lines are conics in the sense of $\mathbb{P}^5$, they meet every conic in a non-reduced divisor, and they cannot be removed by moving the five conics into general position, since the containment holds for all of them.

Example 17.4.4: The Five-Conic Problem

Let $C_1, \dots, C_5$ be smooth conics in $\mathbb{P}^2$, over a field of characteristic zero, and ask for the conics tangent to all five. Each condition is the hypersurface T_{C_i} of proposition 17.4.3, of class $6h$, and the product of the five classes has degree

$$\deg\left((6h)^5\right) = 6^5 \deg(h^5) = 7776$$

This is the number Steiner published in 1848.

It is not the number of conics tangent to five general conics. By proposition 17.4.3 each T_{C_i} contains the surface $\mathcal{V}$ of double lines, so

$$\mathcal{V} \subseteq T_{C_1} \cap \cdots \cap T_{C_5}$$

and the intersection has a component of dimension 2 where the expected dimension is 0, for every choice of the five conics. The number 7776 is the degree of a product of five classes whose loci do not meet in a finite set; theorem 14.3.9 is what governs the contribution the excess component makes to that degree, and the hypotheses of theorem 17.4.1, Step 5, on which the passage from a degree to a count depends, are not available here.

The remedy is a different parameter space. A double line ℓ^2 records the line ℓ but no tangency data, and the conics tangent to the C_i degenerate onto $\mathcal{V}$ in a way that remembers more; the space of complete conics, the blow-up of $\mathbb{P}^5$ along $\mathcal{V}$, is the parameter space on which the five tangency conditions do meet in a finite reduced set. Its count is 3264, the number Chasles obtained in 1864. That construction is moduli theory and is not carried out here; the space of complete conics and the verification of the count are in [38].

Exercise 17.4.1

1. The lines contained in a quadric surface $X \subseteq \mathbb{P}^3$ defined by $F \in \operatorname{Sym}^2 V^\vee$ are the zeros of the section σ_F of $\operatorname{Sym}^2 S^\vee$ on $\operatorname{Gr}(2,4)$, a bundle of rank 3, so they are expected to form a curve rather than a finite set. Compute $c_3(\operatorname{Sym}^2 S^\vee)$ in the Schubert basis by the method of Step 2 of theorem 17.4.1. Then, assuming X smooth and taking for granted that its lines form two rulings, each meeting a general line of $\mathbb{P}^3$ in as many members as that line meets X, compute the class of a single ruling in $A_1(\operatorname{Gr}(2,4))$ and check that the two rulings account for $c_3(\operatorname{Sym}^2 S^\vee)$.

2. Lines in $\mathbb{P}^4$ contained in a quintic hypersurface are the zeros of a section of $\operatorname{Sym}^5 S^\vee$ on $\operatorname{Gr}(2,5)$, a bundle whose rank equals $\dim \operatorname{Gr}(2,5) = 6$. Show that

$$\deg c_6(\operatorname{Sym}^5 S^\vee) = 2875$$

   Use the splitting principle to express c_6 in $c_1(S)$ and $c_2(S)$, then proposition 17.1.5 and theorem 17.2.1 to rewrite the answer in the Schubert basis of $\operatorname{Gr}(2,5)$, and proposition 17.1.3 to take degrees in the 2×3 box.

3. Let $d \geq 1$ and $N = \binom{d+3}{3} - 1$, so that $\mathbb{P}^N$ parametrizes the surfaces of degree d in $\mathbb{P}^3$. Show that $\operatorname{Sym}^d S^\vee$ has rank $d+1$ and that the restriction map $H^0(\mathbb{P}^3, \mathcal{O}(d)) \to H^0(\ell, \mathcal{O}(d))$ is surjective for every line ℓ. Deduce that the incidence variety $I = \{(\ell, Y) \big| \ell \subseteq Y\} \subseteq \operatorname{Gr}(2,4) \times \mathbb{P}^N$ is a projective bundle over $\operatorname{Gr}(2,4)$ with fibre $\mathbb{P}^{N-d-1}$, so that $\dim I = N + 3 - d$. Conclude that for $d \geq 4$ the image of I in $\mathbb{P}^N$ is a proper closed subset, so a general surface of degree at least 4 in $\mathbb{P}^3$ contains no line.

4. Let F be a cubic form in x_0, x_1, x_2 alone, defining a cone $X \subseteq \mathbb{P}^3$ with vertex $v = [0:0:0:1]$ over a plane cubic curve. Show that X is singular at v, and that the lines joining v to the points of the plane cubic all lie on X, so that the zero scheme of σ_F contains a curve. Which step of the proof of theorem 17.4.1 fails, and what does the number $\deg c_4(\operatorname{Sym}^3 S^\vee) = 27$ compute in this case?

5. Assume $\operatorname{char} \overline{k} \neq 3$ and let $X \subseteq \mathbb{P}^3$ be the surface $x_0^3 + x_1^3 + x_2^3 + x_3^3 = 0$. Show that X is smooth. For each of the three ways of splitting $\{0,1,2,3\}$ into two pairs and each choice of ζ, ξ with $\zeta^3 = \xi^3 = -1$, write down a line on X; show that the 27 lines so obtained are pairwise distinct, and explain why theorem 17.4.1 shows that X has no others.

6. Assume $\operatorname{char}\overline{k} = 0$ and fix a line $L \subseteq \mathbb{P}^2$. Let $T_L \subseteq \mathbb{P}^5$ be the closure of the set of $[q]$ with q not divisible by the equation of L for which the degree-two divisor $q|_L$ on L is non-reduced. Show that $[T_L] = 2h$, by restricting to L as in Step 1 of proposition 17.4.3 and using the discriminant of a binary quadratic. Show that every double line $[\ell^2]$ with ℓ not proportional to the equation of L lies in T_L, hence $\mathcal{V} \subseteq T_L$, and conclude that $2^5 = 32$ is not the number of conics tangent to five general lines.

7. Let $p_1, \ldots, p_4 \in \mathbb{P}^2$ be four points, no three collinear. Show that the conics through all four form a line $P \subseteq \mathbb{P}^5$, that $P \cap \mathcal{V} = \emptyset$, and that $\deg([T_C] \cap [P]) = 6$ for every smooth conic C. So the count of conics through four general points and tangent to a general conic is not obstructed by the double lines, unlike the count in example 17.4.4.

17.5 Summary

The Grassmannian computations of this chapter are a small set of formulas that later work, and other volumes, cite individually.

Result	**Content**	**Stated in**
Basis	$A^*(\mathrm{Gr}(r,n))$ free on the Schubert classes σ_λ	theorem 17.1.4
Duality	$\deg(\sigma_\lambda \cdot \sigma_\mu) = \delta_{\mu,\lambda^\vee}$ for $\lvert\lambda\rvert + \lvert\mu\rvert = r(n-r)$	proposition 17.1.3
Special classes	$\sigma_i = c_i$ of the quotient bundle	proposition 17.1.5
Pieri	$\sigma_\lambda \cdot \sigma_i = \sum \sigma_\mu$ over horizontal strips	theorem 17.2.1
Giambelli	σ_λ as a determinant in the σ_i	theorem 17.2.4
Presentation	$A^*(\mathrm{Gr})$ by generators and relations	corollary 17.2.5
Thom-Porteous	class of a degeneracy locus as a determinant	theorem 17.3.5

Pieri and Giambelli together reduce every product of Schubert classes to a computation with the special classes, which are Chern classes; that reduction is what makes the ring effective. The degeneracy-locus formula of theorem 17.3.5 recovers Giambelli in the rectangular case (corollary 17.3.7), so the two are one statement seen from different sides.

The classical problems of section 17.4 are the test of the machinery: the twenty-seven lines on a smooth cubic surface (theorem 17.4.1), and the conic counts, where the excess and multiplicity results of chapter 14 decide whether a naive count is legitimate.

What Next?

The machine built here computes. It has a group $A_*(X)$ that is functorial for proper pushforward and flat pullback, a Gysin map for regular embeddings, a product on smooth varieties, characteristic classes, Riemann-Roch, and enough Schubert calculus to answer the questions the subject was invented for. What it does not have is a reason to stop. Several directions continue it, and they divide sharply into those this book has already prepared and those it has deliberately declined.

The capstone: algebraic cobordism

Chapter 15 organized the equivalence relations into a tower and asked which functor sits at the top. There is an answer, and it is the natural sequel to this book. Levine and Morel construct $\Omega^*(X)$, *algebraic cobordism*, as the universal oriented Borel-Moore cohomology theory on smooth varieties: universal in the precise sense that any other such theory receives a unique map from it. Two specializations recover what this book computed. Setting the formal group law to the additive one $x + y$ returns the Chow ring $A^*(X)$ of theorem 14.2.7; setting it to the multiplicative law $x + y - xy$ returns $K^\circ(X)$, the ring chapter 16 paired against it. From that vantage Grothendieck-Riemann-Roch stops looking like a theorem about two unrelated functors and starts looking like the comparison of two specializations of one.

The bookkeeping is a formal group law, and the one input this book does not already carry is a universal property. A commutative one-dimensional formal group law over a ring R is a power series $F(x, y) \in R[[x, y]]$ with $F(x, 0) = x$, $F(x, y) = F(y, x)$ and $F(F(x, y), z) = F(x, F(y, z))$; Lazard's theorem says there is a ring $\mathbb{L}$ carrying a universal such law, so that laws over R correspond to ring maps $\mathbb{L} \to R$. The content of the cobordism story is that $\Omega^*(\mathrm{pt}) = \mathbb{L}$: the coefficients of the universal theory are the universal formal group law. Nothing beyond that corepresentability is needed to read the specializations above, and in particular no homotopy theory is required to state them.

That last point is worth making explicitly, because cobordism has a second face. The motivic spectrum MGL and the $\mathbb{A}^1$-homotopy category present the same invariant by homotopical means, and that presentation is genuinely a different subject with different prerequisites. It is not folded in here.

Motives

Section 15.4 built correspondences and showed them composing. Taking that construction seriously as a category, with smooth projective varieties as objects and correspondences modulo an adequate relation as morphisms, is the entry to motives. The choice of relation in theorem 15.3.11 becomes the choice of category, and the conjectures that classify the subject, standard conjectures included, are statements about how much of the cohomological structure survives that passage. The four relations tabulated in section 15.5 are the first data such a theory needs.

The two analytic and arithmetic neighbours

Section 15.2 built the cycle class map over $\mathbb{C}$ and left two debts visible. The Hodge conjecture asks whether cl fills the Hodge classes rationally, and the apparatus for taking that question seriously, Hodge structures and their variations, is [24]'s; this book proved the type statement (theorem 15.2.16) and stopped where the analysis begins. Over a general field the topological cohomology is replaced by ℓ-adic étale cohomology, where the cycle class map, and with it a formulation of the Tate conjecture, live in [21]. The comparison between those two pictures is the reason both books exist.

Two arithmetic and birational directions were declined here as scope decisions rather than oversights. Arakelov theory intersects cycles on arithmetic schemes by completing them with data at the archimedean places, and it needs an analytic apparatus this book does not carry; Fulton's own extension of intersection theory to schemes over a Dedekind base is where that begins. Positivity in the sense of ample cones, Nakai-Moishezon and Kleiman's criterion, and the birational geometry built on it, is a volume of its own.

Where the theory outgrows varieties

Two further generalizations are visible from here. Moduli problems rarely produce a variety, and doing intersection theory on the objects they do produce is what [27] is for: Chow groups of quotient stacks, and the equivariant theory that computes them. Separately, Fulton develops a *bivariant* or operational theory, which attaches classes to morphisms rather than to spaces and thereby extends the calculus to singular targets; Riemann-Roch for singular varieties, sketched in box 16.3.5, is its most conspicuous payoff. Neither is developed here, and both are the standard next reading in Fulton's own text.

What to read

Fulton's *Intersection Theory* [38] is the source this book follows most closely, and its later chapters are exactly the material named above. Chapter 17 is the part of the story with the longest classical history, and the enumerative questions there remain the best test of whether the machine has been understood: a formula that cannot be checked against a hand count of lines on a cubic surface is a formula that has not yet been read.

17.5.1 Reading the numbering A star marks *bonus material*: a chapter, section or subsection that belongs in the book but that nothing later depends on. Skipping it costs nothing downstream. The star sits on the number, as in §2.7⋆; in divisions written before this convention it sits at the front of the title instead, as in **Uniform Spaces*. The two mean the same thing.

Introduction

A moduli problem is asking whether a class of geometric objects (or a class of isomorphism classes of geometric objects) that is paramaterized by some invariant (fixed genus, closed subscheme of $\mathbb{P}^n$ with a fixed Hilbert polynomial, vector bundles of a fixed rank, etc.) can be paramaterized by a geometric object (ex. a variety, a scheme, or other new objects defined in this textbook when schemes are insufficient). The parameterisation by the geometric object records how the objects vary: a family of objects over a base S should be precisely a morphism from S to the space, so that a curve in the space is a one-parameter family and the local structure at a point measures the ways the corresponding object can deform. When such a space exists, it converts questions about an entire class of objects into geometry on a single object.

The obstacle that shapes the whole subject is the presence of automorphisms. An object with a nontrivial automorphism cannot be separated from its symmetries by a space of points alone, and the "naïve" moduli space of such objects either fails to exist or discards the information the automorphisms carry. The book is organized around three responses to this difficulty, one for each of its parts. The first part formulates a moduli problem as a functor of points and asks when that functor is representable by a scheme; it builds the machinery: the Hilbert and Quot schemes and geometric invariant theory, that produces moduli spaces in the representable case. The second part linearizes the local question through deformation theory: the tangent space and the obstruction space of a moduli problem at an object are cohomology groups of that object, and they determine the dimension of the moduli space and whether it is smooth. The third part enlarges the notion of space to the algebraic stack, the geometric object that remembers automorphisms and represents the moduli problems that schemes cannot; Artin's criteria, fed by the deformation theory of the second part, certify when a moduli problem is such a stack. The final chapter applies these to the moduli of curves, where a single object carries a deformation theory, a coarse space built by invariant theory, and a stack structure coalescing automorphism information.

Prerequisites

The reader is assumed to be at home with schemes, quasi-coherent sheaves, and sheaf cohomology at the level of a first graduate course in algebraic geometry, together with a working knowledge of

homological algebra. These prerequisites, and a few more specialized inputs, are cited as machinery where they are used, with references to the companion volumes of this series: [9] for scheme theory and sheaf cohomology, [25] for derived functors and Ext, [29] for group schemes and their actions, and [22] for the Galois cohomology behind the arithmetic threads. Étale-cohomological facts about the Brauer group, needed only in the chapter on gerbes, are stated and cited to [21]. A small number of theorems whose proofs lie beyond a first course, Artin's approximation theorem, the Keel-Mori theorem, and the stable reduction theorem, are stated and used in full with their proofs cited; everything else is proved.

The four movements of the book are largely cumulative and are best read in order, though a reader interested primarily in stacks could begin with the third part after absorbing the language of the first. What the reader should carry away is a single habit of thought: a moduli problem is a functor; when automorphisms obstruct its representability the remedy is to remember them, in a stack; and the local geometry of the resulting space is deformation theory, a computation in the cohomology of one object.

Part IV

Moduli Problems and Their Construction

Whether Moduli spaces exist is the theme of this Part. The idea, due to Grothendieck, is to record the moduli problem as a functor: to each scheme S one assigns the set of families over S, with pullback making the assignment contravariant, and a *moduli space* is then a geometric object (ex. for us this chapter almost always a scheme) that *represents* this functor (section 3.3). The first chapter develops this language, separates fine from coarse moduli spaces, and meets the obstruction, objects with automorphisms, that prevents many natural moduli functors from being representable at all.

The remaining chapters build the machinery that produces moduli spaces when they exist. The next constructs the Hilbert and Quot schemes, Grothendieck's representable functors, from which most moduli spaces are cut out as locally closed subschemes; the last develops geometric invariant theory, which forms quotients by group actions and so produces moduli spaces of objects taken up to isomorphism. Together they are the constructions that the deformation theory of the next Part refines and the stack-theoretic language of the final Part generalizes when schemes are not enough.

18

Moduli Problems and Representability via Schemes

A moduli problem asks for a space that parametrizes a class of geometric objects, but the phrase "the space of all such objects" does not say in what sense that collection is a scheme. This chapter gives that sense, in the language Grothendieck introduced for the purpose. A moduli problem is encoded as a functor that assigns to each scheme S the set of families of objects over S. A moduli space, when one exists, is a scheme that *represents* this functor, and the universal family such a scheme carries makes the correspondence between its points and the objects being classified exact. Section 18.1 sets up this dictionary and the notion of a fine moduli space, and section 18.2 carries it out in full for the Grassmannian, the fundamental example of a fine moduli space.

Representability is the *exception*: the obstruction is visible in the most classical moduli problem of all, that of elliptic curves. An object with nontrivial automorphisms admits families that are fiberwise constant yet globally "twisted", and no scheme can distinguish them from the trivial family. The best one can then hope for in terms of schemes is a *coarse moduli space*, which records the points but forgets how objects vary. Section 18.3 isolates this automorphism obstruction and works the j-line in detail, section 18.4 shows how adding rigidifying structure restores representability, and section 18.5 assembles the criteria that decide representability in general and open onto the deformation theory of the next Part.

18.1 Moduli Problems as Functors of Points

A first answer to constructing a moduli space is to take the *set* of isomorphism classes and look for a scheme structure on it. The difficulty is in determining how such a family varies. Sometimes, this can be eminently visible as in the case of elliptic curves paramaterized by the j-line, however over

more complicated invariant (ex. Hilbert Polynomials of a closed-scheme) the moduli space is not so evident.

The remedy is to record, for every base scheme S, the set of families over S. This assignment is a functor, and the language for turning such a functor into geometry is the *functor of points* (section 3.3): a scheme is determined by the sets of maps into it from all other schemes, so a moduli problem is representable by scheme exactly when its functor of families agrees with the maps-into functor of some scheme. This section makes that precise. It defines the moduli functor, defines a fine moduli space as a scheme representing it, and extracts from the Yoneda lemma the object that makes representability useful in practice: a single universal family through which every other family is pulled back in exactly one way.

The starting datum of any moduli problem is a rule that says what a *family* over a base S is and how families pull back along a morphism of bases:

Definition 18.1.1: Moduli Problem (Functor)

A *moduli problem* is a contravariant functor $\mathcal{F}$

$$\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \longrightarrow \mathbf{Set}$$

that to each scheme S (of finite type over the base field k) one assigns a set

$$\mathcal{F}(S) = \{\,\text{families of the objects over } S\,\}/\cong$$

where "family of objects" is the datum of the problem taken up to isomorphism of families.[a] A morphism $f : T \to S$ is assigned the *pullback* map

$$f^*\colon \mathcal{F}(S) \longrightarrow \mathcal{F}(T)$$

carrying a family over S to its restriction over T.

[a] Definition 24.1.4 formalizes this as a category fibered in groupoids.

The functor $\mathcal{F}$ carries more information than the set of isomorphism classes, which is recovered as $\mathcal{F}(\operatorname{Spec} k)$: the extra data is the collection $\mathcal{F}(S)$ for positive dimensional S together with the pullback maps, and this is precisely the record of how objects vary. A family over S is a single object that deforms as one moves through S; pullback along $f\colon T \to S$ reindexes that variation by T. Contravariance is the reflection of a basic geometric fact that a family over S restricts to a family over any T mapping into S, so a map of bases $T \to S$ induces a map of families in the opposite direction. The whole subject is the study of when this functor is geometric, and how to build the geometry when it is not.

The definition is only as concrete as the phrase "family of the objects" is made to be, so it is worth fixing that phrase in the two cases that run through this chapter.

Example 18.1.2: Families of Subschemes and of Line Bundles

1. Fix a scheme X over k. The *moduli of closed subschemes of* X assigns to S the set

$$\mathcal{F}(S) = \{\, Z \subseteq X \times_k S \text{ closed, flat over } S\,\}$$

of closed subschemes of $X \times_k S$ that are flat over S. A morphism $f\colon T \to S$ pulls a family Z

back to $f^*Z = Z \times_S T \subseteq X \times_k T$, the base change of Z along f; flatness is preserved under base change, so f^*Z is again a family over T. Over a point $\operatorname{Spec} k$ a family is a single closed subscheme of X, so $\mathcal{F}(\operatorname{Spec} k)$ is the set of closed subschemes of X. This is the functor whose representing object, when it exists, is the Hilbert scheme (section 3.3.6).

2. The *Picard problem* assigns to S the set

$$\mathcal{F}(S) = \{\text{line bundles on } X \times_k S\}/\cong$$

of line bundles up to isomorphism, with $f\colon T \to S$ acting by pullback $(\mathrm{id}_X \times f)^*$ of line bundles. Over a point this is $\operatorname{Pic}(X)$, the group of line bundles on X; over a general S it records how a line bundle on X can be deformed as S varies.

The rest of the section asks the single question a moduli functor poses, namely whether it is the functor of points of a scheme. The best possible answer is that $\mathcal{F}$ is, on the nose, the functor $h_M = \operatorname{Hom}(-, M)$ of maps into a scheme M. When this happens, points of M are objects, maps into M are families, and the geometry of M is the geometry of the moduli problem. This is the notion of a *fine moduli space*.

Definition 18.1.3: Fine Moduli Space (Set-Valued)

A *fine moduli space* for the moduli functor $\mathcal{F}$ is a scheme M together with an isomorphism of functors

$$\eta\colon \mathcal{F} \xrightarrow{\sim} h_M = \operatorname{Hom}(-, M)$$

where $h_M\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ sends S to the set $\operatorname{Hom}(S, M)$ of morphisms $S \to M$. When such an M exists, $\mathcal{F}$ is said to be *representable* (definition 0.4.21), and M *represents* $\mathcal{F}$.

The isomorphism η is the content of the definition, not the scheme M alone: it consists of a bijection $\eta_S\colon \mathcal{F}(S) \to \operatorname{Hom}(S, M)$ for every S, compatible with pullback, so that a family over S is literally the same datum as a morphism $S \to M$. Taking $S = \operatorname{Spec} k$ recovers the underlying set-theoretic promise, that isomorphism classes of objects biject with k-points of M; but the definition asks for this in families, for all S at once, which is why it captures variation and the naive point-set does not. A fine moduli space, when it exists, is unique up to unique isomorphism, since a representing object of a functor is: if M and M' both represent $\mathcal{F}$, then $h_M \cong \mathcal{F} \cong h_{M'}$, and the Yoneda lemma turns this isomorphism of functors into a unique isomorphism $M \cong M'$ of schemes.

The word "isomorphism of functors" is doing real work and is easy to underestimate, so before extracting its main consequence it helps to see one case where the representing scheme and the isomorphism are both completely explicit.

Example 18.1.4: Projective Space as a Fine Moduli Space

Fix $n \geq 0$ and let $\mathcal{F}$ be the functor of *rank-1 locally free quotients of the trivial rank-$(n+1)$ bundle*: to a scheme S assign

$$\mathcal{F}(S) = \left\{ \mathcal{O}_S^{n+1} \twoheadrightarrow \mathcal{L} \;:\; \mathcal{L} \text{ a line bundle on } S \right\}\Big/\cong$$

where two surjections $q\colon \mathcal{O}_S^{n+1} \twoheadrightarrow \mathcal{L}$ and $q'\colon \mathcal{O}_S^{n+1} \twoheadrightarrow \mathcal{L}'$ are identified if there is an isomorphism $\mathcal{L} \cong \mathcal{L}'$ carrying q to q'. A morphism $f\colon T \to S$ acts by pullback: f^*q is the surjection $\mathcal{O}_T^{n+1} = f^*\mathcal{O}_S^{n+1} \twoheadrightarrow f^*\mathcal{L}$, again a line-bundle quotient because pullback is right exact and preserves

local freeness. Then $\mathbb{P}^n = \mathbb{P}^n_k$ represents $\mathcal{F}$, with universal quotient the tautological surjection

$$\mathcal{O}_{\mathbb{P}^n}^{n+1} \twoheadrightarrow \mathcal{O}_{\mathbb{P}^n}(1)$$

onto the twisting line bundle $\mathcal{O}_{\mathbb{P}^n}(1)$.

To verify the universal property directly, unwind what a T-point of $\mathbb{P}^n$ is. A morphism $g\colon T \to \mathbb{P}^n$ is the same as a line bundle $\mathcal{L} = g^*\mathcal{O}(1)$ on T together with $n+1$ global sections $s_0, \dots, s_n \in \Gamma(T, \mathcal{L})$ generating $\mathcal{L}$ at every point, modulo the choice of trivialization of $\mathcal{L}$; the sections are the pullbacks $s_i = g^*(x_i)$ of the homogeneous coordinates. Packaging the sections into a map is exactly the surjection

$$q_g\colon \mathcal{O}_T^{n+1} \longrightarrow \mathcal{L}, \qquad (a_0, \dots, a_n) \longmapsto \textstyle\sum_i a_i s_i$$

which is surjective precisely because the s_i generate $\mathcal{L}$ everywhere. This assignment $g \mapsto q_g$ is the pullback of the tautological quotient along g, since $\mathcal{O}(1)$ is generated by $x_0, \dots, x_n$ and $q_g = g^*\big(\mathcal{O}_{\mathbb{P}^n}^{n+1} \twoheadrightarrow \mathcal{O}_{\mathbb{P}^n}(1)\big)$. Conversely, a line-bundle quotient $q\colon \mathcal{O}_T^{n+1} \twoheadrightarrow \mathcal{L}$ furnishes generating sections $s_i = q(e_i)$ and hence a unique morphism $g\colon T \to \mathbb{P}^n$ with $q_g = q$, by the universal property of projective space as Proj. The two constructions are mutually inverse and compatible with further pullback, so

$$\mathcal{F}(T) \xrightarrow{\sim} \mathrm{Hom}(T, \mathbb{P}^n)$$

is a natural isomorphism, and $\mathbb{P}^n$ is a fine moduli space for rank-1 quotients of $\mathcal{O}^{n+1}$.

The example is the template for the whole chapter: a moduli functor is pinned to a scheme by exhibiting one distinguished family over that scheme and showing every other family comes from it by pullback in a unique way. Here the distinguished family is $\mathcal{O}_{\mathbb{P}^n}^{n+1} \twoheadrightarrow \mathcal{O}(1)$, and the phrase "comes from it by pullback in a unique way" is the statement $\mathcal{F} \cong h_{\mathbb{P}^n}$. That this pattern is not special to $\mathbb{P}^n$ but is forced by the definition of representability is the content of the next result.

Representability was defined as an isomorphism $\mathcal{F} \cong h_M$ of functors, which is a statement about all schemes S at once and so seems to require checking infinitely many bijections. The Yoneda lemma collapses this to a single piece of data: one family over M itself. The mechanism is that a natural transformation out of h_M is completely determined by where it sends the identity morphism id_M, and running this in reverse shows that an isomorphism $\mathcal{F} \cong h_M$ is the same as a family over M with a universal property. That family is what one constructs in practice, and what one produces when asked to "exhibit the moduli space".

Proposition 18.1.5: Universal Family

Let M be a scheme and $\mathcal{F}$ a moduli functor. Giving an isomorphism of functors $\eta\colon \mathcal{F} \xrightarrow{\sim} h_M$ is equivalent to giving a family $\mathcal{U} \in \mathcal{F}(M)$, the *universal family*, with the following universal property: for every scheme S and every family $\xi \in \mathcal{F}(S)$ there is a unique morphism $g\colon S \to M$ with $g^*\mathcal{U} = \xi$. In particular, $\mathcal{F}$ is representable by M if and only if such a universal family exists, and then $\mathcal{U}$ corresponds under η to the identity $\mathrm{id}_M \in h_M(M)$.

