Let L/K be a finite field extension, $\mathfrak{p} \subseteq \mathcal{O}_K$ a prime ideal and $\mathfrak{B} \subseteq \mathcal{O}_L$ lying over $\mathfrak{p}$. Let $\mathfrak{B}_Z = \mathfrak{B} \cap L_D$ be the prime ideal of L_D below $\mathfrak{B}$. If $\mathfrak{B}$ has inertia degree f and ramification index e, then:

1. $\mathfrak{B}_Z$ is nonsplit in L, that is $\mathfrak{B}$ is the only prime ideal of L above $\mathfrak{B}_D$
2. $\mathfrak{B}$ over L_D has a ramification index e and inertia index f
3. The ramification index and inertia index of $\mathfrak{B}_D$ over K are both 1

Visually, we have:

$$\begin{array}{c} \mathfrak{B}^e J \\ {\scriptstyle e}\uparrow{\scriptstyle f} \\ \mathfrak{B}_D I \\ {\scriptstyle 1}\uparrow{\scriptstyle 1} \\ \mathfrak{p} \end{array}$$

where I and J are the remainder of the factorization. Note that the factorization of each prime factor of J lying above $\mathfrak{p}$ has the same e and f since L/K is Galois, but L_D/K is not necessarily Galois, and so the factorization of I may be quite different (for ex. another prime $\mathfrak{B}'_D$ in L_D lying ove $\mathfrak{B}$ may have ramification and inertia degree)

***Proof*:**

1. Notice that $\mathrm{Gal}_{L_\mathfrak{B}}(L) = D_\mathfrak{B}$: the automorphisms of L that fix $L_\mathfrak{B}$ are by definition the elements of $D_\mathfrak{B}$. Hence, the prime ideals above $\mathfrak{B}_D$ are the $\sigma(\mathfrak{B})$ for $\sigma \in \mathrm{Gal}_{L_\mathfrak{B}}(L)$, but $\sigma(\mathfrak{B}) = \mathfrak{B}$ by definition. Hence, $\mathfrak{B}_D$ is nonsplit in L.

2-3. The fundamental identity gives us:

$$n = efr$$

where $n = |\mathrm{Gal}_K(L)| = |G|$ and $r = [G : D_\mathfrak{B}]$. hence,

$$|D_\mathfrak{B}| = [L : L_\mathfrak{B}] = ef \tag{50.5}$$

Now, let e', e'' be the ramification index of $\mathfrak{B}$ over $L_\mathfrak{B}$ and $\mathfrak{B}_D$ over K respectively. Then $\mathfrak{p}$ is:

$$\mathfrak{p}\mathcal{O}_{L_\mathfrak{B}} = \mathfrak{B}_D^{e''} I$$

for some I and

$$\mathfrak{B}_D \mathcal{O}_L = \mathfrak{B}^{e'}$$

in L. Then

$$\mathfrak{p}\mathcal{O}_L = \mathfrak{B}^{e''e'} J$$

for some J. By the tower property, $e = e'e''$ and $f = f'f''$. Then the fundamental identity for the decomposition of $\mathfrak{B}_D$ in L gives us that the degree of L/L_D is:

$$[L : L_\mathfrak{B}] = e'f'$$

in particular, by equation (50.5), we get,

$$e'f' = ef = e'e''f'f''$$

Hence $e' = e$, $f' = f$, and $e'' = f'' = 1$, as we sought to show

This gives us:

$$K \xrightarrow[1]{1} L_{\mathfrak{B}} \xrightarrow[f]{e} L$$

Next, let us see how we can separate out an extension splitting the ramification and the inertia degree into different groups/fields. Since $\sigma(\mathcal{O}_L) = \mathcal{O}_L$ and $\sigma(\mathfrak{B}) = \mathfrak{B}$ for every $\sigma \in D_{\mathfrak{B}}$, there is an induced automorphism on the residue field $\mathcal{O}_L/\mathfrak{B}$:

$$\begin{aligned} \overline{\sigma} : \mathcal{O}_L/\mathfrak{B} &\to \mathcal{O}_L/\mathfrak{B} \\ (a \bmod \mathfrak{B}) &\mapsto (\sigma(a) \bmod \mathfrak{B}) \end{aligned}$$

Letting $\kappa(\mathfrak{B}) = \mathcal{O}_L/\mathfrak{B}$ and $\kappa(\mathfrak{p}) = \mathcal{O}_K/\mathfrak{p}$, we have that

$$f = [\kappa(\mathfrak{B}) : \kappa(\mathfrak{p})]$$

Recall that in Dedekind-Kummer's theorem, when $\mathfrak{p}$ is relatively prime to the conductor, the inertia degree of $\mathfrak{B}$ is given by the degree of $\overline{m_i}(x)$ which within the proof is derived by $\left[R/(\overline{m_i(x)}) : \overline{\mathcal{O}}_K\right]$. This shows that the above map has information about the inertia degree. The following links this quantity to $D_{\mathfrak{B}}$. To understand the result, the reader may see that $\mathrm{Gal}_K(L)$ would naturally surjects onto $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$ via restriction if the restriction was well-defined. The domain of this map can be restricted to the decomposition group to make it well-defined:

Proposition 50.4.31: Decomposition and Inertia Group Relation

The extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is normal and admits a surjective homomorphism:

$$D_{\mathfrak{B}} \twoheadrightarrow \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

where $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) = \mathrm{Gal}_{\mathcal{O}_K/\mathfrak{p}}(\mathcal{O}_L/\mathfrak{B}) \cong \mathrm{Gal}_{\mathbb{F}_p}(\mathbb{F}_q)$.

***Proof*:**

As we are working over finite fields, we know that $\kappa(\mathfrak{B}) = \kappa(\mathfrak{p})(\overline{\theta})$ for some θ with minimal polynomial $\overline{g}(x)$ over $\kappa(\mathfrak{p})$ ($\overline{g}(x) \in \kappa(\mathfrak{p})[x]$)). Let $\theta \in \mathcal{O}_L$ be a representative of $\overline{\theta}$, and let $f(x)$ be its minimal polynomial over $\mathcal{O}_K$. Then by definition $\overline{g}(\overline{\theta}) \equiv 0 \bmod \mathfrak{B}$. Since $f(\theta) = 0$, $\overline{f}(\overline{\theta}) \equiv 0 \bmod \mathfrak{B}$. Hence, taking $\overline{f}(x) \in \kappa(\mathfrak{p})[x]$, we have by minimality that:

$$\overline{g}(x) \big| \overline{f}(x)$$

Next, we know that finite field extensions are normal as we saw in section 19.7.2, however here is another way of seeing this worth pointing out: since L/K is normal, $f(x)$ splits over $\mathcal{O}_L$ into linear factors. Thus, $\overline{f}(x)$ splits into linear factors over $\kappa(\mathfrak{B})$, and similarly for $\overline{g}(x)$. But then, $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is a normal extension.

Now, consider:

$$\overline{\sigma} \in \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) = \mathrm{Gal}_{\kappa(\mathfrak{p})}\left(\kappa(\mathfrak{p})(\overline{\theta})\right)$$

By corollary 19.2.29, these homomorphisms are determined by where they send the root θ. Then $\overline{\sigma}(\overline{\theta})$ is a root of $\overline{g}(x)$ and hence of $\overline{f}(x)$, that is there exists a root θ' of $f(x)$ such that $\theta' \equiv \overline{\sigma}(\overline{\theta}) \bmod \mathfrak{B}$. θ' is a conjugate of θ, i.e. $\theta' = \sigma(\theta)$ for some $\sigma \in D_{\mathfrak{B}}$ (as the automorphism in $D_{\mathfrak{B}}$ fix $\mathfrak{B}$ and make the map well-defined). Since $\sigma(\theta) \equiv \overline{\sigma}(\overline{\theta}) \bmod \mathfrak{B}$, the automorphism σ is mapped by the homomorphism in question to $\overline{\sigma}$, proving surjectivity, as we sought to show.

Definition 50.4.32: Inertia Group And Field

The kernel $I_{\mathfrak{B}} \subseteq D_{\mathfrak{B}}$ of the homomorphism

$$D_{\mathfrak{B}} \to \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

is called the *inertia group* of $\mathfrak{B}$ over K which is a normal subgroup of $D_{\mathfrak{B}}$ (as it is the kernel of a homomorphism). Equivalently:

$$I_{\mathfrak{B}} = \{\sigma \in \mathrm{Gal}_K(L) \mid \sigma(\alpha) \equiv \alpha \bmod \mathfrak{B}\}$$

The fixed field:

$$L_I = L^{I_{\mathfrak{B}}} = \{x \in L \mid \sigma(x) = x,\ \forall \sigma \in I_{\mathfrak{B}}\}$$

is called the *inertia field* of $\mathfrak{B}$ over K.

We thus get the following tower:

$$K \subseteq L_D \subseteq L_I \subseteq L$$

and short exact sequence:

$$1 \to I_{\mathfrak{B}} \to D_{\mathfrak{B}} \to \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \to 1$$

Corollary 50.4.33: Isomorphism Of Two Galois Groups

Let $L/K/\mathbb{Q}$ be a finite galois extension, and let $\mathfrak{B}$ be a prime lying over $\mathfrak{p} \subseteq \mathcal{O}_K$. Then:

$$\mathrm{Gal}_{L_D}(L_I) \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

***Proof*:**
Write $D = D_{\mathfrak{B}}$ and $I = I_{\mathfrak{B}}$, so that $L_D = L^D$ and $L_I = L^I$ (definition 50.4.26, definition 50.4.32). By proposition 20.1.12, $\mathrm{Gal}_{L_D}(L) = D$ with $|D| = [L : L_D]$, and likewise $\mathrm{Gal}_{L_I}(L) = I$. In particular $|\mathrm{Gal}_{L_D}(L)| = [L : L_D]$, so L/L_D is a Galois extension by theorem 20.1.13. The subgroup $I = \mathrm{Gal}_{L_I}(L)$ is normal in $D = \mathrm{Gal}_{L_D}(L)$, being the kernel of the homomorphism of proposition 50.4.31 (definition 50.4.32). Hence theorem 20.1.23, applied to the Galois extension L/L_D with intermediate field L_I, shows that L_I/L_D is Galois with

$$\mathrm{Gal}_{L_D}(L_I) \cong D/I$$

On the other hand, the homomorphism $D \twoheadrightarrow \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$ of proposition 50.4.31 is surjective with kernel I, so theorem 3.5.1 gives $D/I \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$. Composing the two isomorphisms completes the proof.

Corollary 50.4.34: Quotient Group of Decomposition Group

Let L/K be a finite extension. Then the group $D_{\mathfrak{B}}/I_{\mathfrak{B}}$ is cyclic of order f (hence $[D_{\mathfrak{B}} : I_{\mathfrak{B}}] = f$), and the generator $[\varphi] \in D_{\mathfrak{B}}/I_{\mathfrak{B}}$ that generates the group (and hence $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong \mathbb{Z}/m\mathbb{Z}$) is called the *Frobenius Element*. The Frobenius element $\varphi \in D_{\mathfrak{B}}$ can be represented in the simple form

$$\varphi(x) = x^{\mathfrak{N}(\mathfrak{p})}$$

***Proof*:**
This is an immediate consequence of the surjectivity of $D_{\mathfrak{B}}$ onto the Galois group of finite field extensions, which is always cyclic.

The order of $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is f, giving the order of the quotient. As the galois group of a finite field is cyclic, it is generated by a Frobenius element. The Frobenius element can be explicitly described, namely

$$\varphi(x) = x^{\mathfrak{N}(\mathfrak{p})} = x^f$$

giving us the rest of the results.

Notice that this means that Frobenius elements and Cyclotomic extensions naturally appear when studying galois extensions. This motivates the study of Cyclotomic extensions in section 50.5.

Corollary 50.4.35: Equivalent Characterization Of Inertia Group

L/K be a finite Galois extension, $I_{\mathfrak{B}} \leqslant D_{\mathfrak{B}}$. Then:

$$I_{\mathfrak{B}} = \{\sigma \in \mathrm{Gal}_K(L) \mid \sigma(\mathfrak{B}) = \mathfrak{B}, \text{ and } \forall \alpha \in \mathcal{O}_L, \sigma(\alpha) - \alpha \in \mathfrak{B}\}$$

***Proof*:**
Let $\sigma \in I_{\mathfrak{B}}$ so that $\overline{\sigma\overline{\alpha}} = \overline{\alpha}$. Then $\sigma(\alpha) = \alpha + b$ for $b \in \mathfrak{B}$. But then:

$$\sigma(\alpha) - \alpha = b \in \mathfrak{B}$$

as we sought to show.

Corollary 50.4.36: Finding Element Of Galois Group

Let K be a number field, $f(x) \in \mathcal{O}_K[x]$ an irreducible polynomial over $\mathcal{O}_K$, L/K the splitting field extension of $f(x)$. Let $\mathfrak{p} \subseteq \mathcal{O}_K$ such that

$$f(x) \bmod \mathfrak{p} \equiv g_1(x) \cdots g_m(x)$$

for distinct irreducibles with degree $\deg(g_i(x)) = d_i$. Then in $\mathrm{Gal}_K(L) \lesssim S_n$, there exists an element α with cycle type

$$(d_1, d_2, ..., d_m)$$

***Proof*:**
Since L is the splitting field, let $\alpha_1, \alpha_2, ..., \alpha_m$ be the roots of f so that

$$f(\alpha_i) = 0$$

Let $\mathfrak{B}$ in L lie above $\mathfrak{p}$. Then:

$$f(\alpha_i) \bmod \mathfrak{p} \equiv 0$$

Since each each g_i are distinct, each $\alpha_i \bmod \mathfrak{p}$ are disticnt. Hence, $D_{\mathfrak{B}}$ acts on the roots of $f \bmod \mathfrak{p}$. Now, taking $g \in D_{\mathfrak{B}}$ that maps to the generator of $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$, we shall get the desired cycle type, completing the proof.

Proposition 50.4.37: Inertia Group Properties

The extension L_I/L_D is normal, and

$$\mathrm{Gal}_{L_D}(L_I) \cong \mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B}))$$

and $\mathrm{Gal}_{L_I}(L) = I_{\mathfrak{B}}$. If the residue field extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is separable, then:

$$|I_{\mathfrak{B}}| = [L : L_I] = e \qquad [D_{\mathfrak{B}} : I_{\mathfrak{B}}] = [L_I : L_D] = f$$

and we can find the prime ideals $\mathfrak{B}_I$ of L_I bellow $\mathfrak{B}$:

1. The ramification index of $\mathfrak{B}$ over $\mathfrak{B}_I$ is e and the inertia degree is 1
2. The ramification index of $\mathfrak{B}_I$ over $\mathfrak{B}_D$ is 1, and the inertia degree if f

Hence:

$$\mathfrak{B}_Z\mathcal{O}_{L_I} = \mathfrak{B}_T I \qquad \mathfrak{B}_T\mathcal{O}_K = \mathfrak{B}^e J$$

for some appropriate ideals I, J.

***Proof*:**
The fact that:

$$|I_{\mathfrak{B}}| = [L : L_I] = e \qquad [D_{\mathfrak{B}} : I_{\mathfrak{B}}] = [L_I : L_D] = f$$

follow from $|D_{\mathfrak{B}}| = [L : L_D] = ef$ and Galois theory (namely $[L : L_I] = |\mathrm{Gal}_{L_I}(L)| = |I_{\mathfrak{B}}|$), hence we need to show $(1)-(2)$. Using the fundamental identity, it all follows from $\kappa(\mathfrak{B}_I) = \kappa(\mathfrak{B})$. Since the inertia group $I_{\mathfrak{B}}$ of $\mathfrak{B}$ over K is also the inertia group of $\mathfrak{B}$ over L_I, it follows from proposition 50.4.31 applied to L/L_I that $\mathrm{Gal}_{\kappa(\mathfrak{B}_I)}(\kappa(\mathfrak{B})) = 1$, thus

$$\kappa(\mathfrak{B}_I) = \kappa(\mathfrak{B})$$

but then the rest follows.

To sum up the results in a diagram

$$K \underset{1}{\overset{1}{\to}} L_D \underset{f}{\overset{1}{\to}} L_I \underset{1}{\overset{e}{\to}} L$$

with a corresponding [contravariant] diagram of groups:

$$G \leftarrow D_{\mathfrak{B}} \leftarrow I_{\mathfrak{B}} \leftarrow \{e\}$$

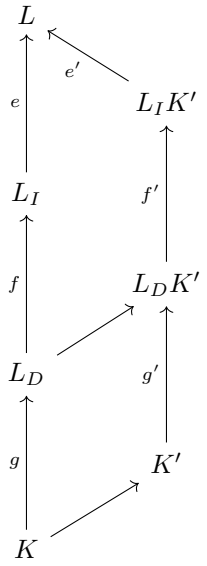
where the ramification index of each field extension is on top, and the inertia degree is on the bottom. If the residue field extension $\kappa(\mathfrak{B})/\kappa(\mathfrak{p})$ is separable, then:

$$I_{\mathfrak{B}} = 1 \qquad \iff \qquad L_I = L \qquad \iff \qquad \mathfrak{p} \text{ is unramified in } L$$

and in this case the Galois group $\mathrm{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong D_{\mathfrak{B}}$, so the galois group of residue field extension can be viewed as a subgroup of $\mathrm{Gal}_K(L)$. This means that the inertia group can be thought of as the "ramification group". In fact, the generalizations of the inertia group (giving more nuanced information on the ramificaion) are called the *higher order ramification group* (which we shall cover soon). The reason the inertia group is not called the 1st ramification group is because the corresponding fixed field only effects the inertia of a prime. Ultimately this is due to the contravariant relation the galois correspondence gives, hence we must make a choice on naming convention depending if fields or groups are prioritised. In this case, fields were prioritised.

From the previous proposition, we may think that L_D and L_I are the *maximal* fields with these properties with respect to $\mathfrak{B}$, and this is indeed the case, making them "natural" with respect to these properties:

Proposition 50.4.38: Intermediary Fields Are Maximal



Let L/K be a finite extension of number fields, $\mathfrak{B}$ live over $\mathfrak{p}$. Then:

1. $L_{D_{\mathfrak{B}}}$ is the smallest intermediary field such that $\mathfrak{B}$ is the only prime of $\mathcal{O}_L$ lying over $\mathfrak{B}' = \mathfrak{B} \cap \mathcal{O}_{L_{D_{\mathfrak{B}}}}$
2. $L_{D_{\mathfrak{B}}}$ is the largest intermediate such that $e(\mathfrak{B}_D/\mathfrak{p}) = f(\mathfrak{B}_D/\mathfrak{p}) = 1$
3. $L_{I_{\mathfrak{B}}}$ is the smallest intermediary field such that $\mathfrak{B}$ is totally ramified over $\mathfrak{B}_I$ (that is $e(\mathfrak{B}/\mathfrak{B}_I) = [L : L_I]$)
4. $L_{I_{\mathfrak{B}}}$ is the largest intermediary field such that $e(\mathfrak{B}_I/\mathfrak{p}) = 1$

***Proof*:**
First, L_D and L_I have these properties as we have in proposition 50.4.30 and proposition 50.4.37, hence we prove they are maximal/minimal.

Let $K' = L^H$ for some $H \leqslant \mathrm{Gal}_K(L)$ where only $\mathfrak{B} \subseteq L$ is lying over $\mathfrak{p}' \subseteq K'$. Since H acts transitively on the primes of L over K' but there is only one prime $H \subseteq D_{\mathfrak{B}}$, so $L_D \subseteq K'$, giving (1).

Next, assume $e_{\mathfrak{p}'/\mathfrak{p}} = f_{\mathfrak{p}'/\mathfrak{p}} = 1$. Consider the following diagram:

Then by multiplicativity of towers, $e = e'$ and $f = f'$. Then by the above diagram, L_D and $L_D K'$ voth ahve the same index in L. Since one contains the other, this means they must be equal, hence

$$K' \subseteq L_D$$

giving (2). A similar arguments works for (3) and (4): if $e_{\mathfrak{p}'/\mathfrak{p}} = 1$, then $e = e'$, so $L_I = L_I K'$, so $K' \subseteq L_I$, and if $\mathfrak{B}$ is totally ramified over $\mathfrak{p}'$, then $[L : K'] = e'$, then by the above diagramwe get $K' = L_I K'$, so $L_I \subseteq K'$, as we sought to show.