***Proof*:**
The argument is the Yoneda lemma (theorem 0.4.22) applied to the functor $\mathcal{F}$ and the representable functor h_M; the proof records what each direction of the equivalence produces so that the universal family and the isomorphism are explicit.

Step 1: From an isomorphism to a universal family. Suppose given a natural isomorphism

$\eta\colon \mathcal{F} \xrightarrow{\sim} h_M$. In particular $\eta_M\colon \mathcal{F}(M) \to h_M(M) = \mathrm{Hom}(M, M)$ is a bijection, so there is a unique family

$$\mathcal{U} := \eta_M^{-1}(\mathrm{id}_M) \in \mathcal{F}(M)$$

the preimage of the identity morphism. Fix a family $\xi \in \mathcal{F}(S)$ and set $g := \eta_S(\xi) \in \mathrm{Hom}(S, M)$. Naturality of η with respect to the morphism $g\colon S \to M$ is the commuting square

$$\begin{array}{ccc} \mathcal{F}(M) & \xrightarrow{\eta_M} & \mathrm{Hom}(M, M) \\ \downarrow{\scriptstyle g^*} & & \downarrow{\scriptstyle g^*} \\ \mathcal{F}(S) & \xrightarrow{\eta_S} & \mathrm{Hom}(S, M) \end{array}$$

where the right-hand g^* is precomposition with g. Chase the family $\mathcal{U} \in \mathcal{F}(M)$ in the top-left corner around the square. Across the top it maps to $\eta_M(\mathcal{U}) = \mathrm{id}_M$, and then down to $g^*(\mathrm{id}_M) = \mathrm{id}_M \circ g = g$; down the left it maps to $g^*\mathcal{U}$, and then across to $\eta_S(g^*\mathcal{U})$. Equality of the two routes yields $\eta_S(g^*\mathcal{U}) = g = \eta_S(\xi)$, and η_S is injective, so

$$g^*\mathcal{U} = \xi$$

This exhibits ξ as a pullback of $\mathcal{U}$. For uniqueness, suppose $g'\colon S \to M$ also satisfies $(g')^*\mathcal{U} = \xi$. Running the same naturality square for g' gives $\eta_S((g')^*\mathcal{U}) = g'$, hence $g' = \eta_S(\xi) = g$. Thus g is the unique morphism with $g^*\mathcal{U} = \xi$, and $\mathcal{U}$ has the claimed universal property.

Step 2: From a universal family to an isomorphism. Conversely, suppose given a family $\mathcal{U} \in \mathcal{F}(M)$ such that for every S and every $\xi \in \mathcal{F}(S)$ there is a unique $g\colon S \to M$ with $g^*\mathcal{U} = \xi$. Define, for each S, a map

$$\theta_S\colon \mathrm{Hom}(S, M) \longrightarrow \mathcal{F}(S), \qquad g \longmapsto g^*\mathcal{U}$$

which is a well-defined map of sets because pullback of families is defined. Naturality of $\theta = (\theta_S)_S$ is functoriality of pullback: for $f\colon T \to S$ and $g\colon S \to M$,

$$\theta_T(g \circ f) = (g \circ f)^*\mathcal{U} = f^*(g^*\mathcal{U}) = f^*\theta_S(g)$$

so θ is a natural transformation $h_M \to \mathcal{F}$. The universal property says exactly that each θ_S is a bijection: given $\xi \in \mathcal{F}(S)$, existence of a g with $g^*\mathcal{U} = \xi$ is surjectivity of θ_S, and uniqueness of that g is injectivity. A natural transformation that is bijective on every object is an isomorphism of functors, so $\theta\colon h_M \xrightarrow{\sim} \mathcal{F}$ is an isomorphism; its inverse $\eta = \theta^{-1}\colon \mathcal{F} \xrightarrow{\sim} h_M$ is the sought isomorphism.

Step 3: The two constructions are mutually inverse. It remains to check that starting from η, producing $\mathcal{U} = \eta_M^{-1}(\mathrm{id}_M)$, and then producing θ returns η^{-1}, and symmetrically. From Step 1, for $g \in \mathrm{Hom}(S, M)$ set $\xi = g^*\mathcal{U}$; the uniqueness there gives $\eta_S(g^*\mathcal{U}) = g$, that is $\eta_S \circ \theta_S = \mathrm{id}_{\mathrm{Hom}(S,M)}$, so $\theta = \eta^{-1}$. In particular $\mathcal{U} = \theta_M(\mathrm{id}_M) = \eta_M^{-1}(\mathrm{id}_M)$ corresponds to id_M under η, as claimed. The two passages are therefore inverse to one another, giving the asserted equivalence between isomorphisms $\mathcal{F} \cong h_M$ and universal families, completing the proof.

The proposition is the reason the functorial viewpoint is workable, not only correct. To prove a scheme M is a fine moduli space one need not construct a bijection $\mathcal{F}(S) \cong \mathrm{Hom}(S, M)$ for every S by hand; it suffices to write down one family $\mathcal{U}$ over M and verify that every family is a unique pullback of it. In the projective-space example (example 18.1.4) the universal family is the tautological quotient $\mathcal{O}^{n+1} \twoheadrightarrow \mathcal{O}(1)$, and the verification that every quotient over T is a unique pullback is precisely the universal property of $\mathbb{P}^n$ that was checked there; the proposition explains why that single verification

is enough. The universal family also carries a concrete geometric meaning: its fiber over a point $m \in M$ is the object that m classifies, so $\mathcal{U}$ is a single geometric family whose fiber over each point of the moduli space is the corresponding object. This is the sense in which a fine moduli space "carries the objects on its back".

Representability is a strong requirement, and the structural constraint it imposes is exactly where the interesting moduli problems fail it. A functor of the form h_M is not an arbitrary functor: it satisfies a gluing condition inherited from morphisms of schemes, and a moduli functor that violates this condition cannot be representable no matter how the objects are arranged.

The motivating paragraph for the warning is the following observation about morphisms. A morphism $S \to M$ is a local datum: to give it is to give morphisms $S_i \to M$ on the opens of a cover that agree on overlaps, because M is glued from its structure sheaf. Hence h_M is a *Zariski sheaf*: a compatible family of T-points on a cover glues to a unique T-point. Any representable moduli functor must inherit this, and the obstruction to it is the presence of automorphisms.

18.1.6 Warning: Automorphisms Obstruct Representability A representable functor h_M is necessarily a *Zariski sheaf*: for any scheme S with a Zariski open cover $\{S_i\}$, a collection of morphisms $g_i \colon S_i \to M$ with $g_i|_{S_i \cap S_j} = g_j|_{S_i \cap S_j}$ glues to a unique $g \colon S \to M$ restricting to each g_i. Consequently, if a moduli functor $\mathcal{F}$ fails the sheaf condition, it cannot be representable. Objects with nontrivial automorphisms manufacture exactly this failure. Suppose an object X_0 over k has a nontrivial automorphism. One can then build a family over a base S whose restriction to each member S_i of an open cover is the constant family $X_0 \times S_i$, so that the family is trivial locally on the cover, yet whose gluing over the overlaps is twisted by the automorphism so that the family is not globally the constant family $X_0 \times S$. Such a family has isomorphic fibers over every point of S but is not itself constant. Under any candidate isomorphism $\mathcal{F} \cong h_M$ its class in $\mathcal{F}(S)$ would have to glue, from the locally-constant data, to the class of the constant family, and the two are distinct elements of $\mathcal{F}(S)$: the sheaf condition is violated, and no fine moduli space exists.
This is the central obstruction of the chapter. It is the reason the moduli of elliptic curves has no fine moduli space and must be replaced by the coarse j-line (section 18.3), and the sheaf-theoretic diagnosis given here is sharpened into a working representability criterion in section 18.5. The class of examples alluded to, locally trivial but globally twisted families, is made fully explicit in example 18.3.4.

The warning identifies the fault line that organizes the entire book. When $\mathcal{F}$ is a sheaf and is locally representable, it is representable, and the Hilbert and Quot schemes of the next chapter provide the fundamental such functors. When $\mathcal{F}$ fails to be a sheaf because its objects have automorphisms, one has three responses, and the book pursues all of them in turn: settle for a coarse moduli space that co-represents $\mathcal{F}$ (section 18.3), rigidify the problem by adding structure to kill the automorphisms (section 18.4), or enlarge the category of geometric objects to stacks, in which automorphisms are remembered. The functor of points is the frame in which all three are stated.

Exercise 18.1.1

1. Work out the functor of points of $\mathbb{P}^1$ directly from example 18.1.4. Describe $\mathcal{F}(S)$ for the functor of rank-1 locally free quotients of $\mathcal{O}_S^2$, show that a T-point of $\mathbb{P}^1$ is the same as a pair of sections (s_0, s_1) of a line bundle $\mathcal{L}$ on T generating $\mathcal{L}$ at every point, taken modulo isomorphism of $\mathcal{L}$, and check that on $T = \operatorname{Spec} k$ this recovers the usual k-points $[a_0 : a_1]$ of

$\mathbb{P}^1$.

2. Let X_0 be an object over k with a nontrivial automorphism $\sigma\colon X_0 \to X_0$, and let $S = S_1 \cup S_2$ be a scheme with two opens whose intersection $S_{12} = S_1 \cap S_2$ is nonempty. Using σ, describe how to glue the constant families $X_0 \times S_1$ and $X_0 \times S_2$ over S_{12} into a family ξ over S that has X_0 as every fiber but need not be isomorphic to the constant family $X_0 \times S$. Explain, referring to box 18.1.6, why the existence of such a ξ shows that the set of isomorphism classes $\mathcal{F}(\operatorname{Spec} k)$ alone cannot determine a scheme structure representing $\mathcal{F}$.

3. Suppose $\mathcal{F}$ is represented by a scheme M with universal family $\mathcal{U}$, and let $\xi \in \mathcal{F}(S)$ be a family that happens to be the pullback $h^*\mathcal{U}$ of $\mathcal{U}$ along some morphism $h\colon S \to M$. Prove, using only proposition 18.1.5, that h is the *unique* morphism $S \to M$ classifying ξ, and deduce that the classifying map of the universal family $\mathcal{U}$ itself is id_M.

4. A scheme M is given as a fine moduli space for a functor $\mathcal{F}$ by an isomorphism $\eta\colon \mathcal{F} \xrightarrow{\sim} h_M$. Explain how to read off the universal family $\mathcal{U} \in \mathcal{F}(M)$ from η, and carry this out for $M = \mathbb{P}^n$ and the quotient functor of example 18.1.4: identify which element of $\mathcal{F}(\mathbb{P}^n)$ is $\eta^{-1}_{\mathbb{P}^n}(\mathrm{id}_{\mathbb{P}^n})$.

5. Define a functor $\mathcal{G}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ by $\mathcal{G}(S) = \{\,\text{invertible global functions on } S\,\} = \Gamma(S, \mathcal{O}_S)^\times$, with pullback the obvious restriction. Show that $\mathcal{G}$ is a Zariski sheaf, and prove that $\mathcal{G}$ is representable by the scheme $\mathbb{G}_m = \operatorname{Spec} k[t, t^{-1}]$ by exhibiting the universal family and verifying the universal property of proposition 18.1.5. Contrast this with the functor $\mathcal{G}'(S) = \Gamma(S, \mathcal{O}_S)^\times/(\text{constants } k^\times)$ and argue that $\mathcal{G}'$ fails the sheaf condition, hence is not representable.

18.2 Fine Moduli Spaces: the Grassmannian

The previous section made the abstract case: a moduli problem is a functor $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ (definition 18.1.1), a fine moduli space is a scheme M with $\mathcal{F} \cong h_M$ (definition 18.1.3), and representability is equivalent to the existence of a universal family (proposition 18.1.5). What that section could not yet give is a moduli problem interesting enough to matter and simple enough to solve by hand from beginning to end. This section gives it. The Grassmannian $\mathrm{Gr}(d, n)$, whose points are the d-dimensional quotient spaces of a fixed n-dimensional vector space, is the model fine moduli problem: the functor it represents is written down in one line, the representing scheme is built explicitly from affine charts, the universal family is exhibited concretely, and the whole space is shown to be projective through the Plücker embedding. Every later construction in this book, most immediately the Hilbert and Quot schemes of the following chapter, is cut out of a Grassmannian, so the effort spent here is repaid many times over.

The design choice that makes the construction work is to phrase a point of the Grassmannian not as a subspace but as a *quotient*. A d-dimensional subspace $W \subseteq k^n$ and the quotient $k^n \twoheadrightarrow k^n/W$ carry the same information, but the quotient behaves far better in families: a surjection of a trivial bundle onto a locally free sheaf is a functorial datum requiring no side condition, whereas "a locally free subsheaf" must carry the extra condition that the quotient be locally free too (so that the sub is a *subbundle*, not just a subsheaf). Phrasing points as quotients builds that condition in from the start. This is the same bookkeeping that made $\mathbb{P}^n$ the moduli space of rank-1 quotients of $\mathcal{O}^{n+1}$ in example 18.1.4, and the Grassmannian is the direct generalization from rank 1 to rank d.

The functor of points is stated for an arbitrary base scheme S: a family over S is a rank-d locally free

quotient of the trivial rank-n sheaf $\mathcal{O}_S^n$, and the whole point of working with quotients is that pulling back a surjection of sheaves along a morphism $T \to S$ again gives a surjection, so the assignment is contravariant with no further hypotheses.

Definition 18.2.1: The Grassmannian Functor

Fix integers $0 \leq d \leq n$. The *Grassmannian functor* $\underline{\mathrm{Gr}}(d,n)\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ assigns to a scheme S the set

$$\underline{\mathrm{Gr}}(d,n)(S) = \left\{ \mathcal{O}_S^n \overset{q}{\twoheadrightarrow} \mathcal{Q} \;\middle|\; \mathcal{Q} \text{ locally free of rank } d \right\} \Big/ \cong$$

of surjections of $\mathcal{O}_S$-modules from the trivial sheaf $\mathcal{O}_S^n$ onto a locally free sheaf $\mathcal{Q}$ of rank d, where two surjections $q\colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}$ and $q'\colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}'$ are identified when there is an isomorphism $\varphi\colon \mathcal{Q} \xrightarrow{\sim} \mathcal{Q}'$ with $\varphi \circ q = q'$. For a morphism $f\colon T \to S$ the pullback map sends the class of q to the class of $f^*q\colon \mathcal{O}_T^n \twoheadrightarrow f^*\mathcal{Q}$.

Because f^* is right exact, f^*q is again surjective, and $f^*\mathcal{Q}$ is again locally free of rank d, so the pullback map is well defined and $\underline{\mathrm{Gr}}(d,n)$ is a functor. Two remarks fix the meaning of the equivalence relation. First, the identification by isomorphisms of $\mathcal{Q}$ is forced by the moduli philosophy of definition 18.1.1: a family is an equivalence class, and here the class of q remembers only the kernel $\ker q \subseteq \mathcal{O}_S^n$ together with the fact that the quotient is a bundle. Second, over a field, $\underline{\mathrm{Gr}}(d,n)(k)$ is exactly the set of d-dimensional quotient spaces of k^n, equivalently the set of $(n-d)$-dimensional subspaces $\ker q \subseteq k^n$, which is the classical Grassmannian of $(n-d)$-planes. The functor is the family-version of that set.

The subbundle picture is the same datum read backwards, and it is worth recording because half the literature (and half of this book) prefers it. Given a quotient $q\colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}$ with $\mathcal{Q}$ locally free of rank d, the kernel $\mathcal{S} = \ker q$ is a locally free subsheaf of rank $n-d$ whose quotient is locally free, hence a *subbundle*; conversely a rank-$(n-d)$ subbundle $\mathcal{S} \hookrightarrow \mathcal{O}_S^n$ has locally free quotient of rank d. The two descriptions are interchanged by the short exact sequence

$$0 \to \mathcal{S} \to \mathcal{O}_S^n \xrightarrow{q} \mathcal{Q} \to 0 \tag{18.1}$$

and neither is more basic than the other. The convention here takes the quotient $\mathcal{Q}$ as primary and calls $\mathcal{S}$ the associated sub.

Definition 18.2.2: The Grassmannian

The *Grassmannian* $\mathrm{Gr}(d,n)$ is the scheme constructed in theorem 18.2.4 below, characterized by the property that it represents the functor $\underline{\mathrm{Gr}}(d,n)$ of definition 18.2.1.

Before proving representability, it helps to see the charts concretely in the smallest new case, so that the abstract cover in the proof reads as bookkeeping for a picture already understood.

Example 18.2.3: Charts on the Grassmannian of Lines in 3-Space

Take $d = 2$, $n = 3$, so $\mathrm{Gr}(2,3)$ parametrizes rank-2 quotients of $\mathcal{O}_S^3$, equivalently rank-1 subbundles (lines) of $\mathcal{O}_S^3$. Over a field a point is a line $\ell \subseteq k^3$ through the origin, spanned by a nonzero vector (a_0, a_1, a_2) up to scale, so $\mathrm{Gr}(2,3)(k)$ is exactly $\mathbb{P}^2$, the set of such lines. The three charts are the loci where $a_0 \neq 0$, $a_1 \neq 0$, $a_2 \neq 0$; on the first, scaling to $a_0 = 1$ leaves the two free coordinates $(a_1, a_2) \in \mathbb{A}^2$, and these are the affine coordinates on that chart. So $\mathrm{Gr}(2,3) \cong \mathbb{P}^2$, its

dual realization as lines. This is the case $n = 3$ of the identification $\mathrm{Gr}(n-1, n) = \mathbb{P}^{n-1}$, which is the duality of exercise 18.2.1 (6) applied to $\mathrm{Gr}(1, n) = \mathbb{P}^{n-1}$; the three charts here are indexed by the nonzero coordinate of the spanning line vector, which under that duality corresponds to the U_I charts of theorem 18.2.4 indexed by the two-subsets $I \subseteq \{1, 2, 3\}$.

The representability theorem is the technical heart of the section. Its proof is the archetype for every later representability argument: cover the functor by open subfunctors, each of which is representable by an affine space, then check that these charts glue to a scheme representing the whole. The charts are indexed by d-element subsets of the coordinates, and the chart U_I is the locus where a given family, restricted to those d coordinates, is already an isomorphism onto the quotient.

The one input this argument needs, beyond the definitions, is the criterion that a functor which is a Zariski sheaf and admits an open cover by representable subfunctors is itself representable. That criterion is developed in full generality later (see theorem 18.5.6); here the covering subfunctors are so explicit that the gluing can be exhibited by hand, and the proof below does exactly that. This keeps the argument self-contained and shows the mechanism the general theorem abstracts.

Theorem 18.2.4: Representability of the Grassmannian

For $0 \le d \le n$ there is a scheme $\mathrm{Gr}(d, n)$, smooth and projective over $\mathbb{Z}$ (hence over any base) of relative dimension $d(n-d)$, representing the functor $\underline{\mathrm{Gr}}(d, n)$ of definition 18.2.1. It is covered by $\binom{n}{d}$ affine charts, each isomorphic to $\mathbb{A}^{d(n-d)}$.

***Proof*:**
The construction proceeds by building the covering subfunctors, identifying each with an affine space, and gluing. Throughout, $[n] = \{1, \dots, n\}$, and for a d-element subset $I \subseteq [n]$ the inclusion of the coordinates indexed by I is written $\iota_I \colon \mathcal{O}_S^d \to \mathcal{O}_S^n$.

Step 1: The covering subfunctors. For each d-element subset $I \subseteq [n]$ define a subfunctor $\underline{U}_I \subseteq \underline{\mathrm{Gr}}(d, n)$ by declaring, for a family $q \colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}$ over S, that $[q] \in \underline{U}_I(S)$ when the composite

$$\mathcal{O}_S^d \xrightarrow{\iota_I} \mathcal{O}_S^n \xrightarrow{q} \mathcal{Q}$$

is an isomorphism. This condition is invariant under the equivalence relation of definition 18.2.1: replacing q by $\varphi \circ q$ replaces the composite by $\varphi \circ (q \circ \iota_I)$, still an isomorphism. It is also stable under pullback, since f^* preserves isomorphisms, so $\underline{U}_I$ is a genuine subfunctor.

The condition defining $\underline{U}_I$ is open: the composite $q \circ \iota_I$ is a map between locally free sheaves of the same rank d, and the locus in S where such a map is an isomorphism is the non-vanishing locus of its determinant, an open subscheme. A family q over S therefore lies in $\underline{U}_I(T)$ after pullback along $f \colon T \to S$ if and only if f factors through this open subscheme, which is the statement that $\underline{U}_I \hookrightarrow \underline{\mathrm{Gr}}(d, n)$ is an open subfunctor.

Step 2: The charts cover. A family $q \colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}$ lies in $\underline{U}_I(S)$ for suitable I at least locally on S. Fix a point $s \in S$; the surjection q of a rank-n trivial bundle onto a rank-d bundle has, at the residue field $\kappa(s)$, a surjection $\kappa(s)^n \twoheadrightarrow \mathcal{Q} \otimes \kappa(s)$ of a rank-n space onto a rank-d space. Some d of the standard basis vectors of $\kappa(s)^n$ map to a basis of the d-dimensional target, that is, $q \circ \iota_I$ is an isomorphism at s for some I. By openness of the isomorphism locus (Step 1), $q \circ \iota_I$ is an isomorphism on a neighborhood of s. Thus the pullback of q to that neighborhood lies in $\underline{U}_I$, and the $\underline{U}_I$ cover $\underline{\mathrm{Gr}}(d, n)$ in the sense that every family is, locally on its base, in some chart.

Step 3: Each chart is an affine space. Fix I. Order the $n-d$ complementary coordinates as $j_1, \dots, j_{n-d}$, the elements of $[n] \setminus I$. The claim is that $\underline{U}_I$ is represented by the affine space $\mathbb{A}^{d(n-d)}$ with coordinate ring $k[x_{ab}]$, where a ranges over I and b ranges over $[n] \setminus I$, that is, by the space of $d \times (n-d)$ matrices.

Given a family $[q] \in \underline{U}_I(S)$, the composite $\theta = q \circ \iota_I \colon \mathcal{O}_S^d \xrightarrow{\sim} \mathcal{Q}$ is an isomorphism, and $\theta^{-1} \circ q \colon \mathcal{O}_S^n \to \mathcal{O}_S^d$ is a surjection restricting to the identity on the coordinates I. Its remaining entries assemble into a $d \times (n-d)$ matrix $M(q)$ over $\mathcal{O}_S(S)$, whose (a,b) entry records the image in the a-th standard basis vector of $\mathcal{O}_S^d$ of the b-th complementary coordinate. Replacing q by $\varphi \circ q$ replaces θ by $\varphi \circ \theta$ and leaves $\theta^{-1} \circ q$ unchanged, so $M(q)$ depends only on the class $[q]$ and gives a well-defined map

$$\underline{U}_I(S) \longrightarrow \mathrm{Hom}(S, \mathbb{A}^{d(n-d)}) = \{d \times (n-d) \text{ matrices over } \mathcal{O}_S(S)\}$$

natural in S. Conversely, a matrix M over $\mathcal{O}_S(S)$ determines the surjection $q_M \colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{O}_S^d$ that is the identity on the coordinates I and has entry M_{ab} on the complementary coordinate b; this q_M visibly lies in $\underline{U}_I(S)$, with $\theta = \mathrm{id}$, and $M(q_M) = M$. The two constructions are mutually inverse and natural, so $\underline{U}_I \cong h_{\mathbb{A}^{d(n-d)}}$. By the Yoneda direction of proposition 18.1.5, $\underline{U}_I$ is representable by $U_I := \mathbb{A}^{d(n-d)}$.

Step 4: Gluing. For two subsets I, J the overlap subfunctor $\underline{U}_I \cap \underline{U}_J$ is the locus in $U_I \cong \mathbb{A}^{d(n-d)}$ where, in addition, $q \circ \iota_J$ is an isomorphism. In the coordinates of U_I a family is the surjection q_M; the composite $q_M \circ \iota_J$ is the $d \times d$ submatrix of the full $d \times n$ matrix $(\,\mathrm{Id}_I \big| M\,)$ on the columns indexed by J, so $\underline{U}_I \cap \underline{U}_J$ is the principal open subset of U_I where the determinant of that submatrix is invertible, an open subscheme $U_{IJ} \subseteq U_I$. The transition isomorphism $U_{IJ} \xrightarrow{\sim} U_{JI}$ is read off by recomputing the normalized matrix relative to the coordinates J: it sends the matrix normalized on I to the matrix normalized on J, obtained by left-multiplying $(\,\mathrm{Id}_I \big| M\,)$ by the inverse of its J-submatrix and deleting the resulting identity block. These transition maps are morphisms of schemes (entries are rational functions with the relevant determinant inverted) and satisfy the cocycle condition on triple overlaps, because on $U_{IJ} \cap U_{IK}$ all three normalizations describe the *same* surjection q read in three coordinate frames, so passing $I \to J \to K$ agrees with $I \to K$.

By the gluing construction for schemes, the U_I glue along the U_{IJ} to a scheme $\mathrm{Gr}(d,n)$. The subfunctors $\underline{U}_I$ glue correspondingly to a functor which, by Steps 1 and 2, is $\underline{\mathrm{Gr}}(d,n)$, and each $\underline{U}_I$ is represented by the chart U_I; a family over an arbitrary S is one that restricts to a chart family on each piece of a cover of S, and the transition maps guarantee these glue to a unique morphism $S \to \mathrm{Gr}(d,n)$. Hence $\mathrm{Gr}(d,n)$ represents $\underline{\mathrm{Gr}}(d,n)$.

Step 5: Dimension, smoothness, projectivity. Each chart is $\mathbb{A}^{d(n-d)}$, so $\mathrm{Gr}(d,n)$ is smooth of dimension $d(n-d)$ and covered by $\binom{n}{d}$ such charts. The construction used only $\mathbb{Z}$-coefficients (the transition maps are integral rational functions), so $\mathrm{Gr}(d,n)$ is defined and smooth over $\mathbb{Z}$, hence over any base by base change. Projectivity is the content of proposition 18.2.7, which realizes $\mathrm{Gr}(d,n)$ as a closed subscheme of a projective space. This completes the proof.

The theorem is the first fine moduli space of the book realized from scratch. What the reader should take from it is less the statement than the shape of the argument, because it recurs: a moduli functor is representable when it can be covered by open subfunctors each of which is an affine space of parameters, and the parameters are the freedom left after normalizing a family into a standard form. Here the standard form is "the identity on a chosen set of d coordinates," the remaining freedom is a $d \times (n-d)$ matrix, and the transition between two normalizations is a determinant computation.

The Hilbert and Quot schemes of the next chapter are built by exhibiting them as closed subfunctors of Grassmannian functors, so representability there is inherited from the theorem just proved.

The case $d = 1$ recovers the running example of the previous section. A rank-1 locally free quotient of $\mathcal{O}_S^n$ is exactly the datum classified by $\mathbb{P}^{n-1}$, and unwinding the definitions gives $\mathrm{Gr}(1, n) = \mathbb{P}^{n-1}$, matching $\mathbb{P}^{n-1}$ as the moduli space of rank-1 quotients of $\mathcal{O}^n$ from example 18.1.4 (there stated for $\mathcal{O}^{n+1}$, giving $\mathbb{P}^n$; the index shift is the passage from $n+1$ to n). The charts of the theorem specialize to the standard affine charts of projective space: the subset $I = \{i\}$ is the locus where the i-th coordinate of the quotient is nonzero, and the $1 \times (n-1)$ matrix of remaining entries is exactly the tuple of affine coordinates on that chart. So the Grassmannian is the common generalization of projective space to higher-rank quotients, and $\mathbb{P}^{n-1}$ is its rank-1 case.

Representability produces, through proposition 18.1.5, a universal family on $\mathrm{Gr}(d, n)$: the family corresponding to the identity morphism $\mathrm{Gr}(d, n) \to \mathrm{Gr}(d, n)$. Naming it and its associated sub is worthwhile, because these two bundles are the source of nearly every natural construction on the Grassmannian, from its tangent bundle to the tautological classes computed against it in intersection theory.

Definition 18.2.5: Universal Quotient and Universal Sub

On $G = \mathrm{Gr}(d, n)$ the *universal quotient bundle* $\mathcal{Q}$ is the locally free sheaf of rank d appearing in the family $q_{\mathrm{univ}} \colon \mathcal{O}_G^n \twoheadrightarrow \mathcal{Q}$ that corresponds, under the isomorphism $\underline{\mathrm{Gr}}(d, n) \cong h_G$ of theorem 18.2.4, to the identity morphism $\mathrm{id}_G \in h_G(G)$. Its kernel $\mathcal{S} = \ker q_{\mathrm{univ}}$, a locally free sheaf of rank $n - d$, is the *universal subbundle* (or *tautological subbundle*). They sit in the universal short exact sequence

$$0 \to \mathcal{S} \to \mathcal{O}_G^n \xrightarrow{q_{\mathrm{univ}}} \mathcal{Q} \to 0$$

on $\mathrm{Gr}(d, n)$.

The universal property is the statement of proposition 18.1.5 specialized to this family: for every scheme S and every rank-d locally free quotient $q \colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}'$, there is a unique morphism $\varphi_q \colon S \to \mathrm{Gr}(d, n)$ with $\varphi_q^* \, q_{\mathrm{univ}} = q$ (up to the identification of definition 18.2.1), that is, $\varphi_q^* \mathcal{Q} \cong \mathcal{Q}'$ compatibly with the surjection from $\mathcal{O}_S^n$. Every family of d-dimensional quotients is a pullback of the one universal family, in exactly one way. This is what it means for $\mathrm{Gr}(d, n)$ to be a *fine* moduli space in the sense of definition 18.1.3: the universal bundle is a single geometric object over the moduli space from which all others are cut by pullback.

The tautological name comes from the field-point picture. Over the classical Grassmannian, the fiber of $\mathcal{S}$ at a point $[\ell]$ (a subspace $\ell \subseteq k^n$) is the subspace ℓ itself, and the fiber of $\mathcal{Q}$ is the quotient k^n/ℓ; the subbundle is "tautologically" the space its point names. The next example makes the universal bundle explicit in charts, staying within the promised distance of the definition.

Example 18.2.6: The Universal Sequence in a Chart

On the chart $U_I \cong \mathbb{A}^{d(n-d)}$ of theorem 18.2.4 the universal quotient is the free sheaf $\mathcal{O}_{U_I}^d$, with universal surjection $q_{\mathrm{univ}}|_{U_I} = (\,\mathrm{Id}_I \,|\, M\,) \colon \mathcal{O}_{U_I}^n \twoheadrightarrow \mathcal{O}_{U_I}^d$, where $M = (x_{ab})$ is the matrix of chart coordinates. The universal sub $\mathcal{S}|_{U_I}$ is the kernel, freely generated by the $n - d$ columns

$$s_b = e_b - \sum_{a \in I} x_{ab} \, e_a \qquad (b \in [n] \setminus I)$$

where $e_1, \dots, e_n$ is the standard basis of $\mathcal{O}_{U_I}^n$: each s_b is annihilated by $(\,\mathrm{Id}_I \big| M\,)$ since its I-coordinates $-x_{ab}$ exactly cancel the contribution of its complementary coordinate e_b. Over the overlap of two charts these local frames differ by the transition matrices of Step 4 of the proof, which is the concrete content of $\mathcal{Q}$ and $\mathcal{S}$ being globally defined bundles rather than trivial ones.

The Grassmannian was built as a smooth scheme covered by affine charts, but its charts alone do not reveal that it is projective; the affine cover exhibits it as separated and of finite type, not as a closed subscheme of any $\mathbb{P}^N$. Projectivity comes from a single global construction: send a d-dimensional subspace to its top exterior power, a line in $\wedge^d k^n$, which is a point of the projective space $\mathbb{P}(\wedge^d k^n)$. In families this is the map classified by the line bundle $\wedge^{n-d}\mathcal{S}^\vee$ (or equivalently $\wedge^d \mathcal{Q}$), and the resulting morphism turns out to be a closed embedding whose image is cut out by explicit quadratic equations. This is the mechanism that makes the Grassmannian, and through it every Hilbert and Quot scheme, a projective variety.

The functorial version uses the quotient. A rank-d quotient $q\colon \mathcal{O}_S^n \twoheadrightarrow \mathcal{Q}$ induces on top exterior powers a surjection $\wedge^d q\colon \wedge^d \mathcal{O}_S^n = \mathcal{O}_S^{\binom{n}{d}} \twoheadrightarrow \wedge^d \mathcal{Q}$ onto a line bundle, which is precisely the datum classifying a morphism $S \to \mathbb{P}(\wedge^d k^n) = \mathbb{P}^{\binom{n}{d}-1}$ (a rank-1 quotient of a trivial bundle, in the sense of example 18.1.4). This assignment is natural in S, hence a morphism of functors, hence a morphism of the representing schemes.

Proposition 18.2.7: The Plücker Embedding

The morphism

$$\mathrm{p}\colon \mathrm{Gr}(d,n) \longrightarrow \mathbb{P}\Big(\bigwedge^d k^n\Big) = \mathbb{P}^{\binom{n}{d}-1}$$

induced by $q \mapsto \wedge^d q$ is a closed embedding. Its image is the zero locus of the quadratic *Plücker relations*: writing the homogeneous coordinates as $p_{i_1 \cdots i_d}$ indexed by d-element subsets $i_1 < \cdots < i_d$ of $[n]$ (the coordinates on the decomposable vectors $e_{i_1} \wedge \cdots \wedge e_{i_d}$), the image is cut out by

$$\sum_{t=0}^{d} (-1)^t \, p_{i_1 \cdots i_{d-1} j_t} \, p_{j_0 \cdots \widehat{j_t} \cdots j_d} = 0 \tag{18.2}$$

for all $i_1 < \cdots < i_{d-1}$ and $j_0 < \cdots < j_d$ in $[n]$, where $\widehat{j_t}$ denotes omission. Consequently $\mathrm{Gr}(d,n)$ is projective over $\mathbb{Z}$, hence over any base.

***Proof*:**

The argument has three parts: the map is a morphism (already established above), it is a locally closed embedding checked on charts, and its image is exactly the Plücker locus, which is closed. Work with the sub $\mathcal{S}$ of rank $n-d$; equivalently one may phrase everything through $\wedge^d \mathcal{Q}$, and the two give the same map since $\wedge^d \mathcal{Q} \cong \wedge^n \mathcal{O}_S^n \otimes (\wedge^{n-d}\mathcal{S})^\vee$ is the same line bundle up to the trivial twist $\wedge^n \mathcal{O}_S^n \cong \mathcal{O}_S$.

Step 1: Injectivity on points and the decomposable coordinates. On $\bar{k}$-points, p sends a subspace $W = \ker q \subseteq \bar{k}^n$ of dimension $n-d$ (equivalently the quotient of dimension d) to the line $\wedge^d(\bar{k}^n/W)$, whose Plücker coordinates $p_{i_1 \cdots i_d}$ are the $d \times d$ minors of a $d \times n$ matrix representing q. A subspace is recovered from these minors: the coordinate $p_{i_1 \cdots i_d}$ is nonzero exactly when $q \circ \iota_I$ is an isomorphism for $I = \{i_1 < \cdots < i_d\}$, that is, exactly on the chart U_I, and on that chart the ratios of minors recover the normalized matrix M of theorem 18.2.4. Hence distinct

points of $\mathrm{Gr}(d,n)$ have distinct images, so p is injective on points; the same computation applies with S-valued families, giving injectivity of the map of functors.

Step 2: A closed embedding on each chart. Fix I and work over the standard affine chart $D_+(p_I) \subseteq \mathbb{P}^{\binom{n}{d}-1}$ where the coordinate p_I is nonzero. By Step 1, $\mathrm{p}^{-1}(D_+(p_I)) = U_I$. On U_I the family is $(\,\mathrm{Id}_I \big| M\,)$, and its $d \times d$ minor on columns J is a polynomial in the entries x_{ab} of M; normalizing so that $p_I = 1$, the minor on the columns I with one index a replaced by a complementary index b equals $\pm x_{ab}$ exactly. Thus the coordinate functions p_J/p_I on $D_+(p_I)$ pull back to polynomials in the x_{ab} that include, among them, all $d(n-d)$ coordinates $\pm x_{ab}$ themselves. The comorphism

$$k\big[\, p_J/p_I \big| J \,\big] \longrightarrow k[x_{ab}] = \mathcal{O}(U_I)$$

is therefore surjective (the generators x_{ab} are in the image), so $\mathrm{p}\,|_{U_I} : U_I \to D_+(p_I)$ is a closed immersion. A morphism that is a closed immersion over each member of an open cover of the target, with the preimages covering the source, is a locally closed immersion; here the images $\mathrm{p}(U_I) = \mathrm{p}(\mathrm{Gr}(d,n)) \cap D_+(p_I)$ cover $\mathrm{p}(\mathrm{Gr}(d,n))$, so p is an immersion onto a locally closed subscheme.

Step 3: The image is the closed Plücker locus. It remains to identify the image with the closed subscheme $Y \subseteq \mathbb{P}^{\binom{n}{d}-1}$ defined by (18.2), which will show the immersion is closed. The relations (18.2) are exactly the condition that a vector $\omega \in \wedge^d k^n$ be *decomposable*, $\omega = v_1 \wedge \cdots \wedge v_d$ for some $v_i \in k^n$: this is the classical decomposability criterion of multilinear algebra: a d-vector is decomposable if and only if its coordinates satisfy the quadratic Plücker relations. It enters here only to describe the underlying point set, since the scheme-theoretic identification of the image is carried out independently at the chart level below. Every point of $\mathrm{p}(\mathrm{Gr}(d,n))$ is decomposable by construction, so $\mathrm{p}(\mathrm{Gr}(d,n)) \subseteq Y$. Conversely, a decomposable line $[v_1 \wedge \cdots \wedge v_d]$ with the v_i linearly independent spans a d-dimensional subspace, hence a point of $\mathrm{Gr}(d,n)$ mapping to it, so $Y \subseteq \mathrm{p}(\mathrm{Gr}(d,n))$ on points. Scheme-theoretically, $Y \cap D_+(p_I)$ is defined by the relations (18.2) normalized at $p_I = 1$, and these solve to express every p_J/p_I as a polynomial in the $\pm x_{ab}$ minors, giving $Y \cap D_+(p_I) \cong \mathbb{A}^{d(n-d)} = U_I$; so the immersion $U_I \hookrightarrow D_+(p_I)$ has image exactly $Y \cap D_+(p_I)$. Therefore p is a closed immersion with image Y.

Since $\mathrm{Gr}(d,n)$ is thereby a closed subscheme of $\mathbb{P}^{\binom{n}{d}-1}$, it is projective over the base, completing the proof.

The proposition closes the account of $\mathrm{Gr}(d,n)$ as a fine moduli space: it is representable (theorem 18.2.4), it carries a universal family (definition 18.2.5), and it is projective (through the Plücker embedding just constructed). The three facts are not independent decorations. The Plücker embedding is itself the classifying map of the line bundle $\wedge^d \mathcal{Q}$ built from the universal quotient, so projectivity is read off the universal family. This is the pattern the book will exploit repeatedly: a moduli space is projective because a natural line bundle on it, assembled from the universal family, is very ample.

The Plücker relations (18.2) deserve a concrete instance, since for $d = 1$ or $d = n-1$ they are vacuous (the Grassmannian is a projective space and there is nothing to cut out) and only become substantive at $d = 2$, $n = 4$.

Example 18.2.8: The Plücker Quadric $\mathrm{Gr}(2,4)$

Take $d=2$, $n=4$: $\mathrm{Gr}(2,4)$ parametrizes rank-2 quotients of $\mathcal{O}_S^4$, equivalently rank-2 subbundles, equivalently (over a field) 2-planes through the origin in k^4, or lines in $\mathbb{P}^3$. Its dimension is $d(n-d)=2\cdot 2=4$, and the Plücker space is $\mathbb{P}(\wedge^2 k^4)=\mathbb{P}^5$ with coordinates $p_{12},p_{13},p_{14},p_{23},p_{24},p_{34}$.

The charts. There are $\binom{4}{2}=6$ charts U_I, one for each pair $I\subseteq\{1,2,3,4\}$. On U_{12} a family is normalized to the 2×4 matrix

$$\begin{pmatrix} 1 & 0 & x_{13} & x_{14} \\ 0 & 1 & x_{23} & x_{24} \end{pmatrix}$$

whose four entries $x_{13},x_{14},x_{23},x_{24}$ are the affine coordinates on $U_{12}\cong\mathbb{A}^4$; here the first two columns (indices $I=\{1,2\}$) are the identity block. The Plücker coordinates are the 2×2 minors: $p_{12}=1$, $p_{13}=x_{23}$, $p_{14}=x_{24}$, $p_{23}=-x_{13}$, $p_{24}=-x_{14}$, and $p_{34}=x_{13}x_{24}-x_{14}x_{23}$. The chart U_{34} normalizes on the last two columns instead, and its coordinates are related to those of U_{12} by inverting the relevant minor, as in Step 4 of theorem 18.2.4.

The single relation. For $d=2$, $n=4$ the relations (18.2) reduce to one quadric. Here $d-1=1$, so there is a single i-index, and $d+1=3$, so there are three j-indices; the only choice up to the labeling is $i_1=1$ and $(j_0,j_1,j_2)=(2,3,4)$, and the sum over $t=0,1,2$ gives $p_{12}p_{34}-p_{13}p_{24}+p_{14}p_{23}$:

$$p_{12}\,p_{34}-p_{13}\,p_{24}+p_{14}\,p_{23}=0 \tag{18.3}$$

Substituting the chart values verifies it: $1\cdot(x_{13}x_{24}-x_{14}x_{23})-x_{23}\cdot(-x_{14})+x_{24}\cdot(-x_{13})=x_{13}x_{24}-x_{14}x_{23}+x_{14}x_{23}-x_{13}x_{24}=0$. Thus $\mathrm{Gr}(2,4)$ is the smooth quadric fourfold in $\mathbb{P}^5$ cut out by (18.3), the smallest Grassmannian that is not itself a projective space.

Exercise 18.2.1

1. Show directly from definition 18.2.1 that the assignment sending a rank-d quotient $q\colon\mathcal{O}_S^n\twoheadrightarrow\mathcal{Q}$ to its kernel subbundle $\mathcal{S}=\ker q$ defines an isomorphism of functors between $\underline{\mathrm{Gr}}(d,n)$ and the functor $S\mapsto\{\text{rank-}(n-d)\text{ subbundles of }\mathcal{O}_S^n\}$. (A rank-$(n-d)$ subbundle means a subsheaf $\mathcal{S}\hookrightarrow\mathcal{O}_S^n$, locally a direct summand, with locally free quotient.)

2. Using the chart $U_I\cong\mathbb{A}^{d(n-d)}$ of theorem 18.2.4, compute the transition map $U_{12}\cap U_{13}\to U_{13}$ explicitly for $\mathrm{Gr}(2,3)$: write the coordinates on U_{13} as rational functions of the coordinates on U_{12}, and identify the open locus of U_{12} on which the transition is defined.

3. Verify that $\mathrm{Gr}(1,n)=\mathbb{P}^{n-1}$ by comparing functors of points: show that a rank-1 locally free quotient $\mathcal{O}_S^n\twoheadrightarrow\mathcal{L}$ is exactly the datum that classifies a morphism $S\to\mathbb{P}^{n-1}$, and match the affine charts of theorem 18.2.4 with the standard charts of $\mathbb{P}^{n-1}$. Relate this to example 18.1.4.

4. On $\mathrm{Gr}(2,4)$, write down the two-plane $W\subseteq k^4$ corresponding to the Plücker point $[p_{12}:p_{13}:p_{14}:p_{23}:p_{24}:p_{34}]=[1:0:0:0:0:0]$, and verify it satisfies (18.3). Which chart U_I does this point lie in, and what are its affine coordinates there? Then check whether the point $[1:0:0:0:0:1]$ satisfies (18.3), and interpret the answer geometrically.

5. Show that the universal quotient bundle $\mathcal{Q}$ on $\mathrm{Gr}(1,n)=\mathbb{P}^{n-1}$ is the line bundle $\mathcal{O}(1)$, and hence that the Plücker embedding of proposition 18.2.7 is the identity in this case. (Use example 18.1.4 to identify the universal rank-1 quotient.)

6. Prove that $\mathrm{Gr}(d,n)$ and $\mathrm{Gr}(n-d,n)$ are isomorphic as schemes, and describe the isomorphism

at the level of functors of points. (Consider the dual: a rank-d quotient of $\mathcal{O}_S^n$ has a rank-$(n-d)$ kernel; dualize the short exact sequence (18.1).)

18.3 Coarse Moduli Spaces and the Automorphism Obstruction

The Grassmannian of section 18.2 is the fortunate case: its moduli functor is representable, and the representing scheme carries a universal family from which every other family is pulled back. Most moduli problems are not so obliging. The functor one writes down at the start almost never has a fine moduli space, and the reason is structural. It is already present in the oldest moduli problem of all, the classification of elliptic curves up to isomorphism, where the culprit can be named precisely: the objects being classified have nontrivial automorphisms.

This section isolates that obstruction and extracts from the wreckage the best geometric object that survives. When no scheme represents $\mathcal{F}$, one may still ask for a scheme M whose $\bar{k}$-points match the isomorphism classes of objects and which receives a map from $\mathcal{F}$ that is as close to an isomorphism as the automorphisms permit. Such an M is a *coarse* moduli space. It remembers which objects there are but forgets how families of them twist, and this forgetting is exactly what a scheme is forced to do in the presence of automorphisms. The elliptic-curve moduli problem is worked in full: its coarse space is the affine j-line $\mathbb{A}^1_j$, and the same automorphisms that produce the coarse space also produce explicit families with pairwise isomorphic fibers that are not isomorphic as families, which is a direct proof that no fine moduli space can exist.

The warning issued at the end of section 18.1 (box 18.1.6) was that a representable functor is a sheaf, so a moduli functor that fails the sheaf condition cannot be representable. The failure mechanism is worth stating in the abstract before meeting it in an example. Suppose $\mathcal{F}$ is a moduli functor in the sense of definition 18.1.1, and suppose an object x of the moduli problem has an automorphism $\alpha \neq \mathrm{id}$. Take the constant family $x \times S$ over a base S. Both id and $\alpha \times \mathrm{id}_S$ are automorphisms of this family, and they are distinct. If $\mathcal{F}$ were represented by a scheme M (definition 18.1.3), a family over S would be the same data as a morphism $S \to M$, and the automorphisms of the family would be the automorphisms of that morphism, of which there is exactly one, the identity. A family that admits two distinct self-isomorphisms therefore cannot correspond to a morphism into any scheme. The automorphism is the obstruction, and it does not go away by choosing a cleverer scheme.

There is a weaker requirement a scheme can meet. Ask only that M receive a natural map from $\mathcal{F}$ that is initial among all such maps to schemes, and that on geometric points this map be a bijection onto the isomorphism classes. This is the notion of a coarse moduli space.

Definition 18.3.1: Coarse Moduli Space

Let $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ be a moduli functor over k (definition 18.1.1). A *coarse moduli space* for $\mathcal{F}$ is a scheme M over k together with a natural transformation

$$\eta\colon \mathcal{F} \to h_M$$

satisfying the following two conditions.

1. *Universality.* For every scheme N over k and every natural transformation $\theta\colon \mathcal{F} \to h_N$, there is a unique morphism of schemes $g\colon M \to N$ with $\theta = h_g \circ \eta$, where $h_g\colon h_M \to h_N$ is postcomposition with g.
2. *Bijection on geometric points.* The map

$$\eta(\operatorname{Spec}\bar{k})\colon \mathcal{F}(\operatorname{Spec}\bar{k}) \to h_M(\operatorname{Spec}\bar{k}) = M(\bar{k})$$

is a bijection.

A moduli functor is said to *admit a coarse moduli space* when such a pair (M, η) exists.

Condition (1) is a universal property, so it pins down the pair (M, η) up to unique isomorphism when it exists: the coarse space is the closest scheme-valued functor h_M underneath $\mathcal{F}$, or in categorical language, M corepresents $\mathcal{F}$ (h_M is the universal object under $\mathcal{F}$ in the category of representable functors). Condition (2) gives the geometric content that a bare universal property would not: without it, the constant map from $\mathcal{F}$ to a point would satisfy (1) vacuously in trivial cases, and one wants M to parametrize the isomorphism classes. Together the two conditions say that M is a scheme whose $\bar{k}$-points *are* the isomorphism classes of objects, compatibly with all families, and that among schemes carrying such a map M is the finest. What M does not do is carry a universal family: there is a map $\mathcal{F} \to h_M$ but in general no inverse, so a morphism $S \to M$ need not come from any single family over S. A coarse moduli space records the objects but not the moduli of families.

Proposition 18.3.2: A Fine Moduli Space is Coarse

Let $\mathcal{F}$ be a moduli functor over k, and suppose $\mathcal{F}$ is represented by a scheme M in the sense of definition 18.1.3, with a natural isomorphism $\Phi\colon \mathcal{F} \xrightarrow{\sim} h_M$. Then (M, Φ) is a coarse moduli space for $\mathcal{F}$.

***Proof*:**

Both defining conditions of definition 18.3.1 must be checked for the pair (M, Φ).

Step 1: Universality. Let N be any scheme over k and $\theta\colon \mathcal{F} \to h_N$ a natural transformation. Since Φ is a natural isomorphism it has an inverse $\Phi^{-1}\colon h_M \to \mathcal{F}$, and $\theta \circ \Phi^{-1}\colon h_M \to h_N$ is a natural transformation between representable functors. By the Yoneda lemma (theorem 0.4.22), natural transformations $h_M \to h_N$ correspond bijectively to morphisms $M \to N$, so there is a unique morphism $g\colon M \to N$ with $h_g = \theta \circ \Phi^{-1}$. Composing on the right with Φ gives $h_g \circ \Phi = \theta$, which is the required factorization. Uniqueness of g is immediate: any g' with $h_{g'} \circ \Phi = \theta$ satisfies $h_{g'} = \theta \circ \Phi^{-1} = h_g$, and Yoneda forces $g' = g$.

Step 2: Bijection on geometric points. The component of Φ at $\operatorname{Spec}\bar{k}$ is a bijection $\mathcal{F}(\operatorname{Spec}\bar{k}) \to$

$h_M(\operatorname{Spec}\bar{k})$ because Φ is a natural isomorphism, so every component is an isomorphism of sets. This is precisely condition (2).

Both conditions hold, so (M, Φ) is a coarse moduli space for $\mathcal{F}$, completing the proof.

The proposition says that fineness is strictly stronger than coarseness: a fine moduli space is automatically a coarse one, with the coarsening map η taken to be the representing isomorphism Φ itself. The converse fails, and the gap between the two notions is exactly the phenomenon this section exists to explain. A coarse space exists in many cases where a fine one does not, and when a fine space does exist the two coincide. This is why the search for a moduli space proceeds in two stages: first ask for the ideal object (a fine space), and when the automorphism obstruction blocks it, retreat to the coarse space, which measures how much was lost.

The loss is not abstract. It manifests as families that a fine moduli space would have to distinguish but a coarse one cannot, because the families have identical fibers everywhere yet are not isomorphic. Such families are the fingerprint of a nontrivial automorphism, and they deserve a name.

Definition 18.3.3: Isotrivial Family

Fix a class of objects with a notion of family, and let x_0 be a fixed object over k. A family $\pi\colon X \to S$ over a k-scheme S is *isotrivial* (with fiber type x_0) if

1. every geometric fiber $X_{\bar{s}}$, for $\bar{s}$ a geometric point of S, is isomorphic to x_0; yet
2. $X \to S$ is not isomorphic, as a family over S, to the constant family $x_0 \times S \to S$.

A family satisfying (1) alone is said to have *constant fibers*; the point of the definition is that (1) does not force triviality.

An isotrivial nontrivial family is the local-to-global gap made concrete. Pointwise it looks exactly like the constant family $x_0 \times S$, since every fiber is a copy of x_0, but globally the copies are stitched together with a twist that no fiberwise isomorphism can undo. A moduli functor sends both this family and the constant family to the *same* data over each geometric point (both assign x_0 to every point), so any natural map $\mathcal{F} \to h_M$ to a scheme sends the two families to the same morphism $S \to M$. If $\mathcal{F}$ were representable, families would be determined by their classifying morphism, and the two families would have to be isomorphic, contradicting nontriviality. The existence of a single isotrivial nontrivial family thus rules out a fine moduli space. The mechanism producing such families is always the same: an automorphism of x_0 used as gluing data.

Example 18.3.4: An Isotrivial Nontrivial Family of Elliptic Curves

Work over an algebraically closed field k with $\operatorname{char} k \neq 2$, and let E be an elliptic curve over k with j-invariant $j(E) \notin \{0, 1728\}$, so that $\operatorname{Aut}(E) = \{\pm 1\}$, generated by the inversion automorphism $\iota = [-1]\colon E \to E$, $P \mapsto -P$ (the automorphism group and the special values $0, 1728$ are recorded in [20]). The involution ι is nontrivial because E has points with $2P \neq 0$, on which $\iota(P) = -P \neq P$; indeed the fixed points of ι are exactly the 2-torsion $\{P \,|\, 2P = 0\}$, a proper closed subscheme, so $\iota \neq \mathrm{id}$ on the rest of E.

Let $S = \operatorname{Spec} R$ where $R = k[t, t^{-1}]$, so $S = \mathbb{G}_m$ is the punctured affine line, and consider its connected double cover

$$\varphi\colon \tilde{S} = \operatorname{Spec} k[u, u^{-1}] \to S, \qquad \varphi^{\#}(t) = u^2$$

which is an étale $\mathbb{Z}/2\mathbb{Z}$-torsor for $\mathrm{char} k \neq 2$; the nontrivial deck transformation is $\sigma\colon u \mapsto -u$. Form the constant family $E \times \tilde{S} \to \tilde{S}$ and glue it to itself over the two sheets of φ using the automorphism ι: concretely, take the quotient

$$X \;=\; \big(E \times \tilde{S}\big)/(\iota \times \sigma)$$

by the free $\mathbb{Z}/2\mathbb{Z}$-action that acts as ι on the fiber and as σ on the base. Since σ is free on $\tilde{S}$, the action is free, and the projection $E \times \tilde{S} \to \tilde{S}$ descends to a morphism $\pi\colon X \to \tilde{S}/\sigma = S$. This is the *quadratic twist* of E along the cover φ.

Every geometric fiber of π is isomorphic to E. Fix a geometric point $\bar{s}$ of S; its two preimages $\bar{u}, \sigma(\bar{u})$ in $\tilde{S}$ each carry the fiber E, and the gluing identifies $E \times \{\bar{u}\}$ with $E \times \{\sigma\bar{u}\}$ via ι. The fiber $X_{\bar{s}}$ is therefore a single copy of E, so condition (1) of definition 18.3.3 holds with fiber type $x_0 = E$. In particular every fiber has the same j-invariant $j(E)$.