Ramification

An importance consequence of this is that we may consider primes that are completely ramified/totally unramified in their galois closure. we first require the following result:

Theorem 50.4.39: Composition Field And Primes

Let L/K and M/K be finite extensions of number fields, and let $\mathfrak{p}$ be a prime of K. Then if $\mathfrak{p}$ is unramified in both L and M, then $\mathfrak{p}$ is unramified in LM. If $\mathfrak{p}$ splits completely in L and M, then $\mathfrak{p}$ splits completely in LM

***Proof*:**
Let $\mathfrak{p}$ be unramified in L and M, and take $\mathfrak{B}$ to be any prime in LM lying over $\mathfrak{p}$. We want to show $e(\mathfrak{B}/\mathfrak{p}) = 1$. Let F be the normal closure of K containing LM, and let $\mathfrak{A}$ be any prime in F lying over $\mathfrak{B}$, namely it lies over $\mathfrak{p}$. Let $I_{\mathfrak{A}/\mathfrak{p}}$ be the inertial group corresponding to the field F_I. Then we see that F_I contains both L and M since the primes $\mathfrak{A} \cap L$ and $\mathfrak{A} \cap M$ are necessarily unramified over $\mathfrak{p}$. Hence, F_I contains LM, implying that $\mathfrak{A} \cap LM$ is unramified over

$\mathfrak{p}$.

The argument for splitting follows exactly the same pattern, replacing $I_{\mathfrak{B}}$ with $D_{\mathfrak{B}}$.

Corollary 50.4.40: Primes In Normal Closure

Let L/K be a finite extension of number fields and $\mathfrak{p}$ a prime in K. Then:

1. If $\mathfrak{p}$ is unramified in L, then it is unramified in the normal closure of M of L over K
2. If $\mathfrak{p}$ splits completely in L, then it splits completely in the normal closure of M of L over K

***Proof*:**
If $\mathfrak{p}$ is unramified in L, then it is unramified in every $\sigma_i(L)$ where i runs over all the automorphism. But since $M = L\sigma_1(L)\cdots\sigma_n(L)$, we use induction on theorem 50.4.39 to get our desired result (similarly for splitting completely).

Example 50.4.41: More Decomposition Of Primes

Let $K = \mathbb{Q}(i, \sqrt{2}, \sqrt{5})$, which is abelian of degree 8. Take the prime $5 \in \mathbb{Z}$. Then it splits into tow primes in $\mathbb{Q}(i)$, stays inert in $\mathbb{Q}(\sqrt{2})$, and becomes a square in $\mathbb{Q}(\sqrt{5})$. Hence in L 5 must have ramification index at least 2, and split into at least 2 primes. Since the inertia field must be a field of degree 4 over $\mathbb{Q}$ in which 5 is unramified, the only choice is $\mathbb{Q}(i, \sqrt{2})$. Now, $(2+i)$ and $(2-i)$ remain prime in $\mathbb{Q}(\sqrt{i}, \sqrt{2})$, and become squares in L, hence 5 must have exactly 2 primes and ramification index 2.

Since normal subgroups over characteristic 0 fields are galois, it is meaningful to ask the behavior of normal subgroups of the galois subgroups:

Proposition 50.4.42: Decomposition Subgroup Is Normal

Suppose $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$. Then $\mathfrak{p}\mathcal{O}_L$ splits into r distinct primes in L_D. If $I_{\mathfrak{B}} \trianglelefteq G$, then each prime remains as primes in L_I (i.e. they are inert). Furthermore, each become an eth power in L.

In general, we can only hope for:

$$\mathfrak{B}_D\mathcal{O}_{L_I} = \mathfrak{B}_I I \qquad \mathfrak{B}_I\mathcal{O}_K = \mathfrak{B}^e J$$

for some ideals, while in the normal case of D and I, we get:

$$\begin{aligned}\mathfrak{p}\mathcal{O}_{L_D} &= \mathfrak{B}_{L_1}\cdots\mathfrak{B}_{L_e}\\ \mathfrak{p}\mathcal{O}_{L_I} &= \mathfrak{B}_{L_1}\cdots\mathfrak{B}_{L_e}\\ \mathfrak{p}\mathcal{O}_L &= \mathfrak{B}_1^e\cdots\mathfrak{B}_g^e\end{aligned}$$

which also shows better why the groups $D_{\mathfrak{B}}$ and $I_{\mathfrak{B}}$ are called the "decomposition" and "inertia" groups respectively.

***Proof*:**
This is taking advantage of the fact that $L^{D_{\mathfrak{B}}}/K$ would now be a Galois extension since $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$. Then we know that

$$f(\mathfrak{B}_D) = e(\mathfrak{B}_D) = 1$$

and that (since $L^{D_{\mathfrak{B}}}$ is Galois), each other prime must also have the same ramification and inertia degree. Thus, $\mathfrak{p}$ splits into exactly g distinct primes in $L^{D_{\mathfrak{B}}}$. Then by a simple counting argument, we see that each $\mathfrak{B}_D$ must lie under a unique $\mathfrak{B}_I$. It may be that some of these ramify. However, if $I_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$, then we have that each prime must have ramification index 1, showing they are all inert. Finally, a counting argument gives that each $\mathfrak{B}_I$ becomes an eth power in L

Corollary 50.4.43: Normal Subgroup And Completely Split Prime

Let $D_{\mathfrak{B}} \trianglelefteq \mathrm{Gal}_K(L)$ and let K' be an intermediate field of L/K. Then $\mathfrak{p}$ splits completely in K' if and only if $K' \subseteq L_D$

***Proof*:**
Suppose first that $\mathfrak{p}$ splits completely in K'. Then every prime of K' above $\mathfrak{p}$ has ramification index and inertia degree 1 over $\mathfrak{p}$, in particular the prime $\mathfrak{B} \cap K'$. By proposition 50.4.38(2), L_D is the largest intermediate field whose prime below $\mathfrak{B}$ has this property, so $K' \subseteq L_D$. This direction does not use the normality of $D_{\mathfrak{B}}$.

Conversely, suppose $K' \subseteq L_D$. We first check that $\mathfrak{p}$ splits completely in L_D. Since $L_D = L^{D_{\mathfrak{B}}}$, proposition 20.1.12 gives $\mathrm{Gal}_{L_D}(L) = D_{\mathfrak{B}}$, which is normal in $\mathrm{Gal}_K(L)$ by hypothesis, so L_D/K is Galois by theorem 20.1.23. By proposition 50.4.28, all primes in the factorization of $\mathfrak{p}\mathcal{O}_{L_D}$ have the same ramification index and the same inertia degree, and by proposition 50.4.30(3) the prime $\mathfrak{B}_D = \mathfrak{B} \cap L_D$ has both equal to 1. The fundamental identity (proposition 50.4.3) then forces the number of primes above $\mathfrak{p}$ in L_D to be $[L_D : K]$, so $\mathfrak{p}$ splits completely in L_D (definition 50.4.2).

Now let $\mathfrak{q}$ be any prime of K' above $\mathfrak{p}$. By proposition 50.3.10, $\mathfrak{q}\mathcal{O}_{L_D} \neq \mathcal{O}_{L_D}$, so some prime $\mathfrak{q}'$ of L_D divides $\mathfrak{q}\mathcal{O}_{L_D}$, and $\mathfrak{q}' \supseteq \mathfrak{q} \supseteq \mathfrak{p}$ shows that $\mathfrak{q}'$ lies above both $\mathfrak{q}$ and $\mathfrak{p}$ (proposition 50.3.11). Extending the factorization of $\mathfrak{p}\mathcal{O}_{K'}$ to $\mathcal{O}_{L_D}$ and factoring $\mathfrak{q}\mathcal{O}_{L_D}$ gives

$$e(\mathfrak{q}'/\mathfrak{p}) = e(\mathfrak{q}'/\mathfrak{q})\, e(\mathfrak{q}/\mathfrak{p})$$

since distinct primes of K' contribute disjoint sets of prime factors (corollary 50.3.12). Both factors are at least 1 and $e(\mathfrak{q}'/\mathfrak{p}) = 1$, so $e(\mathfrak{q}/\mathfrak{p}) = 1$. Similarly the residue field inclusions $\mathcal{O}_K/\mathfrak{p} \subseteq \mathcal{O}_{K'}/\mathfrak{q} \subseteq \mathcal{O}_{L_D}/\mathfrak{q}'$ give $f(\mathfrak{q}'/\mathfrak{p}) = f(\mathfrak{q}'/\mathfrak{q})f(\mathfrak{q}/\mathfrak{p})$ by theorem 19.3.7, so $f(\mathfrak{q}/\mathfrak{p}) = 1$. Every prime of K' above $\mathfrak{p}$ therefore has ramification index and inertia degree 1, and the fundamental identity (proposition 50.4.3) makes their number $[K' : K]$. Thus $\mathfrak{p}$ splits completely in K', as we sought to show.

In the non-Galois case L/K, take $M/L/K$ where M/K is the Galois closure of L. Then M/L is

Galois. Let $G = \mathrm{Gal}_K(M)$ and $H = \mathrm{Gal}_L(M)$ so that $H \leqslant G$. Take the following tower of primes:

$$\begin{array}{ccc} M & \longrightarrow & \mathfrak{A} \\ \uparrow & & \uparrow \\ L & \longrightarrow & \mathfrak{B} \\ \uparrow & & \uparrow \\ K & \longrightarrow & \mathfrak{p} \end{array}$$

Then by definition:

$$D_{\mathfrak{A}/\mathfrak{p}} \cap H = D_{\mathfrak{A}/\mathfrak{B}}$$
$$I_{\mathfrak{A}/\mathfrak{p}} \cap H = I_{\mathfrak{A}/\mathfrak{B}}$$

Proposition 50.4.44: Prime Decomposition Over Finite Extension

Let

$$\mathfrak{p}_M = \prod_1^{g_{M/K}} \mathfrak{A}_i^{e_i}$$

Let $\mathfrak{O}_1, \mathfrak{O}_2, ..., \mathfrak{O}_{g_{L/K}}$ be the orbits of H acting on the primes $\{\mathfrak{A}_1, \mathfrak{A}_2, ..., \mathfrak{A}_{g_{M/K}}\}$. Then:

$$\mathfrak{p}_L = \prod_i^{g_{L/K}} \mathfrak{B}_i^{e_{\mathfrak{B}_i/\mathfrak{p}}}$$

where each $\mathfrak{B}_i$ comes from an $\mathfrak{O}_i$. Furthermore:

$$e_{\mathfrak{B}_i/\mathfrak{p}} = \frac{|I_{\mathfrak{A}_i/\mathfrak{p}}|}{|\mathrm{stab}_H(\mathfrak{A}_i) \cap I_{\mathfrak{A}_i/\mathfrak{p}}|} \qquad f_{\mathfrak{B}_i/\mathfrak{p}} = \frac{[D_{\mathfrak{A}_i/\mathfrak{p}} : I_{\mathfrak{A}_i/\mathfrak{p}}]}{[\mathrm{stab}_H(\mathfrak{A}_i) : \mathrm{stab}_H(\mathfrak{A}_i) \cap I_{\mathfrak{A}_i/\mathfrak{p}}]}$$

***Proof*:**

Throughout, the setup is the one fixed above: M/K is Galois with group G, $H = \mathrm{Gal}_L(M)$, and M/L is Galois with group H.

First, the primes of L above $\mathfrak{p}$ correspond to the orbits $\mathfrak{O}_1, \ldots, \mathfrak{O}_{g_{L/K}}$. Each $\mathfrak{A}_j$ contracts to the prime $\mathfrak{A}_j \cap L$ of L, which lies above $\mathfrak{p}$. If $\eta \in H$, then η fixes L pointwise, so $\eta(\mathfrak{A}_j) \cap L = \mathfrak{A}_j \cap L$: primes in the same orbit have the same contraction. Conversely, if $\mathfrak{A}_j \cap L = \mathfrak{A}_k \cap L = \mathfrak{B}$, then $\mathfrak{A}_j$ and $\mathfrak{A}_k$ both divide $\mathfrak{B}\mathcal{O}_M$ (proposition 50.3.11), so proposition 50.4.25, applied to the Galois extension M/L, provides $\eta \in H$ with $\eta(\mathfrak{A}_j) = \mathfrak{A}_k$: equal contractions force the same orbit. Finally, every prime $\mathfrak{B}$ of L above $\mathfrak{p}$ arises this way: $\mathfrak{B}\mathcal{O}_M \neq \mathcal{O}_M$ by proposition 50.3.10, and any prime factor of $\mathfrak{B}\mathcal{O}_M$ lies above $\mathfrak{p}$ and contracts to $\mathfrak{B}$ (proposition 50.3.11). Hence $\mathfrak{A}_j \mapsto \mathfrak{A}_j \cap L$ induces a bijection from the orbits onto the primes of L above $\mathfrak{p}$, and writing $\mathfrak{B}_i$ for the common contraction of the orbit $\mathfrak{O}_i$, the factorization

$$\mathfrak{p}_L = \prod_i^{g_{L/K}} \mathfrak{B}_i^{e_{\mathfrak{B}_i/\mathfrak{p}}}$$

holds by the definition of the ramification index.

For the formulas, fix i, write $\mathfrak{A} = \mathfrak{A}_i$ and $\mathfrak{B} = \mathfrak{B}_i$, and abbreviate $D = D_{\mathfrak{A}/\mathfrak{p}}$ and $I = I_{\mathfrak{A}/\mathfrak{p}}$. By definition 50.4.26 and definition 50.4.32 applied in M/L,

$$D_{\mathfrak{A}/\mathfrak{B}} = D \cap H = \mathrm{stab}_H(\mathfrak{A}) \qquad I_{\mathfrak{A}/\mathfrak{B}} = I \cap H = \mathrm{stab}_H(\mathfrak{A}) \cap I$$

where the last equality holds because $I \subseteq D$. The residue fields are finite, so the separability hypothesis of proposition 50.4.37 holds, and applying that proposition in M/K and in M/L gives

$$e_{\mathfrak{A}/\mathfrak{p}} = |I| \qquad f_{\mathfrak{A}/\mathfrak{p}} = [D : I] \qquad e_{\mathfrak{A}/\mathfrak{B}} = |\mathrm{stab}_H(\mathfrak{A}) \cap I| \qquad f_{\mathfrak{A}/\mathfrak{B}} = [\mathrm{stab}_H(\mathfrak{A}) : \mathrm{stab}_H(\mathfrak{A}) \cap I]$$

Extending the factorization of $\mathfrak{p}\mathcal{O}_L$ to $\mathcal{O}_M$ and factoring $\mathfrak{B}\mathcal{O}_M$ gives $e_{\mathfrak{A}/\mathfrak{p}} = e_{\mathfrak{A}/\mathfrak{B}}\, e_{\mathfrak{B}/\mathfrak{p}}$, since distinct primes of L contribute disjoint sets of prime factors (corollary 50.3.12). The residue field inclusions $\mathcal{O}_K/\mathfrak{p} \subseteq \mathcal{O}_L/\mathfrak{B} \subseteq \mathcal{O}_M/\mathfrak{A}$ give $f_{\mathfrak{A}/\mathfrak{p}} = f_{\mathfrak{A}/\mathfrak{B}}\, f_{\mathfrak{B}/\mathfrak{p}}$ by theorem 19.3.7. Dividing the two displayed computations of e and of f yields

$$e_{\mathfrak{B}/\mathfrak{p}} = \frac{|I|}{|\mathrm{stab}_H(\mathfrak{A}) \cap I|} \qquad f_{\mathfrak{B}/\mathfrak{p}} = \frac{[D : I]}{[\mathrm{stab}_H(\mathfrak{A}) : \mathrm{stab}_H(\mathfrak{A}) \cap I]}$$

as we sought to show.

It is also enlightening to have a second perspective here: for subgroup $U, V \leqslant G$, we may consider the equivalence class $\sigma \sim \sigma' \iff \sigma' = u\sigma v$ giving us the double-coset[26]:

$$U\sigma V = \{u\sigma v \mid u \in U, v \in V\}$$

This partition will give us the similar information in the non-Galois case. Let $N/L/K$ be two separable extensions where N/K is Galois with Galois group G. Let $H = \mathrm{Gal}_L(N) \leqslant \mathrm{Gal}_K(N)$. Let $\mathfrak{p}$ be a prime ideal of K and $P_{\mathfrak{p}}$ the set of all prime ideal of L above $\mathfrak{p}$. Then if $\mathfrak{B}$ is a prime ideal of N above $\mathfrak{p}$, then we get a well-defined bijection:

$$H \setminus G / D_{\mathfrak{B}} \to P_{\mathfrak{p}} \qquad H\sigma D_{\mathfrak{B}} \mapsto \sigma\mathfrak{B} \cap L$$

Exercise 50.4.1

1. Let L/K be a galois extension of Number fields, $G = \mathrm{Gal}_K(L)$, $\mathfrak{B}$ lie over $\mathfrak{p}$.
   a) If $\mathfrak{B}$ is inert, then G Is cyclic
   b) If $\mathfrak{p}$ is totally ramified in each intermediary field but not totally ramified in L, then there does not exist non-trivial proper intermediary field, hence G is cyclic (of prime order)
   c) Simiarly, Suppose every intermediate field contains a unique prime lying over $\mathfrak{p}$, but L does not. Show the same as the previous
   d) Let $\mathfrak{p}$ be unramified in every proper non-trivial intermediate field, but ramified in L. Show that G has unique smallest subgroup H and that $H \trianglelefteq G$. Use this to show that $|G| = p^k$ for some k and prime p, that $|H| = p^l$ for some l, and $H \leqslant Z(G)$.
   e) Similarly, show the same for when $\mathfrak{p}$ splits compeltely in every proper non-trivial intermediate field, but not in L.

[26] warning: double cosets need not all have the same size!

f) Let $\mathfrak{p}$ be inert in every proper non-trivial intermediate field but not in L. Prove that G is a cyclic where $|G| = p^k$.

2. (the non-normal case for Frobenius element by taking normal closure, p.78 Marcus)

50.4.3 Detecting Ramification

50.4.45 AKLB setup For generality, let A be a Dedekind domain, K the field of fraction of A, L a finite separable extension of K, and B the integral closure of A in L.

Furthermore, let κ be the residue field of A and λ be the residue field for L. Assume λ/κ and B/A are separable extensions.

Definition 50.4.46: Trace Dual of Fractional Ideal

Take AKLB and let $\mathfrak{P} \subseteq B$ be a fractional ideal. Then the *trace dual* of $\mathfrak{P}$ is:

$$^*\mathfrak{P} = \{x \in L \mid \mathrm{tr}(x\mathfrak{P}) \subseteq A\}$$

By proposition 50.1.32, $^*\mathfrak{P}$ is a finitely generated B-module, and hence by definition a fractional ideal. Note that as the trace-pairing is non-degenerate:

$$^*\mathfrak{P} \xrightarrow{\cong} \mathrm{Hom}_A(\mathfrak{P}, A) \qquad x \mapsto (y \mapsto \mathrm{tr}(xy))$$

which works even when $\mathfrak{P} = (1)_B$, that is:

$$^*B \cong \mathrm{Hom}_A(B, A)$$

This particular trace dual shall be very relevant in detecting ramification:

Definition 50.4.47: Different

Assume AKLB. The fractional ideal

$$\mathfrak{C}_{B/A} = \{x \in L \mid \mathrm{tr}(xB) \subseteq A\} = {}^*B$$

is called *Dedekind's complementary module*, or the *inverse different*. Its inverse

$$\mathfrak{D}_{B/A} := \mathfrak{C}_{B/A}^{-1}$$

is called the *Different* of B/A

Since $\mathfrak{C}_{B/A} \supseteq \mathcal{O}$, $\mathfrak{D}_{B/A} \subseteq \mathcal{O}$ is an integral ideal of L. Naturally, we will often denote the different as $\mathfrak{D}_{L/K}$ and $\mathfrak{C}_{B/A}$ as $\mathfrak{C}_{L/K}$ given the rings B an A are evident from context.

Proposition 50.4.48: Tower Law For Different

Assume $AKLB$ and let M/L be a finite separable extension. Then

1. If $M/L/K$, then $\mathfrak{D}_{M/K} = \mathfrak{D}_{M/L}\mathfrak{D}_{L/K}$
2. If $S \subseteq \mathfrak{o}$ is a multiplicative subset with $0 \notin S$, then $\mathfrak{D}_{S^{-1}\mathcal{O}/S^{-1}\mathfrak{o}} = S^{-1}\mathfrak{D}_{\mathcal{O}/\mathfrak{o}}$

***Proof*:**

1. Write $\mathcal{O}_K = A$, $\mathcal{O}_L = B$ and $\mathcal{O}_M$ for the integral closure of A in M, which is also the integral closure of $\mathcal{O}_L$ in M (corollary 26.1.5). Write $\mathfrak{C}_{M/K}$, $\mathfrak{C}_{M/L}$ and $\mathfrak{C}_{L/K}$ for the complementary modules of $\mathcal{O}_M/\mathcal{O}_K$, $\mathcal{O}_M/\mathcal{O}_L$ and $\mathcal{O}_L/\mathcal{O}_K$, so that $\mathfrak{D}_{L/K}$ in the statement stands for its extension $\mathfrak{D}_{L/K}\mathcal{O}_M$. Let $x \in M$ and put $T = \mathrm{tr}_{M/L}(x\mathcal{O}_M)$, an $\mathcal{O}_L$-submodule of L because $\mathrm{tr}_{M/L}$ is L-linear. The extensions M/L and L/K are separable, by hypothesis and by the AKLB setup, so proposition 50.1.15 gives $\mathrm{tr}_{M/K} = \mathrm{tr}_{L/K} \circ \mathrm{tr}_{M/L}$, and

$$x \in \mathfrak{C}_{M/K} \iff \mathrm{tr}_{L/K}(T) \subseteq \mathcal{O}_K \iff T \subseteq \mathfrak{C}_{L/K}$$

   where the second equivalence holds because $T\mathcal{O}_L = T$. Since $\mathfrak{C}_{L/K}\mathfrak{D}_{L/K} = \mathcal{O}_L$ (theorem 50.2.22), $T \subseteq \mathfrak{C}_{L/K}$ holds exactly when $\mathfrak{D}_{L/K}T \subseteq \mathcal{O}_L$: multiply by $\mathfrak{D}_{L/K}$ for one direction and by $\mathfrak{C}_{L/K}$ for the other. As $\mathrm{tr}_{M/L}$ is L-linear, $\mathfrak{D}_{L/K}T = \mathrm{tr}_{M/L}(x\mathfrak{D}_{L/K}\mathcal{O}_M)$, and since $x\mathfrak{D}_{L/K}\mathcal{O}_M$ is an $\mathcal{O}_M$-module, the condition $\mathrm{tr}_{M/L}(x\mathfrak{D}_{L/K}\mathcal{O}_M) \subseteq \mathcal{O}_L$ says that $x\mathfrak{D}_{L/K}\mathcal{O}_M \subseteq \mathfrak{C}_{M/L}$. Extension of ideals is multiplicative, both sides being generated by the same products, so $(\mathfrak{D}_{L/K}\mathcal{O}_M)(\mathfrak{C}_{L/K}\mathcal{O}_M) = (\mathfrak{D}_{L/K}\mathfrak{C}_{L/K})\mathcal{O}_M = \mathcal{O}_L\mathcal{O}_M = \mathcal{O}_M$. Multiplying by $\mathfrak{C}_{L/K}\mathcal{O}_M$ for one direction and by $\mathfrak{D}_{L/K}\mathcal{O}_M$ for the other,

$$x\mathfrak{D}_{L/K}\mathcal{O}_M \subseteq \mathfrak{C}_{M/L} \iff x \in \mathfrak{C}_{M/L}\mathfrak{C}_{L/K}\mathcal{O}_M$$

   Altogether $\mathfrak{C}_{M/K} = \mathfrak{C}_{M/L}\mathfrak{C}_{L/K}\mathcal{O}_M$, and taking inverses in the group of fractional ideals of $\mathcal{O}_M$ (theorem 50.2.22) gives $\mathfrak{D}_{M/K} = \mathfrak{D}_{M/L}\mathfrak{D}_{L/K}\mathcal{O}_M$.

2. Let $S \subseteq \mathfrak{o}$ be multiplicative with $0 \notin S$. If $x \in L$ satisfies $x^d + (a_1/s_1)x^{d-1} + \cdots + a_d/s_d = 0$ with $a_i \in \mathfrak{o}$ and $s_i \in S$, then multiplying by s^d, where $s = s_1 \cdots s_d$, shows that sx is integral over $\mathfrak{o}$, so $sx \in \mathcal{O}$ and $x \in S^{-1}\mathcal{O}$. Conversely, if $b \in \mathcal{O}$ satisfies a monic equation of degree d over $\mathfrak{o}$, dividing it by s^d shows that b/s is integral over $S^{-1}\mathfrak{o}$ for every $s \in S$. So $S^{-1}\mathcal{O}$ is the integral closure of $S^{-1}\mathfrak{o}$ in L.

   Next, $\mathfrak{C}_{S^{-1}\mathcal{O}/S^{-1}\mathfrak{o}} = S^{-1}\mathfrak{C}_{\mathcal{O}/\mathfrak{o}}$. If $x \in \mathfrak{C}_{\mathcal{O}/\mathfrak{o}}$, then $\mathrm{tr}_{L/K}((x/s)(b/t)) = \mathrm{tr}_{L/K}(xb)/(st)$ lies in $S^{-1}\mathfrak{o}$ for all $s, t \in S$ and $b \in \mathcal{O}$, so x/s lies in the left-hand side. Conversely, let x lie in the left-hand side. The ring $\mathfrak{o}$ is Noetherian, so $\mathcal{O}$ is a finitely generated $\mathfrak{o}$-module (proposition 50.1.32), say by $b_1, \ldots, b_r$, and $\mathrm{tr}_{L/K}(xb_k) = c_k/t_k$ with $c_k \in \mathfrak{o}$ and $t_k \in S$. With $t = t_1 \cdots t_r$, the K-linearity of the trace gives $\mathrm{tr}_{L/K}(txb_k) \in \mathfrak{o}$ for every k, hence $\mathrm{tr}_{L/K}(tx\mathcal{O}) \subseteq \mathfrak{o}$. So $tx \in \mathfrak{C}_{\mathcal{O}/\mathfrak{o}}$ and $x \in S^{-1}\mathfrak{C}_{\mathcal{O}/\mathfrak{o}}$.

   Finally, $S^{-1}\mathcal{O}$ is a Dedekind domain (lemma 50.2.5), and putting a finite sum of products over a common denominator shows that localization carries products of $\mathcal{O}$-modules to products, so

$$\mathfrak{C}_{S^{-1}\mathcal{O}/S^{-1}\mathfrak{o}} \cdot S^{-1}\mathfrak{D}_{\mathcal{O}/\mathfrak{o}} = S^{-1}\left(\mathfrak{C}_{\mathcal{O}/\mathfrak{o}}\mathfrak{D}_{\mathcal{O}/\mathfrak{o}}\right) = S^{-1}\mathcal{O}$$

by theorem 50.2.22. Inverses in the group of fractional ideals of $S^{-1}\mathcal{O}$ are unique, so $S^{-1}\mathfrak{D}_{\mathcal{O}/o}$ is the inverse of $\mathfrak{C}_{S^{-1}\mathcal{O}/S^{-1}o}$, which is $\mathfrak{D}_{S^{-1}\mathcal{O}/S^{-1}o}$, completing the proof.

50.4.49 The Different and Completion The different is also compatible with completion: if $\mathfrak{B}$ is a prime of $\mathcal{O}$ above $\mathfrak{p}$ and $\mathcal{O}_{\mathfrak{B}}$, $o_{\mathfrak{p}}$ denote the completions, then $\mathfrak{D}_{\mathcal{O}/o}\mathcal{O}_{\mathfrak{B}} = \mathfrak{D}_{\mathcal{O}_{\mathfrak{B}}/o_{\mathfrak{p}}}$. This book does not construct completions and does not prove this statement. Its proof rests on the decomposition of $L \otimes_K K_{\mathfrak{p}}$ into the completions of L at the primes above $\mathfrak{p}$, *Local Field Theory* [33, Global To Local Correspondence], under which the trace of L/K becomes the sum of the local traces, [33, Global To Local Correspondence, Norm and Trace].

Example 50.4.50: Different

1. Let $K = \mathbb{Q}(\sqrt{5})$ so that $\mathcal{O}_K = \mathbb{Z}\left[\frac{1+\sqrt{5}}{2}\right]$. Then:
$$\mathfrak{C}_{K/\mathbb{Q}} = \sqrt{5}^{-1}\mathcal{O}_K \implies \mathfrak{D}_{K/\mathbb{Q}} = \sqrt{5}\mathcal{O}_K$$
2. Let $K = \mathbb{Q}(\sqrt{3})$. So that $\mathcal{O}_K = \mathbb{Z}[\sqrt{3}]$. Then:
$$\mathfrak{C}_{K/\mathbb{Q}} = \langle \frac{1}{2}, \frac{1}{\sqrt{3}} \rangle_{\mathbb{Z}} = \frac{1}{2\sqrt{3}}\mathcal{O}_K \implies \mathfrak{D}_{K/\mathbb{Q}} = 2\sqrt{3}\mathcal{O}_K$$

Theorem 50.4.51: Norm Of Different

$$\mathfrak{N}(\mathfrak{D}_{K/\mathbb{Q}}) = |\mathrm{disc}(\mathcal{O}_K)|$$

***Proof*:**
Here $A = \mathbb{Z}$ and $B = \mathcal{O}_K$. Write $\mathfrak{C} = \mathfrak{C}_{K/\mathbb{Q}}$ and $\mathfrak{D} = \mathfrak{D}_{K/\mathbb{Q}} = \mathfrak{C}^{-1}$ (definition 50.4.47), let $n = [K : \mathbb{Q}]$, and let $\omega_1, \dots, \omega_n$ be an integral basis of $\mathcal{O}_K$ (corollary 50.1.33).

Step 1: $\mathfrak{C}$ is free on the dual basis. The extension $K/\mathbb{Q}$ is separable, so by proposition 19.6.31 there is a $\mathbb{Q}$-basis $\omega_1^*, \dots, \omega_n^*$ of K with $\mathrm{tr}_{K/\mathbb{Q}}(\omega_i\omega_j^*) = \delta_{ij}$. Write $x \in K$ as $x = \sum_j c_j\omega_j^*$ with $c_j \in \mathbb{Q}$. Then $\mathrm{tr}_{K/\mathbb{Q}}(x\omega_i) = c_i$, and since $\mathcal{O}_K = \bigoplus_i \mathbb{Z}\omega_i$ and the trace is $\mathbb{Z}$-linear, $\mathrm{tr}_{K/\mathbb{Q}}(x\mathcal{O}_K) \subseteq \mathbb{Z}$ holds exactly when every $c_i \in \mathbb{Z}$. So $\mathfrak{C} = \bigoplus_j \mathbb{Z}\omega_j^*$.

Step 2: $[\mathfrak{C} : \mathcal{O}_K] = |d_K|$. Applying Step 1 to $x = \omega_i$ gives
$$\omega_i = \sum_{j=1}^{n} T_{ij}\,\omega_j^* \qquad T_{ij} = \mathrm{tr}_{K/\mathbb{Q}}(\omega_i\omega_j)$$
where $T_{ij} \in \mathbb{Z}$ by corollary 50.1.14, so that $\mathcal{O}_K \subseteq \mathfrak{C}$. Moreover $\det(T) = d_K$ by proposition 50.1.26 and definition 50.1.38, a nonzero integer (corollary 50.1.28). Let $\sigma_1, \dots, \sigma_n$ be the embeddings of K into $\mathbb{C}$. Applying σ_k to the display shows that the matrix $(\sigma_k(\omega_i))_{k,i}$ equals $(\sigma_k(\omega_j^*))_{k,j}\,T^t$,

so definition 50.1.24 gives

$$d_K = \mathrm{disc}_{K/\mathbb{Q}}(\omega_1, \dots, \omega_n) = \det(T)^2 \mathrm{disc}_{K/\mathbb{Q}}(\omega_1^*, \dots, \omega_n^*)$$

Multiplying the first display by the adjugate of T, which has integer entries, gives $d_K \omega_j^* \in \bigoplus_i \mathbb{Z}\omega_i$ for every j. So $d_K \mathfrak{C} \subseteq \mathcal{O}_K \subseteq \mathfrak{C}$, and $\mathfrak{C}/\mathcal{O}_K$ is finite, being a quotient of $\mathfrak{C}/d_K\mathfrak{C} \cong (\mathbb{Z}/d_K\mathbb{Z})^n$. By proposition 50.1.39,

$$d_K = [\mathfrak{C} : \mathcal{O}_K]^2 \mathrm{disc}_{K/\mathbb{Q}}(\omega_1^*, \dots, \omega_n^*)$$

The discriminant of the $\mathbb{Q}$-basis $\omega_1^*, \dots, \omega_n^*$ is nonzero (corollary 50.1.28), so comparing the two displays gives $[\mathfrak{C} : \mathcal{O}_K]^2 = \det(T)^2 = d_K^2$, that is $[\mathfrak{C} : \mathcal{O}_K] = |d_K|$.

Step 3: $\mathfrak{N}(\mathfrak{D}) = [\mathfrak{C} : \mathcal{O}_K]$. Since $\mathcal{O}_K \subseteq \mathfrak{C}$ (Step 2) and $\mathfrak{C}\mathfrak{D} = \mathcal{O}_K$ (theorem 50.2.22), multiplying the inclusion by $\mathfrak{D}$ gives $\mathfrak{D} \subseteq \mathcal{O}_K$, so $\mathfrak{D}$ is a nonzero ideal of $\mathcal{O}_K$ and $\mathfrak{N}(\mathfrak{D})$ is defined (definition 50.1.61). Put $m = |d_K|$ and $\mathfrak{b} = m\mathfrak{C}$, a nonzero ideal of $\mathcal{O}_K$ by Step 2. Then $\mathfrak{b}\mathfrak{D} = m\mathcal{O}_K$. The absolute norm is multiplicative (proposition 50.2.30), so by lemma 50.1.63

$$\mathfrak{N}(\mathfrak{b})\mathfrak{N}(\mathfrak{D}) = \mathfrak{N}(m\mathcal{O}_K) = \left|\mathrm{Nm}_{K/\mathbb{Q}}(m)\right| = m^n$$

On the other hand $m\mathcal{O}_K \subseteq \mathfrak{b} \subseteq \mathcal{O}_K$, and multiplication by m is a group isomorphism $\mathfrak{C} \to \mathfrak{b}$ carrying $\mathcal{O}_K$ onto $m\mathcal{O}_K$, so

$$m^n = [\mathcal{O}_K : m\mathcal{O}_K] = [\mathcal{O}_K : \mathfrak{b}]\,[\mathfrak{b} : m\mathcal{O}_K] = \mathfrak{N}(\mathfrak{b})\,[\mathfrak{C} : \mathcal{O}_K]$$

Comparing the two displays and dividing by $\mathfrak{N}(\mathfrak{b}) > 0$ gives $\mathfrak{N}(\mathfrak{D}) = [\mathfrak{C} : \mathcal{O}_K] = |d_K|$, as claimed.

(This next proposition gives a special case of the different and the origin of it's name)

Proposition 50.4.52: Different In Monogenic Extension

Let $\mathcal{O} = o[\alpha]$ and let $f \in o[X]$ be the minimal polynomial of α over K. Then the different is equal to:

$$\mathfrak{D}_{L/K} = (\delta_{L/K}(\alpha))$$

where

$$\delta_{L/K}(\alpha) = \begin{cases} f'(\alpha) & L = K(\alpha) \\ 0 & L \neq K(\alpha) \end{cases}$$

***Proof*:**
The ring $\mathcal{O}$ is the integral closure of o in L and has fraction field L, so $\mathcal{O} = o[\alpha]$ forces $L = K(\alpha)$ and $\delta_{L/K}(\alpha) = f'(\alpha)$. Write $n = [L : K]$ and $f(X) = a_0 + a_1 X + \cdots + a_n X^n$ with $a_n = 1$, let $\alpha_1, \dots, \alpha_n$ be the roots of f in a normal closure of L/K, and define $b_0, \dots, b_{n-1} \in \mathcal{O}$ by

$$\frac{f(X)}{X - \alpha} = b_0 + b_1 X + \cdots + b_{n-1} X^{n-1}$$

The first step is that $b_0/f'(\alpha), \dots, b_{n-1}/f'(\alpha)$ is the basis dual to $1, \alpha, \dots, \alpha^{n-1}$ for the trace

pairing. For $0 \le s \le n-1$ the polynomial identity

$$\sum_{i=1}^{n} \frac{f(X)}{X-\alpha_i} \cdot \frac{\alpha_i^s}{f'(\alpha_i)} = X^s$$

holds, because the difference of the two sides has degree at most $n-1$ and vanishes at each α_j: the jth summand contributes $f'(\alpha_j)\alpha_j^s/f'(\alpha_j) = \alpha_j^s$ and the others vanish, since $f(X)/(X-\alpha_i) = \prod_{k\neq i}(X-\alpha_k)$. The n summands on the left are the images of $\frac{f(X)}{X-\alpha}\cdot\frac{\alpha^s}{f'(\alpha)}$ under the n embeddings of L over K, so by corollary 50.1.13 the identity reads

$$\operatorname{tr}_{L/K}\left(\frac{f(X)}{X-\alpha}\cdot\frac{\alpha^s}{f'(\alpha)}\right) = X^s$$

and comparing the coefficient of X^i on each side gives that $\operatorname{tr}_{L/K}(b_i\alpha^s/f'(\alpha))$ is 1 when $i=s$ and 0 otherwise.

The elements $b_i/f'(\alpha)$ therefore form a K-basis of L, and for $x = \sum_i c_i b_i/f'(\alpha)$ with $c_i \in K$ one has $\operatorname{tr}_{L/K}(x\alpha^s) = c_s$. Since $\mathcal{O} = \mathfrak{o} + \mathfrak{o}\alpha + \cdots + \mathfrak{o}\alpha^{n-1}$, the condition $\operatorname{tr}_{L/K}(x\mathcal{O}) \subseteq \mathfrak{o}$ is exactly the condition that every c_i lie in $\mathfrak{o}$, so

$$\mathfrak{C}_{L/K} = {}^*\mathcal{O} = \frac{1}{f'(\alpha)}\left(\mathfrak{o}b_0 + \cdots + \mathfrak{o}b_{n-1}\right)$$

Expanding $f(X) = (X-\alpha)(b_0 + b_1X + \cdots + b_{n-1}X^{n-1})$ and comparing coefficients gives $b_{n-1} = 1$ and $b_{k-1} = a_k + \alpha b_k$ for $1 \le k \le n-1$, hence

$$b_{n-i} = \alpha^{i-1} + a_{n-1}\alpha^{i-2} + \cdots + a_{n-i+1} \qquad (1 \le i \le n)$$

Each b_{n-i} is monic of degree $i-1$ in α with coefficients in $\mathfrak{o}$, so the b_i are a second $\mathfrak{o}$-basis of $\mathfrak{o} + \mathfrak{o}\alpha + \cdots + \mathfrak{o}\alpha^{n-1} = \mathcal{O}$. Therefore $\mathfrak{C}_{L/K} = f'(\alpha)^{-1}\mathcal{O}$ and

$$\mathfrak{D}_{L/K} = \mathfrak{C}_{L/K}^{-1} = (f'(\alpha)) = (\delta_{L/K}(\alpha))$$

Only the $\mathfrak{o}$-basis $1, \alpha, \ldots, \alpha^{n-1}$ of $\mathfrak{o}[\alpha]$ entered this computation, never the equality $\mathcal{O} = \mathfrak{o}[\alpha]$. Since $\mathfrak{o}$ is integrally closed, the minimal polynomial of any $\alpha \in \mathcal{O}$ again has coefficients in $\mathfrak{o}$, so for *any* $\alpha \in \mathcal{O}$ with $L = K(\alpha)$ the same argument gives the dual of the $\mathfrak{o}$-module $\mathfrak{o}[\alpha]$,

$${}^*\mathfrak{o}[\alpha] := \left\{x \in L \;\middle|\; \operatorname{tr}_{L/K}(x\,\mathfrak{o}[\alpha]) \subseteq \mathfrak{o}\right\} = \frac{1}{f'(\alpha)}\mathfrak{o}[\alpha] \tag{50.6}$$

a fact used in the next proof.