The family $X \to S$ is not the constant family $E \times S$. Suppose it were, say via an S-isomorphism $\psi\colon E \times S \xrightarrow{\sim} X$. Pulling back along φ trivializes both sides over $\tilde{S}$, and ψ becomes an automorphism of $E \times \tilde{S}$ over $\tilde{S}$ commuting with the two descent data. The descent datum for the constant family is the identity gluing $\mathrm{id} \times \sigma$, while that for X is $\iota \times \sigma$; an isomorphism of the two families is a $\tilde{S}$-automorphism β of $E \times \tilde{S}$ with $\beta \circ (\mathrm{id} \times \sigma) = (\iota \times \sigma) \circ \beta$, that is, a family of automorphisms $\beta_u \in \mathrm{Aut}(E)$ with $\beta_{-u} = \iota \circ \beta_u$. Since $\mathrm{Aut}(E) = \{\pm 1\}$ is a constant (hence étale) group scheme and $\tilde{S} = \mathbb{G}_m$ is connected, the classifying morphism $u \mapsto \beta_u$ from $\tilde{S}$ to $\mathrm{Aut}(E)$ is constant, so β_u is a single automorphism independent of u, forcing $\beta = \iota \circ \beta$, hence $\iota = \mathrm{id}$. This contradicts $\iota \neq \mathrm{id}$, which holds for every elliptic curve. (The hypothesis $j(E) \neq 0, 1728$ is not needed for $\iota \neq \mathrm{id}$; it enters only to pin $\mathrm{Aut}(E)$ to exactly $\{\pm 1\}$, so that the classifying morphism lands in a constant group and the constancy argument applies cleanly.) So no such ψ exists, and condition (2) holds.

The family $X \to S$ is therefore isotrivial and nontrivial. Its very existence proves that the elliptic-curve moduli functor $\mathcal{M}_{1,1}$ (a moduli functor in the sense of definition 18.1.1) is not representable: a fine moduli space would send $X \to S$ and $E \times S \to S$, which have identical fibers everywhere, to the same classifying morphism $S \to M$, and would then be forced to declare the two families isomorphic. They are not.

The construction pinpoints where representability breaks. Every ingredient is standard, an elliptic curve, its inversion automorphism, and an étale double cover, and the twist is assembled from nothing more than the automorphism ι acting as gluing data over a nonsimply-connected base. The same recipe works whenever the objects of a moduli problem have a nontrivial automorphism and the base has a nontrivial torsor for the relevant automorphism group. This is the general shape of the automorphism obstruction: automorphisms of objects become gluing data for locally trivial but globally twisted families, and the moduli functor, which sees only fibers, cannot separate them.

Having seen that $\mathcal{M}_{1,1}$ is not representable, the task is to identify the coarse space that survives. Over $\bar{k}$ the isomorphism classes of elliptic curves are classified by a single number, the j-invariant, and the scheme whose points are those numbers is the affine line. This affine line, the *j-line*, is the coarse moduli space.

18.3.5 Note: the moduli functor $\mathcal{M}_{1,1}$ Throughout this section $\mathcal{M}_{1,1}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ denotes the moduli functor of elliptic curves in the sense of definition 18.1.1: for a k-scheme S, $\mathcal{M}_{1,1}(S)$ is the set of isomorphism classes of families $(E \to S, \sigma)$ with $E \to S$ smooth and proper of relative dimension 1, geometric fibers of genus 1, and σ a section. Pullback of families makes it contravariant. The j-invariant of a single elliptic curve over a field is developed in [20, The j-Invariant, Classification by the j-Invariant].

Theorem 18.3.6: The j-Line is a Coarse Moduli Space

Let k be an algebraically closed field. The affine line $\mathbb{A}^1_j = \operatorname{Spec} k[j]$, the *$j$-line*, is a coarse moduli space for the moduli functor $\mathcal{M}_{1,1}$ of elliptic curves, with the natural transformation

$$\eta\colon \mathcal{M}_{1,1} \to h_{\mathbb{A}^1_j}$$

sending a family $(E \to S) \in \mathcal{M}_{1,1}(S)$ to the morphism $S \to \mathbb{A}^1_j$ classifying its fiberwise j-invariant. The pair $(\mathbb{A}^1_j, \eta)$ satisfies both conditions of definition 18.3.1. However, $\mathcal{M}_{1,1}$ is not representable, so $\mathbb{A}^1_j$ is not a fine moduli space.

***Proof*:**
The j-invariant of a single elliptic curve over k takes every value of k and determines the isomorphism class over $\bar{k} = k$: two elliptic curves over an algebraically closed field are isomorphic if and only if they have the same j-invariant, and every element of k arises as a j-invariant ([20, Classification by the j-Invariant, Surjectivity of j]). This standard input is used freely below.

Step 1: The natural transformation η is well defined. For a family $E \to S$ the assignment $s \mapsto j(E_s)$ is a morphism of schemes $j_E\colon S \to \mathbb{A}^1_j$. Concretely, working locally where $E \to S$ is given by a Weierstrass equation with coefficients in $\mathcal{O}_S(U)$ and discriminant a unit, the j-invariant is the universal rational expression in those coefficients, which is a regular function on U; these glue to a global morphism $j_E\colon S \to \mathbb{A}^1_j$ independent of the chosen Weierstrass presentation, since j is an isomorphism invariant. Setting $\eta_S(E \to S) = j_E$ gives a map $\mathcal{M}_{1,1}(S) \to h_{\mathbb{A}^1_j}(S)$, and naturality in S holds because forming a Weierstrass presentation and computing j commute with base change: for $f\colon T \to S$ one has $j_{f^*E} = j_E \circ f$, which is the equation $h_{\mathbb{A}^1_j}(f) \circ \eta_S = \eta_T \circ \mathcal{M}_{1,1}(f)$.

Step 2: Bijection on geometric points. A $\bar{k}$-point of $\mathbb{A}^1_j$ is an element of $k = \bar{k}$, and $\eta(\operatorname{Spec} \bar{k})$ sends an elliptic curve over $\bar{k}$ to its j-invariant. By the classification input, this map $\mathcal{M}_{1,1}(\operatorname{Spec} \bar{k}) \to \mathbb{A}^1_j(\bar{k}) = k$ is a bijection: it is surjective because every value of k is a j-invariant, and injective because equal j-invariants force an isomorphism over $\bar{k}$. This is condition (2) of definition 18.3.1.

Step 3: Universality. Let N be a scheme over k and $\theta\colon \mathcal{M}_{1,1} \to h_N$ a natural transformation; a morphism $g\colon \mathbb{A}^1_j \to N$ with $h_g \circ \eta = \theta$ must be produced, and shown unique. No hypothesis is placed on N: it need not be separated, so the argument is arranged so that every step rests on the naturality of θ with respect to *scheme* morphisms (restriction along open immersions and base change of families), never on the determination of a morphism into N by its values on closed points. The strategy is to realize g over an open cover of $\mathbb{A}^1_j$ by applying θ to tautological families, then to glue and to verify the factorization by functoriality.

Cover $\mathbb{A}^1_j$ by finitely many affine opens U_i each carrying a Weierstrass family $\mathcal{E}_{U_i} \to U_i$ whose fiberwise j-invariant is the restriction of the coordinate j. Such a cover exists: away from $j = 0$ and $j = 1728$ the family $y^2 = x^3 + a(j)x + b(j)$ with $a(j), b(j)$ regular and chosen so the fiberwise j-invariant equals the coordinate provides one open, and small opens around 0 and 1728 carrying suitable Weierstrass equations (with the two special j-values omitted from each of the other charts) complete the cover; on each U_i the class $\mathcal{E}_{U_i} \in \mathcal{M}_{1,1}(U_i)$ has $\eta_{U_i}(\mathcal{E}_{U_i}) = \iota_i$, the open immersion $\iota_i \colon U_i \hookrightarrow \mathbb{A}^1_j$, by Step 1. Applying θ gives a morphism $g_i := \theta_{U_i}(\mathcal{E}_{U_i}) \in h_N(U_i) = \mathrm{Hom}(U_i, N)$.

The g_i agree on overlaps as *morphisms of schemes*. Write $U_{ij} = U_i \cap U_j$ with open immersions $r_i \colon U_{ij} \hookrightarrow U_i$ and $r_j \colon U_{ij} \hookrightarrow U_j$. Both restricted families $r_i^*\mathcal{E}_{U_i}$ and $r_j^*\mathcal{E}_{U_j}$ over U_{ij} have fiberwise j-invariant the coordinate $j|_{U_{ij}}$, but they need not be isomorphic as families over U_{ij}: two Weierstrass families with equal j-invariant function are forms of one another, and can differ by a nontrivial quadratic twist recorded by a class in $H^1_{\text{ét}}(U_{ij}, \underline{\mathrm{Aut}}(\mathcal{E}))$ for the automorphism group scheme $\underline{\mathrm{Aut}}(\mathcal{E})$ of the fiber, which is exactly the twisting phenomenon that example 18.3.4 exhibits over $\mathbb{G}_m$ (reducedness of U_{ij} does not kill it, since $\mathbb{G}_m$ is reduced yet carries the nontrivial twist). The two families do become isomorphic after an étale cover, however: any two elliptic curves over a base with the same j-invariant are locally isomorphic in the étale topology, since a twist is split by the finite étale cover trivializing its class. Choose a surjective étale morphism $p \colon U'_{ij} \to U_{ij}$ over which $p^*r_i^*\mathcal{E}_{U_i}$ and $p^*r_j^*\mathcal{E}_{U_j}$ are isomorphic as families over U'_{ij}, hence equal in $\mathcal{M}_{1,1}(U'_{ij})$. Naturality of θ along $r_i \circ p$ and $r_j \circ p$ then gives, in $\mathrm{Hom}(U'_{ij}, N)$,

$$g_i \circ r_i \circ p = \theta_{U'_{ij}}(p^*r_i^*\mathcal{E}_{U_i}) = \theta_{U'_{ij}}(p^*r_j^*\mathcal{E}_{U_j}) = g_j \circ r_j \circ p$$

so the two morphisms $g_i \circ r_i$ and $g_j \circ r_j$ from U_{ij} to N agree after the base change p. Since p is faithfully flat of finite presentation, it is an epimorphism of schemes, and two morphisms into any scheme N that agree after such a base change are equal; hence $g_i \circ r_i = g_j \circ r_j$ in $\mathrm{Hom}(U_{ij}, N)$, an identity valid whether or not N is separated (the descent uses only that p is an fppf epimorphism, not any separatedness of N). The morphisms g_i therefore glue to a single morphism $g \colon \mathbb{A}^1_j \to N$ with $g \circ \iota_i = g_i$.

This g satisfies $h_g \circ \eta = \theta$. Both are natural transformations $\mathcal{M}_{1,1} \to h_N$, so it suffices to check that $(h_g \circ \eta)_S(E \to S) = \theta_S(E \to S)$ for every family $E \to S$; equivalently, that $g \circ j_E = \theta_S(E \to S)$ as morphisms $S \to N$, where $j_E = \eta_S(E \to S)$. The families $\{j_E^{-1}(U_i)\}$ cover S by open subschemes, so it suffices to verify equality after restriction to each $V_i := j_E^{-1}(U_i)$. On V_i the morphism j_E factors as $j_E|_{V_i} = \iota_i \circ f_i$ through a morphism $f_i \colon V_i \to U_i$, and $f_i^*\mathcal{E}_{U_i}$ is a Weierstrass family over V_i whose fiberwise j-invariant equals $j_E|_{V_i}$, the same as that of $E|_{V_i} \to V_i$. As on the overlaps, the two families $E|_{V_i}$ and $f_i^*\mathcal{E}_{U_i}$ need not be isomorphic over V_i (they may differ by a twist), but they become isomorphic after a surjective étale cover $q \colon V'_i \to V_i$, so they agree in $\mathcal{M}_{1,1}(V'_i)$. Naturality of θ along q and $f_i \circ q$ gives

$$\theta_{V'_i}(q^*E|_{V_i}) = \theta_{V'_i}(q^*f_i^*\mathcal{E}_{U_i}) = g_i \circ f_i \circ q = g \circ \iota_i \circ f_i \circ q = g \circ j_E|_{V_i} \circ q$$

so $\theta_{V_i}(E|_{V_i}) \circ q = (g \circ j_E|_{V_i}) \circ q$ as morphisms $V'_i \to N$; since q is a faithfully flat epimorphism these agree already over V_i, giving $\theta_{V_i}(E|_{V_i}) = g \circ j_E|_{V_i}$. Since these agree on the open cover $\{V_i\}$ of S, $\theta_S(E \to S) = g \circ j_E$ as required, so $h_g \circ \eta = \theta$.

Uniqueness of g is forced by the same functoriality, with no appeal to separatedness. If g' also satisfies $h_{g'} \circ \eta = \theta$, then applying both sides to the tautological family $\mathcal{E}_{U_i}$ over U_i gives $g' \circ \iota_i = g' \circ \eta_{U_i}(\mathcal{E}_{U_i}) = \theta_{U_i}(\mathcal{E}_{U_i}) = g_i = g \circ \iota_i$ as morphisms $U_i \to N$, that is, $g'|_{U_i} = g|_{U_i}$. Since $\{U_i\}$ is an open cover of $\mathbb{A}^1_j$ and morphisms of schemes into N form a Zariski sheaf (two

morphisms agreeing on each member of an open cover of the source are equal, for any target N), $g' = g$. This establishes condition (1).

Step 4: $\mathcal{M}_{1,1}$ is not representable, so $\mathbb{A}^1_j$ is not fine. If $\mathcal{M}_{1,1}$ were representable by a scheme M, then by proposition 18.3.2 the pair (M, Φ) would be a coarse moduli space, and by the uniqueness of coarse spaces (the universal property of definition 18.3.1 determines M up to unique isomorphism) one would have $M \cong \mathbb{A}^1_j$ with Φ an isomorphism $\mathcal{M}_{1,1} \cong h_{\mathbb{A}^1_j}$. But example 18.3.4 exhibits, for $\mathrm{char} k \neq 2$, two families over $S = \mathbb{G}_m$, the constant family $E \times S$ and its quadratic twist $X \to S$, with the same fiberwise j-invariant, hence $\eta_S(E \times S) = \eta_S(X) = j_E$ the same morphism $S \to \mathbb{A}^1_j$. Under an isomorphism $\Phi \cong \eta$ these two families would be equal in $\mathcal{M}_{1,1}(S)$, that is, isomorphic as families over S, contradicting the nontriviality proved in example 18.3.4. Therefore $\mathcal{M}_{1,1}$ is not representable. When $\mathrm{char} k = 2$ the quadratic-twist construction of example 18.3.4 does not apply verbatim, since the double cover $u \mapsto u^2$ is inseparable; non-representability still holds, now witnessed by the extra automorphisms of the supersingular curve (whose j-invariant is $0 = 1728$ in characteristic 2), which produce a nontrivial twist by the same recipe over a base carrying an étale torsor for its larger automorphism group ([20]). In every characteristic, then, the coarse space $\mathbb{A}^1_j$ is not a fine moduli space, as we sought to show.

The theorem is the prototype every later chapter measures itself against. It exhibits both halves of the moduli story at once: a genuine geometric object, the j-line, that correctly parametrizes isomorphism classes, and a precise accounting of what that object cannot see, namely the twisting of families recorded in example 18.3.4. The coarse space is not a failure but a compromise forced by the automorphisms: it is the best scheme available, and proposition 18.3.2 guarantees it would upgrade to a fine space the instant the automorphisms were removed. The diagnosis also points at the cure. The obstruction is that $\mathcal{M}_{1,1}$ fails the sheaf condition (box 18.1.6) because étale-locally trivial families need not be globally trivial, and the twisting is governed by the automorphism group $\mathrm{Aut}(E)$. Two later strategies repair this: rigidify the objects until their automorphism groups become trivial, which recovers a fine moduli space for the rigidified problem, and enlarge the category of geometric objects to stacks, which remember automorphisms. The first is taken up in section 18.4; the second is the subject of the descent and algebraic-stacks chapters later in the book.

Concretely, the coarse-versus-fine gap can be read off the automorphism groups directly. Over $\bar{k}$ with $\mathrm{char} k \notin \{2, 3\}$, a generic elliptic curve has $\mathrm{Aut}(E) = \{\pm 1\}$ of order 2, while the two special curves have larger groups: $j = 1728$ gives $\mathrm{Aut}(E) = \mathbb{Z}/4\mathbb{Z}$ and $j = 0$ gives $\mathrm{Aut}(E) = \mathbb{Z}/6\mathbb{Z}$ ([20, Automorphism Group of an Elliptic Curve]). The coarse space $\mathbb{A}^1_j$ is a smooth affine line, but the two special points $j = 0$ and $j = 1728$ are where the automorphism group jumps, and it is precisely at those points that a stack-theoretic refinement would record extra structure. The coarse space smooths over this jump; the fine-moduli-theoretic content lives in the automorphism groups the coarse space discards.

Exercise 18.3.1

1. Let (M, η) be a coarse moduli space for a moduli functor $\mathcal{F}$ in the sense of definition 18.3.1. Prove that (M, η) is unique up to unique isomorphism: if (M', η') is another coarse moduli space for $\mathcal{F}$, there is a unique isomorphism $g \colon M \to M'$ of schemes with $h_g \circ \eta = \eta'$.

2. Consider the terminal functor $\mathcal{F}(S) = \{*\}$ (a one-point set for every S). Show that the universality condition (1) of definition 18.3.1 already forces the coarse space to be the reduced point $M \cong \mathrm{Spec}\, k$ (so here condition (1) determines the geometry and condition (2) holds

automatically). Then show that condition (2) alone does *not* pin down M: exhibit a scheme M' over k with a natural transformation $\eta' \colon \mathcal{F} \to h_{M'}$ for which condition (2) holds but condition (1) fails, and explain in one sentence what universality contributes beyond a bijection on geometric points.

3. In the setup of example 18.3.4, suppose instead that E is an elliptic curve with $j(E) = 0$ over $\bar{k}$ with $\mathrm{char} k \notin \{2, 3\}$, so that $\mathrm{Aut}(E) = \mathbb{Z}/6\mathbb{Z}$. Using an order-3 automorphism ζ of E and a connected étale $\mathbb{Z}/3\mathbb{Z}$-cover $\tilde{S} \to S = \mathbb{G}_m$, construct an isotrivial nontrivial family whose fibers are all isomorphic to E. Verify conditions (1) and (2) of definition 18.3.3, and explain why the argument requires $\mathrm{char} k \neq 3$.

4. Let $\pi \colon X \to S$ be the quadratic twist of example 18.3.4, with $S = \mathbb{G}_m = \operatorname{Spec} k[t, t^{-1}]$. Compute the classifying morphism $\eta_S(X) \colon S \to \mathbb{A}^1_j$ explicitly, and confirm that it equals $\eta_S(E \times S)$. Deduce that $\eta_S(X)$ and $\eta_S(E \times S)$ take the same value at each closed point of S, a single point of $\mathbb{A}^1_j$, and explain why this equality of classifying morphisms is exactly the statement that $\mathbb{A}^1_j$ cannot distinguish the two families.

5. Prove the converse-type statement implicit in definition 18.3.3: if a moduli functor $\mathcal{F}$ admits *no* isotrivial nontrivial family (that is, every family with constant fibers of a fixed type is isomorphic to the constant family), does it follow that $\mathcal{F}$ is representable? Either prove it or give a counterexample, identifying which of the two conditions for a fine moduli space can still fail.

6. Let $\mathcal{F}$ be a moduli functor with a coarse moduli space (M, η), and suppose $\mathcal{F}$ happens to have *no* nontrivial automorphisms (every object x has $\mathrm{Aut}(x) = \{\mathrm{id}\}$) but is nonetheless not representable by a scheme. Explain, using box 18.1.6, why the existence of a coarse moduli space (M, η) (constructed as in the j-line argument, by hand from an invariant) does not immediately produce a fine moduli space, and name (in prose) the kind of geometric object that can represent such an $\mathcal{F}$.

18.4 Rigidification and Level Structure

The previous section diagnosed a precise failure. The moduli functor of elliptic curves is not representable, and the obstruction is not a technicality of the construction but a feature of the objects themselves: every elliptic curve carries the automorphism $[-1]$, and this automorphism produces families that are locally trivial yet globally nontrivial, exactly the families a representable functor cannot support (theorem 18.3.6). The j-line $\mathbb{A}^1_j$ survives only as a coarse moduli space (definition 18.3.1), recording isomorphism classes on geometric points but carrying no universal family.

There are two responses to this obstruction, and this book pursues both. The deep response, developed in Part VI, keeps the objects as they are and enlarges the category of geometric spaces until the functor becomes representable by a stack. The present section pursues the elementary response: change the moduli problem by decorating each object with extra data, chosen so that no nontrivial automorphism fixes the data. An object rigidified in this way has no automorphisms as a decorated object, the mechanism of theorem 18.3.6 shuts off, and the decorated moduli functor becomes fine. The archetype of such decorating data is a *level structure* on an elliptic curve, a choice of basis for the N-torsion. Throughout, N is a positive integer invertible in k, so that the N-torsion is well behaved in every family under consideration.

The guiding principle is that automorphisms are the enemy of representability, so the cure is to add structure on which the automorphisms act freely enough to leave no fixed points but the trivial one. What "structure" means is best fixed by an explicit example before the general notion, and the N-torsion of an elliptic curve gives it. Recall that for an elliptic curve E over a field in which N is invertible, the group of N-torsion points $E[N] = \{P \in E \,|\, NP = O\}$ is free of rank two over $\mathbb{Z}/N$, so $E[N] \cong (\mathbb{Z}/N)^2$ ([20, Structure of the n-Torsion]). A basis of $E[N]$ is the same as an isomorphism $(\mathbb{Z}/N)^2 \to E[N]$, and this is the datum to be added.

Definition 18.4.1: Level Structure

Let N be a positive integer invertible in k, and let E be an elliptic curve over a k-scheme S (a smooth proper morphism $E \to S$ of relative dimension one with geometrically connected genus one fibers, equipped with a section $O\colon S \to E$). The N-torsion $E[N] = \ker([N]\colon E \to E)$ is then a finite étale group scheme over S, locally on S isomorphic to the constant group $(\mathbb{Z}/N)^2$. A *level-N structure* on E is an isomorphism of S-group schemes

$$\alpha\colon (\mathbb{Z}/N)^2_S \xrightarrow{\sim} E[N]$$

where $(\mathbb{Z}/N)^2_S$ denotes the constant group scheme on S. Equivalently, over a field it is an ordered basis (P, Q) of $E[N]$ as a $\mathbb{Z}/N$-module, namely α sends the standard generators e_1, e_2 to P, Q.

This construction instantiates a general pattern. A class of geometric objects is *rigidified* by a choice of *rigidifying data*: extra structure attached to each object, functorial in the base, whose only automorphism compatible with a fixed object is the identity of that object. A level-N structure is the instance of this pattern for elliptic curves: it is a coordinate system on the N-torsion, and just as a choice of basis rigidifies a vector space by eliminating its linear automorphisms as ambient symmetries, a level structure is meant to eliminate the automorphisms of the elliptic curve. The role of the hypothesis N invertible in k is to keep $E[N]$ étale of the expected rank; in characteristic p dividing N the p-part of the torsion collapses (an ordinary curve has $E[p] \cong \mathbb{Z}/p$), and the definition would attach the wrong amount of data. The second paragraph abstracts the pattern: the useful feature of a level structure is not that it involves torsion points but that a nontrivial automorphism of E must move it, and any decorating datum with that property will serve the same rigidifying purpose.

The level-N structures assemble into a moduli functor exactly as bare elliptic curves did, now with the decorating datum carried along.

Definition 18.4.2: The Level-N Moduli Functor

Fix N invertible in k. The *level-N moduli functor* $\mathcal{F}_N\colon \mathbf{Sch}_k^{\mathrm{op}} \to \mathbf{Set}$ assigns to a k-scheme S the set

$$\mathcal{F}_N(S) = \left\{ (E, \alpha) \;\middle|\; \begin{array}{l} E \to S \text{ an elliptic curve,} \\ \alpha\colon (\mathbb{Z}/N)^2_S \xrightarrow{\sim} E[N] \text{ a level-}N\text{ structure} \end{array} \right\} \Big/ \cong$$

of isomorphism classes of pairs, where an isomorphism $(E, \alpha) \to (E', \alpha')$ is an isomorphism $\varphi\colon E \to E'$ of elliptic curves over S carrying α to α', meaning $\varphi[N] \circ \alpha = \alpha'$ on N-torsion. Pullback along $f\colon T \to S$ sends (E, α) to $(f^*E, f^*\alpha)$, making $\mathcal{F}_N$ contravariant.

The condition $\varphi[N] \circ \alpha = \alpha'$ is what distinguishes the level-N problem from the bare one. Two elliptic curves with level structure are identified only by an isomorphism that respects the chosen bases of their N-torsion, so the set $\mathcal{F}_N(S)$ remembers strictly more than the underlying moduli functor $\mathcal{F}$ of elliptic curves: forgetting α defines a natural transformation $\mathcal{F}_N \to \mathcal{F}$ that is generally many to one, since a single curve E admits many level structures. What has been gained by this extra bookkeeping is that the isomorphisms in $\mathcal{F}_N$ are far more rigid, and the next result measures precisely how rigid.

The obstruction to representing $\mathcal{F}$ was that the automorphism group of an object was nontrivial, which forced a family to be gluable from its restrictions in more than one way (box 18.1.6). The decisive property of a level structure is that it collapses the automorphism group of a decorated object to the trivial group, provided N is at least 3. The following lemma isolates this fact; it is the engine of the representability theorem.

Lemma 18.4.3: Level Structures Kill Automorphisms

Let $N \geq 3$ be invertible in k, let E be an elliptic curve over an algebraically closed field, and let α be a level-N structure on E. If $\varphi \in \mathrm{Aut}(E)$ is an automorphism of E as an elliptic curve fixing α, that is $\varphi[N] \circ \alpha = \alpha$, then $\varphi = \mathrm{id}_E$.

***Proof*:**
Write $\varphi[N]$ for the induced automorphism of $E[N]$. The condition $\varphi[N] \circ \alpha = \alpha$ says that $\varphi[N]$ is the identity on $E[N]$, because α is an isomorphism and so right-cancellable. The proof reduces to showing that an automorphism of E acting trivially on $E[N]$ is the identity, for $N \geq 3$.

Step 1: The automorphism group and its faithful action. An automorphism of E as an elliptic curve fixes the origin O, hence is a group automorphism of E ([20, Isogenies are Group Homomorphisms]). Every such φ restricts to a $\mathbb{Z}/N$-linear automorphism of the N-torsion, giving a group homomorphism

$$\rho_N \colon \mathrm{Aut}(E) \to \mathrm{Aut}_{\mathbb{Z}/N}(E[N]) \cong \mathrm{GL}_2(\mathbb{Z}/N)$$

the last isomorphism induced by any basis of $E[N]$. The claim is that ρ_N is injective for $N \geq 3$.

Step 2: Injectivity via the degree bound. Let $\varphi \in \ker \rho_N$, so φ acts as the identity on $E[N]$. The endomorphism $\psi = \varphi - \mathrm{id}$ of E then kills $E[N]$, so $E[N] \subseteq \ker \psi$. If $\psi \neq 0$, then ψ is an isogeny (a nonzero endomorphism of an elliptic curve is surjective with finite kernel). Since N is invertible in k, the group $E[N] \cong (\mathbb{Z}/N)^2$ consists of N^2 distinct étale (geometric) points, all lying in $\ker \psi$; the number of geometric points of the kernel is the separable degree $\deg_s \psi$, so $\deg_s \psi \geq N^2$. As $\deg \psi \geq \deg_s \psi$ always, this forces $\deg \psi \geq N^2$.

Now bound $\deg \psi$ from above. The endomorphism ring $\mathrm{End}(E)$ is either $\mathbb{Z}$ or an order in an imaginary quadratic field or, in characteristic p, an order in a quaternion algebra; in every case the degree is the norm form, a positive definite quadratic form, and φ is an automorphism, hence a unit, so $\deg \varphi = 1$. The triangle inequality for the norm on $\mathrm{End}(E)$ gives

$$\sqrt{\deg \psi} = \|\varphi - \mathrm{id}\| \leq \|\varphi\| + \|\mathrm{id}\| = \sqrt{\deg \varphi} + \sqrt{\deg(\mathrm{id})} = 1 + 1 = 2$$

so $\deg\psi \le 4$. Combining $\deg\psi \ge N^2$ with $\deg\psi \le 4$ yields $N^2 \le 4$, that is $N \le 2$, contrary to $N \ge 3$. Therefore $\psi = 0$, that is $\varphi = \mathrm{id}_E$, which shows $\ker\rho_N$ is trivial and ρ_N is injective.

Step 3: Conclusion. The automorphism φ of the hypothesis lies in $\ker\rho_N$ by the reduction in the opening paragraph, and $\ker\rho_N$ is trivial by Step 2. Hence $\varphi = \mathrm{id}_E$, completing the proof.

The numerical heart of the argument is the failure of $[-1]$ to fix a level-N structure once $N \ge 3$. The automorphism $[-1]$, present on every elliptic curve, acts on $E[N]$ as multiplication by -1; this is the identity on $E[N]$ precisely when $2P = O$ for all $P \in E[N]$, that is precisely when $N \le 2$. So for $N = 1$ or $N = 2$ the automorphism $[-1]$ fixes every level structure and the rigidification fails to remove it, whereas for $N \ge 3$ it moves each level structure, and with the last universal automorphism broken the object becomes rigid. The endomorphism norm inequality in Step 2 is what upgrades this observation from $[-1]$ to *all* automorphisms simultaneously, including the extra automorphisms at $j = 0$ and $j = 1728$ ([20, Automorphism Group of an Elliptic Curve]). This is the exact sense in which a level-N structure "rigidifies" an elliptic curve.

The representability theorem that the lemma powers can now be stated.

Theorem 18.4.4: Representability of Level-N Moduli

Let $N \ge 3$ be invertible in k. The level-N moduli functor $\mathcal{F}_N$ of definition 18.4.2 is representable by a smooth affine k-scheme $Y(N)$: there is an isomorphism of functors $\mathcal{F}_N \cong h_{Y(N)}$, so $Y(N)$ is a fine moduli space (definition 18.1.3) for elliptic curves with level-N structure. In particular $Y(N)$ carries a universal elliptic curve with level-N structure $(\mathcal{E}, \alpha^{\mathrm{univ}})$ through which every family is a unique pullback.

***Proof*:**
The proof has two parts: the removal of the automorphism obstruction, which is the conceptual content and where lemma 18.4.3 enters, and the actual construction of $Y(N)$, which proceeds by cutting the representing scheme out of a space that is already known to be fine.

Step 1: Rigidity of objects. Fix a pair (E, α) over an algebraically closed field. An automorphism of (E, α) in the sense of definition 18.4.2 is an automorphism φ of E with $\varphi[N] \circ \alpha = \alpha$, and lemma 18.4.3 shows the only such φ is id_E. Thus every object of the level-N problem has trivial automorphism group. This is exactly the hypothesis whose failure obstructed representability of the bare functor $\mathcal{F}$ (theorem 18.3.6): with no nontrivial automorphisms there is no room to build a locally trivial but globally nontrivial family, so the obstruction of box 18.1.6 is removed.

Step 2: A rigid family is determined by its restrictions. Make Step 1 quantitative. Let (E, α) and (E', α') be two families over S that become isomorphic over each member of a Zariski (indeed étale) cover $\{S_i \to S\}$. On each overlap S_{ij} the two given isomorphisms φ_i, φ_j differ by an automorphism of the pair $(E|_{S_{ij}}, \alpha|_{S_{ij}})$. The scheme of automorphisms of a rigidified elliptic curve is unramified over the base (an automorphism is rigid, being determined by finitely

many torsion conditions), and by Step 1 it has trivial geometric fibers; an unramified group scheme with trivial fibers is the trivial group, so the automorphism in question is the identity and $\varphi_i = \varphi_j$ on S_{ij}. The local isomorphisms therefore agree on overlaps and glue to a global isomorphism $(E, \alpha) \cong (E', \alpha')$. So a family with level structure is determined up to unique isomorphism by its restrictions to a cover, which is the sheaf property that a representable functor must have and that $\mathcal{F}$ lacked.

Step 3: Construction of the representing scheme. It remains to exhibit a scheme representing $\mathcal{F}_N$. Every elliptic curve is a plane cubic in Weierstrass form after a choice of origin and invariant differential, and the coefficients of a Weierstrass equation define a scheme mapping to the affine space of coefficients; the substitutions relating two Weierstrass equations of the same curve form the action of a solvable group G, and the representing scheme is the quotient by this action, which exists as a scheme precisely because the added data makes the action free (no residual automorphisms remain to fix a point). Concretely, fix a Weierstrass family

$$\mathcal{W}\colon \quad y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6$$

over the affine space $\mathbb{A}^5 = \operatorname{Spec} k[a_1, a_2, a_3, a_4, a_6]$, and let $U \subseteq \mathbb{A}^5$ be the open locus where the discriminant Δ is invertible, so $\mathcal{W}|_U \to U$ is an elliptic curve. Adjoining a level-N structure means adjoining an ordered basis of the N-torsion. The N-torsion $\mathcal{W}[N] \to U$ is finite étale, and the functor on U-schemes assigning to $T \to U$ the set of bases of $(\mathcal{W}[N])_T$ is representable by a scheme $\widetilde{U} \to U$ finite étale (it is a torsor under the constant group $\mathrm{GL}_2(\mathbb{Z}/N)$ over the locus where N is invertible, cut out inside a product of copies of $\mathcal{W}[N]$ by the nondegeneracy conditions). The pair $(\mathcal{W}_{\widetilde{U}}, \alpha^{\mathrm{univ}})$ is then a family with level structure over $\widetilde{U}$, where α^{univ} is the tautological basis.

The redundancy in this presentation is the freedom to change Weierstrass coordinates. Two triples over the same base give the same elliptic curve exactly when they differ by a substitution

$$(x, y) \longmapsto (u^2x + r,\ u^3y + su^2x + t), \qquad u \in \mathbb{G}_m,\ r, s, t \in \mathbb{G}_a$$

and these substitutions form the solvable group $G = \mathbb{G}_m \ltimes \mathbb{G}_a^3$ of the opening sentence, of dimension 4, acting on the coefficient space $\mathbb{A}^5$ and lifting to an action on $\widetilde{U}$ that transports the tautological torsion basis along the coordinate change. Two points of $\widetilde{U}$ give isomorphic pairs (E, α) if and only if they lie in one G-orbit: a coordinate change matching both the curves and their level structures is exactly an element of G carrying one point to the other. By Step 1 such an element is unique when it exists (no automorphisms to spoil uniqueness), which is precisely the statement that G acts *freely* on $\widetilde{U}$ (a nonidentity element fixing a point would be a nontrivial automorphism of the corresponding rigidified pair). A free action of the smooth affine solvable group G on the smooth affine scheme $\widetilde{U}$ admits a geometric quotient

$$Y(N) = \widetilde{U}/G$$

which is again a smooth affine scheme; the quotient collapses the 4 redundant coordinate-change directions, so $Y(N)$ has dimension $\dim \widetilde{U} - \dim G = 5 - 4 = 1$, a curve, as the geometry requires. Its functor of points is by construction

$$h_{Y(N)}(T) = \{\, T \to \widetilde{U} \,\}/{\sim} = \{\text{elliptic curves over } T \text{ with level-}N \text{ structure}\}/{\cong} = \mathcal{F}_N(T)$$

naturally in T. The chain of equalities is exactly the assertion $\mathcal{F}_N \cong h_{Y(N)}$: the first equality is the definition of the quotient, and the middle equality holds because every pair (E, α) over T is Zariski-locally Weierstrass with a chosen torsion basis, hence Zariski-locally a T-point of $\widetilde{U}$, and these local charts glue uniquely by Step 2. Smoothness of $Y(N)$ follows from smoothness of $\widetilde{U}$ over the smooth base U and the freeness of the G-action. Therefore $Y(N)$ is a fine moduli space for $\mathcal{F}_N$, with universal family the descent of $(\mathcal{W}_{\widetilde{U}}, \alpha^{\mathrm{univ}})$, as we sought to show.

The theorem is the payoff of the entire chapter in miniature: a moduli problem that failed to be representable has been repaired, not by changing the category of geometric spaces but by refining the objects until their automorphism groups vanish. Steps 1 and 2 are the conceptual core and are where lemma 18.4.3 is spent; they say that rigidity of objects implies rigidity of families, which is the sheaf-theoretic condition a representable functor requires. Step 3 then constructs $Y(N)$ concretely, and the construction is instructive: the representing scheme is a free quotient of an étale cover of the Weierstrass parameter space by the solvable group of coordinate changes, a pattern that recurs when GIT builds moduli spaces as quotients in chapter 20. The hypothesis $N \geq 3$ is not a convenience but the exact threshold from lemma 18.4.3: for $N \leq 2$ the universal automorphism $[-1]$ survives, the quotient in Step 3 is not free, and $\mathcal{F}_N$ is again only coarsely representable.

The fine moduli space produced by the theorem has a name and a classical life of its own, and it is worth seeing it as a concrete curve.

Example 18.4.5: The Modular Curve $Y(N)$

The scheme $Y(N)$ of theorem 18.4.4 is the (affine) *modular curve of full level* N. Over $\mathbb{C}$ it has a transcendental description that makes its geometry visible, though the description has one feature that is easy to miss: an elliptic curve over $\mathbb{C}$ is a complex torus $\mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$ with τ in the upper half-plane $\mathfrak{H}$, and its N-torsion is $\frac{1}{N}(\mathbb{Z}+\mathbb{Z}\tau)/(\mathbb{Z}+\mathbb{Z}\tau)$, with the standard basis $\{\frac{1}{N}, \frac{\tau}{N}\}$. A level-$N$ structure is a choice of ordered basis of this torsion, an *arbitrary* isomorphism $\alpha\colon (\mathbb{Z}/N)^2 \to E[N]$ as in definition 18.4.1, and here a discrete invariant enters. The Weil pairing e_N attaches to α the primitive N-th root of unity $\zeta_\alpha = e_N(\alpha(e_1), \alpha(e_2)) \in \mu_N$, and any isomorphism of pairs preserves ζ_α (the Weil pairing is functorial in the curve), so ζ_α is constant on each connected component of the moduli. There are $\varphi(N) = |(\mathbb{Z}/N)^\times|$ primitive N-th roots of unity, and the change of variables $g \in \mathrm{SL}_2(\mathbb{Z}/N)$ (determinant 1) fixes ζ_α while a general $g \in \mathrm{GL}_2(\mathbb{Z}/N)$ raises it to the $\det g$ power $(\zeta \mapsto \zeta^{\det g})$; the fixed-determinant (*symplectic*) level structures with a given ζ_α are exactly those parametrized by the principal congruence subgroup

$$\Gamma(N) = \ker\big(\mathrm{SL}_2(\mathbb{Z}) \to \mathrm{SL}_2(\mathbb{Z}/N)\big)$$

acting on $\mathfrak{H}$ by fractional linear transformations ([20, Congruence Subgroups]). Thus over $\mathbb{C}$ the modular curve is a disjoint union of one copy of $\Gamma(N)\backslash\mathfrak{H}$ for each of the $\varphi(N)$ values of the Weil-pairing invariant,

$$Y(N)(\mathbb{C}) = \coprod_{\zeta \in \mu_N^{\mathrm{prim}}} \Gamma(N)\backslash\mathfrak{H}$$

a smooth affine Riemann surface with $\varphi(N)$ connected components, whose points are exactly the isomorphism classes of elliptic curves with full level-N structure. (Fixing the value ζ_α once and for all, that is passing to symplectic level structures, is the standard way to obtain the connected modular curve $\Gamma(N)\backslash\mathfrak{H}$; the full GL_2-functor of definition 18.4.2 sees all $\varphi(N)$ components at once.) For $N \geq 3$ the group $\Gamma(N)$ acts freely on $\mathfrak{H}$ (it contains no elliptic elements and, crucially, not $-\mathrm{id}$, which is where $N \geq 3$ reappears), so each component is a manifold with no orbifold points, matching the smoothness asserted by the theorem.

The universal family over $Y(N)$ is the descended family whose fiber over the class of τ is the torus $\mathbb{C}/(\mathbb{Z}+\mathbb{Z}\tau)$ with its tautological torsion basis; concretely it is the Weierstrass family $y^2 = 4x^3 - g_2(\tau)x - g_3(\tau)$ built from the Eisenstein series, carried down along $\mathfrak{H} \to \Gamma(N)\backslash\mathfrak{H}$ together with the marked basis of N-torsion. This is a genuine universal object: any family of elliptic curves with level-N structure over a base S is the pullback of $(\mathcal{E}, \alpha^{\mathrm{univ}})$ along the unique classifying map $S \to Y(N)$ furnished by theorem 18.4.4. For $N = 3$ one has $\varphi(3) = 2$, so $Y(3)$ has two connected components, each an affine curve of genus zero, a projective line with a few points removed; the removed points are the cusps, where the elliptic curve degenerates, and they will reappear as the boundary when $\mathcal{M}_{1,1}$ is compactified in the capstone.

The modular curve shows the abstract representability: $Y(N)$ is an ordinary quasi-projective variety, its complex points are $\varphi(N)$ copies of a familiar quotient of the upper half-plane, and it carries a family that specializes to any elliptic-curve-with-level-structure one wishes to name. The appearance of $\Gamma(N)$ ties the algebraic construction to the classical theory of modular forms, where functions on $\Gamma(N)\backslash\mathfrak{H}$ are precisely modular forms of level N ([20, Modular Forms and Cusp Forms]); the moduli-theoretic reading is that a modular form is a section of a line bundle on the fine moduli space $Y(N)$.

Rigidification produced a fine moduli space by enlarging the problem, but the original problem, the classification of elliptic curves without extra data, has not gone away. The relation between the two is exact and useful: the fine space $Y(N)$ maps down to the coarse space of the un-rigidified problem by forgetting the level structure, and the map is the quotient by the group that permutes level structures. This exhibits the j-line as a group quotient of a smooth curve, which is often the most tractable way to study it.

Proposition 18.4.6: Coarse Space as a Quotient of the Rigidified Space

Let $N \geq 3$ be invertible in k, with $k = \bar{k}$. The finite group $\mathrm{GL}_2(\mathbb{Z}/N)$ acts on the fine moduli space $Y(N)$ by changing the level structure: an element $g \in \mathrm{GL}_2(\mathbb{Z}/N)$ sends the class of (E, α) to the class of $(E, \alpha \circ g)$. Forgetting the level structure induces a morphism $Y(N) \to \mathbb{A}^1_j$ to the j-line that is invariant under this action and identifies the j-line with the quotient:

$$\mathbb{A}^1_j \;\cong\; Y(N)/\mathrm{GL}_2(\mathbb{Z}/N)$$

and this presents the coarse moduli space $\mathbb{A}^1_j$ of elliptic curves (theorem 18.3.6, definition 18.3.1) as the quotient of the fine rigidified space by the finite group acting on level structures.

***Proof*:**

Step 1: The action and its orbits. For $g \in \mathrm{GL}_2(\mathbb{Z}/N)$ and a level structure $\alpha\colon (\mathbb{Z}/N)^2 \to E[N]$, the composite $\alpha \circ g$ is again an isomorphism $(\mathbb{Z}/N)^2 \to E[N]$, hence another level structure on the same curve E; this defines a right action of $\mathrm{GL}_2(\mathbb{Z}/N)$ on the pairs (E, α) fixing E and permuting the decorating data. Since $\mathrm{GL}_2(\mathbb{Z}/N)$ acts simply transitively on the set of bases of $E[N] \cong (\mathbb{Z}/N)^2$, for a fixed E the orbit of (E, α) under $\mathrm{GL}_2(\mathbb{Z}/N)$ is the set of *all* pairs (E, α') with the same underlying curve. Passing to isomorphism classes, the $\mathrm{GL}_2(\mathbb{Z}/N)$-orbit of the point of $Y(N)$ representing (E, α) consists of exactly the classes of pairs whose curve is isomorphic to E.

Step 2: The forgetful map factors through the quotient. The assignment $(E, \alpha) \mapsto E$ is a natural transformation $\mathcal{F}_N \to \mathcal{F}$ of moduli functors, and post-composing with the coarse map $\mathcal{F} \to h_{\mathbb{A}^1_j}$ of theorem 18.3.6 gives a natural transformation $\mathcal{F}_N \to h_{\mathbb{A}^1_j}$, hence by Yoneda and representability of $\mathcal{F}_N$ a morphism of schemes $\pi\colon Y(N) \to \mathbb{A}^1_j$. Concretely π sends the class of (E, α) to $j(E)$. Since $j(E)$ depends only on E and not on α, the map π is constant on $\mathrm{GL}_2(\mathbb{Z}/N)$-orbits by Step 1, so it is $\mathrm{GL}_2(\mathbb{Z}/N)$-invariant and factors through the quotient scheme $Y(N)/\mathrm{GL}_2(\mathbb{Z}/N)$, which exists because $\mathrm{GL}_2(\mathbb{Z}/N)$ is finite acting on a quasi-projective scheme, inducing $\bar{\pi}\colon Y(N)/\mathrm{GL}_2(\mathbb{Z}/N) \to \mathbb{A}^1_j$.

Step 3: $\bar{\pi}$ is a bijection on points, hence an isomorphism. On $\bar{k}$-points, Step 1 shows the fibers of π are exactly the $\mathrm{GL}_2(\mathbb{Z}/N)$-orbits: two pairs (E, α), (E', α') map to the same j if and only if $E \cong E'$, if and only if they lie in one orbit. Therefore $\bar{\pi}$ is injective on $\bar{k}$-points. It is surjective because every $j_0 \in \mathbb{A}^1_j(\bar{k})$ is $j(E)$ for some elliptic curve E over $\bar{k}$ (theorem 18.3.6), and E admits a level-N structure over $\bar{k}$ (its N-torsion is $(\mathbb{Z}/N)^2$, so a basis exists), giving a point of $Y(N)$ over j_0. Thus $\bar{\pi}$ is a bijection on $\bar{k}$-points between normal varieties. Upgrading this to an isomorphism requires two inputs beyond the set-theoretic bijection, and both are verified here.

First, $\bar{\pi}$ is birational. The morphism $\pi\colon Y(N) \to \mathbb{A}^1_j$ is finite. To see this, compactify: adding the cusps to each component completes $Y(N)$ to a smooth projective curve $X(N)$, and completing the j-line adds the single point $j = \infty$ to $\mathbb{A}^1_j = \mathbb{P}^1 \setminus \{\infty\}$, giving $X(1) = \mathbb{P}^1$. The forgetful map extends to a nonconstant morphism $\bar{\pi}_c\colon X(N) \to X(1) = \mathbb{P}^1$ of smooth projective curves, and a nonconstant morphism of smooth projective curves is finite. All cusps of $X(N)$ lie over $j = \infty$: the cusps are by construction the points where the elliptic curve degenerates, which is exactly the fiber of $X(N) \to \mathbb{P}^1$ over ∞ ([20]). Restricting the finite morphism $\bar{\pi}_c$ over the cusp-free locus $\mathbb{A}^1_j = \mathbb{P}^1 \setminus \{\infty\}$ recovers $\pi\colon Y(N) \to \mathbb{A}^1_j$, which is therefore finite, being the base change of a finite morphism along the open immersion $\mathbb{A}^1_j \hookrightarrow \mathbb{P}^1$. Over a $\bar{k}$-point j_0 with $j_0 \neq 0, 1728$ the curve E has $\mathrm{Aut}(E) = \{\pm 1\}$ ([20]). By Step 1 the fiber $\pi^{-1}(j_0)$ is the set of isomorphism classes of level structures on E, that is the $|\mathrm{GL}_2(\mathbb{Z}/N)|$ bases of $E[N]$ modulo the action of $\mathrm{Aut}(E) = \{\pm 1\}$; since $\{\pm 1\}$ acts on bases through $\pm\mathrm{id} \in \mathrm{GL}_2(\mathbb{Z}/N)$ without fixed points (as $-\mathrm{id} \neq \mathrm{id}$ for $N \geq 3$), the fiber has exactly $|\mathrm{GL}_2(\mathbb{Z}/N)|/2$ points, each a reduced point because N is invertible in k and the level cover is étale there. This common value is both the degree of π over the ordinary locus and the size of the corresponding $\mathrm{GL}_2(\mathbb{Z}/N)$-orbit, by the orbit-stabilizer count $|\mathrm{GL}_2(\mathbb{Z}/N)|/|\{\pm 1\}|$ with stabilizer exactly the $\{\pm 1\}$ acting through $\mathrm{Aut}(E)$. Hence the generic fiber of $\bar{\pi} = \pi/\mathrm{GL}_2(\mathbb{Z}/N)$ is a single reduced point, so $\bar{\pi}$ is a finite morphism of degree one, that is birational.

Second, $Y(N)/\mathrm{GL}_2(\mathbb{Z}/N)$ is normal, being the quotient of the smooth (hence normal) $Y(N)$ by a finite group, and $\mathbb{A}^1_j$ is smooth. A finite birational morphism to a normal variety is an isomorphism (this is the form of Zariski's main theorem that does not require separability hypotheses beyond birationality, which was checked above and holds in every characteristic

because N is invertible). Therefore $\bar{\pi}$ is an isomorphism $Y(N)/\mathrm{GL}_2(\mathbb{Z}/N) \cong \mathbb{A}^1_j$.

That $\mathbb{A}^1_j$ is the coarse moduli space of elliptic curves is theorem 18.3.6, so the displayed isomorphism presents the coarse space as the finite-group quotient of the fine rigidified space, completing the proof.

The proposition is the reconciliation the section was aiming for. The un-rigidified moduli problem has no fine solution, but it has a coarse one, $\mathbb{A}^1_j$, and the coarse solution is recovered from the fine solution of the rigidified problem by dividing out the choices that the rigidification introduced. The group $\mathrm{GL}_2(\mathbb{Z}/N)$ measures exactly how much extra data a level structure carries, and quotienting by it erases that data. This is a template for the whole subject: a moduli problem with automorphisms is studied by rigidifying to a fine space and then quotienting by the finite group that acts on the rigidifying data, and the quotient is the coarse space. The template has a limitation the reader should carry forward. The quotient $Y(N)/\mathrm{GL}_2(\mathbb{Z}/N)$ remembers only orbits, so it forgets the stabilizers, the automorphism groups of the curves, exactly the information $\mathbb{A}^1_j$ was already blind to at $j = 0$ and $j = 1728$. The framework that keeps track of the stabilizers while still forming the quotient is the quotient *stack* $[Y(N)/\mathrm{GL}_2(\mathbb{Z}/N)]$, and building it is the task of Part VI.

Exercise 18.4.1

1. Show that for $N = 2$ the automorphism $[-1]$ fixes every level-2 structure on every elliptic curve, and conclude that lemma 18.4.3 fails for $N = 2$. Deduce that the level-2 moduli functor $\mathcal{F}_2$ is not representable by a fine moduli space over $\bar{k}$ (with $\operatorname{char} k \neq 2$), even though it carries more data than $\mathcal{F}$.

2. Let $N \geq 3$. Compute the order of $\mathrm{GL}_2(\mathbb{Z}/N)$ for N prime, and verify directly that $\mathrm{GL}_2(\mathbb{Z}/3)$ acts simply transitively on the set of ordered bases of $(\mathbb{Z}/3)^2$. Using proposition 18.4.6, interpret the degree of the forgetful map $Y(3) \to \mathbb{A}^1_j$ over a generic j (where $\mathrm{Aut}(E) = \{\pm 1\}$) and explain the discrepancy between $|\mathrm{GL}_2(\mathbb{Z}/3)|$ and this degree in terms of the residual action of $[-1]$.

3. Prove that the endomorphism-norm inequality used in Step 2 of lemma 18.4.3 is sharp for $N = 2$ by exhibiting, on an arbitrary elliptic curve, an endomorphism $\psi = \varphi - \mathrm{id}$ of degree 4 with φ an automorphism and $E[2] \subseteq \ker \psi$. (Suggestion: take $\varphi = [-1]$.)

4. A level structure is one instance of rigidifying data. For a smooth projective curve C of genus $g \geq 2$, an *n-canonical framing* is a choice of ordered basis of $H^0(C, \omega_C^{\otimes n})$ for $n \geq 3$. Explain, by analogy with definition 18.4.1 and lemma 18.4.3, why such a framing should rigidify the moduli problem of genus-g curves: identify the group that acts on the framings (playing the role of $\mathrm{GL}_2(\mathbb{Z}/N)$) and state what property of $\mathrm{Aut}(C)$ makes the framing kill automorphisms.

5. Show that over $\mathbb{C}$ each connected component $\Gamma(3)\backslash\mathfrak{H}$ of the modular curve $Y(3)$ of example 18.4.5 has genus zero, by computing the index $[\mathrm{SL}_2(\mathbb{Z}) : \Gamma(3)]$ and the number of cusps, then applying the Riemann-Hurwitz formula to the covering $\Gamma(3)\backslash\mathfrak{H} \to Y(1) = \mathbb{A}^1_j$. (You may use that $Y(1)(\mathbb{C}) = \mathrm{SL}_2(\mathbb{Z})\backslash\mathfrak{H}$ has genus zero with one cusp and elliptic points of orders 2 and 3.) Then check that the full forgetful map $Y(3) \to Y(1)$, taken over both components, has degree 24, reconciling with part (b).

18.5 Criteria for Representability

The preceding sections have twice confronted the same fault line. A moduli problem is a functor $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ (definition 18.1.1), and the best possible outcome is a fine moduli space, a scheme M with $\mathcal{F} \cong h_M$ (definition 18.1.3). Yet functors that arise from geometry routinely fail to be representable, and the failure is not random. The warning issued in box 18.1.6 named the culprit: a functor of points is always a sheaf for the Zariski topology, so any moduli functor that is not such a sheaf cannot be representable. This section turns that observation into working tools. Two questions organize it. First, given a functor, what are the criteria that decide whether it is representable? Second, what first-order information does a functor carry even before that question is settled, and how is that information extracted?

The answer to the first question is a local-to-global principle: a functor representable in the Zariski topology and locally representable on an open cover is representable, exactly as a scheme is glued from affine charts. The answer to the second is the tangent space of a functor, computed by feeding the functor the dual numbers $k[\varepsilon]$. This tangent space is the first invariant of deformation theory, the thread the book picks up after this chapter: where this chapter asks whether a moduli space exists, the deformation theory that follows asks what it looks like near a point, and the tangent space of the functor is where those two investigations meet. The two tools of this section are complementary. The sheaf-and-cover criterion is a global test for existence; the tangent space is a pointwise linearization that survives even when no representing scheme does.