Theorem 50.4.53: Generation Of Different

For every $\alpha \in \mathcal{O}$, the different $\mathfrak{D}_{L/K}$ divides the principal ideal $(\delta_{L/K}(\alpha))$. In other words, the ideal generated by the elements $\delta_{L/K}(\alpha)$ for $\alpha \in \mathcal{O}$ is contained in $\mathfrak{D}_{L/K}$.

***Proof*:**
Let $\mathfrak{a} \subseteq \mathcal{O}$ be the ideal generated by all $\delta_{L/K}(\alpha)$ for $\alpha \in \mathcal{O}$. Only those α with $L = K(\alpha)$ contribute, since $\delta_{L/K}(\alpha) = 0$ otherwise.

Fix such an α, let f be its minimal polynomial over K, and put $b = f'(\alpha)$, which is nonzero because L/K is separable. Let $\mathscr{F}_\alpha = \{x \in L \mid x\mathcal{O} \subseteq \mathfrak{o}[\alpha]\}$ be the conductor of $\mathfrak{o}[\alpha]$ in the sense of definition 50.4.6. For $x \in L$ the chain of equivalences

$$x\mathcal{O} \subseteq \mathfrak{o}[\alpha] \iff b^{-1}x\mathcal{O} \subseteq \frac{1}{b}\mathfrak{o}[\alpha] = {}^*\mathfrak{o}[\alpha] \iff \operatorname{tr}_{L/K}(b^{-1}x\mathcal{O}) \subseteq \mathfrak{o} \iff b^{-1}x \in {}^*\mathcal{O} = \mathfrak{C}_{L/K}$$

holds: the first equivalence is multiplication by b^{-1} together with equation (50.6), and the second holds because $\mathfrak{o}[\alpha]$ is a subring of $\mathcal{O}$ containing 1, so $\mathcal{O} \cdot \mathfrak{o}[\alpha] = \mathcal{O}$ turns the defining condition of ${}^*\mathfrak{o}[\alpha]$ on $b^{-1}x\mathcal{O}$ into $\operatorname{tr}_{L/K}(b^{-1}x\mathcal{O}) \subseteq \mathfrak{o}$, while the converse direction is the case $1 \in \mathfrak{o}[\alpha]$. The third is the definition of ${}^*\mathcal{O}$. Hence $\mathscr{F}_\alpha = b\,\mathfrak{C}_{L/K} = b\,\mathfrak{D}_{L/K}^{-1}$, that is

$$(\delta_{L/K}(\alpha)) = \mathscr{F}_\alpha \mathfrak{D}_{L/K} \tag{50.7}$$

Since $\mathscr{F}_\alpha \subseteq \mathcal{O}$ is an integral ideal, $\mathfrak{D}_{L/K}$ divides $(\delta_{L/K}(\alpha))$. This holds for every α, so $\mathfrak{a} \subseteq \mathfrak{D}_{L/K}$, as claimed.

Equality holds: $\mathfrak{D}_{L/K}$ is the ideal generated by all $\delta_{L/K}(\alpha)$. Summing (50.7) over all $\alpha \in \mathcal{O}$ with $L = K(\alpha)$ shows that the reverse inclusion amounts to $\sum_\alpha \mathscr{F}_\alpha = \mathcal{O}$, that is, to finding for every prime $\mathfrak{B}$ of $\mathcal{O}$ some α with $L = K(\alpha)$ and $\mathfrak{B} \nmid \mathscr{F}_\alpha$. This is proved by completing at $\mathfrak{B}$, where the valuation ring of the completion of L is generated by one element over that of $K_\mathfrak{p}$, *Local Field Theory* [33, Local Dedekind-Kummer Theorem], and passing back through the compatibility of the different with completion (box 50.4.49). Nothing in this book uses the reverse inclusion.

Theorem 50.4.54: Detecting Ramification Using Different

A prime ideal $\mathfrak{P}$ of L is ramified over K if and only if

$$\mathfrak{P} \mid \mathfrak{D}_{L/K}$$

***Proof*:**
Let $\mathfrak{p} = \mathfrak{P} \cap \mathfrak{o}$, let $e = e(\mathfrak{P}/\mathfrak{p})$, and let $\lambda = \mathcal{O}/\mathfrak{P}$ and $\kappa = \mathfrak{o}/\mathfrak{p}$ be the residue fields, with λ/κ separable by the AKLB setup. Factor

$$\mathfrak{p}\mathcal{O} = \mathfrak{P}^e\mathfrak{q} \qquad \mathfrak{q} = \prod_{\mathfrak{P}' \neq \mathfrak{P}} \mathfrak{P}'^{\,e(\mathfrak{P}'/\mathfrak{p})}$$

by theorem 50.2.15, so $\mathfrak{q}$ is coprime to $\mathfrak{P}$. By definition 50.4.10 and the separability of λ/κ, the prime $\mathfrak{P}$ is ramified over K exactly when $e \geq 2$.

First, $\mathfrak{P} \mid \mathfrak{D}_{L/K}$ is equivalent to $\mathfrak{P}^{-1} \subseteq \mathfrak{D}_{L/K}^{-1} = \mathfrak{C}_{L/K}$, and since $\mathfrak{P}^{-1}\mathcal{O} = \mathfrak{P}^{-1}$ the defining condition of $\mathfrak{C}_{L/K}$ reduces to

$$\mathfrak{P} \mid \mathfrak{D}_{L/K} \iff \operatorname{tr}_{L/K}(\mathfrak{P}^{-1}) \subseteq \mathfrak{o}$$

Extension of ideals is multiplicative, so $\mathfrak{p}^{-1}\mathcal{O} = (\mathfrak{p}\mathcal{O})^{-1}$ and

$$\mathfrak{p}^{-1}\mathfrak{b} = (\mathfrak{P}^e\mathfrak{q})^{-1}\mathfrak{P}^{e-1}\mathfrak{q} = \mathfrak{P}^{-1} \qquad \mathfrak{b} := \mathfrak{P}^{e-1}\mathfrak{q}$$

The trace is o-linear and $\mathfrak{p}^{-1} \subseteq K$, so $\mathrm{tr}_{L/K}(\mathfrak{P}^{-1}) = \mathfrak{p}^{-1}\mathrm{tr}_{L/K}(\mathfrak{b})$, and therefore $\mathfrak{P} \big| \mathfrak{D}_{L/K}$ if and only if $\mathrm{tr}_{L/K}(\mathfrak{b}) \subseteq \mathfrak{p}$.

Next, pass to $o_{\mathfrak{p}}$, a discrete valuation ring. Localisation commutes with integral closure: if $x \in L$ satisfies a monic equation over $o_{\mathfrak{p}}$ then clearing denominators makes sx integral over o for some $s \in o \setminus \mathfrak{p}$, so $x \in \mathcal{O}_{\mathfrak{p}}$, and conversely $\mathcal{O}_{\mathfrak{p}}$ is integral over $o_{\mathfrak{p}}$. Hence $\mathcal{O}_{\mathfrak{p}}$ is the integral closure of $o_{\mathfrak{p}}$ in L and is a free $o_{\mathfrak{p}}$-module of rank $n = [L : K]$ by proposition 50.1.32. A $o_{\mathfrak{p}}$-basis of $\mathcal{O}_{\mathfrak{p}}$ is a K-basis of L, so by definition 50.1.10 the element $\mathrm{tr}_{L/K}(x)$ is the trace of the matrix of multiplication by x in that basis, with entries in $o_{\mathfrak{p}}$. Every element of $o \setminus \mathfrak{p}$ acts invertibly on $\mathcal{O}/\mathfrak{p}\mathcal{O}$, so $\overline{B} := \mathcal{O}_{\mathfrak{p}}/\mathfrak{p}\mathcal{O}_{\mathfrak{p}} = \mathcal{O}/\mathfrak{p}\mathcal{O}$, a κ-algebra of dimension n, and reducing the matrix modulo $\mathfrak{p}$ gives

$$\mathrm{tr}_{L/K}(x) \bmod \mathfrak{p} = \mathrm{tr}_{\overline{B}/\kappa}(\overline{x}) \qquad (x \in \mathcal{O}_{\mathfrak{p}})$$

Since $\mathfrak{p}\mathcal{O} \subseteq \mathfrak{b}$, the condition $\mathrm{tr}_{L/K}(\mathfrak{b}) \subseteq \mathfrak{p}$ says that $\mathrm{tr}_{\overline{B}/\kappa}$ vanishes on the image $\overline{\mathfrak{b}} = \mathfrak{b}/\mathfrak{p}\mathcal{O}$.

The Chinese remainder theorem splits $\overline{B}$ as a product of κ-algebras

$$\overline{B} = \mathcal{O}/\mathfrak{p}\mathcal{O} \cong \mathcal{O}/\mathfrak{P}^e \times \prod_{\mathfrak{P}' \neq \mathfrak{P}} \mathcal{O}/\mathfrak{P}'^{\,e(\mathfrak{P}'/\mathfrak{p})}$$

The image of $\mathfrak{b} = \mathfrak{P}^{e-1}\mathfrak{q}$ is 0 in every factor beyond the first, because $\mathfrak{q} \subseteq \mathfrak{P}'^{\,e(\mathfrak{P}'/\mathfrak{p})}$, and it is $(\mathfrak{P}^{e-1}\mathfrak{q} + \mathfrak{P}^e)/\mathfrak{P}^e = \mathfrak{P}^{e-1}/\mathfrak{P}^e$ in the first, because $\mathfrak{q} + \mathfrak{P} = \mathcal{O}$. Multiplication by an element supported in one factor of a product of κ-algebras annihilates the other factors, so $\mathrm{tr}_{\overline{B}/\kappa}$ restricted to $\overline{\mathfrak{b}}$ is the trace map of $\mathcal{O}/\mathfrak{P}^e$ over κ restricted to $\mathfrak{P}^{e-1}/\mathfrak{P}^e$.

If $e \geq 2$ then $\mathfrak{P}^{2e-2} \subseteq \mathfrak{P}^e$, so every element of $\mathfrak{P}^{e-1}/\mathfrak{P}^e$ squares to zero in $\mathcal{O}/\mathfrak{P}^e$. Multiplication by such an element is a nilpotent endomorphism of a finite-dimensional κ-vector space, and a nilpotent endomorphism has trace 0, its characteristic polynomial being a power of X. So $\mathrm{tr}_{\overline{B}/\kappa}$ vanishes on $\overline{\mathfrak{b}}$ and $\mathfrak{P} \big| \mathfrak{D}_{L/K}$.

If $e = 1$ then $\mathcal{O}/\mathfrak{P}^e = \lambda$ and $\mathfrak{P}^{e-1}/\mathfrak{P}^e = \lambda$, so the map in question is $\mathrm{tr}_{\lambda/\kappa}$. The extension λ/κ is separable, so its trace form is nondegenerate by proposition 19.6.31, and applying nondegeneracy to $x = 1$ produces $y \in \lambda$ with $\mathrm{tr}_{\lambda/\kappa}(y) \neq 0$. So $\mathrm{tr}_{\overline{B}/\kappa}$ does not vanish on $\overline{\mathfrak{b}}$ and $\mathfrak{P} \nmid \mathfrak{D}_{L/K}$.

Thus $\mathfrak{P} \big| \mathfrak{D}_{L/K}$ if and only if $e \geq 2$, which is ramification of $\mathfrak{P}$ over K.

(relation between different and discriminant)

Definition 50.4.55: Relative Discriminant

The *discriminant* $\mathfrak{d}_{\mathcal{O}/o}$ is the ideal of o generated by the discriminants $d(\alpha_1, ..., \alpha_n)$ for all bases $\alpha_1, \alpha_2, ..., \alpha_n$ of L/K contained in $\mathcal{O}$:

$$\mathfrak{d}_{\mathcal{O}/o} = \langle \{ d(\alpha_1, \alpha_2, ..., \alpha_n) \mid \alpha_1, \alpha_2, ..., \alpha_n \text{ basis }, \alpha_i \in \mathcal{O} \} \rangle_o$$

In the case where $K = \mathbb{Q}$ and $L/\mathbb{Q}$ is a number field, then $\mathfrak{d} = (d_L)$ is the principal ideal of the usual discriminant.

Theorem 50.4.56: Relating Different And Relative Discriminant

$$\mathfrak{d}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{D}_{L/K})$$

***Proof*:**
Both sides are ideals of o, and an ideal of a Dedekind domain is determined by the exponents in its prime factorisation (corollary 50.2.23), which may be read off after localising at each prime. All three constructions survive localisation at a multiplicative set $S \subseteq o \setminus \{0\}$. For the different this is proposition 50.4.48(2). For the discriminant, a basis of L/K inside $S^{-1}\mathcal{O}$ may be scaled by a single $s \in S$ into $\mathcal{O}$, and $d(s\alpha_1, \dots, s\alpha_n) = s^{2n} d(\alpha_1, \dots, \alpha_n)$ by definition 50.1.24, so $S^{-1}\mathfrak{d}_{\mathcal{O}/o} = \mathfrak{d}_{S^{-1}\mathcal{O}/S^{-1}o}$. For the norm, definition 50.3.13 generates $\mathfrak{N}_{L/K}(I)$ by the $\mathrm{Nm}_{L/K}(\alpha)$ with $\alpha \in I$, and $\mathrm{Nm}_{L/K}(\alpha/s) = \mathrm{Nm}_{L/K}(\alpha)/s^n$, so $S^{-1}\mathfrak{N}_{L/K}(I) = \mathfrak{N}_{L/K}(S^{-1}I)$. We may therefore assume o is a discrete valuation ring with maximal ideal $\mathfrak{p}$.

Under that assumption $\mathcal{O}$ is a Dedekind domain (lemma 50.3.2) with finitely many primes $\mathfrak{P}_1, \dots, \mathfrak{P}_g$, namely the primes dividing $\mathfrak{p}\mathcal{O}$. A nonzero prime $\mathfrak{P}$ of $\mathcal{O}$ contains a nonzero x, whose minimal polynomial over K has coefficients in o and nonzero constant term, and that constant term lies in $\mathfrak{P} \cap o$. So $\mathfrak{P} \cap o$ is a nonzero prime of o, which is $\mathfrak{p}$, and $\mathfrak{P}$ divides $\mathfrak{p}\mathcal{O}$ by proposition 50.3.11. Such a ring is a principal ideal domain: given $\mathfrak{a} = \prod_i \mathfrak{P}_i^{a_i}$, the Chinese remainder theorem gives $x \in \mathcal{O}$ with $x \in \mathfrak{P}_i^{a_i} \setminus \mathfrak{P}_i^{a_i+1}$ for every i, and since there is no other prime, $(x) = \mathfrak{a}$. Also $\mathcal{O}$ is a free o-module of rank $n = [L : K]$ by proposition 50.1.32. Fix a o-basis $\alpha_1, \dots, \alpha_n$ of $\mathcal{O}$. Any K-basis of L contained in $\mathcal{O}$ is obtained from it by a matrix over o, so definition 50.1.24 gives $\mathfrak{d}_{L/K} = (d(\alpha_1, \dots, \alpha_n))$.

Let $\alpha'_1, \dots, \alpha'_n$ be the dual basis for the trace pairing, which exists by proposition 19.6.31. Writing $x \in L$ as $x = \sum_j c_j \alpha'_j$ with $c_j \in K$, we get $\mathrm{tr}_{L/K}(x\alpha_i) = c_i$. As $\mathcal{O} = \bigoplus_i o\alpha_i$ and the trace is K-linear, $\mathrm{tr}_{L/K}(x\mathcal{O}) \subseteq o$ exactly when every c_i lies in o, so $\mathfrak{C}_{L/K}$ is o-free on $\alpha'_1, \dots, \alpha'_n$. Since $\mathfrak{D}_{L/K} \subseteq \mathcal{O}$ is integral and $\mathcal{O}$ is a principal ideal domain, $\mathfrak{D}_{L/K} = (\gamma)$ for some $\gamma \in \mathcal{O}$, and $\mathfrak{C}_{L/K} = \gamma^{-1}\mathcal{O}$ is o-free on $\gamma^{-1}\alpha_1, \dots, \gamma^{-1}\alpha_n$. Two o-bases of the same free module differ by a matrix in $\mathrm{GL}_n(o)$, whose determinant is a unit, so

$$(d(\alpha'_1, \dots, \alpha'_n)) = (d(\gamma^{-1}\alpha_1, \dots, \gamma^{-1}\alpha_n))$$

Writing $P = (\sigma_i(\alpha_j))$ and $Q = (\sigma_i(\alpha'_j))$ for the K-embeddings σ_i of L, corollary 50.1.13 gives $(P^tQ)_{jk} = \mathrm{tr}_{L/K}(\alpha_j\alpha'_k)$, which is the identity matrix, so $\det P \det Q = 1$ and

$$d(\alpha_1, \dots, \alpha_n)\, d(\alpha'_1, \dots, \alpha'_n) = 1$$

Likewise $(\sigma_i(\gamma^{-1}\alpha_j)) = \mathrm{diag}(\sigma_i(\gamma^{-1})) \cdot P$, so

$$d(\gamma^{-1}\alpha_1, \dots, \gamma^{-1}\alpha_n) = \mathrm{Nm}_{L/K}(\gamma)^{-2} d(\alpha_1, \dots, \alpha_n)$$

Finally $\mathfrak{N}_{L/K}(\mathfrak{D}_{L/K}) = (\mathrm{Nm}_{L/K}(\gamma))$: by definition 50.3.13 the left side is generated by the $\mathrm{Nm}_{L/K}(\gamma x) = \mathrm{Nm}_{L/K}(\gamma)\mathrm{Nm}_{L/K}(x)$ for $x \in \mathcal{O}$, and the $\mathrm{Nm}_{L/K}(x)$ generate o because they lie in o by corollary 50.1.14 and include $\mathrm{Nm}_{L/K}(1) = 1$. This is lemma 50.3.15(1) in the number field case. Combining,

$$\mathfrak{d}_{L/K}^{-1} = (d(\alpha_1, \dots, \alpha_n)^{-1}) = (d(\alpha'_1, \dots, \alpha'_n)) = (\mathrm{Nm}_{L/K}(\gamma)^{-2})\, \mathfrak{d}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{D}_{L/K})^{-2}\mathfrak{d}_{L/K}$$

so $\mathfrak{d}_{L/K}^2 = \mathfrak{N}_{L/K}(\mathfrak{D}_{L/K})^2$. Both are powers of $\mathfrak{p}$, so the exponents agree and $\mathfrak{d}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{D}_{L/K})$.

Corollary 50.4.57: Tower For Relative Discriminant

Let $M/L/K$. Then:

$$\mathfrak{d}_{M/K} = \mathfrak{d}_{L/K}^{[M:L]} \mathfrak{N}_{L/K}(\mathfrak{d}_{M/L})$$

***Proof*:**

Take $M/L/K$ to be number fields, the setting in which the ideal norm of definition 50.3.13 carries the properties collected in lemma 50.3.15. The tower law for the different, proposition 50.4.48(1), reads

$$\mathfrak{D}_{M/K} = \mathfrak{D}_{M/L} \left(\mathfrak{D}_{L/K} \mathcal{O}_M \right)$$

Apply $\mathfrak{N}_{M/K}$ and use theorem 50.4.56 on the left, transitivity $\mathfrak{N}_{M/K} = \mathfrak{N}_{L/K} \circ \mathfrak{N}_{M/L}$ from lemma 50.3.15(2), and multiplicativity from lemma 50.3.15(3):

$$\mathfrak{d}_{M/K} = \mathfrak{N}_{L/K} \left(\mathfrak{N}_{M/L}(\mathfrak{D}_{M/L}) \cdot \mathfrak{N}_{M/L} \left(\mathfrak{D}_{L/K} \mathcal{O}_M \right) \right)$$

The first inner factor is $\mathfrak{d}_{M/L}$ by theorem 50.4.56, and the second is $\mathfrak{D}_{L/K}^{[M:L]}$ by lemma 50.3.15(4). Multiplicativity of $\mathfrak{N}_{L/K}$ then gives

$$\mathfrak{d}_{M/K} = \mathfrak{N}_{L/K}(\mathfrak{d}_{M/L}) \cdot \mathfrak{N}_{L/K}(\mathfrak{D}_{L/K})^{[M:L]} = \mathfrak{N}_{L/K}(\mathfrak{d}_{M/L}) \, \mathfrak{d}_{L/K}^{[M:L]}$$

where the last step is theorem 50.4.56 once more.