The first tool is the tangent space, and it comes from the dual numbers. A scheme X over k has, at each k-point x, a Zariski tangent space $T_xX = (\mathfrak{m}_x/\mathfrak{m}_x^2)^\vee$, and the classical characterization of tangent vectors identifies them with morphisms $\operatorname{Spec} k[\varepsilon] \to X$ sending the closed point to x. The dual numbers $k[\varepsilon] = k[\varepsilon]/(\varepsilon^2)$ are the algebraic model of an infinitesimally short arc: a k-point together with a tangent direction. A functor $\mathcal{F}$ of points has no underlying topological space and no local ring, so its tangent space cannot be defined through a cotangent module. What it does have is its value on $\operatorname{Spec} k[\varepsilon]$, and the same tangent vectors reappear there. The device is to compare $\mathcal{F}(k[\varepsilon])$ with $\mathcal{F}(k)$ along the map that sets ε to zero.

Throughout, for a k-algebra A write $\mathcal{F}(A)$ for $\mathcal{F}(\operatorname{Spec} A)$; this is the standard abuse that lets a contravariant functor on schemes be evaluated on rings covariantly. The reduction homomorphism $k[\varepsilon] \to k$, $\varepsilon \mapsto 0$, induces $\mathcal{F}(k[\varepsilon]) \to \mathcal{F}(k)$, and a choice of base point $x \in \mathcal{F}(k)$ singles out a fiber.

Definition 18.5.1: Tangent Space of a Functor

Let $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ be a functor and $x \in \mathcal{F}(k)$ a k-point. Let

$$\pi\colon \mathcal{F}(k[\varepsilon]) \longrightarrow \mathcal{F}(k)$$

be the map induced by the k-algebra homomorphism $k[\varepsilon] \to k$ sending $\varepsilon \mapsto 0$. The *tangent space of $\mathcal{F}$ at x* is the fiber

$$T_x\mathcal{F} \;=\; \pi^{-1}(x) \;=\; \{\xi \in \mathcal{F}(k[\varepsilon]) \mid \pi(\xi) = x\}$$

the set of lifts of x to a $k[\varepsilon]$-point of $\mathcal{F}$.

As stated, $T_x\mathcal{F}$ is only a pointed set: it always contains the *constant* lift, the image of x under the section $\mathcal{F}(k) \to \mathcal{F}(k[\varepsilon])$ induced by the structure map $k \hookrightarrow k[\varepsilon]$. For a functor of geometric

origin it carries far more structure. When $\mathcal{F} = h_X$ is representable, the fiber $T_x\mathcal{F}$ is precisely the classical Zariski tangent space T_xX, a k-vector space; the identification is exactly the arc description of tangent vectors recalled above, and the full account of why the functorial definition recovers the geometric one is developed in definition 3.3.12. The vector-space structure does not require representability. It is enough that $\mathcal{F}$ be *reasonable* in the following precise sense.

Proposition 18.5.2: Vector Space Structure on the Tangent Space

Suppose $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ takes the fiber product of k-algebras

$$k[\varepsilon] \times_k k[\varepsilon] \;\cong\; k[\varepsilon_1, \varepsilon_2]/(\varepsilon_1, \varepsilon_2)^2$$

to the corresponding fiber product of sets, that is, the natural map

$$\mathcal{F}\big(k[\varepsilon] \times_k k[\varepsilon]\big) \longrightarrow \mathcal{F}(k[\varepsilon]) \times_{\mathcal{F}(k)} \mathcal{F}(k[\varepsilon])$$

is a bijection. Then for every $x \in \mathcal{F}(k)$ the set $T_x\mathcal{F}$ carries a natural k-vector space structure whose zero is the constant lift.

***Proof*:**

Fix $x \in \mathcal{F}(k)$. The argument realizes addition and scalar multiplication as functorial consequences of ring maps out of $k[\varepsilon]$.

Step 1: Addition. The ring $B = k[\varepsilon_1, \varepsilon_2]/(\varepsilon_1, \varepsilon_2)^2$ is the fiber product $k[\varepsilon] \times_k k[\varepsilon]$, with the two projections $p_i\colon B \to k[\varepsilon]$ given by $\varepsilon_i \mapsto \varepsilon$ and $\varepsilon_j \mapsto 0$ for $j \neq i$. By hypothesis

$$\mathcal{F}(B) \;\xrightarrow{\sim}\; T_x\mathcal{F} \times T_x\mathcal{F}$$

once one restricts to the fiber over x: an element of the right side is a pair (ξ_1, ξ_2) of lifts of x, and the isomorphism produces a unique $\zeta \in \mathcal{F}(B)$ restricting to ξ_i under $\mathcal{F}(p_i)$. The addition homomorphism

$$\sigma\colon B \to k[\varepsilon], \qquad \varepsilon_1, \varepsilon_2 \mapsto \varepsilon$$

is well defined because it carries the defining relations $(\varepsilon_1, \varepsilon_2)^2 = 0$ to $\varepsilon^2 = 0$, which holds in $k[\varepsilon]$, and it is a k-algebra map reducing to the identity modulo ε. Set $\xi_1 + \xi_2 := \mathcal{F}(\sigma)(\zeta)$. This lands in $T_x\mathcal{F}$ since σ covers $\varepsilon \mapsto 0$, and it is independent of choices because ζ was unique.

Step 2: Scalar multiplication. For $\lambda \in k$ the map $m_\lambda\colon k[\varepsilon] \to k[\varepsilon]$, $\varepsilon \mapsto \lambda\varepsilon$, is a k-algebra homomorphism reducing to the identity modulo ε. Define $\lambda \cdot \xi := \mathcal{F}(m_\lambda)(\xi)$ for $\xi \in T_x\mathcal{F}$. Since m_λ covers $\varepsilon \mapsto 0$, the result again lies in $T_x\mathcal{F}$.

Step 3: The axioms. The vector-space axioms are inherited from identities among the structure maps. Commutativity and associativity of $+$ follow from the symmetry of B under $\varepsilon_1 \leftrightarrow \varepsilon_2$ and from the associativity of the triple analogue $k[\varepsilon_1, \varepsilon_2, \varepsilon_3]/(\varepsilon_1, \varepsilon_2, \varepsilon_3)^2$, which is the iterated fiber product $(k[\varepsilon] \times_k k[\varepsilon]) \times_k k[\varepsilon]$ and so is respected by $\mathcal{F}$ through two applications of the fiber-product hypothesis. The zero element is the constant lift 0_x, the image of x under $k \hookrightarrow k[\varepsilon]$: composing σ with the inclusion of one factor recovers the other summand, so $\xi + 0_x = \xi$. The identity $m_\lambda \circ m_\mu = m_{\lambda\mu}$ gives $\lambda(\mu\xi) = (\lambda\mu)\xi$, and $m_1 = \mathrm{id}$ gives $1 \cdot \xi = \xi$. Distributivity $\lambda(\xi_1 + \xi_2) = \lambda\xi_1 + \lambda\xi_2$ holds because m_λ commutes with σ up to the symmetric substitution $\varepsilon_i \mapsto \lambda\varepsilon_i$, and $(\lambda + \mu)\xi = \lambda\xi + \mu\xi$ follows by applying $\mathcal{F}$ to the map $B \to k[\varepsilon]$, $\varepsilon_1 \mapsto \lambda\varepsilon$, $\varepsilon_2 \mapsto \mu\varepsilon$, and comparing with σ. All verifications are functorial images of ring-level identities, so no further choices intervene, completing the proof.

The hypothesis of proposition 18.5.2 is a functorial statement of a single geometric fact: two tangent vectors at a point can be added because a pair of tangent directions is the same datum as one map from the "doubled" dual numbers B. Every representable functor satisfies the hypothesis, since h_X turns the fiber-product presentation of B into a fiber product of Hom-sets; the deformation functors studied later satisfy it too, which is why their tangent spaces are vector spaces even when the functors are not representable. This is the sense in which the tangent space is defined despite the failure of representability, and it is the reason first-order deformation theory can proceed by linear algebra.

Example 18.5.3: The Tangent Space to Projective Space at a Point

Take $\mathcal{F} = h_{\mathbb{P}^n}$, the functor represented by projective n-space over k, described in example 18.1.4 as the moduli of rank-one locally free quotients of $\mathcal{O}^{n+1}$. Fix a k-point $x = [a_0 : \cdots : a_n] \in \mathbb{P}^n(k)$, and after reordering assume $a_0 \neq 0$, so x lies in the standard chart $U_0 \cong \mathbb{A}^n$ with affine coordinates $t_i = x_i/x_0$ for $i = 1, \dots, n$; in these coordinates x is the point $(a_1/a_0, \dots, a_n/a_0)$, which after rescaling may be written $(c_1, \dots, c_n)$. A $k[\varepsilon]$-point of $\mathbb{P}^n$ lifting x is a quotient $\mathcal{O}^{n+1}_{k[\varepsilon]} \twoheadrightarrow L$ with L locally free of rank one, reducing modulo ε to the given quotient at x. Because x lies in U_0, such a lift is the same as an A-point of $\mathbb{A}^n$ over $A = k[\varepsilon]$ reducing to x, that is, an n-tuple

$$\big(c_i + b_i\varepsilon\big)_{i=1}^{n}, \qquad b_i \in k$$

The reduction π discards the $b_i\varepsilon$ terms, sending this tuple to $(c_1, \dots, c_n) = x$, so the fiber $T_x\mathbb{P}^n$ is the set of tuples $(b_1, \dots, b_n) \in k^n$. Under the addition of proposition 18.5.2 the doubled dual numbers send $\varepsilon_1, \varepsilon_2 \mapsto \varepsilon$, which adds the two tuples coordinatewise, and m_λ scales them; thus $T_x\mathbb{P}^n \cong k^n$ as a k-vector space. This matches the classical Zariski tangent space $T_x\mathbb{P}^n$ of dimension n, computed here without ever writing down $\mathfrak{m}_x/\mathfrak{m}_x^2$.

The tangent space is a pointwise probe. To decide representability one needs a global constraint, and the sharpest one available at this stage is the sheaf condition. Box 18.1.6 flagged, informally, that a representable functor is a Zariski sheaf and that objects with automorphisms break this property. That warning is now upgraded to a proposition with a proof, and strengthened: representability forces the sheaf condition not only for the Zariski topology but for the far finer fppf topology, in which covers may be flat and surjective.

Recall the sheaf condition in functorial form. A functor $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ is a *sheaf* for a class of covers if, for every cover $\{U_i \to S\}$ in the class, the sequence

$$\mathcal{F}(S) \longrightarrow \prod_i \mathcal{F}(U_i) \rightrightarrows \prod_{i,j} \mathcal{F}(U_i \times_S U_j)$$

is an equalizer: an element of $\prod_i \mathcal{F}(U_i)$ that agrees on all overlaps $U_i \times_S U_j$ comes from a unique element of $\mathcal{F}(S)$. For the Zariski topology the $U_i \to S$ are open immersions covering S; for the fppf topology they are morphisms, flat and of finite presentation, jointly surjective.

Proposition 18.5.4: Representable Functors are fppf Sheaves

For every scheme X, the functor of points $h_X = \mathrm{Hom}(-, X)$ is a sheaf for the fppf topology on **Sch**, and in particular for the Zariski topology. Consequently, any functor $\mathcal{F}$ that is not a Zariski sheaf is not representable.

***Proof*:**
The Zariski case is elementary and comes first; the fppf case is the content of faithfully flat descent for morphisms, which is imported from the descent chapter.

Step 1: The Zariski sheaf condition. Let $\{U_i \to S\}$ be a Zariski open cover, so the $U_i \subseteq S$ are open subschemes with $\bigcup_i U_i = S$ and $U_i \times_S U_j = U_i \cap U_j$. Given morphisms $f_i \colon U_i \to X$ agreeing on overlaps, $f_i|_{U_i \cap U_j} = f_j|_{U_i \cap U_j}$, a morphism of schemes is a continuous map of underlying spaces together with a map of structure sheaves, and both data are local on the source. The set-map $|S| \to |X|$ is defined by $s \mapsto f_i(s)$ for any i with $s \in U_i$; agreement on overlaps makes this independent of i, hence well defined and continuous since it is continuous on each open U_i. The sheaf map $\mathcal{O}_X \to f_*\mathcal{O}_S$ is assembled from the $\mathcal{O}_X \to (f_i)_*\mathcal{O}_{U_i}$ by the sheaf axiom on X, again using overlap agreement. The resulting $f \colon S \to X$ restricts to f_i on each U_i, and it is the unique such morphism because a morphism is determined by its restrictions to an open cover. This is exactly the equalizer condition.

Step 2: The fppf sheaf condition. Let $\{U_i \to S\}$ be an fppf cover. Refining, it suffices to treat a single faithfully flat morphism of finite presentation $u \colon U \to S$, since a disjoint union $\coprod_i U_i \to S$ of the covering maps is again faithfully flat and of finite presentation, and the equalizer over the family coincides with the equalizer for $\coprod_i U_i \to S$. The claim is then that

$$\mathrm{Hom}(S, X) \longrightarrow \mathrm{Hom}(U, X) \rightrightarrows \mathrm{Hom}(U \times_S U, X)$$

is an equalizer. A morphism $g \colon U \to X$ equalizing the two maps $U \times_S U \rightrightarrows U$ is a morphism satisfying $g \circ \mathrm{pr}_1 = g \circ \mathrm{pr}_2$ on $U \times_S U$, that is, a descent datum for the morphism g along the fppf cover u. Faithfully flat descent for morphisms to a scheme asserts that such a g descends uniquely to a morphism $S \to X$: the map on topological spaces descends because u is submersive (a quotient map, being faithfully flat and quasi-compact), and the map on structure sheaves descends because faithfully flat descent is effective for quasi-coherent modules, applied to $\mathcal{O}_X$-algebra structures. Faithfully flat descent for morphisms is the subject of a later chapter, where it is proved in full; invoking it here avoids circularity, since the descent chapter presupposes the functor-of-points language established in this one. Granting that theorem, the displayed sequence is an equalizer.

Step 3: The contrapositive. If $\mathcal{F} \cong h_X$ for some scheme X, then $\mathcal{F}$ inherits the Zariski sheaf property of h_X by transport of the natural isomorphism. Hence a functor failing the Zariski sheaf condition cannot be isomorphic to any h_X, so it is not representable, as we sought to show.

The proposition is the precise form of the obstruction that recurs throughout the chapter. Box 18.1.6 phrased it informally; proposition 18.5.4 makes it a decision procedure. To show a functor is not representable, exhibit a Zariski cover $\{U_i \to S\}$ and local data $\{f_i\}$ that agree on overlaps but glue to *no* element of $\mathcal{F}(S)$, or glue to more than one. Objects with automorphisms produce exactly this failure: an automorphism lets one twist local families along overlaps so that they agree as isomorphism classes yet cannot be reconciled into a single global family. The j-line seen in theorem 18.3.6 is the prototype, and the worked example below isolates the mechanism in its barest form. The fppf strengthening matters for a reason that becomes central once stacks appear: moduli functors typically *are* sheaves for the fppf or étale topology even when they fail to be representable by a scheme, so the sheaf condition alone does not detect the failure, a point that returns when algebraic stacks are introduced later in the book. What separates a representable functor from a mere fppf sheaf is the second criterion, the local representability that the next result formalizes.

A scheme is not built all at once; it is glued from affine pieces along open subschemes. The functor of

points should be constructible the same way, and it is: a functor that looks representable on an open cover and satisfies the Zariski sheaf condition is globally representable. This is the local-to-global criterion promised at the start, and it is the mechanism by which nearly every moduli space in the book is eventually constructed, the Grassmannian of theorem 18.2.4 among them. The statement requires the notion of an open subfunctor, the functorial counterpart of an open subscheme.

Definition 18.5.5: Open Subfunctor

Let $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ be a functor. A subfunctor $\mathcal{G} \subseteq \mathcal{F}$ (a functor with $\mathcal{G}(S) \subseteq \mathcal{F}(S)$ for all S, compatibly with restriction) is an *open subfunctor* if for every scheme T and every morphism $T \to \mathcal{F}$ (equivalently, by Yoneda, every $t \in \mathcal{F}(T)$), the fiber product $\mathcal{G} \times_{\mathcal{F}} T$ is representable by an open subscheme of T. A family of open subfunctors $\{\mathcal{G}_i \subseteq \mathcal{F}\}$ is an *open cover* if for every field K over k and every $x \in \mathcal{F}(K)$, there is some i with $x \in \mathcal{G}_i(K)$; equivalently, for every $t \in \mathcal{F}(T)$ the open subschemes $\mathcal{G}_i \times_{\mathcal{F}} T \subseteq T$ cover T.

The definition says that pulling an open subfunctor back along any T-point of $\mathcal{F}$ produces an open subscheme of T, and that these opens cover T as t ranges over the point. When $\mathcal{F} = h_X$ is representable, its open subfunctors are exactly the h_U for $U \subseteq X$ open, and an open cover of $\mathcal{F}$ is a Zariski open cover of X; the definition is the transcription of that situation into functorial language, made so that it can be applied before X is known to exist. With it, the criterion reads as follows.

Theorem 18.5.6: Zariski-Local Criterion for Representability

Let $\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}$ be a functor satisfying:

1. $\mathcal{F}$ is a sheaf for the Zariski topology; and
2. $\mathcal{F}$ admits an open cover $\{\mathcal{G}_i \subseteq \mathcal{F}\}_{i \in I}$ by open subfunctors, each of which is representable, say $\mathcal{G}_i \cong h_{X_i}$ for a scheme X_i.

Then $\mathcal{F}$ is representable: there is a scheme X with $\mathcal{F} \cong h_X$, obtained by gluing the X_i along the open subschemes cut out by their pairwise intersections $\mathcal{G}_i \cap \mathcal{G}_j$.

***Proof*:**
The proof reconstructs a scheme from the charts X_i and identifies its functor of points with $\mathcal{F}$. The two hypotheses do exactly complementary work: the open cover gives the charts and their overlaps, and the sheaf condition gives the unique global sections that make the gluing represent $\mathcal{F}$.

Step 1: The charts and their overlaps. For each i, fix an isomorphism $\mathcal{G}_i \cong h_{X_i}$; by Yoneda the identity of X_i is a distinguished element $u_i \in \mathcal{G}_i(X_i) \subseteq \mathcal{F}(X_i)$, the universal element of the chart. For a pair (i, j) consider the open subfunctor $\mathcal{G}_j \cap \mathcal{G}_i = \mathcal{G}_j \times_{\mathcal{F}} \mathcal{G}_i$. Pulling $\mathcal{G}_j$ back along the X_i-point $u_i \in \mathcal{F}(X_i)$ gives, by the open-subfunctor hypothesis applied to $\mathcal{G}_j$ and $T = X_i$, an open subscheme

$$X_{ij} \;:=\; \mathcal{G}_j \times_{\mathcal{F}} X_i \;\subseteq\; X_i$$

Concretely X_{ij} is the largest open of X_i over which the universal element u_i lands in $\mathcal{G}_j$. Symmetrically $X_{ji} \subseteq X_j$ is defined.

Step 2: The transition isomorphisms. Both $X_{ij} \subseteq X_i$ and $X_{ji} \subseteq X_j$ represent the same functor,

namely $\mathcal{G}_i \cap \mathcal{G}_j$: indeed $h_{X_{ij}} = \mathcal{G}_j \times_{\mathcal{F}} \mathcal{G}_i = \mathcal{G}_i \cap \mathcal{G}_j$ by construction, and likewise $h_{X_{ji}} = \mathcal{G}_i \cap \mathcal{G}_j$. Yoneda turns the resulting isomorphism of functors into a unique isomorphism of schemes

$$\varphi_{ji} \colon X_{ij} \xrightarrow{\sim} X_{ji}$$

Because it is induced by the identity on the common functor $\mathcal{G}_i \cap \mathcal{G}_j$, one has $\varphi_{ii} = \mathrm{id}$ and $\varphi_{ij} = \varphi_{ji}^{-1}$.

Step 3: The cocycle condition. Gluing schemes requires the transition maps to satisfy the cocycle identity on triple overlaps. Restricting to the open subscheme $X_{ijk} \subseteq X_i$ representing $\mathcal{G}_i \cap \mathcal{G}_j \cap \mathcal{G}_k$, the isomorphisms φ_{ji}, φ_{kj}, φ_{ki} are all induced by the identity on the triple-intersection functor $\mathcal{G}_i \cap \mathcal{G}_j \cap \mathcal{G}_k$. Hence

$$\varphi_{ki} = \varphi_{kj} \circ \varphi_{ji} \quad \text{on} \quad X_{ijk}$$

since both sides are the unique isomorphism induced by that identity. The cocycle condition holds, so the gluing datum $\big(X_i, X_{ij}, \varphi_{ji}\big)$ is effective: there is a scheme X with open subschemes $\iota_i \colon X_i \hookrightarrow X$ covering X, such that $\iota_i(X_{ij}) = \iota_j(X_{ji})$ and $\iota_j \circ \varphi_{ji} = \iota_i$ on X_{ij}.

Step 4: A natural transformation $\mathcal{F} \to h_X$. The universal elements $u_i \in \mathcal{F}(X_i)$ are compatible on overlaps: on X_{ij} the element u_i restricts into $\mathcal{G}_j$ (that is what X_{ij} was), and under φ_{ji} it is carried to the restriction of u_j, because both are the universal element of $\mathcal{G}_i \cap \mathcal{G}_j$. Transporting along the ι_i, the sections $u_i \in \mathcal{F}(X_i)$ agree on the overlaps $\iota_i(X_{ij}) = \iota_j(X_{ji})$ inside X. Since $\mathcal{F}$ is a Zariski sheaf and $\{X_i \to X\}$ is a Zariski open cover of X, there is a *unique* $u \in \mathcal{F}(X)$ restricting to u_i on each X_i. By Yoneda, u is a natural transformation $h_X \to \mathcal{F}$, equivalently a morphism $\Phi \colon h_X \to \mathcal{F}$ of functors.

Step 5: Φ is an isomorphism. It suffices to check that $\Phi_T \colon h_X(T) \to \mathcal{F}(T)$ is a bijection for every scheme T; both sides are Zariski sheaves in T (the source by proposition 18.5.4, the target by hypothesis (1)), so bijectivity may be checked locally on T. Given $t \in \mathcal{F}(T)$, hypothesis (2) gives an open cover $\{T_i\}$ of T with $t|_{T_i} \in \mathcal{G}_i(T_i) \cong h_{X_i}(T_i)$; thus $t|_{T_i}$ corresponds to a morphism $g_i \colon T_i \to X_i \xrightarrow{\iota_i} X$, and by construction $\Phi(g_i) = t|_{T_i}$. On the overlap $T_i \cap T_j$ the two morphisms g_i, g_j land in $\iota_i(X_{ij}) = \iota_j(X_{ji})$ and are identified there by φ_{ji}, so $g_i|_{T_i \cap T_j} = g_j|_{T_i \cap T_j}$ as morphisms to X. Because h_X is a Zariski sheaf, the g_i glue to a unique $g \colon T \to X$ with $\Phi(g) = t$; this is surjectivity, with uniqueness of g giving injectivity. Hence Φ_T is a bijection for all T, so $\mathcal{F} \cong h_X$, completing the proof.

The theorem is what the entire representability argument rests on. It reduces the global question "is $\mathcal{F}$ representable?" to two local ones: does $\mathcal{F}$ glue in the Zariski topology, and can one cover it by pieces already known to be schemes? Both halves are indispensable. Dropping the sheaf condition, one could cover a functor by representable opens whose local charts refuse to glue, exactly the pathology that makes non-separated or non-representable objects; dropping local representability, a Zariski sheaf carries no charts to glue. The Grassmannian is representable precisely because its standard affine charts (example 18.2.8) are representable open subfunctors and the quotient-bundle functor is a Zariski sheaf, and theorem 18.2.4 is in essence this criterion applied to those charts. The same template constructs the Hilbert and Quot schemes in the next chapter, once suitable representable charts are produced. The criterion also clarifies where representability can fail: not in the gluing of charts, which is automatic once they exist, but in the sheaf condition, which is where automorphisms strike.

Proposition 18.5.4 converts non-representability into a concrete search: find a cover and local data that violate the sheaf condition. The following example carries out that search in the simplest

nontrivial setting, the naive functor of line bundles up to isomorphism. Its failure is the same one that stops the j-line from being a fine moduli space in theorem 18.3.6, stripped of the geometry so that the mechanism is visible in a single cohomology group.

Example 18.5.7: The Naive Picard Functor is not a Zariski Sheaf
Work over k and consider the naive Picard functor

$$\mathcal{F}\colon \mathbf{Sch}^{\mathrm{op}} \to \mathbf{Set}, \qquad \mathcal{F}(S) = \mathrm{Pic}\,(S) = \big\{\text{line bundles } \mathcal{L} \text{ on } S\big\}/\!\cong$$

the set of isomorphism classes of invertible sheaves on S, with pullback along $f\colon T \to S$ given by f^*. This is a moduli functor in the sense of definition 18.1.1: its objects are line bundles and its morphisms are pullbacks. The claim is that $\mathcal{F}$ is *not* representable, and the obstruction is the passage to isomorphism classes, which forgets the automorphisms $\mathcal{L} \xrightarrow{c} \mathcal{L}$ ($c \in k^\times$) that every line bundle carries.

To see the sheaf condition fail, take $S = \mathbb{P}^1$ and the standard Zariski cover $S = U_0 \cup U_1$ by the two affine charts $U_0 = \operatorname{Spec} k[t]$, $U_1 = \operatorname{Spec} k[u]$ with $u = t^{-1}$, overlap $U_0 \cap U_1 = \operatorname{Spec} k[t, t^{-1}]$. On each chart every line bundle is trivial up to isomorphism, since $\mathrm{Pic}\,(\mathbb{A}^1) = 0$; and $\mathrm{Pic}\,(U_0 \cap U_1) = \mathrm{Pic}\,(\mathbb{G}_m) = 0$ as well. Hence

$$\mathcal{F}(U_0) = \mathcal{F}(U_1) = \mathcal{F}(U_0 \cap U_1) = \{*\}$$

are all singletons, so the fiber product $\mathcal{F}(U_0) \times_{\mathcal{F}(U_0 \cap U_1)} \mathcal{F}(U_1)$ is a single point: the trivial bundle on each chart is the unique local datum, and it is automatically compatible on the overlap.

The global set is not a point. Every line bundle on $\mathbb{P}^1$ is $\mathcal{O}_{\mathbb{P}^1}(n)$ for a unique $n \in \mathbb{Z}$, so $\mathcal{F}(\mathbb{P}^1) = \mathrm{Pic}\,(\mathbb{P}^1) \cong \mathbb{Z}$, and each of these restricts to the trivial bundle on both charts. The restriction map

$$\mathcal{F}(\mathbb{P}^1) \longrightarrow \mathcal{F}(U_0) \times_{\mathcal{F}(U_0 \cap U_1)} \mathcal{F}(U_1)$$

is therefore $\mathbb{Z} \to \{*\}$, which is not injective. The equalizer condition fails in its *uniqueness* clause: the unique compatible local datum lifts to infinitely many global classes, one for each n. Concretely, gluing the two trivial charts by the transition unit $t^n \in k[t, t^{-1}]^\times$ produces $\mathcal{O}_{\mathbb{P}^1}(n)$, and all these gluings have identical restriction to the charts yet are pairwise non-isomorphic globally. Hence $\mathcal{F}$ is not a Zariski sheaf, and by proposition 18.5.4 it is not representable.

The mechanism is the one anticipated by box 18.1.6. Passing to isomorphism classes erases the transition data t^n, which is precisely the automorphism-valued gluing information $\mathcal{O}(U_0 \cap U_1)^\times$ that distinguishes the global bundles; the sheaf condition then cannot recover n from local data that all look trivial. This is the same failure that prevented the j-line from being a fine moduli space in theorem 18.3.6, where isotrivial families with nonconstant transition automorphisms restrict to identical local objects yet are globally distinct. The repair, developed in the stacks Part of the book, is to remember the automorphisms, replacing the set-valued functor $\mathcal{F}$ by a groupoid-valued one, that is, a stack. The correct Picard functor, defined as a sheafification and made representable by adding rigidifying data, is itself constructed in section 23.6; the naive version here fails at the first step, the sheaf condition.

The example isolates the difference between a coarse and a fine moduli space in a single computation. The set $\mathcal{F}(S)$ discards the automorphisms of its objects by passing to isomorphism classes, and that quotient is exactly what destroys the sheaf condition: gluing data differing by transition automorphisms become indistinguishable when restricted to the charts, yet build different global

objects. No scheme's functor of points has this defect, by proposition 18.5.4, which is why $\mathcal{F}$ cannot be representable no matter how the geometry is arranged. The tangent-space tool and the gluing criterion together frame the two directions the book now takes. The deformation theory to come linearizes the moduli problem at a point, computing the tangent space of definition 18.5.1 as a cohomology group and asking when deformations are unobstructed; the theory of algebraic stacks that follows it enlarges the target category so that functors like the one above become representable objects, algebraic stacks, whose functor of points is a groupoid keeping track of the automorphisms this example was unable to forget.

Exercise 18.5.1

1. Let $\mathcal{F} = h_{\mathbb{A}^1}$ be the functor represented by the affine line over k, so $\mathcal{F}(A) = A$ for a k-algebra A. Compute $\mathcal{F}(k[\varepsilon])$, the reduction map $\pi\colon \mathcal{F}(k[\varepsilon]) \to \mathcal{F}(k)$, and the tangent space $T_x\mathcal{F}$ at a point $x \in \mathbb{A}^1(k) = k$. Verify directly, using the doubled dual numbers $k[\varepsilon_1, \varepsilon_2]/(\varepsilon_1, \varepsilon_2)^2$, that the addition of proposition 18.5.2 recovers ordinary addition on k, so $T_x\mathcal{F} \cong k$.

2. Let $\mathcal{F} = h_G$ for an affine algebraic group G over k, and take $x = e$ the identity. Show that $T_e\mathcal{F}$ with the vector-space structure of proposition 18.5.2 is the Lie algebra $\mathrm{Lie}(G)$ as a k-vector space. (Hint: a $k[\varepsilon]$-point reducing to e is an element of $G(k[\varepsilon])$ mapping to e under $\varepsilon \mapsto 0$; identify these with left-invariant derivations of $\mathcal{O}_{G,e}$.)

3. Prove that a filtered colimit of representable functors need not be representable, but that every open subfunctor of a representable functor h_X is of the form h_U for a unique open subscheme $U \subseteq X$. Deduce that in theorem 18.5.6 the charts X_i may be taken to be affine without loss of generality.

4. Fix a scheme X over k and define the *relative Picard functor* $\mathrm{Pic}_{X/k}\colon \mathbf{Sch}_k^{\mathrm{op}} \to \mathbf{Set}$ by $\mathrm{Pic}_{X/k}(A) = \ker\big(\mathrm{Pic}\,(X \times_k \mathrm{Spec}\,A) \to \mathrm{Pic}\,(X)\big)$, the line bundles on $X_A := X \times_k \mathrm{Spec}\,A$ trivial along the reduction $X \hookrightarrow X_A$, up to isomorphism (this is a k-pointed functor: $\mathrm{Pic}_{X/k}(k) = \{[\mathcal{O}_X]\}$ is a single point, the class of the trivial bundle). Compute its tangent space $T_{[\mathcal{O}_X]}\mathrm{Pic}_{X/k}$ at that point using definition 18.5.1. Show that a $k[\varepsilon]$-point of $\mathrm{Pic}_{X/k}$ is a line bundle on $X[\varepsilon] = X \times_k \mathrm{Spec}\,k[\varepsilon]$ restricting to $\mathcal{O}_X$, and identify the resulting set with $H^1(X, \mathcal{O}_X)$. (Hint: line bundles are classified by H^1 of the units sheaf, and $1 + \varepsilon\mathcal{O}_X$ is a subgroup of $\mathcal{O}^\times_{X[\varepsilon]}$ isomorphic to the additive group $\mathcal{O}_X$.) Conclude that even though the naive functor $\mathcal{F} = \mathrm{Pic}$ of example 18.5.7 is not representable, the associated relative functor has a well-defined tangent space, a k-vector space, illustrating proposition 18.5.2.

5. Let $\mathcal{F}$ be a Zariski sheaf admitting a cover by two representable open subfunctors $\mathcal{G}_0 \cong h_{X_0}$, $\mathcal{G}_1 \cong h_{X_1}$ with $\mathcal{G}_0 \cap \mathcal{G}_1 \cong h_{X_{01}}$. Write out the scheme X produced by theorem 18.5.6 explicitly when $X_0 = X_1 = \mathbb{A}^1$ and $X_{01} = \mathbb{A}^1 \setminus \{0\} = \mathrm{Spec}\,k[t, t^{-1}]$, for the two gluings $t \mapsto t$ and $t \mapsto t^{-1}$. Identify the two resulting schemes and explain, via the sheaf condition, why one of them fails to be separated.

6. Let $n \geq 2$ be invertible in k and consider the presheaf $\mathcal{F}(S) = \mathcal{O}(S)^\times/(\mathcal{O}(S)^\times)^n$, global units modulo n-th powers. Show that $\mathcal{F}$ fails the fppf sheaf condition already over the single base $S = \mathrm{Spec}\,k$: for a suitable k, exhibit a nontrivial fppf cover $S' \to S$ on which a class becomes trivial though it is nonzero over S. Explain why the Zariski sheaf condition over $\mathrm{Spec}\,k$ imposes no such constraint (a point has no nontrivial Zariski cover), so $\mathcal{F}$ passes the Zariski test at this base while failing the fppf test. Conclude that the fppf half of proposition 18.5.4 is stronger than its Zariski half and rests on descent.

19

The Hilbert and Quot Schemes

The previous chapter reduced a moduli problem to a functor and asked when that functor is representable; the Grassmannian was the model case in which the answer is yes. This chapter produces the two representable functors from which most moduli spaces in algebraic geometry are cut out: the Quot scheme, parametrizing quotients of a fixed coherent sheaf, and its special case the Hilbert scheme, parametrizing closed subschemes of a fixed projective scheme with a fixed Hilbert polynomial. Grothendieck's existence theorem, that these functors are representable by projective schemes, is the foundation on which Hilbert schemes, moduli of sheaves, and the quotient constructions of the next chapter all rest.

Both functors are defined through flat families, and the Hilbert polynomial is locally constant on the base of a flat family. Section 19.1 sets up the Quot and Hilbert functors on this basis. Section 19.2 controls which sheaves can occur, through Castelnuovo-Mumford regularity, boundedness, and the flattening stratification. Section 19.3 assembles these into the representability theorem, realizing Quot and Hilb as closed subschemes of a Grassmannian. Section 19.4 identifies the tangent space to the Hilbert scheme with the global sections of the normal sheaf. This is the first computation of deformation theory, the subject of Part V. Section 19.5 closes with worked schemes: the Hilbert scheme of points, hypersurfaces, and the Grassmannian recovered as a Quot scheme.

19.1 Flat Families and Hilbert Polynomials

Before any Hilbert or Quot scheme can be built, the moduli problem it represents has to be pinned down, and that requires answering a question the first chapter deferred: what, precisely, is a family of subschemes, or of quotient sheaves? A family should be a collection of objects varying *continuously* over a base S, but "continuously" has to be given algebraic content, since over a scheme there is no metric to appeal to. The content is flatness. A family that is flat over S is one whose members do not jump in a way that changes their discrete invariants as the parameter moves, and the discrete

invariant that flatness holds fixed is the Hilbert polynomial.

This section fixes the two notions the whole chapter runs on. It recalls the Hilbert polynomial of a coherent sheaf on projective space, proves that in a flat family the fiberwise Hilbert polynomial is locally constant on the base, and then uses that fact to define the Quot and Hilbert functors, the moduli functors whose representability is the theorem of section 19.3. Flatness is the reason those functors are sheaves in the first place, and the fixed Hilbert polynomial P is the label that carves the boundless functor of all quotients into the bounded, representable pieces $\underline{\mathrm{Quot}}^{P}$ that individual moduli spaces attach to. The chapter's guiding image, a flat family versus a non-flat one in which the Hilbert polynomial jumps, appears at the end of the section and exhibits the flatness condition.

The first of the two notions is the Hilbert polynomial, a single element of $\mathbb{Q}[t]$ that packages the numerical invariants of a coherent sheaf on projective space. Fix once and for all a projective scheme $Y \subseteq \mathbb{P}^n_k$ over the base field k, with $\mathcal{O}_Y(1)$ the restriction of the twisting sheaf $\mathcal{O}_{\mathbb{P}^n}(1)$. For a coherent sheaf $\mathcal{F}$ on Y and an integer m, write $\mathcal{F}(m) = \mathcal{F} \otimes_{\mathcal{O}_Y} \mathcal{O}_Y(m)$ for the m-th Serre twist. The one piece of upstream machinery needed here is that the cohomology of a coherent sheaf on a projective scheme is finite dimensional over k and vanishes in high degree after twisting. This is Serre's finiteness theorem (corollary 6.6.7) together with Serre vanishing (lemma 23.6.12), which the reader may take as given.

The Euler characteristic packages the cohomology of $\mathcal{F}$ into a single integer.

Definition 19.1.1: Hilbert Polynomial of a Coherent Sheaf

Let $Y \subseteq \mathbb{P}^n_k$ be projective and $\mathcal{F}$ a coherent sheaf on Y. Recall the *Euler characteristic*

$$\chi(\mathcal{F}) = \sum_{i \geq 0} (-1)^i \dim_k H^i(Y, \mathcal{F})$$

a finite sum, since $H^i(Y, \mathcal{F}) = 0$ for $i > \dim Y$ and each term is finite dimensional (section 6.7). The *Hilbert polynomial* of $\mathcal{F}$ is the function of the twisting parameter m given by

$$P_{\mathcal{F}}(m) = \chi\big(\mathcal{F}(m)\big)$$

which agrees with a polynomial in m of degree $\dim \mathrm{Supp}\mathcal{F}$ (theorem 6.7.5); for $\mathcal{F} = \mathcal{O}_Y$ it recovers the classical Hilbert polynomial of the homogeneous coordinate ring of Y (proposition 6.7.8).

The name "polynomial" is justified by a theorem of Snapper and Grothendieck: $P_{\mathcal{F}}$ agrees, for all integers m, with a polynomial in m with rational coefficients, of degree equal to $\dim \mathrm{Supp}\mathcal{F}$. This is proved in full in theorem 6.7.5. The argument is an induction on the dimension of the support using a hyperplane section, and it is the reason the Hilbert polynomial is an object of $\mathbb{Q}[t]$. Two features make $P_{\mathcal{F}}$ the right invariant for moduli. First, it is computed from cohomology, so it is a deformation invariant. Second, for $m \gg 0$ the higher cohomology $H^i(Y, \mathcal{F}(m))$ vanishes for $i > 0$, so $P_{\mathcal{F}}(m) = \dim_k H^0(Y, \mathcal{F}(m))$ counts the twisted global sections, and this ties the polynomial to the classical Hilbert function of a graded module. The leading coefficients encode the geometry: for a subscheme the degree of P is the dimension, and the top coefficient is $(\deg Z)/(\dim Z)!$, so it records the degree of the subscheme in $\mathbb{P}^n$ up to the factorial normalization (the two coincide outright when $\dim Z = 1$, as in the plane-curve example below).

Example 19.1.2: The Hilbert Polynomial of a Plane Curve

Let $C \subseteq \mathbb{P}^2_k$ be a curve of degree d, the zero scheme of a single homogeneous polynomial of degree d, and let $\mathcal{O}_C$ be its structure sheaf. The Hilbert polynomial of $\mathcal{O}_C$ is computed from the ideal-sheaf sequence

$$0 \longrightarrow \mathcal{O}_{\mathbb{P}^2}(-d) \longrightarrow \mathcal{O}_{\mathbb{P}^2} \longrightarrow \mathcal{O}_C \longrightarrow 0$$

the ideal sheaf $\mathcal{I}_C = \mathcal{O}_{\mathbb{P}^2}(-d)$ being generated by the degree-d equation. Twisting this exact sequence by $\mathcal{O}(m)$ gives $0 \to \mathcal{O}_{\mathbb{P}^2}(m-d) \to \mathcal{O}_{\mathbb{P}^2}(m) \to \mathcal{O}_C(m) \to 0$, and Euler characteristic is additive on short exact sequences, so

$$\chi(\mathcal{O}_C(m)) = \chi(\mathcal{O}_{\mathbb{P}^2}(m)) - \chi(\mathcal{O}_{\mathbb{P}^2}(m-d))$$

Using $\chi(\mathcal{O}_{\mathbb{P}^2}(m)) = \binom{m+2}{2}$, this gives

$$P_{\mathcal{O}_C}(m) = \binom{m+2}{2} - \binom{m-d+2}{2} = d\,m + \frac{-d^2+3d}{2} = d\,m + 1 - \frac{(d-1)(d-2)}{2}$$

The polynomial has degree 1, recording that C is a curve; its leading coefficient d is the degree of C; and its constant term $1-g$ with $g = \binom{d-1}{2}$ is 1 minus the arithmetic genus, the genus-degree formula read off the Hilbert polynomial. For a conic $d=2$ this reads $P(m) = 2m+1$, and for a cubic $d=3$ it reads $P(m) = 3m$, so that $\chi(\mathcal{O}_C) = P(0)$ equals 1 and 0 respectively, matching $g=0$ and $g=1$.

The example already shows the polynomial doing its job as a bookkeeper: a single element of $\mathbb{Q}[t]$ simultaneously records dimension, degree, and genus. In a moduli problem these are exactly the discrete data one wants held fixed while the geometry deforms, and the next result is what guarantees they *are* held fixed.

With the Hilbert polynomial in hand, the second notion is flatness, and the result binding the two together is that flatness holds the Hilbert polynomial constant along a family. A family of subschemes or sheaves parametrized by S is a single sheaf on $Y \times_k S$, whose restriction to the fiber $Y_s = Y \times_k \kappa(s)$ over a point $s \in S$ is the member of the family sitting over s. For the family to deserve the name, the members should vary continuously, and the algebraic form of continuity is that the sheaf on the total space $Y \times S$ be *flat* over S. Flatness is developed in full in section 6.8, and the following refresher records the one statement this chapter leans on.

Definition 19.1.3: Flat Family over a Base

Let Y be a scheme over k, S a k-scheme, and $p\colon Y \times_k S \to S$ the projection. A coherent sheaf $\mathcal{G}$ on $Y \times_k S$ is a *flat family over* S if $\mathcal{G}$ is flat over S, meaning that for every point of $Y \times_k S$ the stalk $\mathcal{G}_x$ is a flat module over the local ring $\mathcal{O}_{S,p(x)}$. For $s \in S$ the *fiber* of the family is the coherent sheaf

$$\mathcal{G}_s = \mathcal{G} \otimes_{\mathcal{O}_S} \kappa(s)$$

on $Y_s = Y \times_k \kappa(s)$, the restriction of $\mathcal{G}$ to the fiber over s.

Flatness is not visible on any single fiber; it is a condition on how the fibers fit together as s moves. The archetype to keep in mind is that a family of divisors on $\mathbb{P}^1$ is flat exactly when the number of points, counted with multiplicity, is constant, whereas allowing a point to appear or disappear as the parameter passes through a special value destroys flatness. This is the discrete-invariant discipline

flatness enforces, and the following proposition is its precise cohomological expression: the entire Hilbert polynomial, not just one of its coefficients, is locally constant along a flat family.

The proof rests on a single import, the theorem on cohomology and base change, which controls how the cohomology of a family interacts with restriction to a fiber. In the form needed here it says: for a coherent sheaf $\mathcal{G}$ on a scheme proper over a Noetherian S and flat over S, the cohomology of the fibers is computed, locally on S, by a bounded complex of finite locally free $\mathcal{O}_S$-modules, and when the fiber dimension h^i is constant on a reduced S, the ith higher direct image of $\mathcal{G}$ is locally free of that rank and its formation commutes with every base change from a locally Noetherian scheme. These are box 6.8.22 and theorem 6.8.19, whose proof there is an outline that defers to [50, Theorem III.12.11]. The theorem is used in every constancy result in this chapter.

Proposition 19.1.4: Local Constancy of the Hilbert Polynomial

Let $Y \subseteq \mathbb{P}^n_k$ be projective, S a Noetherian k-scheme, and $\mathcal{G}$ a flat family over S of coherent sheaves on Y, that is, a coherent sheaf on $Y \times_k S$ flat over S with proper support over S. For $s \in S$ let $P_s \in \mathbb{Q}[t]$ be the Hilbert polynomial of the fiber $\mathcal{G}_s$ on Y_s, computed with respect to $\mathcal{O}_{Y_s}(1)$. Then the map

$$s \longmapsto P_s$$

is locally constant on S: every point of S has an open neighborhood on which P_s is a fixed polynomial. In particular, if S is connected, the fiberwise Hilbert polynomial is the same for every $s \in S$.

***Proof*:**

The claim is local on S, so it suffices to prove that the function $s \mapsto P_s(m)$ is locally constant on S for each fixed integer m, since a polynomial in $\mathbb{Q}[t]$ of bounded degree is determined by its values at enough integers and the local constancy of each value will then force local constancy of the polynomial. Fix m.

Step 1: Reduce to the vanishing of higher cohomology. Let $p\colon Y \times_k S \to S$ be the projection and $q\colon Y \times_k S \to Y$ the other one, so that $\mathcal{G}(m) := \mathcal{G} \otimes q^*\mathcal{O}_Y(m)$ is the m-twisted family, again flat over S with proper support, and its fiber over s is $\mathcal{G}_s(m)$. By definition

$$P_s(m) = \chi(\mathcal{G}_s(m)) = \sum_{i \geq 0} (-1)^i \dim_{\kappa(s)} H^i(Y_s, \mathcal{G}_s(m))$$

The strategy is to show each individual term $s \mapsto \dim_{\kappa(s)} H^i(Y_s, \mathcal{G}_s(m))$ is locally constant. This is false term by term for arbitrary m, since cohomology can jump on special fibers, but the alternating sum is stable, and the cleanest route to the alternating sum is to twist so hard that all but the zeroth term vanish and then descend.

Step 2: The Euler characteristic is locally constant. By the theorem on cohomology and base change (box 6.8.22) applied to the flat proper family $\mathcal{G}(m)$ over S, there is, locally on S, a bounded complex

$$K^\bullet\colon \quad 0 \to K^0 \to K^1 \to \cdots \to K^N \to 0$$

of finite locally free $\mathcal{O}_S$-modules whose cohomology computes the cohomology of the family universally, in the sense that for every base change $T \to S$ the cohomology of $K^\bullet \otimes_{\mathcal{O}_S} \mathcal{O}_T$ computes $H^\bullet$ of the pulled-back family. Specializing $T = \operatorname{Spec} \kappa(s)$, the complex $K^\bullet \otimes \kappa(s)$ computes $H^\bullet(Y_s, \mathcal{G}_s(m))$. Now the Euler characteristic of a bounded complex of finite-dimensional

vector spaces equals the Euler characteristic of its cohomology, so

$$\sum_i (-1)^i \dim_{\kappa(s)} H^i(Y_s, \mathcal{G}_s(m)) = \sum_i (-1)^i \dim_{\kappa(s)} \left(K^i \otimes \kappa(s)\right)$$

Each K^i is locally free of some rank r_i over $\mathcal{O}_S$, so $\dim_{\kappa(s)}(K^i \otimes \kappa(s)) = r_i$ is constant on the open where $K^\bullet$ is defined and K^i has that rank. Hence

$$P_s(m) = \sum_i (-1)^i r_i$$

is constant on that open neighborhood of the chosen point. This is where flatness enters: without it the base-change complex $K^\bullet$ of finite locally free modules need not exist, and the Euler characteristic could jump.

Step 3: From one twist to the polynomial. Step 2 gives local constancy of $s \mapsto P_s(m)$ for the fixed m. Running the argument for every m shows that each coefficient of the polynomial, being a fixed $\mathbb{Q}$-linear combination of finitely many values $P_s(m)$, is locally constant, so the polynomial P_s itself is locally constant on S. On a connected S a locally constant function is constant, giving the final assertion, as we sought to show.

The proposition is the technical fact that makes the Hilbert polynomial a usable moduli label. It says that flatness and the Hilbert polynomial are two sides of one coin: a flat family cannot change its members' Hilbert polynomials, and conversely the Hilbert polynomial is exactly the invariant whose constancy flatness certifies. This is why the moduli functors below are indexed by a fixed polynomial P. Over a connected base every member of a flat family carries the same P, so requiring a fixed P is the same as asking for the connected component of the space of all flat families, and it is on such a component that a moduli space has any hope of being of finite type. The converse direction, that a family with locally constant Hilbert polynomial over a reduced base is automatically flat, is a standard criterion ([9]), and it will be used silently when verifying flatness of explicit families.

With flatness and the Hilbert polynomial in hand, the moduli problems this chapter solves can be written down. The primary one classifies quotient sheaves of a fixed coherent sheaf. Fix a coherent sheaf $\mathcal{F}$ on the projective scheme Y; think of $\mathcal{F}$ as an ambient sheaf whose quotients are to be parametrized. A family of quotients over a base S is a quotient of the pullback of $\mathcal{F}$ to $Y \times S$, and the family is admissible when it is flat over S, so that its Hilbert polynomial is constant, and when that polynomial is a prescribed P.

For a k-scheme S write $Y_S = Y \times_k S$, with projection $p_S \colon Y_S \to Y$, and $\mathcal{F}_S = p_S^*\mathcal{F}$ for the pullback of $\mathcal{F}$ to Y_S. A morphism $g \colon T \to S$ induces $\mathrm{id}_Y \times g \colon Y_T \to Y_S$, and pulling back along it carries data over Y_S to data over Y_T; this is the mechanism of contravariance.

Definition 19.1.5: The Quot Functor

Let $Y \subseteq \mathbb{P}^n_k$ be projective, $\mathcal{F}$ a coherent sheaf on Y, and $P \in \mathbb{Q}[t]$ a polynomial. The *Quot functor*

$$\underline{\mathrm{Quot}}^{P}_{\mathcal{F}/Y} \colon \mathbf{Sch}_k^{\mathrm{op}} \longrightarrow \mathbf{Set}$$

assigns to a k-scheme S the set of isomorphism classes of surjections of coherent sheaves on $Y_S = Y \times_k S$

$$\mathcal{F}_S \twoheadrightarrow \mathcal{Q}$$

such that $\mathcal{Q}$ is flat over S and each fiber $\mathcal{Q}_s$ has Hilbert polynomial P on Y_s. Two quotients $\mathcal{F}_S \twoheadrightarrow \mathcal{Q}$ and $\mathcal{F}_S \twoheadrightarrow \mathcal{Q}'$ are identified when there is an isomorphism $\mathcal{Q} \cong \mathcal{Q}'$ commuting with the surjections from $\mathcal{F}_S$, that is, having the same kernel subsheaf of $\mathcal{F}_S$. To a morphism $g \colon T \to S$ the functor assigns the pullback

$$g^* \colon \underline{\mathrm{Quot}}^{P}_{\mathcal{F}/Y}(S) \longrightarrow \underline{\mathrm{Quot}}^{P}_{\mathcal{F}/Y}(T), \qquad \big(\mathcal{F}_S \twoheadrightarrow \mathcal{Q}\big) \longmapsto \big(\mathcal{F}_T \twoheadrightarrow (\mathrm{id}_Y \times g)^* \mathcal{Q}\big)$$

the surjection obtained by pulling $\mathcal{F}_S \twoheadrightarrow \mathcal{Q}$ back along $\mathrm{id}_Y \times g$.

Two points make this a well-posed moduli functor. First, pullback preserves the defining conditions: pulling back a surjection along $\mathrm{id}_Y \times g$ keeps it surjective, because $\otimes$ is right exact, and it preserves flatness over the base and hence the fiberwise Hilbert polynomial, since the fibers of the pulled-back family over points of T are the fibers of the original family over their images in S (proposition 19.1.4 guarantees the polynomial is the same P). So g^* lands in $\underline{\mathrm{Quot}}^{P}_{\mathcal{F}/Y}(T)$, and functoriality $(g \circ h)^* = h^* \circ g^*$ is the standard compatibility of pullbacks. Second, quotients are recorded up to the coarsest sensible equivalence: identifying $\mathcal{F}_S \twoheadrightarrow \mathcal{Q}$ with its isomorphic siblings is the same as recording only the kernel subsheaf $\mathcal{K} = \ker(\mathcal{F}_S \to \mathcal{Q}) \subseteq \mathcal{F}_S$, so a $\underline{\mathrm{Quot}}$-point is equally a flat family of *subsheaves* of $\mathcal{F}$ with the complementary Hilbert polynomial. The functor thus captures both quotients and sub-objects at once, which is why it subsumes so many moduli problems.

The single most important special case is the one where $\mathcal{F}$ is the structure sheaf of Y. A surjection $\mathcal{O}_{Y_S} \twoheadrightarrow \mathcal{Q}$ has for its kernel an ideal sheaf, so its quotient is the structure sheaf of a closed subscheme of Y_S; flatness over S makes this a flat family of closed subschemes. This is the moduli problem of closed subschemes with which the first chapter opened, now made precise.

Definition 19.1.6: The Hilbert Functor

Let $Y \subseteq \mathbb{P}^n_k$ be projective and $P \in \mathbb{Q}[t]$. The *Hilbert functor*

$$\underline{\mathrm{Hilb}}^P_Y : \mathbf{Sch}^{\mathrm{op}}_k \longrightarrow \mathbf{Set}$$

is the special case $\mathcal{F} = \mathcal{O}_Y$ of the Quot functor. It assigns to a k-scheme S the set of closed subschemes $Z \subseteq Y_S = Y \times_k S$ that are flat over S and whose fibers $Z_s \subseteq Y_s$ have Hilbert polynomial P; equivalently, the set of surjections $\mathcal{O}_{Y_S} \twoheadrightarrow \mathcal{O}_Z$ that are flat over S with fiberwise Hilbert polynomial P. To $g\colon T \to S$ it assigns the pullback

$$Z \longmapsto (\mathrm{id}_Y \times g)^{-1}(Z) = Z \times_S T$$

the scheme-theoretic preimage, which is the closed subscheme of Y_T cut out by the pulled-back ideal sheaf.

The Hilbert functor is the moduli of closed subschemes of Y with fixed numerical type P: dimension, degree, and, for curves, genus, all read off P as in example 19.1.2. A $\underline{\mathrm{Hilb}}^P_Y$-point over S is a subscheme $Z \subseteq Y \times S$ whose fiber over each $s \in S$ is a subscheme of Y with the prescribed invariants, varying flatly with s. When $S = \operatorname{Spec} k$ this is a single closed subscheme $Z \subseteq Y$ with Hilbert polynomial P, so the k-points of the eventual Hilbert scheme are exactly the subschemes one wants to parametrize; the content of the next sections is that these k-points assemble into an actual projective scheme, with the flat families over general S recorded as its S-points. That this functor decomposes the "all subschemes" functor by discrete type is the reason a fixed P is imposed: the functor of all closed subschemes of Y, flat over the base, is the disjoint union $\coprod_P \underline{\mathrm{Hilb}}^P_Y$ over all Hilbert polynomials, and each piece is representable while the whole is only a countable coproduct.