Corollary 50.4.58: Discriminant And Ramified Primes

Let L/K be an extension of number fields and let $\mathfrak{p}$ be a nonzero prime of $\mathcal{O}_K$. Then $\mathfrak{p}$ is ramified in L if and only if

$$\mathfrak{p} \big| \mathfrak{d}_{L/K}$$

In particular, the extension L/K is unramified if and only if

$$\mathfrak{d}_{L/K} = (1)$$

***Proof*:**

Write $\mathfrak{D} = \mathfrak{D}_{L/K}$ and $\mathfrak{C} = \mathfrak{C}_{L/K}$. Traces of elements of $\mathcal{O}_L$ lie in $\mathcal{O}_K$ (corollary 50.1.14), so $\mathcal{O}_L \subseteq \mathfrak{C}$, and multiplying by $\mathfrak{D}$ gives $\mathfrak{D} \subseteq \mathfrak{C}\mathfrak{D} = \mathcal{O}_L$ (theorem 50.2.22). So $\mathfrak{D}$ is a nonzero integral ideal, and $\mathfrak{D} = \prod_{\mathfrak{P}} \mathfrak{P}^{d_{\mathfrak{P}}}$ with integers $d_{\mathfrak{P}} \geq 0$, almost all zero (theorem 50.2.15). By theorem 50.4.56, the multiplicativity of the ideal norm (lemma 50.3.15(3)) and corollary 50.3.16,

$$\mathfrak{d}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{D}) = \prod_{\mathfrak{P}} \mathfrak{N}_{L/K}(\mathfrak{P})^{d_{\mathfrak{P}}} = \prod_{\mathfrak{P}} (\mathfrak{P} \cap \mathcal{O}_K)^{f(\mathfrak{P}) d_{\mathfrak{P}}}$$

where $f(\mathfrak{P})$ is the inertia degree of $\mathfrak{P}$ over $\mathfrak{P} \cap \mathcal{O}_K$. By unique factorization in $\mathcal{O}_K$, the exponent of $\mathfrak{p}$ in $\mathfrak{d}_{L/K}$ is $\sum_{\mathfrak{P}} f(\mathfrak{P}) d_{\mathfrak{P}}$, the sum running over the primes $\mathfrak{P}$ of $\mathcal{O}_L$ above $\mathfrak{p}$. Every $f(\mathfrak{P}) \geq 1$, so $\mathfrak{p} \big| \mathfrak{d}_{L/K}$ if and only if $\mathfrak{P} \big| \mathfrak{D}$ for some $\mathfrak{P}$ above $\mathfrak{p}$. By theorem 50.4.54, this happens if and only if some prime above $\mathfrak{p}$ is ramified over K, that is, if and only if $\mathfrak{p}$ is ramified in L (definition 50.4.10).

For the second statement, $\mathfrak{d}_{L/K} = \mathfrak{N}_{L/K}(\mathfrak{D})$ is a nonzero integral ideal of $\mathcal{O}_K$, being generated by the norms of the elements of $\mathfrak{D} \subseteq \mathcal{O}_L$, which lie in $\mathcal{O}_K$ (corollary 50.1.14). By theorem 50.2.15, it equals (1) exactly when no prime divides it, that is, by the first statement, exactly when no prime of $\mathcal{O}_K$ is ramified in L, as claimed.

Proposition 50.4.59: Coprime Discriminants And Difference

Let K_1, K_2 be Galois over $\mathbb{Q}$ with coprime discriminants, of degrees n_1 and n_2, with $K_1 \cap K_2 = \mathbb{Q}$, and let $K = K_1K_2$. Then:

$$\mathfrak{d}_{K/\mathbb{Q}} = \mathfrak{d}_{K_1/\mathbb{Q}}^{n_2} \mathfrak{d}_{K_2/\mathbb{Q}}^{n_1}$$

***Proof*:**
This is theorem 50.1.47 applied over the base field $\mathbb{Q}$: its hypotheses are that $K_1/\mathbb{Q}$ and $K_2/\mathbb{Q}$ are Galois with coprime discriminants and intersection $\mathbb{Q}$, and over $\mathbb{Q}$ the integral bases it posits exist. Its conclusion gives the integral basis $\omega_i\omega_j'$ of $\mathcal{O}_K$ together with the discriminant $\mathfrak{d}_{K_1/\mathbb{Q}}^{n_2}\mathfrak{d}_{K_2/\mathbb{Q}}^{n_1}$, an identity of integers that reads as the stated identity of ideals.

(Neukirch goes on to prove some important results which are really cool! For example, if K is an algebraic number field and S a finite set of primes of K, then there exists only finitely many extensions L/K of degree n which are unramified outside of S!)

Exercise 50.4.2

1. Show that L_D is the maximal field in which the ramification and inertial degree is 1, and similarly for L_I.
2. Let K be a number fields. Show that if $\operatorname{disc}(K)$ is square free, then K has no intermediary number field

Wild and Tame Ramification

(see this! here)

(This section is essentially here for the proof of Kronecker-Weber Theorem. May choose to move it down to that section).

We end off by exploring some more about the inertia group, namely we shall like at *wild* and *tame* inertia.

Definition 50.4.60: Wild Inertia Group

Let L/K be an extension of number fields, $I_{\mathfrak{B}} \leqslant D_{\mathfrak{B}}$ be the inertia group. Then $W_{\mathfrak{B}} \trianglelefteq I_{\mathfrak{B}}$ is defined to be:

$$W_{\mathfrak{B}} := \left\{ g \in I_{\mathfrak{B}} \;\middle|\; \forall \overline{\alpha} \in \mathcal{O}_L/\mathfrak{B}^2,\ g(\overline{\alpha}) = \overline{\alpha} \right\}$$

the wild inertia group can be thought of as a parallel to "local coordinates". In particular if we have an extension $K/\mathbb{Q}$ of number fields, then we have an extension $K/\mathbb{Q}_p$ then $W_{\mathfrak{B}}$ is the unique sylow

p-subgroup of the inertia group. If you know some algebraic geometry, an intuitive reason to see why the quotient $\mathfrak{B}^2$ shows up is since the tangent space of a variety/scheme is given by $\mathfrak{m}/\mathfrak{m}^2$.

Theorem 50.4.61: Wild Inertia Group Is Sylow Subgroup

Let L/K be a Galois extension of number fields (for instance $K = \mathbb{Q}$), let Q be a nonzero prime of $\mathcal{O}_L$, $\kappa = \mathcal{O}_L/Q$, and let p be the prime number with $Q \cap \mathbb{Z} = p\mathbb{Z}$. For $\sigma \in I_Q$ there is a unique $\theta(\sigma) \in \kappa^\times$ with $\sigma(x) + Q^2 = \theta(\sigma)(x + Q^2)$ for every $x \in Q$, where Q/Q^2 is a κ-vector space through $(a + Q)(x + Q^2) = ax + Q^2$. The map $\theta\colon I_Q \to \kappa^\times$ is a group homomorphism with kernel W_Q, and W_Q is the unique Sylow p-subgroup of I_Q, hence $W_Q \trianglelefteq I_Q$.

***Proof*:**
Write $I = I_Q$, $W = W_Q$, $\kappa = \mathcal{O}_L/Q$ and $q = |\kappa|$. By lemma 50.2.29, κ is a finite field of characteristic p, so q is a power of p, and $p \in Q$. By definition 50.4.32 and corollary 50.4.35, every $\sigma \in I$ satisfies $\sigma(Q) = Q$ and $\sigma(\alpha) - \alpha \in Q$ for all $\alpha \in \mathcal{O}_L$, and by definition 50.4.60 such a σ lies in W exactly when $\sigma(\alpha) - \alpha \in Q^2$ for all $\alpha \in \mathcal{O}_L$. Each $\sigma \in I$ is a ring automorphism of $\mathcal{O}_L$ (lemma 50.4.23) with $\sigma(Q) = Q$, so $\sigma(Q^k) = Q^k$ for every $k \geq 1$.

Step 1: W is the kernel of a homomorphism $I \to \kappa^\times$. The group $V = Q/Q^2$ is a κ-vector space under $(a + Q)(x + Q^2) = ax + Q^2$, which is well defined since $Q \cdot Q = Q^2$. It has $[Q : Q^2] = \mathfrak{N}(Q^2)/\mathfrak{N}(Q) = \mathfrak{N}(Q) = q$ elements (definition 50.1.61, proposition 50.2.30), so $\dim_\kappa V = 1$. Each $\sigma \in I$ induces a bijection $\overline{\sigma}\colon V \to V$, $x + Q^2 \mapsto \sigma(x) + Q^2$, which is κ-linear: for $a \in \mathcal{O}_L$ and $x \in Q$,

$$\sigma(ax) - a\sigma(x) = (\sigma(a) - a)\sigma(x) \in Q \cdot Q = Q^2$$

A κ-linear bijection of the one-dimensional space V is multiplication by a unique scalar, so $\overline{\sigma}$ is multiplication by some $\theta(\sigma) \in \kappa^\times$. Since $\overline{\sigma\tau} = \overline{\sigma}\,\overline{\tau}$, the map $\theta\colon I \to \kappa^\times$ is a group homomorphism, and $W \subseteq \ker\theta$.

For the reverse inclusion let $\sigma \in \ker\theta$, so that $\sigma(x) - x \in Q^2$ for every $x \in Q$, and let $\alpha \in \mathcal{O}_L$. Every $y \in \kappa$ satisfies $y^q = y$, for $y \neq 0$ by theorem 3.3.1 in $\kappa^\times$, which has order $q - 1$. So $x := \alpha - \alpha^q \in Q$. Write $\sigma(\alpha) = \alpha + z$ with $z \in Q$. By the binomial theorem,

$$\sigma(\alpha^q) = (\alpha + z)^q = \alpha^q + q\alpha^{q-1}z + \sum_{k=2}^{q} \binom{q}{k} \alpha^{q-k} z^k$$

where $q\alpha^{q-1}z \in Q^2$ because $q \in p\mathbb{Z} \subseteq Q$ and $z \in Q$, and each later term lies in Q^2. So $\sigma(\alpha^q) - \alpha^q \in Q^2$, and

$$\sigma(\alpha) - \alpha = (\sigma(\alpha^q) - \alpha^q) + (\sigma(x) - x) \in Q^2$$

Hence $\sigma \in W$ and $W = \ker\theta$. In particular $W \trianglelefteq I$, and I/W is isomorphic to a subgroup of $\kappa^\times$ (theorem 3.5.1), so $[I : W]$ divides $q - 1$ (theorem 3.3.1). As q is a power of p, $p \nmid [I : W]$.

Step 2: an element of W of order prime to p is trivial. Let $\tau \in W$ have order m with $p \nmid m$, and put $\delta(\alpha) = \tau(\alpha) - \alpha$ for $\alpha \in \mathcal{O}_L$. We show by induction on $k \geq 2$ that $\delta(\mathcal{O}_L) \subseteq Q^k$. The case

$k = 2$ is $\tau \in W$. Assume $\delta(\mathcal{O}_L) \subseteq Q^k$ for some $k \geq 2$. First, $\delta(Q^k) \subseteq Q^{k+1}$: the group Q^k is additively generated by products $y_1 \cdots y_k$ with $y_i \in Q$, the map δ is additive, and

$$\delta(y_1 \cdots y_k) = \sum_{i=1}^{k} \tau(y_1) \cdots \tau(y_{i-1})\, \delta(y_i)\, y_{i+1} \cdots y_k$$

where in each term $\delta(y_i) \in Q^k$ and the other $k-1$ factors lie in Q, so each term lies in $Q^{2k-1} \subseteq Q^{k+1}$. Next, by induction on $j \geq 1$,

$$\tau^j(\alpha) - \alpha - j\delta(\alpha) \in Q^{k+1} \qquad \alpha \in \mathcal{O}_L$$

The case $j = 1$ is the definition of δ. If it holds for j, write $\tau^j(\alpha) = \alpha + j\delta(\alpha) + z$ with $z \in Q^{k+1}$. Then $\tau^{j+1}(\alpha) = \alpha + \delta(\alpha) + j\delta(\alpha) + j\delta(\delta(\alpha)) + \tau(z)$, where $\delta(\delta(\alpha)) \in \delta(Q^k) \subseteq Q^{k+1}$ and $\tau(z) \in Q^{k+1}$, which is the case $j+1$. Taking $j = m$ gives $m\delta(\alpha) \in Q^{k+1}$. If $\delta(\alpha) \neq 0$, then the exponent of Q in the factorization of $m\delta(\alpha)\mathcal{O}_L = (m\mathcal{O}_L)(\delta(\alpha)\mathcal{O}_L)$ is at least $k+1$ (corollary 50.2.18, theorem 50.2.15). As $m \notin p\mathbb{Z} = Q \cap \mathbb{Z}$, the prime Q does not divide $m\mathcal{O}_L$, so the exponent of Q in $\delta(\alpha)\mathcal{O}_L$ is at least $k+1$, that is $\delta(\alpha) \in Q^{k+1}$. This completes the induction.

So $\delta(\alpha) \in Q^k$ for every k. If $\delta(\alpha) \neq 0$, then Q^k divides $\delta(\alpha)\mathcal{O}_L$ for every k, which is impossible because the exponent of Q in the factorization of $\delta(\alpha)\mathcal{O}_L$ is finite. Hence τ fixes $\mathcal{O}_L$ pointwise, and therefore fixes L pointwise, as every element of L is a quotient of elements of $\mathcal{O}_L$ (proposition 50.1.7). So $\tau = \mathrm{id}$.

Step 3: conclusion. Let $\sigma \in W$ have order $p^a m$ with $p \nmid m$. Then $\sigma^{p^a} \in W$ has order m, so $\sigma^{p^a} = \mathrm{id}$ by Step 2, and $m = 1$. If a prime $\ell \neq p$ divided $|W|$, then theorem 4.8.7 would give an element of W of order ℓ, which is impossible. So $|W|$ is a power of p. Since $|I| = |W|\,[I : W]$ with $p \nmid [I : W]$ by Step 1, W is a Sylow p-subgroup of I. It is normal in I by Step 1, so it is the unique Sylow p-subgroup of I (corollary 4.8.9), as we sought to show.

Lemma 50.4.62: Wild Inertia And Uniformizer

In the setting of theorem 50.4.61, let $\pi \in Q \setminus Q^2$ be a uniformizer for Q and let $\sigma \in I_Q$. Then:

$$\sigma \in W_Q \qquad \Leftrightarrow \qquad \sigma(\pi) - \pi \in Q^2$$

that is, $\sigma(\pi) = \pi \bmod Q^2$

***Proof*:**
By theorem 50.4.61, $\sigma \in W_Q$ exactly when $\theta(\sigma) = 1$, and $\sigma(\pi) + Q^2 = \theta(\sigma)(\pi + Q^2)$. So $\sigma(\pi) - \pi + Q^2 = (\theta(\sigma) - 1)(\pi + Q^2)$. As $\pi \notin Q^2$, the vector $\pi + Q^2$ of the κ-vector space Q/Q^2 is nonzero, so this is 0 exactly when $\theta(\sigma) = 1$, completing the proof.

Example 50.4.63: Example from Class for wild inertia
Let $\zeta = e^{2\pi i/8}$, a primitive 8th root of unity, and $K = \mathbb{Q}(\zeta)$, which contains $i = \zeta^2$ and $\sqrt{2} = \zeta + \zeta^{-1}$. By definition 19.7.2 and proposition 19.7.7, the minimal polynomial of ζ is

$\Phi_8(x) = \prod_{a\in\{1,3,5,7\}}(x-\zeta^a) = x^4+1$, so $[K:\mathbb{Q}] = 4$ and $G = \mathrm{Gal}_{\mathbb{Q}}(K) = \{\sigma_1,\sigma_3,\sigma_5,\sigma_7\}$ with $\sigma_a(\zeta) = \zeta^a$.

The prime above 2. Setting $x = 1$ gives $2 = \prod_a(1-\zeta^a)$. For odd a, $1-\zeta^a = (1-\zeta)(1+\zeta+\cdots+\zeta^{a-1})$, and the second factor is a unit, with inverse $(1-\zeta)/(1-\zeta^a) = 1+\zeta^a+\cdots+\zeta^{a(a'-1)}$ for $aa' \equiv 1 \bmod 8$. So $2\mathcal{O}_K = \mathfrak{B}^4$ with $\mathfrak{B} = (1-\zeta)$, which is a proper ideal as $1/2 \notin \mathcal{O}_K$ (theorem 50.1.9(1)). If $\mathfrak{B} = \mathfrak{q}_1^{a_1}\cdots\mathfrak{q}_t^{a_t}$, then proposition 50.4.3 gives $\sum_j 4a_jf_j = [K:\mathbb{Q}] = 4$, so $\mathfrak{B}$ is a prime of degree 1. So 2 is totally ramified, and $I_{\mathfrak{B}} = G$, as $|I_{\mathfrak{B}}| = e = 4 = |G|$ (proposition 50.4.37, the residue fields being finite).

The wild inertia group. Let $v(x)$ be the exponent of $\mathfrak{B}$ in $x\mathcal{O}_K$, so that $v(xy) = v(x)+v(y)$, $v(2) = 4$, and $\pi = 1-\zeta$ has $v(\pi) = 1$, a uniformizer. For $\sigma_a \neq \sigma_1$, $\sigma_a(\pi)-\pi = \zeta-\zeta^a = \zeta(1-\zeta^{a-1})$ with ζ a unit, so $v(\sigma_a(\pi)-\pi) = v(1-\zeta^{a-1})$, and:

- for $a = 3$, $1-\zeta^2 = 1-i$ and $(1-i)^2 = -2i$, so $2v(1-i) = v(2) = 4$ and $v = 2$
- for $a = 7$, $1-\zeta^6 = 1+i = i(1-i)$, so $v = 2$
- for $a = 5$, $1-\zeta^4 = 2$, so $v = 4$

So $\sigma(\pi)-\pi \in \mathfrak{B}^2$ for every $\sigma \in G$, and lemma 50.4.62 gives $W_{\mathfrak{B}} = I_{\mathfrak{B}} = G$, a 2-group, as theorem 50.4.61 predicts. The subgroups $\{\sigma \in G \mid v(\sigma(\pi)-\pi) \geq j\}$, with $v(0) = \infty$, are G for $j \leq 2$, then $\{\sigma_1,\sigma_5\}$ for $j = 3,4$, then $\{\sigma_1\}$ for $j \geq 5$.

Theorem 50.4.64: Abelian Extension Wild Map

Let L/K be a Galois extension of number fields, $G = \mathrm{Gal}_K(L)$, $P \subseteq \mathcal{O}_K$ a nonzero prime, Q a prime of $\mathcal{O}_L$ lying over P, W_Q the wild inertia group, and $\theta\colon I_Q \to \mathbb{F}_Q^\times$ the homomorphism of theorem 50.4.61, where $\mathbb{F}_Q = \mathcal{O}_L/Q$ and $\mathbb{F}_P = \mathcal{O}_K/P \subseteq \mathbb{F}_Q$. For a uniformizer π of Q, $\theta(\sigma)$ is the class of $\sigma(\pi)/\pi$ in the sense that $\sigma(\pi) \equiv \theta(\sigma)\pi \bmod Q^2$, and θ induces an injective homomorphism

$$\varphi : I_Q/W_Q \hookrightarrow \mathbb{F}_Q^\times \qquad [\sigma] \mapsto \theta(\sigma)$$

If G is abelian, then $\mathrm{im}\varphi \subseteq \mathbb{F}_P^\times$.

***Proof*:**
Step 1: the map. By theorem 50.4.61, θ is a homomorphism with kernel W_Q, so it induces the injective homomorphism φ (theorem 3.5.1), and $\sigma(\pi)+Q^2 = \theta(\sigma)(\pi+Q^2)$ by definition.

Step 2: conjugation. Let $\tau \in D_Q$ and $\sigma \in I_Q$, and let $\overline{\tau}$ be the automorphism $a+Q \mapsto \tau(a)+Q$ of $\mathbb{F}_Q$ fixing $\mathbb{F}_P$. Lift $\theta(\sigma)$ to $c \in \mathcal{O}_L$, so that $\sigma(y)-cy \in Q^2$ for $y \in Q$. For $x \in Q$ we have $\tau^{-1}(x) \in Q$, so $\sigma(\tau^{-1}(x)) - c\tau^{-1}(x) \in Q^2$, and applying τ, which preserves Q^2, gives $\tau\sigma\tau^{-1}(x) - \tau(c)x \in Q^2$. So $\theta(\tau\sigma\tau^{-1}) = \overline{\tau}(\theta(\sigma))$.

Step 3: abelian groups. If G is abelian, then $\tau\sigma\tau^{-1} = \sigma$, so $\theta(\sigma)$ is fixed by $\overline{\tau}$ for every $\tau \in D_Q$. The homomorphism $D_Q \to \mathrm{Gal}_{\mathbb{F}_P}(\mathbb{F}_Q)$, $\tau \mapsto \overline{\tau}$, is surjective (proposition 50.4.31), so $\theta(\sigma)$ is

fixed by $\text{Gal}_{\mathbb{F}_P}(\mathbb{F}_Q)$. Let $q = |\mathbb{F}_P|$. Every $a \in \mathbb{F}_P$ satisfies $a^q = a$, by theorem 3.3.1 in $\mathbb{F}_P^\times$, so the map $y \mapsto y^q$ is an injective ring endomorphism of the finite field $\mathbb{F}_Q$ fixing $\mathbb{F}_P$, hence an element of $\text{Gal}_{\mathbb{F}_P}(\mathbb{F}_Q)$. So $\theta(\sigma)$ is a root of $X^q - X$, whose at most q roots in $\mathbb{F}_Q$ are the elements of $\mathbb{F}_P$, and $\theta(\sigma) \in \mathbb{F}_P^\times$, completing the proof.

Exercise 50.4.3

1. (Define higher-order ramification. Show that the inertia group is solvable, and when the residue fields are finite then the decomposition group is solvable).

50.4.4 Frobenius Automorphism

This is a short section to single out the Frobenius automorphisms from corollary 50.4.34 due to its importance in Class Field Theory (CFT). Namely the Frobenius automorphism is central to relating the structure of abelian galois groups to the structure of the class group. The full exposition is beyond the scope of this textbook, but the reader can still get an appreciation behind why the Frobenius automorphism is so important. For a full exposition, see [77].

Assume $\mathfrak{B}$ over $\mathfrak{p}$ is unramified in $L/K/\mathbb{Q}$, so that $I_{\mathfrak{B}}$ is trivial (which by proposition 50.4.12 and proposition 50.4.16 can be shown to be the case for all put finitely many primes). Then $D_{\mathfrak{B}} \cong \text{Gal}_{\kappa(\mathfrak{p})}(\kappa(\mathfrak{B})) \cong (\mathbb{Z}/n\mathbb{Z})$. By finite field theory, we know that there exists the *Frobenius generator* sending $x \mapsto x^{\mathfrak{N}(\mathfrak{B})}$ since $\mathfrak{N}(\mathfrak{B}) = f$ and the order of this group is f. Thus, for each prime $\mathfrak{B}/\mathfrak{p}$, have a corresponding automorphism in the decomposition group, and hence the Galois group:

Definition 50.4.65: Frobenius Automorphism of a Prime

Let $\sigma \in D_{\mathfrak{B}}$. Then σ is called the *Frobenius* if $\sigma(\alpha) \equiv \alpha^f \mod \mathfrak{B}$ where f is the inertia degree of $\mathfrak{B}$ over $\mathfrak{p}$. The collection of element $\sigma \in D_{\mathfrak{B}}$ with this property is denoted $\text{Frob}_{\mathfrak{B}/\mathfrak{p}}$ so that is $\sigma \in \text{Frob}_{\mathfrak{B}/\mathfrak{p}}$:

$$\sigma(\alpha) \equiv \alpha^f \mod \mathfrak{B}$$

Note that if $\mathfrak{B}$ were ramified, then the Frobenius automorphism is defined up to the coset $I_{\mathfrak{B}}$: $\sigma + I_{\mathfrak{B}}$. If another $\mathfrak{B}' = \sigma(\mathfrak{B})$[27] is considered, the Frobenius element differ conjugation:

$$\text{Frob}_{\sigma(\mathfrak{B}/\mathfrak{p})} = \sigma \text{Frob}_{\mathfrak{B}/\mathfrak{p}} \sigma^{-1}$$

If $D_{\mathfrak{B}}$ is abelian, then the Frobenius element is *only* determined by the prime $\mathfrak{p}$ as

$$\text{Frob}_{\sigma(\mathfrak{B}/\mathfrak{p})} = \sigma \text{Frob}_{\mathfrak{B}/\mathfrak{p}} \sigma^{-1} = \text{Frob}_{\mathfrak{B}/\mathfrak{p}}$$

Thus, we may denote it as $\text{Frob}_{\mathfrak{p}}$. In this case, we have:

$$\sigma(\alpha) = \alpha^{\mathfrak{N}(\mathfrak{p})} \mod \mathfrak{p}\mathcal{O}_L$$

because $\mathfrak{p}\mathcal{O}_L$ is the product of all primes $\mathfrak{B}$ over $\mathfrak{p}$. Another immediate observation is that if $\mathfrak{p}$ spits completely, then $f = 1$, and the Frobenius element for $\mathfrak{p}$ shall be the identity, and hence the Frobenius element captures behaviour in the case where a prime does not completely split.

[27] by transitivity and definition of the decomposition group, any $\mathfrak{B}'$ is of this form

The important realization is that if $\text{Gal}_k(F)$ is abelian, there exist $\sigma \in \text{Gal}_k(F)$ that are associated to primes $\mathfrak{p}$ in the sense that the structure of σ mod $\mathfrak{B}/\mathfrak{p}$ is simply the power map (i.e. cyclic)! If each element $\sigma \in \text{Gal}_k(F)$ can have such an association, then that means that primes have a strong link to the structure of an abelian galois group. Class field theory [77] makes this precise: for a finite abelian extension F/k of number fields, the Artin map, which sends an unramified prime $\mathfrak{p}$ to its Frobenius element, identifies $\text{Gal}_k(F)$ with a quotient of a ray class group of k.

When $\text{Gal}_k(F)$ is non-abelian, the situation become more tenuous. Robert Langland is credited for finding the right framework to extend this correspondence through the use of *representation theory*. This is the origins of the famous *Langland's Conjecture*.

50.4.5 Example: Cyclotomic Fields

By example 50.1.31, the discriminant of $\mathbb{Z}[\zeta_{p^k}]$, which is the ring of integers of $\mathbb{Q}(\zeta_{p^k})$ by proposition 50.1.50, is up to sign a power of p. So by corollary 50.4.58, a prime that ramifies in $\mathbb{Q}(\zeta_{p^k})$ divides this discriminant, hence equals p.

Lemma 50.4.66: Cyclotomic Fields Lemma

Let $n = p^k$ be a prime power, ζ_{p^k} a primitive p^kth root of unity, and $\lambda = 1 - \zeta_{p^k}$. Then the principal ideal $(\lambda) \subseteq \mathcal{O}$ in the ring of integers of $\mathbb{Q}(\zeta_{p^k})$ is a prime ideal of degree 1, and:

$$p\mathcal{O} = (\lambda)^d$$

where $d = \varphi(n) = [\mathbb{Q}(\zeta_{p^k}) : \mathbb{Q}]$. Furthermore, the basis $1, \zeta_{p^k}, ..., \zeta_{p^k}^{d-1}$ of $\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}$ has discriminant:

$$d_{\mathbb{Q}(\zeta_{p^k})/\mathbb{Q}}(1, \zeta_{p^k}, ..., \zeta_{p^k}^{d-1}) = \pm p^s$$

where $s = p^{k-1}(kp - k - 1)$

***Proof*:**
Write $\zeta = \zeta_{p^k}$, $K = \mathbb{Q}(\zeta)$ and $\Phi = \Phi_{p^k}$.

Step 1: $p = \prod_r (1 - \zeta^r)$. By definition 19.7.2 and lemma 19.7.4,

$$\Phi(x) = \prod_{r \in (\mathbb{Z}/p^k\mathbb{Z})^\times} (x - \zeta^r) = \frac{x^{p^k} - 1}{x^{p^{k-1}} - 1} = x^{p^{k-1}(p-1)} + \cdots + x^{p^{k-1}} + 1$$

It is irreducible over $\mathbb{Q}$ (proposition 19.7.7), so it is the minimal polynomial of ζ and $d = [K : \mathbb{Q}] = \varphi(p^k)$. Setting $x = 1$ gives

$$p = \Phi(1) = \prod_{r \in (\mathbb{Z}/p^k\mathbb{Z})^\times} (1 - \zeta^r)$$

Step 2: $p\mathcal{O} = (\lambda)^d$. For $r \in (\mathbb{Z}/p^k\mathbb{Z})^\times$, represented by a positive integer, $1 - \zeta^r = (1 - \zeta)\epsilon_r$ with

$\epsilon_r = 1 + \zeta + \cdots + \zeta^{r-1} \in \mathcal{O}$. If r' is a positive integer with $rr' \equiv 1 \bmod p^k$, then

$$\frac{1-\zeta}{1-\zeta^r} = \frac{1-(\zeta^r)^{r'}}{1-\zeta^r} = 1 + \zeta^r + \cdots + (\zeta^r)^{r'-1} \in \mathcal{O}$$

so ϵ_r is a unit of $\mathcal{O}$. By Step 1, $p = \epsilon\lambda^d$ with the unit $\epsilon = \prod_r \epsilon_r$, so $p\mathcal{O} = (\lambda)^d$.

Step 3: (λ) is prime of degree 1. The element λ is not a unit, since otherwise $p\mathcal{O} = \mathcal{O}$ and $1/p \in \mathcal{O} \cap \mathbb{Q} = \mathbb{Z}$ (theorem 50.1.9(1)). Write $(\lambda) = \mathfrak{q}_1^{a_1} \cdots \mathfrak{q}_t^{a_t}$ with distinct primes and $a_j \geq 1$, so that $p\mathcal{O} = \mathfrak{q}_1^{da_1} \cdots \mathfrak{q}_t^{da_t}$. By proposition 50.4.3, with $o = \mathbb{Z}$ and $\mathcal{O} = \mathcal{O}_K$, $\sum_j da_j f_j = d$, so $t = 1$, $a_1 = 1$ and $f_1 = 1$: (λ) is a prime of degree 1.

Step 4: the discriminant. Let $\eta = \zeta^{p^{k-1}}$, a primitive pth root of unity. By proposition 50.1.29, $\operatorname{disc}(1, \zeta, \ldots, \zeta^{d-1}) = \pm \operatorname{Nm}_{K/\mathbb{Q}}(\Phi'(\zeta))$. Differentiating $(x^{p^{k-1}} - 1)\Phi(x) = x^{p^k} - 1$ and substituting $x = \zeta$, where $\Phi(\zeta) = 0$, gives

$$(\eta - 1)\Phi'(\zeta) = p^k \zeta^{p^k - 1} = p^k \zeta^{-1}$$

The norm is multiplicative, $\operatorname{Nm}_{K/\mathbb{Q}}(p^k) = p^{kd}$, and $\operatorname{Nm}_{K/\mathbb{Q}}(\zeta^{-1}) = \pm 1$ as ζ^{-1} is a unit (proposition 50.1.18). By Step 1 for $k = 1$ and corollary 50.1.13, $\operatorname{Nm}_{\mathbb{Q}(\eta)/\mathbb{Q}}(1-\eta) = \prod_{r \in (\mathbb{Z}/p\mathbb{Z})^\times}(1-\eta^r) = p$, so $\operatorname{Nm}_{\mathbb{Q}(\eta)/\mathbb{Q}}(\eta - 1) = \pm p$. As $[K : \mathbb{Q}(\eta)] = \varphi(p^k)/\varphi(p) = p^{k-1}$, proposition 50.1.12 gives $\operatorname{Nm}_{K/\mathbb{Q}}(\eta - 1) = \operatorname{Nm}_{\mathbb{Q}(\eta)/\mathbb{Q}}(\eta - 1)^{p^{k-1}} = \pm p^{p^{k-1}}$. Hence

$$\operatorname{Nm}_{K/\mathbb{Q}}(\Phi'(\zeta)) = \pm \frac{\operatorname{Nm}_{K/\mathbb{Q}}(p^k \zeta^{-1})}{\operatorname{Nm}_{K/\mathbb{Q}}(\eta - 1)} = \pm \frac{p^{k\varphi(p^k)}}{p^{p^{k-1}}} = \pm p^{p^{k-1}(kp-k-1)}$$

and $\operatorname{disc}(1, \zeta, \ldots, \zeta^{d-1}) = \pm p^s$, completing the proof.

For general n, the ring of integers of $\mathbb{Q}(\zeta_n)$ is $\mathbb{Z}[\zeta_n]$ (proposition 50.1.51), and its discriminant $\operatorname{disc}(\zeta_n)$ divides $n^{\varphi(n)}$ (example 50.1.31). So by corollary 50.4.58, only primes dividing n can ramify in $\mathbb{Q}(\zeta_n)$.

Proposition 50.4.67: Prime Decomposition In Cyclotomic Field

Let $p_1, p_2, \ldots$ enumerate the primes, and let $n = \prod_k p_k^{n_k}$, almost all $n_k = 0$, be the prime factorization of $n \in \mathbb{Z}_{>0}$. Let f_k be the smallest positive integer such that

$$p_k^{f_k} \equiv 1 \bmod (n/p_k^{n_k})$$

Then in $\mathbb{Q}(\zeta_n)$, we have:

$$p_k = (\mathfrak{p}_1 \cdots \mathfrak{p}_r)^{\varphi(p_k^{n_k})}$$

where $\mathfrak{p}_1, ..., \mathfrak{p}_r$ are distinct prime ideals all of degree f_k.

Note that if $p_k \nmid n$, then $n_k = 0$, so the condition becomes

$$p_k^{f_k} \equiv 1 \bmod n$$

and $\varphi(p_k^{n_k}) = 1$, giving us:

$$p_k = \mathfrak{p}_1 \cdots \mathfrak{p}_r$$

***Proof*:**
Fix $p = p_k$, write $\nu = n_k$ and $m = n/p^\nu$, so $p \nmid m$, and let $f = f_k$, the least positive integer with $p^f \equiv 1 \bmod m$. Let $K = \mathbb{Q}(\zeta_n)$.

Step 1: reduction to Φ_m. By proposition 50.1.51, $\mathcal{O}_K = \mathbb{Z}[\zeta_n]$, so the conductor of $\mathbb{Z}[\zeta_n]$ is $\mathcal{O}_K$ and theorem 50.4.7 applies to every prime: $p\mathcal{O}_K$ factors as Φ_n, the minimal polynomial of ζ_n (proposition 19.7.7), factors modulo p. As $\gcd(m, p^\nu) = 1$, the primitive nth roots of unity are the products $\xi\eta$ of a primitive mth root of unity ξ and a primitive p^νth root of unity η, so

$$\Phi_n(x) = \prod_{\xi,\eta}(x - \xi\eta)$$

Let $\mathfrak{p}$ be a prime of $\mathcal{O}_K$ over p. Each η satisfies $(\eta - 1)^{p^\nu} \equiv \eta^{p^\nu} - 1 = 0 \bmod p$, as the binomial coefficients $\binom{p}{i}$ with $0 < i < p$ are divisible by p, so $\eta - 1 \in \mathfrak{p}$. Hence $\Phi_n(x) \equiv \prod_{\xi,\eta}(x - \xi) = \Phi_m(x)^{\varphi(p^\nu)}$ coefficientwise modulo $\mathfrak{p}$, and as both sides lie in $\mathbb{Z}[x]$ and $\mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$, the congruence $\Phi_n \equiv \Phi_m^{\varphi(p^\nu)}$ holds modulo p.

Step 2: $\overline{\Phi}_m$ has distinct irreducible factors. Let $\overline{g}$ denote reduction modulo p. As $p \nmid m$, the derivative mx^{m-1} of $x^m - 1$ is coprime to it over $\mathbb{F}_p$, so $x^m - 1$ is separable over $\mathbb{F}_p$ (proposition 19.6.6). By lemma 19.7.4, $x^m - 1 = \prod_{e \mid m} \overline{\Phi}_e$ over $\mathbb{F}_p$, so $\overline{\Phi}_m$ has no repeated irreducible factor.

Step 3: each factor has degree f. Let $h \in \mathbb{F}_p[x]$ be an irreducible factor of $\overline{\Phi}_m$. In the principal ideal domain $\mathbb{F}_p[x]$ (corollary 11.1.2) the irreducible h is prime (proposition 10.1.33), so (h) is maximal (proposition 10.1.32) and $\mathbb{F}_p[x]/(h)$ is a field. Let $\overline{\xi}$ be the class of x in it, a root of $\overline{\Phi}_m$. Then $\overline{\xi}^m = 1$. If $\overline{\xi}$ had order $e < m$, it would be a root of $x^e - 1 = \prod_{e' \mid e} \overline{\Phi}_{e'}$, hence a root of two different factors $\overline{\Phi}_{e'}$ and $\overline{\Phi}_m$ of $x^m - 1$, a repeated root, contrary to Step 2. So $\overline{\xi}$ has order m. Let $f' = \deg h$, so that $\mathbb{F}_p(\overline{\xi})$ has $p^{f'}$ elements. As $\overline{\xi}$ has order m in $\mathbb{F}_p(\overline{\xi})^\times$, theorem 3.3.1 gives $m \mid p^{f'} - 1$, so $f \leq f'$. Conversely, $y \mapsto y^p$ is a ring endomorphism of $\mathbb{F}_p(\overline{\xi})$, and $y \mapsto y^{p^f}$ fixes $\overline{\xi}$, as $\overline{\xi}^{p^f - 1} = 1$, and fixes $\mathbb{F}_p$, so it fixes every element of $\mathbb{F}_p(\overline{\xi}) = \mathbb{F}_p[\overline{\xi}]$. So the $p^{f'}$ elements of $\mathbb{F}_p(\overline{\xi})$ are roots of $x^{p^f} - x$, and $p^{f'} \leq p^f$. Hence $f' = f$.

Step 4: conclusion. By Steps 2 and 3, $\overline{\Phi}_m = h_1 \cdots h_r$ with distinct irreducible h_i of degree f, and by Step 1, $\overline{\Phi}_n = (h_1 \cdots h_r)^{\varphi(p^\nu)}$. Theorem 50.4.7 gives $p\mathcal{O}_K = (\mathfrak{p}_1 \cdots \mathfrak{p}_r)^{\varphi(p^\nu)}$ with distinct primes $\mathfrak{p}_i$ of inertia degree f, completing the proof.

Corollary 50.4.68: Special Case Of Factorization

Let $n \geq 1$ and let p be a prime number.

1. If $p \nmid n$, then p is unramified in $\mathbb{Q}(\zeta_n)$, and it is totally split if and only if $p \equiv 1 \bmod n$.
2. If $p \mid n$, then p is ramified in $\mathbb{Q}(\zeta_n)$, except when $p = 2$ and $n \equiv 2 \bmod 4$, in which case 2 is unramified.

***Proof*:**
Write $n = p^\nu m$ with $p \nmid m$. By proposition 50.4.67, $p\mathcal{O} = (\mathfrak{p}_1 \cdots \mathfrak{p}_r)^{\varphi(p^\nu)}$ with distinct primes $\mathfrak{p}_i$, all of inertia degree f, the least positive integer with $p^f \equiv 1 \bmod m$. So every ramification index equals $\varphi(p^\nu)$.