Example 19.1.7: The Hilbert Functor of Points on the Line

Take $Y = \mathbb{P}^1_k$ and the constant polynomial $P = d$, a positive integer. A subscheme $Z \subseteq \mathbb{P}^1$ with Hilbert polynomial the constant d is a zero-dimensional subscheme of length d: since P has degree 0, $\dim Z = 0$, and $\chi(\mathcal{O}_Z(m)) = \dim_k H^0(Z, \mathcal{O}_Z) = d$ for all m because Z is affine, so Z is d points counted with multiplicity. Over S, a $\underline{\mathrm{Hilb}}^d_{\mathbb{P}^1}$-point is a closed subscheme $Z \subseteq \mathbb{P}^1 \times S$, flat over S, whose every fiber is length d. Working in the affine chart $\mathbb{A}^1 = \operatorname{Spec} k[x]$, such a Z over an affine base $S = \operatorname{Spec} A$ is cut out by a single monic polynomial

$$f(x) = x^d + a_{d-1}x^{d-1} + \cdots + a_1 x + a_0 \in A[x]$$

with $a_i \in A$, since flatness of $A[x]/(f)$ over A forces the generator to be monic of degree d so that $A[x]/(f)$ is free of rank d over A. The coefficients $(a_0, \ldots, a_{d-1})$ are d free parameters, so on this chart the functor is represented by affine space $\mathbb{A}^d = \operatorname{Spec} k[a_0, \ldots, a_{d-1}]$: the Hilbert scheme of d points on the line is $\mathbb{A}^d$ over the affine chart, the space of monic degree-d polynomials, and globally $\mathrm{Hilb}^d_{\mathbb{P}^1} \cong \mathbb{P}^d$, the space of binary forms of degree d up to scalar. A fiber over S jumps from d distinct points to a fat point exactly as the discriminant of f vanishes, and flatness is what keeps the length pinned at d throughout.

The example exhibits the entire program in miniature: a moduli functor of flat families with fixed Hilbert polynomial turns out to be represented by an explicit scheme, here $\mathbb{P}^d$, whose points are the objects being classified. The general theorem of section 19.3 promotes this from $\mathbb{P}^1$ and points to arbitrary Y and arbitrary P, and the intervening section 19.2 gives the boundedness that makes

the Grassmannian into which everything embeds finite dimensional. For the broader role of Hilbert schemes in moduli theory, see section 3.3.6.

The abstractions above are worth grounding in a case where flatness visibly succeeds and fails, so that the reader can see the Hilbert polynomial jump. The cleanest such case is a plane cubic acquiring an extra embedded point as a parameter degenerates.

Example 19.1.8: A Non-Flat Degeneration

Work over $S = \mathbb{A}^1_k = \operatorname{Spec} k[t]$ and inside $Y = \mathbb{P}^2_k$ with homogeneous coordinates $[x_0 : x_1 : x_2]$; pass to the affine chart $\mathbb{A}^2 = \operatorname{Spec} k[x, y]$ with $x = x_1/x_0$, $y = x_2/x_0$ to do the algebra. Consider the family of subschemes $Z_t \subseteq \mathbb{A}^2$ defined, for $t \in \mathbb{A}^1$, by the ideal

$$I_t = (xy,\ tx)$$

of $k[x, y]$. The total space is $Z \subseteq \mathbb{A}^2 \times \mathbb{A}^1 = \operatorname{Spec} k[x, y, t]$ cut out by $I = (xy, tx) \subseteq k[x, y, t]$, and the family is the projection to $S = \operatorname{Spec} k[t]$.

The general fiber. For $t \neq 0$ the element tx is a unit multiple of x, so $I_t = (xy, x) = (x)$, and $Z_t = \{x = 0\}$ is the line $x = 0$, a copy of $\mathbb{A}^1$ with coordinate y. Compactifying in $\mathbb{P}^2$, the closure is a line, with Hilbert polynomial $P_t(m) = m + 1$: degree 1, dimension 1, and $\chi(\mathcal{O}_{Z_t}) = 1$.

The special fiber. For $t = 0$ the ideal is $I_0 = (xy)$, so $Z_0 = \{xy = 0\}$ is the union of the two coordinate lines $x = 0$ and $y = 0$, the degree-2 plane curve cut out by the single degree-2 form xy. By example 19.1.2 with $d = 2$ its Hilbert polynomial on the projective closure is $P_0(m) = 2m + 1$: degree 2, dimension 1, and $\chi(\mathcal{O}_{Z_0}) = P_0(0) = 1$, so arithmetic genus $p_a = 1 - \chi = 0$. The Hilbert polynomial has jumped from $m + 1$ to the degree-2 polynomial $2m + 1$.

By proposition 19.1.4 the family $Z \to S$ cannot be flat, since $\mathbb{A}^1$ is connected yet the fiberwise Hilbert polynomial is not constant. The failure is visible in the algebra: in $k[x, y, t]$ the element x is annihilated modulo I by both y and t, so $\operatorname{Ann}(x) = (y, t) \bmod I$. Since $I = (xy, tx) = (x) \cap (y, t)$, the associated primes of $k[x, y, t]/I$ are (x) and (y, t), and the second one, (y, t), cuts out the horizontal line $\{y = 0, t = 0\}$ whose image in S is the single point $t = 0$. A component of the total space maps to a proper closed subset of the base, which is precisely the obstruction to flatness: the fiber over $t = 0$ acquires the extra line $y = 0$ that no nearby fiber sees. Concretely, the length of $\mathcal{O}_Z$ localized along $\{t = 0\}$ is not the flat limit of the nearby fibers; a whole extra line materializes at $t = 0$, and the Euler characteristic records it.

The flat repair. The flat limit of the lines $\{x = 0\}$ as $t \to 0$ is just the line $\{x = 0\}$ again: the flat family extending $Z_t = \{x = 0\}$ for $t \neq 0$ over the whole base is the constant family $\{x = 0\} \times \mathbb{A}^1$, cut out by the flat ideal $(x) \subseteq k[x, y, t]$. This constant family has $P_t(m) = m + 1$ for every t, in accordance with proposition 19.1.4, and it is the unique flat family agreeing with Z_t away from $t = 0$. The non-flat Z above differs from it only in the embedded jump at the origin, and the flat limit systematically discards exactly such jumps. This is the sense in which flatness selects the geometrically correct limit: it forbids the fiber from gaining or losing pieces as the parameter specializes.

The two families in the example are the picture to carry through the chapter. A flat family is one whose Hilbert polynomial is a constant of the motion; a non-flat family is one in which the polynomial jumps at special parameters, and the flat families are recovered by taking flat limits that suppress the jumps. The Hilbert and Quot functors are built from flat families precisely so that each of their S-points has a well-defined, constant Hilbert polynomial, and the fixed P in $\underline{\mathrm{Hilb}}^P_Y$ and $\underline{\mathrm{Quot}}^P_{\mathcal{F}/Y}$

is the value of that constant. The task of the rest of the chapter is to show that these functors, so constrained, are representable, and the first step is to prove that the flat families with a given P form a *bounded* collection, which is the subject of section 19.2.

Exercise 19.1.1

1. Let $S \subseteq \mathbb{P}^3_k$ be a smooth surface of degree d, the zero scheme of one homogeneous polynomial of degree d. Using the ideal-sheaf sequence $0 \to \mathcal{O}_{\mathbb{P}^3}(-d) \to \mathcal{O}_{\mathbb{P}^3} \to \mathcal{O}_S \to 0$ and the values $\chi(\mathcal{O}_{\mathbb{P}^3}(m)) = \binom{m+3}{3}$, compute the Hilbert polynomial $P_{\mathcal{O}_S}(m)$. Read off from it the dimension and the degree of S, and evaluate $P_{\mathcal{O}_S}(0) = \chi(\mathcal{O}_S)$ for $d = 4$ (a quartic K3 surface), confirming that $\chi(\mathcal{O}_S) = 2$.

2. Consider the family over $S = \operatorname{Spec} k[t]$ given in $\mathbb{A}^2 = \operatorname{Spec} k[x, y]$ by the ideal $I_t = (y - tx^2)$ as t varies, a family of parabolas degenerating to the line $y = 0$. Show that the total-space ideal $(y - tx^2) \subseteq k[x, y, t]$ presents a family that *is* flat over $\operatorname{Spec} k[t]$, by exhibiting $k[x, y, t]/(y - tx^2)$ as a free $k[t]$-module, and confirm that every fiber is a copy of $\mathbb{A}^1$ over its residue field. Contrast this with example 19.1.8: why does this affine degeneration stay flat while that one does not? (Caution: taking the projective closure of each affine fiber separately does *not* give a flat family, since the smooth conic $\{yz = tx^2\}$ for $t \neq 0$ acquires an embedded point at infinity in its flat limit; the flatness here is a statement about the affine total space over $\operatorname{Spec} k[t]$.)

3. Let $\mathcal{G}$ be a flat family over a connected base S with fiberwise Hilbert polynomial P. Suppose $\deg P = 0$, so P is a constant d. Prove that every fiber $\mathcal{G}_s$ is a zero-dimensional sheaf of length d, and deduce that the function $s \mapsto \dim_{\kappa(s)} H^0(Y_s, \mathcal{G}_s)$ is constant equal to d (you may use that for a zero-dimensional sheaf all higher cohomology vanishes). Where in the argument is flatness used?

4. Fix $Y = \operatorname{Spec} k$ (the case $Y = \mathbb{P}^0_k$, a single point) and $\mathcal{F} = \mathcal{O}_Y^{\oplus r} = k^{\oplus r}$. Describe the S-points of $\underline{\mathrm{Quot}}^P_{\mathcal{F}/Y}$ for $S = \operatorname{Spec} k$ in the case P is the constant $r' \leq r$. On a point every coherent sheaf is locally free, so Hilbert polynomial r' means a rank-r' quotient. Show that such a $\operatorname{Spec} k$-point is exactly a rank-r' quotient of $k^{\oplus r}$, and explain in one sentence how this recovers the Grassmannian $\mathrm{Gr}(r', r)$ of section 18.2 as $\underline{\mathrm{Quot}}$ over the point. (The full identification, including the passage from a point to $Y = \mathbb{P}^n$ where the analogous locally free quotients of $\mathcal{O}_{\mathbb{P}^n}^{\oplus r}$ have Hilbert polynomial $r'\binom{m+n}{n}$, is example 19.5.4.)

5. Prove that the Quot functor is a functor, that is, verify the two claims left implicit in definition 19.1.5: that pulling a surjection $\mathcal{F}_S \twoheadrightarrow \mathcal{Q}$ back along $\mathrm{id}_Y \times g$ for $g\colon T \to S$ yields a surjection with $\mathcal{Q}$-pullback flat over T and fiberwise Hilbert polynomial still P; and that $(g \circ h)^* = h^* \circ g^*$. You may cite proposition 19.1.4 for the Hilbert-polynomial claim and the right-exactness of $\otimes$ for surjectivity.

6. Let $Y = \mathbb{P}^1_k$ and $P = d$ as in example 19.1.7. Give the flat family over $S = \mathbb{A}^1 = \operatorname{Spec} k[t]$ whose fiber over $t \neq 0$ is the d reduced points $\{0, 1, 2, \ldots, d-1\}$ scaled by t, namely $\{0, t, 2t, \ldots, (d-1)t\}$, and whose fiber over $t = 0$ is a single fat point of length d at the origin. Write the monic polynomial $f_t(x) \in k[t][x]$ cutting it out, verify flatness, and identify the limiting ideal at $t = 0$ as (x^d).

19.2 Boundedness and the Flattening Stratification

The Quot and Hilbert functors of section 19.1 package an entire universe of coherent quotients into a single functor of points, and the whole point of the chapter is to show that this functor is representable by a scheme. Representability by a scheme is a finiteness statement: a scheme locally of finite type is cut out, chart by chart, from affine space by finitely many equations, so its functor of points cannot see more than a bounded amount of data at once. The Quot functor, by contrast, is defined with no a priori bound at all. It ranges over *every* coherent quotient of $\mathcal{F}$ with a fixed Hilbert polynomial P, across every base scheme S, and nothing in the definition shows that these quotients form anything like a set of bounded complexity. Before a construction can even begin, this must be brought under control.

The controlling principle is *boundedness*: the sheaves that can occur as fibers of a flat family with Hilbert polynomial P do not form an unlimited zoo, but a family that a single finite-dimensional object can capture. Concretely, all of them become generated by their global sections, with vanishing higher cohomology, after twisting by one and the same power $\mathcal{O}(m)$ of the hyperplane bundle, once m is large enough (depending only on P). Fixing such an m replaces each quotient by a linear-algebra datum, a quotient of the fixed vector space $H^0(\mathcal{F}(m))$, and this is exactly the datum a Grassmannian parametrizes. Boundedness is what lets a single Grassmannian catch every quotient with a given Hilbert polynomial simultaneously; this section proves it. The measure of "large enough" is Castelnuovo-Mumford regularity, developed first, and the same circle of ideas produces Grothendieck's flattening stratification, the tool that later carves the locus of flat quotients out of the Grassmannian as a locally closed subscheme.

Throughout, $\mathbb{P}^n = \mathbb{P}^n_k$ over a fixed base field k, and $\mathcal{O}(1)$ is the twisting sheaf. For a coherent sheaf $\mathcal{F}$ on $\mathbb{P}^n$ and $m \in \mathbb{Z}$ write $\mathcal{F}(m) = \mathcal{F} \otimes \mathcal{O}(m)$, and $H^i(\mathcal{F}) = H^i(\mathbb{P}^n, \mathcal{F})$ with $h^i(\mathcal{F}) = \dim_k H^i(\mathcal{F})$.

Regularity, the numerical invariant that measures "large enough", is where the section begins. Mumford isolated a single number of a coherent sheaf that simultaneously controls global generation, the vanishing of higher cohomology, and the surjectivity of multiplication maps on global sections. The definition looks asymmetric, tracking $H^i(\mathcal{F}(m-i))$ with the twist shifted down by the cohomological degree, but this shift is precisely what makes regularity propagate upward: if a sheaf is m-regular, it is m'-regular for every $m' \geq m$, so regularity has a well-defined threshold. That threshold is the numerical handle boundedness needs.

Definition 19.2.1: Castelnuovo-Mumford Regularity

Let $\mathcal{F}$ be a coherent sheaf on $\mathbb{P}^n_k$ and let $m \in \mathbb{Z}$. The sheaf $\mathcal{F}$ is *m-regular* (in the sense of Castelnuovo and Mumford) if

$$H^i\big(\mathbb{P}^n, \mathcal{F}(m-i)\big) = 0 \qquad \text{for all } i \geq 1$$

The *Castelnuovo-Mumford regularity* of $\mathcal{F}$ is

$$\operatorname{reg}(\mathcal{F}) = \min\{\, m \in \mathbb{Z} \,\big|\, \mathcal{F} \text{ is } m\text{-regular} \,\}$$

when the set on the right is nonempty and bounded below, and $\operatorname{reg}(\mathcal{F}) = -\infty$ if $\mathcal{F}$ is m-regular for all m (that is, if $\mathcal{F}$ has finite length).

The single index i runs over $1, 2, \ldots, n$ because H^i of a coherent sheaf on $\mathbb{P}^n$ vanishes for $i > n$. Thus

m-regularity is a finite list of cohomological vanishings: $H^1(\mathcal{F}(m-1)) = 0$, $H^2(\mathcal{F}(m-2)) = 0$, and so on down to $H^n(\mathcal{F}(m-n)) = 0$. The definition asks each higher cohomology group to vanish after a twist that increases with the cohomological degree, and it is this staircase of twists that makes the regularity threshold well behaved. The following theorem records the three properties that make regularity the right invariant; it is the technical engine of the section.

Theorem 19.2.2: Mumford's Regularity Theorem

Let $\mathcal{F}$ be an m-regular coherent sheaf on $\mathbb{P}^n_k$. Then for every $\ell \geq 0$:

1. $\mathcal{F}$ is $(m+\ell)$-regular; in particular $H^i(\mathcal{F}(m+\ell-i)) = 0$ for all $i \geq 1$, and $H^i(\mathcal{F}(j)) = 0$ for all $i \geq 1$ and all $j \geq m-i$.
2. The twisted sheaf $\mathcal{F}(m+\ell)$ is generated by its global sections.
3. The multiplication map
$$H^0(\mathbb{P}^n, \mathcal{F}(m+\ell)) \otimes_k H^0(\mathbb{P}^n, \mathcal{O}(1)) \longrightarrow H^0(\mathbb{P}^n, \mathcal{F}(m+\ell+1))$$
is surjective.

***Proof*:**
The argument is an induction on $n = \dim \mathbb{P}^n$ using a general hyperplane, and the three statements are proved together because part (1) for $\mathbb{P}^{n-1}$ feeds parts (2) and (3) for $\mathbb{P}^n$. Assume first that the base field k is infinite; the general case is recovered at the end by a base extension that does not change any of the cohomology groups involved.

Step 1: Restriction to a hyperplane preserves regularity. Choose a hyperplane $H \subseteq \mathbb{P}^n$ whose defining section $s \in H^0(\mathcal{O}(1))$ is a non-zerodivisor on $\mathcal{F}$, meaning that the multiplication map $\mathcal{F}(-1) \xrightarrow{\cdot s} \mathcal{F}$ is injective. Such an H exists because k is infinite: the associated points of $\mathcal{F}$ are finite in number, and a general hyperplane avoids all of them, so s does not lie in any associated prime and multiplication by s has zero kernel. Let $\mathcal{F}_H = \mathcal{F}|_H = \mathcal{F} \otimes \mathcal{O}_H$ be the restriction, a coherent sheaf on $H \cong \mathbb{P}^{n-1}$. The short exact sequence

$$0 \longrightarrow \mathcal{F}(-1) \xrightarrow{\cdot s} \mathcal{F} \longrightarrow \mathcal{F}_H \longrightarrow 0 \tag{19.1}$$

twisted by $\mathcal{O}(m-i)$ gives the long exact cohomology sequence

$$H^i(\mathcal{F}(m-i)) \longrightarrow H^i(\mathcal{F}_H(m-i)) \longrightarrow H^{i+1}(\mathcal{F}(m-1-i))$$

For $i \geq 1$ the left group vanishes because $\mathcal{F}$ is m-regular, and the right group is $H^{i+1}(\mathcal{F}(m-(i+1)))$, which also vanishes because $\mathcal{F}$ is m-regular (the twist $m-1-i$ is exactly the one that m-regularity kills in degree $i+1$). Hence $H^i(\mathcal{F}_H(m-i)) = 0$ for all $i \geq 1$, so $\mathcal{F}_H$ is m-regular as a sheaf on $\mathbb{P}^{n-1}$.

Step 2: The vanishing $H^i(\mathcal{F}(m+\ell-i)) = 0$ for $\ell \geq 0$. Induct on n. When $n = 0$ every higher cohomology group vanishes trivially and there is nothing to prove. For $n \geq 1$, by Step 1 and the inductive hypothesis applied to $\mathcal{F}_H$ on $\mathbb{P}^{n-1}$, the sheaf $\mathcal{F}_H$ satisfies $H^i(\mathcal{F}_H(m+\ell-i)) = 0$ for all $i \geq 1$ and all $\ell \geq 0$. Twist (19.1) by $\mathcal{O}(m+\ell-i)$ and read off the piece

$$H^i(\mathcal{F}_H(m+\ell-i)) \longrightarrow H^{i+1}(\mathcal{F}(m+\ell-1-i)) \xrightarrow{\cdot s} H^{i+1}(\mathcal{F}(m+\ell-i))$$

Fix $i \geq 1$. The first group vanishes by the case just established for $\mathcal{F}_H$, so the multiplication map $\cdot s$ on $H^{i+1}(\mathcal{F}(m+\ell-1-i))$ is injective for every $\ell \geq 0$; equivalently, writing $j = m+\ell-1-i$, multiplication by s is injective on $H^{i+1}(\mathcal{F}(j))$ for all $j \geq m-1-i$. By Serre vanishing $H^{i+1}(\mathcal{F}(j)) = 0$ for $j \gg 0$. An injective endomorphism-up-to-twist of a sequence of groups that eventually vanishes forces the whole sequence to vanish: if $\cdot s\colon H^{i+1}(\mathcal{F}(j)) \hookrightarrow H^{i+1}(\mathcal{F}(j+1))$ is injective for all $j \geq m-1-i$ and the target vanishes for j large, then reading the injections backward, each $H^{i+1}(\mathcal{F}(j))$ injects into a vanishing group and so is itself zero. Reindexing by $i' = i+1 \geq 2$ and $j = m+\ell-i'$ gives $H^{i'}(\mathcal{F}(m+\ell-i')) = 0$ for all $i' \geq 2$ and $\ell \geq 0$. The remaining case $i' = 1$ is the vanishing $H^1(\mathcal{F}(m+\ell-1)) = 0$, and it is proved by a separate induction on ℓ that avoids any appeal to Step 3. The base case $\ell = 0$ is the vanishing $H^1(\mathcal{F}(m-1)) = 0$, which is part of the hypothesis that $\mathcal{F}$ is m-regular. For the inductive step, fix $\ell \geq 1$ and twist (19.1) by $\mathcal{O}(m+\ell-1)$, giving in cohomology the piece

$$H^1(\mathcal{F}(m+\ell-2)) \longrightarrow H^1(\mathcal{F}(m+\ell-1)) \longrightarrow H^1(\mathcal{F}_H(m+\ell-1))$$

The left group is $H^1(\mathcal{F}(m+(\ell-1)-1)) = 0$ by the inductive hypothesis on ℓ. The right group is $H^1(\mathcal{F}_H((m+\ell)-1)) = 0$: by Step 1 the sheaf $\mathcal{F}_H$ is m-regular on $\mathbb{P}^{n-1}$, so by the inductive hypothesis on n it is $(m+\ell)$-regular, and its degree-1 vanishing at level $m+\ell$ is exactly this group. Squeezed between two vanishing groups, $H^1(\mathcal{F}(m+\ell-1)) = 0$, closing the induction on ℓ. This uses only the vanishing of H^1 for $\mathcal{F}_H$ and for $\mathcal{F}$ at the previous level, and in particular no surjectivity of a multiplication map. Combining, $\mathcal{F}$ is $(m+\ell)$-regular for every $\ell \geq 0$, which is part (1); the auxiliary form $H^i(\mathcal{F}(j)) = 0$ for $j \geq m-i$ is the same statement reindexed.

Step 3: Surjectivity of multiplication, part (3). The claim is that

$$\mu_\ell\colon H^0(\mathcal{F}(m+\ell)) \otimes H^0(\mathcal{O}(1)) \longrightarrow H^0(\mathcal{F}(m+\ell+1))$$

is surjective for all $\ell \geq 0$. Restricting to the hyperplane H gives a commutative diagram whose rows come from (19.1). Consider

$$0 \to H^0(\mathcal{F}(m+\ell)) \to H^0(\mathcal{F}(m+\ell+1)) \to H^0(\mathcal{F}_H(m+\ell+1)) \to 0$$

which is exact on the right because $H^1(\mathcal{F}(m+\ell)) = 0$ by part (1). Pick $t \in H^0(\mathcal{F}(m+\ell+1))$. Its restriction $t|_H \in H^0(\mathcal{F}_H(m+\ell+1))$ lies in the image of the multiplication map for $\mathcal{F}_H$, which is surjective by the inductive hypothesis on $\mathbb{P}^{n-1}$ applied to the m-regular sheaf $\mathcal{F}_H$. So $t|_H = \sum_a \bar{u}_a \cdot \bar{v}_a$ with $\bar{u}_a \in H^0(\mathcal{F}_H(m+\ell))$ and $\bar{v}_a \in H^0(\mathcal{O}_H(1))$. Lift each $\bar{u}_a$ to $u_a \in H^0(\mathcal{F}(m+\ell))$ (possible since $H^0(\mathcal{F}(m+\ell)) \to H^0(\mathcal{F}_H(m+\ell))$ is surjective, again because $H^1(\mathcal{F}(m+\ell-1)) = 0$) and each $\bar{v}_a$ to $v_a \in H^0(\mathcal{O}(1))$. Then $t - \sum_a u_a v_a$ restricts to 0 on H, so it is divisible by s: it equals $s \cdot t'$ for a unique $t' \in H^0(\mathcal{F}(m+\ell))$, using the exactness of (19.1) on global sections. Writing $s = \bar{s} \in H^0(\mathcal{O}(1))$, we obtain $t = \sum_a u_a v_a + t' \cdot s$, which exhibits t in the image of μ_ℓ. The base case $n = 0$ is trivial: on a point $\mathcal{F}(m+\ell)$ and $\mathcal{F}(m+\ell+1)$ are the same finite-dimensional vector space, while $H^0(\mathcal{O}(1)) \cong k$ is one-dimensional and its nonzero elements act invertibly, so the multiplication map is surjective.

Step 4: Global generation, part (2). Fix $\ell \geq 0$. By part (3) applied repeatedly, the graded module $\bigoplus_{p \geq 0} H^0(\mathcal{F}(m+\ell+p))$ is generated in degree 0 over the homogeneous coordinate ring $\bigoplus_{p \geq 0} H^0(\mathcal{O}(p))$. Global generation of $\mathcal{F}(m+\ell)$ is a statement about stalks at closed points, and it follows once the evaluation map $H^0(\mathcal{F}(m+\ell)) \otimes \mathcal{O} \to \mathcal{F}(m+\ell)$ is surjective. This surjectivity is local, and at a closed point x the module $\bigoplus_p H^0(\mathcal{F}(m+\ell+p))$ being generated in degree 0 means precisely that sections of $\mathcal{F}(m+\ell)$ generate the stalk after inverting a linear

form nonvanishing at x; since such a linear form is a unit at x, the sections already generate $\mathcal{F}(m+\ell)_x$ over $\mathcal{O}_x$ by Nakayama. Hence $\mathcal{F}(m+\ell)$ is globally generated.

Finally, for a base field k that is not infinite, pass to the algebraic closure $\bar{k}$. Cohomology of $\mathcal{F}$ commutes with the flat base change $\mathbb{P}^n_{\bar{k}} \to \mathbb{P}^n_k$, so $\mathcal{F}_{\bar{k}}$ is m-regular, the three conclusions hold for $\mathcal{F}_{\bar{k}}$, and each descends because the maps in (2) and (3) are defined over k and become surjective after a faithfully flat extension, hence were surjective already. This establishes all three parts, completing the proof.

The theorem says that a single number, the regularity, dominates the entire positive-twist behavior of $\mathcal{F}$: past the threshold every higher cohomology group is dead, every twist is globally generated, and the graded module of sections is generated in the lowest surviving degree. The asymmetry in the definition (twisting H^i by $m-i$) is what powers part (1), the propagation upward, and part (1) is what makes "m-regular for $m \gg 0$" a meaningful uniform statement across a family: to bound a whole family it suffices to bound its regularity by a single integer. That is the bridge to boundedness.

A first concrete instance shows the invariant is computable and grounds the definition immediately.

Example 19.2.3: The Regularity of the Ideal Sheaf of a Point

Let $Z = \{x\} \subseteq \mathbb{P}^n$ be a single reduced closed point, with ideal sheaf $\mathcal{I}_Z$ and structure sheaf $\mathcal{O}_Z = k(x)$, a skyscraper. The defining sequence is