1. If $p \nmid n$, then $\nu = 0$ and $\varphi(1) = 1$, so p is unramified. It is totally split exactly when also $f = 1$, that is, when $p \equiv 1 \bmod m = n$.
2. If $p \mid n$, then $\nu \geq 1$ and $\varphi(p^\nu) = p^{\nu-1}(p-1)$, which equals 1 only for $p = 2$ and $\nu = 1$, that is, $n \equiv 2 \bmod 4$. Otherwise the ramification index exceeds 1 and p ramifies.

This completes the proof.

Corollary 50.4.69: Subfield Of Cyclotomic Field

Let $K \subseteq \mathbb{Q}(\zeta_n) = L$ with corresponding subgroup $H = \mathrm{Gal}_K(L) \leqslant \mathrm{Gal}_\mathbb{Q}(L)$, considered as a subgroup of $(\mathbb{Z}/n\mathbb{Z})^\times$ through the isomorphism $\mathrm{Gal}_\mathbb{Q}(L) \cong (\mathbb{Z}/n\mathbb{Z})^\times$ matching the automorphism σ_a with $\sigma_a(\zeta_n) = \zeta_n^a$ to the class of a. For prime p where $p \nmid n$, let f be the least positive integer such that $\overline{p^f} \in H$. Then for prime $\mathfrak{p}$ lying above p in K:

$$f = f_{\mathfrak{p}/p}$$

***Proof*:**
Let $G = \mathrm{Gal}_\mathbb{Q}(L)$. The field L is the splitting field of $x^n - 1$ over $\mathbb{Q}$, so $L/\mathbb{Q}$ is Galois (theorem 19.5.13, corollary 19.6.8), and so is L/K, with group H (proposition 19.5.16). By proposition 19.7.9, $G \cong (\mathbb{Z}/n\mathbb{Z})^\times$, the class of a corresponding to the automorphism σ_a with $\sigma_a(\zeta_n) = \zeta_n^a$. Then $\sigma_a\sigma_b = \sigma_{ab}$, so $\sigma_p^j = \sigma_{p^j}$ for every $j \geq 1$. Let $\mathfrak{B}$ be a prime of $\mathcal{O}_L$ above $\mathfrak{p}$, which exists because $\mathfrak{p}\mathcal{O}_L \neq \mathcal{O}_L$ (proposition 50.3.10).

Step 1: the inertia degree as an index. Since $p \nmid n$, proposition 50.4.67 gives $p\mathcal{O}_L = \mathfrak{p}_1 \cdots \mathfrak{p}_r$ with distinct primes, so $e(\mathfrak{B}/p) = 1$, and $e(\mathfrak{B}/\mathfrak{p}) = 1$ by corollary 50.4.4. The residue fields are finite, hence perfect (corollary 19.6.12), so proposition 50.4.37 applies to $\mathfrak{B}$ in $L/\mathbb{Q}$ and in L/K. With $D = D_{\mathfrak{B}/p} \leqslant G$ the decomposition group in $L/\mathbb{Q}$, it gives $|D| = f(\mathfrak{B}/p)$ and $|I_{\mathfrak{B}/p}| = 1$. The decomposition group of $\mathfrak{B}$ in L/K is $\{\tau \in H \mid \tau(\mathfrak{B}) = \mathfrak{B}\} = D \cap H$ (definition 50.4.26), so $|D \cap H| = f(\mathfrak{B}/\mathfrak{p})$. By corollary 50.4.4,

$$f(\mathfrak{p}/p) = \frac{f(\mathfrak{B}/p)}{f(\mathfrak{B}/\mathfrak{p})} = \frac{|D|}{|D \cap H|}$$

Step 2: D is generated by σ_p. By proposition 50.1.51, $\mathcal{O}_L = \mathbb{Z}[\zeta_n]$. For $u, v \in \mathcal{O}_L$, the binomial theorem gives $(u+v)^p - u^p - v^p \in p\mathcal{O}_L$, since p divides $\binom{p}{k}$ for $0 < k < p$, and $c^p \equiv c \bmod p$ for $c \in \mathbb{Z}$ by theorem 3.3.1 in $(\mathbb{Z}/p\mathbb{Z})^\times$. Applying the first fact repeatedly, for $x = \sum_i c_i\zeta_n^i$ with $c_i \in \mathbb{Z}$,

$$x^p \equiv \sum_i c_i^p \zeta_n^{ip} \equiv \sum_i c_i \zeta_n^{ip} = \sigma_p(x) \bmod p\mathcal{O}_L$$

and $\sigma_p(x) - x^p \in p\mathcal{O}_L \subseteq \mathfrak{B}$ for every $x \in \mathcal{O}_L$. In particular $\sigma_p(\mathfrak{B}) \subseteq \mathfrak{B}$, and $\sigma_p(\mathfrak{B})$ is a nonzero

prime of $\mathcal{O}_L$ (lemma 50.4.23), hence maximal (theorem 50.2.6), so $\sigma_p(\mathfrak{B}) = \mathfrak{B}$ and $\sigma_p \in D$. The homomorphism $D \to \mathrm{Gal}_{\mathbb{F}_p}(\mathcal{O}_L/\mathfrak{B})$ of proposition 50.4.31 is surjective, with kernel $I_{\mathfrak{B}/p}$ (definition 50.4.32), which is trivial by Step 1. So it is an isomorphism. It sends σ_p to the map $y \mapsto y^p$ of $\mathcal{O}_L/\mathfrak{B}$, which generates $\mathrm{Gal}_{\mathbb{F}_p}(\mathcal{O}_L/\mathfrak{B})$ by proposition 19.7.19. Hence $D = \langle \sigma_p \rangle$.

Step 3: conclusion. Let f_0 be the least positive integer with $\sigma_p^{f_0} \in H$, which exists because σ_p has finite order N. If $\sigma_p^j \in H$, write $j = af_0 + b$ with $0 \leq b < f_0$. Then $\sigma_p^b = \sigma_p^j(\sigma_p^{f_0})^{-a} \in H$, so $b = 0$. Hence $\langle \sigma_p \rangle \cap H = \langle \sigma_p^{f_0} \rangle$, and f_0 divides N, as $\sigma_p^N = 1 \in H$. The subgroup $\langle \sigma_p^{f_0} \rangle$ has order N/f_0, so Steps 1 and 2 give

$$f(\mathfrak{p}/p) = \frac{|\langle \sigma_p \rangle|}{|\langle \sigma_p \rangle \cap H|} = \frac{N}{N/f_0} = f_0$$

Under $G \cong (\mathbb{Z}/n\mathbb{Z})^\times$, $\sigma_p^j = \sigma_{p^j}$ corresponds to $\overline{p^j}$, so f_0 is the least positive integer with $\overline{p^{f_0}} \in H$, that is $f_0 = f$, completing the proof.

In summary, the ring of integers of $\mathbb{Q}(\zeta_n)$ is $\mathbb{Z}[\zeta_n]$ (proposition 50.1.51), so it is monogenic, and proposition 50.4.67 gives the factorization of every prime in it. By corollary 50.4.68, a prime p ramifies in $\mathbb{Q}(\zeta_n)$ if and only if $p \mid n$, except that 2 is unramified when $n \equiv 2 \bmod 4$.

50.4.6 Application: Quadratic Extensions and Quadratic Reciprocity

We now take a moment to solve a classical number theory problems with the developed tools. Let $p \in \mathbb{Z}$ be a prime number. In section 10.3, it was shown that p can be written as the sum of two squares if and only if $p \equiv 1 \bmod 4$. Let us now ask another question that may shed further light on the nature of primes: the square-root of primes is always an irrational number. However, when modding by $n \in \mathbb{N}$, it is possible that there is an answer. By the Chinese Remainder Theorem, it suffices to check when $n = q$ is a prime. Thus:

what primes p have the property that there exists an n such that $n^2 \equiv p \bmod q$

Example 50.4.70: Concrete Example
Let $p = 3$. Then:

mod	1^2	2^2	3^2	4^2	5^2	6^2
2	1					
3	1	1				
5	1	4	4	1		
7	1	4	2	2	4	1
11	1	4	9	5	***3***	***3***

Note the table is mirrored as $(-n)^2 = n^2$. Hence, for a reason that is yet to be explained in this book, the prime 3 is somehow tied to 11 when looking for square-roots of 3. The reader can verify that 13, 23, 37, and so forth also have a square-root of 3.

The reader should play around with different pairs (p, q) and flip them around to consider (q, p), there shall appear some symmetry that at first is not obvious.

This relation between primes and square-root in modular arithmetics was first documented to be discovered by Euler, however it took a generation before a complete proof by Gauss appeared. As it turns out, the condition translates into a condition on rings of integers of quadratic extensions!

Definition 50.4.71: Quadratic Residue

Let p be a prime and $n \in \mathbb{Z}$. If there exists an $m \in \mathbb{Z}$ such that $m^2 \equiv n \bmod p$, then n is called a *quadratic residue* mod p.

Whether p has a square root modulo q is the question whether $x^2 - p \equiv 0 \bmod q$ has a solution. Let $K = \mathbb{Q}(\sqrt{p})$ and consider $\mathcal{O}_K/q\mathcal{O}_K$, which is isomorphic to $(\mathbb{Z}/q\mathbb{Z})^2$ as an abelian group. The factorization of $q\mathcal{O}_K$ detects the answer: for odd $q \nmid p$, theorem 50.4.72(3) below shows that $q\mathcal{O}_K$ is a product of two distinct primes exactly when p is a square modulo q, and the same holds for $K = \mathbb{Q}(\sqrt{m})$ with m square-free and $q \nmid m$. By example 50.1.17, $\mathcal{O}_K$ has the integral basis

$$\begin{cases} \{1, \sqrt{m}\} & m \not\equiv 1 \bmod 4 \\ \left\{1, \dfrac{1+\sqrt{m}}{2}\right\} & m \equiv 1 \bmod 4 \end{cases}$$

and $\operatorname{disc}(\mathcal{O}_K) = 4m$ in the first case and $\operatorname{disc}(\mathcal{O}_K) = m$ in the second. Now, take $(p) \subseteq \mathbb{Z}$ a prime ideal. Then we know that either p can split as:

$$p\mathcal{O}_K = \mathfrak{B} \qquad p\mathcal{O}_K = \mathfrak{B}^2 \qquad p\mathcal{O}_K = \mathfrak{B}_1\mathfrak{B}_2$$

and that only m and possibly 2 ramifies.

Theorem 50.4.72: Primes In Quadratic Extensions

Let p be a prime number and $K = \mathbb{Q}(\sqrt{m})$ a quadratic extension where $m \neq 0, 1$ is square-free. Then:

1. If $p \mid m$:
$$p\mathcal{O}_K = (p, \sqrt{m})^2$$
with $(p, \sqrt{m})$ a prime ideal.

2. If m is odd, then 2 splits as:
$$2\mathcal{O}_K = \begin{cases} (2, 1+\sqrt{m})^2 & m \equiv 3 \bmod 4 \\ \left(2, \frac{1+\sqrt{m}}{2}\right)\left(2, \frac{1-\sqrt{m}}{2}\right) & m \equiv 1 \bmod 8 \\ (2) & m \equiv 5 \bmod 8 \end{cases}$$

3. If p is odd and $p \nmid m$:
$$p\mathcal{O}_K = \begin{cases} (p, n+\sqrt{m})(p, n-\sqrt{m}) & m \equiv n^2 \bmod p \\ (p) & m \text{ not a square modulo } p \end{cases}$$

In each case the ideals displayed on the right are distinct prime ideals.

***Proof*:**
All cases come from corollary 50.4.8 with $K = \mathbb{Q}$ and $\mathfrak{p} = p\mathbb{Z}$, applied to a generator θ of K whose minimal polynomial lies in $\mathbb{Z}[x]$. By example 50.1.17, $\mathcal{O}_K = \mathbb{Z}[\sqrt{m}]$ if $m \equiv 2, 3 \bmod 4$, and $\mathcal{O}_K = \mathbb{Z}[\omega] = \mathbb{Z} + \mathbb{Z}\omega$ with $\omega = \frac{1+\sqrt{m}}{2}$ if $m \equiv 1 \bmod 4$. In the second case $\mathbb{Z}[\sqrt{m}] = \mathbb{Z} + 2\mathbb{Z}\omega$, as $\sqrt{m} = 2\omega - 1$, so $[\mathcal{O}_K : \mathbb{Z}[\sqrt{m}]] = 2$. So for $\theta = \sqrt{m}$, with minimal polynomial $x^2 - m$, the index $[\mathcal{O}_K : \mathbb{Z}[\theta]]$ is 1 or 2, and for $\theta = \omega$ when $m \equiv 1 \bmod 4$, with minimal polynomial $x^2 - x + \frac{1-m}{4}$, the index is 1.

Step 1: proof of (1). Take $\theta = \sqrt{m}$. If p is odd, p does not divide the index. If $p = 2$, then m is even and square-free, so $m \equiv 2 \bmod 4$ and the index is 1. As $p \mid m$, $x^2 - m \equiv x^2 \bmod p$, so corollary 50.4.8 gives the prime $(p, \sqrt{m})$ of inertia degree 1 with $p\mathcal{O}_K = (p, \sqrt{m})^2$.

Step 2: proof of (2). If $m \equiv 3 \bmod 4$, take $\theta = \sqrt{m}$, of index 1. Modulo 2, $x^2 - m \equiv x^2 + 1 \equiv (x+1)^2$, so $2\mathcal{O}_K = (2, 1+\sqrt{m})^2$. If $m \equiv 1 \bmod 4$, take $\theta = \omega$. If $m \equiv 1 \bmod 8$, then $\frac{1-m}{4}$ is even and $x^2 - x + \frac{1-m}{4} \equiv x(x-1) \bmod 2$, so $2\mathcal{O}_K = (2, \omega)(2, \omega - 1)$, and $(2, \omega - 1) = (2, \frac{1-\sqrt{m}}{2})$ because $\frac{1-\sqrt{m}}{2} = 1 - \omega$. If $m \equiv 5 \bmod 8$, then $\frac{1-m}{4}$ is odd and $x^2 - x + \frac{1-m}{4} \equiv x^2 + x + 1 \bmod 2$, which has no root in $\mathbb{F}_2$ and so is irreducible, being of degree 2. Then $2\mathcal{O}_K$ is prime, of inertia degree 2.

Step 3: proof of (3). Take $\theta = \sqrt{m}$, whose index 1 or 2 is prime to the odd p. If $m \equiv n^2 \bmod p$, then $n \not\equiv 0$ and $n \not\equiv -n \bmod p$, as $p \nmid m$ and p is odd, so $x^2 - m \equiv (x-n)(x+n) \bmod p$ with distinct factors, and $p\mathcal{O}_K = (p, \sqrt{m} - n)(p, \sqrt{m} + n)$. If m is not a square modulo p, then $x^2 - m$

has no root in $\mathbb{F}_p$ and is irreducible, so $p\mathcal{O}_K$ is prime, completing the proof.

Definition 50.4.73: Legendre Symbol

Let p be an odd prime in $\mathbb{Z}$. Then for $n \in \mathbb{Z}$, $p \nmid n$, the *Legendre symbol* is defined to be:

$$\left(\frac{n}{p}\right) = \begin{cases} 1 & \exists m,\ m^2 \equiv n \bmod p \\ -1 & \text{otherwise} \end{cases}$$

The symbol depends only on the class of n modulo p, since the congruence $m^2 \equiv n \bmod p$ does.

Lemma 50.4.74: Multiplicativity Of The Legendre Symbol

Let p be an odd prime. The squares in $(\mathbb{Z}/p\mathbb{Z})^\times$ form a subgroup S of index 2, and for $a, b \in \mathbb{Z}$ prime to p

$$\left(\frac{ab}{p}\right) = \left(\frac{a}{p}\right)\left(\frac{b}{p}\right)$$

***Proof*:**
The map $(\mathbb{Z}/p\mathbb{Z})^\times \to (\mathbb{Z}/p\mathbb{Z})^\times$, $x \mapsto x^2$, is a homomorphism, as the group is abelian, and its image is S. Its kernel consists of the x with $(x-1)(x+1) = x^2 - 1 = 0$ in the field $\mathbb{Z}/p\mathbb{Z}$, namely $x = 1$ and $x = -1$, which are distinct as p is odd. So $|S| = (p-1)/2$ (theorem 3.5.1, theorem 3.3.1), and S has index 2.

By definition 50.4.73, $\left(\frac{a}{p}\right) = 1$ exactly when the class $\bar{a}$ lies in S. The quotient $(\mathbb{Z}/p\mathbb{Z})^\times/S$ has order 2, so the bijection from it to the group $\{\pm 1\}$ sending S to 1 and the other coset to -1 is an isomorphism. Composing it with the quotient map gives $\bar{a} \mapsto \left(\frac{a}{p}\right)$, which is therefore a homomorphism, as claimed.

Proposition 50.4.75: First Supplement To Quadratic Reciprocity

Let p be an odd prime. Then

$$\left(\frac{-1}{p}\right) = (-1)^{\frac{p-1}{2}}$$

that is, -1 is a quadratic residue modulo p if and only if $p \equiv 1 \bmod 4$.

***Proof*:**
As $i = \zeta_4$, the field $K = \mathbb{Q}(\zeta_4)$ is the quadratic field $\mathbb{Q}(\sqrt{-1})$. Apply corollary 50.4.69 with $n = 4$ and $K = L = \mathbb{Q}(\zeta_4)$, so that $H = \{\bar{1}\}$, to the prime $p \nmid 4$. A prime $\mathfrak{p}$ of K above p has inertia degree the least $f \geq 1$ with $\overline{p^f} = \bar{1}$ in $(\mathbb{Z}/4\mathbb{Z})^\times$, so $f(\mathfrak{p}/p) = 1$ if and only if $p \equiv 1 \bmod 4$.

On the other hand, p is odd and does not divide $m = -1$, so by theorem 50.4.72(3), $p\mathcal{O}_K$ is a product of two distinct primes if -1 is a square modulo p, and is prime otherwise. As $\sum_i e_i f_i = 2$

by proposition 50.4.3, the primes above p have inertia degree 1 in the first case and 2 in the second. So -1 is a square modulo p if and only if $p \equiv 1 \bmod 4$, that is, if and only if $\frac{p-1}{2}$ is even, as we sought to show.

Theorem 50.4.76: Quadratic Reciprocity

Let p, q be distinct odd primes, and let $p^* = (-1)^{\frac{p-1}{2}} p$, so that $p^* = p$ if $p \equiv 1 \bmod 4$ and $p^* = -p$ if $p \equiv 3 \bmod 4$. Then:

1. q is a quadratic residue modulo p if and only if p^* is a quadratic residue modulo q, that is, $\left(\frac{q}{p}\right) = \left(\frac{p^*}{q}\right)$.
2. The two symbols satisfy
$$\left(\frac{q}{p}\right)\left(\frac{p}{q}\right) = (-1)^{\frac{p-1}{2}\frac{q-1}{2}}$$
3. $\left(\frac{q}{p}\right) = \left(\frac{p}{q}\right)$ if $p \equiv 1 \bmod 4$ or $q \equiv 1 \bmod 4$, and $\left(\frac{q}{p}\right) = -\left(\frac{p}{q}\right)$ if $p \equiv q \equiv 3 \bmod 4$.

***Proof*:**
Let $\zeta = \zeta_p$ and $L = \mathbb{Q}(\zeta)$, and for $b \in \mathbb{Z}$ prime to p let $\sigma_b \in \mathrm{Gal}_{\mathbb{Q}}(L)$ be the automorphism with $\sigma_b(\zeta) = \zeta^b$, which corresponds to $\bar{b} \in (\mathbb{Z}/p\mathbb{Z})^\times$ as in corollary 50.4.69. Write $\chi(a) = \left(\frac{a}{p}\right)$ for a prime to p. It depends only on a modulo p, it satisfies $\chi(a)^2 = 1$, and it is multiplicative by lemma 50.4.74.

A square root of p^* in L. Let $g = \sum_{a=1}^{p-1} \chi(a)\zeta^a \in L$. If $p \nmid d$, then $\eta = \zeta^d$ is a pth root of unity other than 1, and $(\eta - 1)\sum_{a=0}^{p-1} \eta^a = \eta^p - 1 = 0$ gives $\sum_{a=1}^{p-1} \zeta^{ad} = -1$. For fixed a, as b runs through $1, \dots, p-1$, the integer $c \in \{1, \dots, p-1\}$ with $b \equiv ac \bmod p$ runs through $1, \dots, p-1$, and $\chi(a)\chi(b) = \chi(a)^2\chi(c) = \chi(c)$. Hence

$$g^2 = \sum_{a=1}^{p-1}\sum_{b=1}^{p-1} \chi(a)\chi(b)\zeta^{a+b} = \sum_{c=1}^{p-1} \chi(c) \sum_{a=1}^{p-1} \zeta^{a(1+c)}$$

The inner sum is $p-1$ for $c = p-1$, and -1 for the other c by the case $d = 1 + c$ of the sum above. By lemma 50.4.74, χ takes the value 1 at exactly half of $1, \dots, p-1$, so $\sum_{c=1}^{p-1} \chi(c) = 0$ and

$$g^2 = (p-1)\chi(-1) - \sum_{c=1}^{p-2} \chi(c) = p\chi(-1) - \sum_{c=1}^{p-1} \chi(c) = p\chi(-1)$$

By proposition 50.4.75, $\chi(-1) = (-1)^{\frac{p-1}{2}}$, so $g^2 = p^*$. As $p^* = \pm p$ is square-free and differs from 0 and 1, the field $K = \mathbb{Q}(g) \subseteq L$ is the quadratic field $\mathbb{Q}(\sqrt{p^*})$, with $\sqrt{p^*} = g$.

The subgroup of K. Let b be prime to p. As a runs through $1, \dots, p-1$, the integer $c \in \{1, \dots, p-1\}$ with $c \equiv ab \bmod p$ runs through $1, \dots, p-1$, and $\chi(a) = \chi(a)\chi(b)^2 = \chi(c)\chi(b)$.

So

$$\sigma_b(g) = \sum_{a=1}^{p-1} \chi(a)\zeta^{ab} = \chi(b)\sum_{c=1}^{p-1} \chi(c)\zeta^c = \chi(b)g$$

As $g^2 = p^* \neq 0$, σ_b fixes g, equivalently fixes $K = \mathbb{Q}(g)$ pointwise, if and only if $\chi(b) = 1$. So the subgroup $H = \mathrm{Gal}_K(L)$ of corollary 50.4.69, viewed in $(\mathbb{Z}/p\mathbb{Z})^\times$, is the subgroup of squares.

1. Let $\mathfrak{q}$ be a prime of K above q. As $q \nmid p$, corollary 50.4.69 gives $f(\mathfrak{q}/q) = 1$ if and only if $\bar{q} \in H$, that is, if and only if q is a quadratic residue modulo p. On the other hand, q is odd and does not divide p^*, so by theorem 50.4.72(3) with $m = p^*$, $q\mathcal{O}_K$ is a product of two distinct primes if p^* is a square modulo q, and is prime otherwise. As $\sum_i e_i f_i = 2$ by proposition 50.4.3, $f(\mathfrak{q}/q) = 1$ in the first case and $f(\mathfrak{q}/q) = 2$ in the second. So $\left(\frac{q}{p}\right) = 1$ if and only if $\left(\frac{p^*}{q}\right) = 1$, and the two symbols, each equal to ± 1, coincide.
2. By lemma 50.4.74 and proposition 50.4.75 for the prime q,

$$\left(\frac{p^*}{q}\right) = \left(\frac{-1}{q}\right)^{\frac{p-1}{2}} \left(\frac{p}{q}\right) = (-1)^{\frac{q-1}{2}\frac{p-1}{2}} \left(\frac{p}{q}\right)$$

   Multiplying (1) by $\left(\frac{p}{q}\right)$ and using $\left(\frac{p}{q}\right)^2 = 1$ gives the product formula.
3. The exponent $\frac{p-1}{2}\frac{q-1}{2}$ is odd exactly when $\frac{p-1}{2}$ and $\frac{q-1}{2}$ are both odd, that is, when $p \equiv q \equiv 3 \bmod 4$. Multiplying (2) by $\left(\frac{p}{q}\right)$ gives (3).

This completes the proof.

Proposition 50.4.77: Second Supplement To Quadratic Reciprocity

Let p be an odd prime. Then

$$\left(\frac{2}{p}\right) = (-1)^{\frac{p^2-1}{8}}$$

that is, 2 is a quadratic residue modulo p if and only if $p \equiv \pm 1 \bmod 8$.

***Proof*:**

Let $\zeta = \zeta_8$, $L = \mathbb{Q}(\zeta)$ and $\theta = \zeta + \zeta^{-1}$. As $\zeta^2 = i$ and $\zeta^{-2} = -i$, $\theta^2 = \zeta^2 + 2 + \zeta^{-2} = 2$, so $K = \mathbb{Q}(\theta) \subseteq L$ is the quadratic field $\mathbb{Q}(\sqrt{2})$, with $\sqrt{2} = \theta \neq 0$. For odd b let $\sigma_b \in \mathrm{Gal}_{\mathbb{Q}}(L)$ be the automorphism with $\sigma_b(\zeta) = \zeta^b$. Then $\sigma_{-1}(\theta) = \zeta^{-1} + \zeta = \theta$. As $\zeta^4 = -1$, $\zeta^3 = -\zeta^{-1}$ and $\zeta^{-3} = -\zeta$, so $\sigma_3(\theta) = \sigma_{-3}(\theta) = \zeta^3 + \zeta^{-3} = -\theta \neq \theta$. So the subgroup $H = \mathrm{Gal}_K(L)$ of corollary 50.4.69 is $\{\pm\bar{1}\}$ inside $(\mathbb{Z}/8\mathbb{Z})^\times = \{\pm\bar{1}, \pm\bar{3}\}$.

As $p \nmid 8$, corollary 50.4.69 shows that a prime of K above p has inertia degree 1 if and only if $\bar{p} \in H$, that is, $p \equiv \pm 1 \bmod 8$. As p is odd and does not divide $m = 2$, theorem 50.4.72(3) shows that $p\mathcal{O}_K$ is a product of two distinct primes if 2 is a square modulo p, and is prime otherwise, so by proposition 50.4.3 the primes above p have inertia degree 1 exactly when 2 is a square modulo p. So 2 is a square modulo p if and only if $p \equiv \pm 1 \bmod 8$. Finally, writing $p = 8k + r$

with $k \in \mathbb{Z}$ and $r \in \{\pm 1, \pm 3\}$,

$$\frac{p^2-1}{8} = 8k^2 + 2kr + \frac{r^2-1}{8}$$

where $\frac{r^2-1}{8}$ is 0 for $r = \pm 1$ and 1 for $r = \pm 3$. So $(-1)^{\frac{p^2-1}{8}} = 1$ exactly when $p \equiv \pm 1 \bmod 8$, as we sought to show.

50.5 Application: Kronecker Weber Theorem

We now apply our finding to Field Theory and find some important consequences' on *Abelian Extension*. This shall also lead to proving one of the central theorems in field theory, The *Kronecker-Weber Theorem*, which states that all finite abelian extensions show up as sub-extensions of Cyclotomic extensions over $\mathbb{Q}$! Since Cyclotomic extensions are generated by roots of unity, every algebraic integers whose Galois group is abelian can be written as a $\mathbb{Q}$-linear combination of roots of unity! For example:

$$\sqrt{5} = e^{2\pi i/5} - e^{4\pi i/5} - e^{6\pi i/5} + e^{8\pi i/5}$$

namely, all square roots of integers may be written as $\mathbb{Q}$-linear combinations of roots of unity! We first give the setting in which we work in:

Definition 50.5.1: Universal Cyclotomic Field and Abelian Closure

1. Let $K^{\mathbf{cycl}} = \bigcup_{n\in\mathbb{N}} K(\zeta_n)$. If $K = \mathbb{Q}$, then:

   $$\mathrm{Gal}(\mathbb{Q}^{\mathbf{cycl}}) = \varprojlim \mathrm{Gal}(\mathbb{Q}(\zeta_n)) = \varprojlim (\mathbb{Z}/n\mathbb{Z})^\times = \hat{\mathbb{Z}}^\times$$

   is the pro-finite group given by the limit of units of cyclic groups.

2. Let K be a field. Then

   $$K^{\mathbf{ab}} \subseteq \overline{K}$$

   is the maximal extension for which $\mathrm{Gal}_K(K^{\mathbf{ab}})$ is abelian.

Proposition 50.5.2: Properties of Abelian Extensions

1. If $L_1, L_2 \subseteq K^{\mathrm{ab}}$ have finite abelian groups, then $\mathrm{Gal}_K(L_1L_2)$ is a finite abelian group.
2. If $G_K = \mathrm{Gal}_K(\overline{K})$ and $H = [G, G]$ (the commutator [closed] subgroup), then

   $$K^{\mathrm{ab}} = \overline{K}^H$$

   with Galois group G_K/H.

***Proof*:**

1. See proposition 20.1.32
2. This comes from the universal property of abelian quotients, see proposition 5.2.3

Note that in general, $K^{\mathbf{cycl}} \subsetneq K^{\text{ab}}$:

Example 50.5.3: Abelian, But Not Cyclotomic

Let $k = \mathbb{Q}(i)$ and $F = \mathbb{Q}(\sqrt{1+2i})/\mathbb{Q}(i)$. Since every quadratic extension is abelian, F is an abelian extension. However, it is not a cyclotomic extension: for if it was a sub-cyclotomic extension, then since $\mathbb{Q}(i)$ is a cyclotomic extension over $\mathbb{Q}$, then $\mathbb{Q}(\sqrt{1+2i})$ would be a cyclotomic extension, but that is not possible since $\mathbb{Q}(\sqrt{1+2i})/\mathbb{Q}$ is not Galois (but all sub-extensions of a cyclotomic extension are necessarily Galois).

It is thus quite interesting that if $K = \mathbb{Q}$, we have the following:

Theorem 50.5.4: Kronecker Weber's Theorem

Let $K = \mathbb{Q}$. Then:

$$\mathbb{Q}^{\mathbf{cycl}} = \mathbb{Q}^{\text{ab}}$$

In other words, every abelian extension of $\mathbb{Q}$ is contained in a cyclotomic extension.

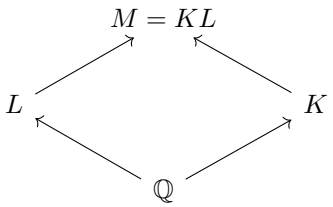
We will first show we can assume $\text{Gal}_{\mathbb{Q}}(K)$ is a p-group for some prime p. For if $\text{Gal}_{\mathbb{Q}}(K)$ is abelian, we have

$$\text{Gal}_{\mathbb{Q}}(K) \cong \bigoplus_{p} G_p$$

where G_p is a p-group.

Proof. **Reduction #1**:

Define $K_{p'} = K^{(\bigoplus_{p \neq p'} G_p)}$. Then $K = K_2 K_3 \cdots$ is the join of all these fields. Hence, if all such fields is inside a Cyclotomic extension, so is K. This can naturally be extended to reduce to cyclic groups in the same manner. □



Next, we show that p is the *only* prime which ramifies in K

Proof. **Reduction #2**:

Assume not. Assume ℓ ramifies in K as well. Let I be the inertia group (does not matter what prime we pick). Then the wield inertia group W is trivial (by group theory). Then by theorem 50.4.64:

$$I \hookrightarrow \mathbb{F}_\ell^\times \qquad I \cong \mathbb{Z}/\ell\mathbb{Z}, \quad e \big| \ell - 1$$

Let $L \in \mathbb{Q}(\mu_\ell)$ be the (unique) extension such that $[L:\mathbb{Q}] = e$. So ℓ totally ramifies in L. Then take:

K and L are abelian, thus so is M. Let I_M be the inertia group of a prime over ℓ. Then

$$I_M \hookrightarrow \mathbb{Z}/e\mathbb{Z} \oplus \mathbb{Z}/\ell\mathbb{Z}$$

Hence

$$I_M \cong \mathbb{Z}/e\mathbb{Z}$$

Let $K' = M^{I_M}$. Then $K' \cap L = \mathbb{Q}$ since nothing ramifies in $K' \cap L$.

Now, $K'L/K'$ has degree at least e, in particular$\geq e$, since ℓ has to ramify (ℓ does not ramify in K', and ramifies in L by e). But then,

$$K'L = M = KL$$

Note that we have not introduced any new ramifications, since no other primes ramify that ramify in L, K. We can afterward inductively remove (if it ramifies, it has to have some inertia group, but it will be trivial in the intermediate extensions).

With this, let's now prove the $p = 2$ case.

Assume $K/\mathbb{Q}$ is abelian $[K:\mathbb{Q}] = 2^n$ and 2 is the only prime which ramifies. I claim that K is cyclotomic.

Without loss of generality, let's assume $\mathbb{Q}(i) \subseteq K$ (just adjoin it if need be). Then $K_0 = K \cap \mathbb{R}$ (fixed field under conjugation). This is still abelian since K is abelian, and $[K:K_0] = 2$, so $K = K_0(i)$. Now, let $K_n/\mathbb{Q}$ be the real cyclotomic field where $\mathrm{Gal}(K_n/\mathbb{Q}) \cong \mathbb{Z}/2^n\mathbb{Z}$ (done it in comments). Consider now

$$M = KK_n$$

Then $\mathrm{Gal}_{\mathbb{Q}}(M) \subseteq \mathbb{Z}/2^n\mathbb{Z} \oplus \mathbb{Z}/2^n\mathbb{Z}$. If $K_n \neq K$, then this Galois group is *not* cyclic (too large order). Therefore, M has ≥ 3 real quadratic subfields (real, since everything is real). But there is only 2 with ramified primes, a contradiction ($\mathbb{Q}(\sqrt{2})$ is the only real quadratic extension in which 2 ramifies). $\square$

Now, for the other primes, we have the following key proposition:

Proposition 50.5.5: Ramification Of Primes in $\mathbb{Z}/n\mathbb{Z}$-Extensions

Let p be an odd prime. Then there exists a unique field $K/\mathbb{Q}$ which is Galois with Galois group $\mathbb{Z}/p\mathbb{Z}$ in which p is the only ramified prime.

***Proof*:**
Let ζ be a pth primitive root of 1, let $L = \mathbb{Q}(\zeta)$. $\pi = 1 - \zeta$. So that $(\pi)^{p-1} = (p)$. Let $\gamma \in \mathcal{O}_L$ be a non pth power. Assume $\gamma \equiv 1 \bmod \pi^p$. Take the field $M = L(\sqrt[p]{\gamma})/L$. Then π is unramified.

Suppose not. Then $\pi\mathcal{O}_M = Q^p$ for some prime Q where $\mathbb{F}_Q \cong \mathbb{F}_{(\pi)} \cong \mathbb{F}_p$. Let δ be such that $\delta^p = \gamma$. Let $r = \frac{\delta-1}{\pi}$. Claim that $r \in \mathcal{O}_M$. Take the conjugates of r over L, i.e. they are

$$\frac{\zeta^i\delta - 1}{\pi} \qquad i \in \mathbb{Z}/p\mathbb{Z}$$

So the minimal polynomial is the product:

$$\prod\left(x - \frac{\zeta^i\delta - 1}{\pi}\right) = \frac{1}{\pi^p}\prod_{i=1}^{p-1}((\pi x - 1) - \zeta^i\delta) = \frac{(\pi x - 1)^p - \gamma}{\pi^p}$$

So this is inside $\mathcal{O}_L[x]$, so r is inside of integers. Thus, there exists some $m \in \mathbb{Z}$ such that $r - m \in \mathbb{Q}$ (because $\mathbb{F}_Q$ is just $\mathbb{F}_p$). But then for all $\sigma \in \mathrm{Gal}_K(M)$, $\sigma(r-m) \in \mathbb{Q}$ since it's the inerta group. But

$$\frac{\zeta\gamma - 1}{\pi} - m \in \mathbb{Q}$$

and so is $\frac{\gamma-1}{\pi} \in \mathbb{Q}$. Subtracting we get

$$\frac{1-\gamma}{\pi}\gamma = \frac{\pi}{\pi}\gamma = \gamma \in \mathbb{Q}$$

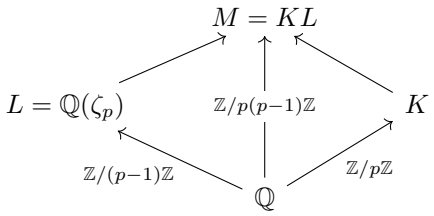
But this is a contradiction of our $\gamma \equiv 1 \bmod Q$, as we sought to show.

With this, we can continue the second reduction

Proof. **Reduction #2 cont.**:

By reduction # 2, we only need to work with $K/\mathbb{Q}$ abelian of prime power order p^n, and without loss of generality $K/\mathbb{Q}$ may be assumed to be cyclic since every field is a compositum which have cyclic subgroups.

Now consider $K_n \subseteq \mathbb{Q}(\zeta_{n+1})$ be the field such that



$$[K_n : \mathbb{Q}] = p^n \qquad \mathrm{Gal}(K_n/\mathbb{Q}) \cong \mathbb{Z}/p^n\mathbb{Z}$$

Let $M + KK_n$. In general $\mathrm{Gal}(M/\mathbb{Q}) \hookrightarrow \mathbb{Z}/p^n\mathbb{Z} \oplus \mathbb{Z}/p^n\mathbb{Z}$. If $K \neq K_n$, then like for the $p = 2$ case, this Galois group is not cyclic. Thus, M contains at least $p+1$ subfields which have Galois group $\mathbb{Z}/p\mathbb{Z}$ over $\mathbb{Q}$ in which only p ramifies, a contradiction □

***Proof*:**
Of Kronecker-Weber's Theorem

We shall show that if p is an odd prime, $K/\mathbb{Q}$ is a $\mathbb{Z}/p\mathbb{Z}$ extension, and p is the only prime that ramified in K, then $K \subseteq \mathbb{Q}(\zeta_{p^2})$, which by our earlier reduction shall complete the proof.

Let $\text{Gal}_{\mathbb{Q}}(M) = \langle \sigma \mid \sigma^{p(p-1)} = \text{id} \rangle$, $K = M^{\langle \sigma^p \rangle}$ and $L = M^{\langle \sigma^{p-1} \rangle}$. Consider:

We hat that p is the only prime that ramifies in M. Thus, by Kummer theory, we know that $M = L(\alpha)$ where $\alpha^p = \beta \in L^\times$. Next, we know that

$$\frac{\sigma(\alpha)}{\alpha}$$

is a non-trivial rot of unity. Without loss of generality say that $\frac{\sigma^{p-1}(\alpha)}{\alpha} = \zeta_p$ (so $\langle \sigma^{p-1} \rangle = \text{Gal}_L(M)$). Note that $\sigma(\zeta_p) = \zeta_p^n$, where $\overline{n} \in (\mathbb{Z}/p\mathbb{Z})^\times$ (i.e. is a primitive root).

I claim that

$$M = L\left(\frac{\sigma(\alpha)}{\alpha}\right)$$

For suppose not. Then $\frac{\sigma(a)}{\alpha} \in L$, and

$$\frac{\sigma(\alpha)}{\alpha} = \sigma^{p-1}\left(\frac{\sigma(\alpha)}{\alpha}\right) = \frac{\sigma^p(\alpha)}{\sigma^{p-1}(\alpha)} = \frac{\sigma(\zeta_p\alpha)}{\zeta_p\alpha} \implies 1 = \frac{\sigma(\zeta_p)}{\zeta_p}$$

but that is a contradiction, hence $M = L\left(\frac{\sigma(\alpha)}{\alpha}\right)$.

For the rest of this proof, we write

$$\alpha \mapsto \frac{\sigma(\alpha)}{\alpha} = \alpha' \qquad \beta \mapsto \frac{\sigma(\beta)}{\beta} = \beta'$$

Let P_k, P_L, P_M be the primes ideals above $p\mathbb{Z}$. Take the prime decomposition:

$$\beta\mathcal{O}_L = \prod Q^{n_Q} = P_L^r \cdot \prod_{Q \neq P} Q^{n_Q} \qquad n_Q \in \mathbb{Z}$$

Then:

$$\sigma(\beta)\mathcal{O}_L = P_L^r \prod_{Q \neq P_L} \sigma(Q)^{n_Q}$$

$$\frac{\sigma(\beta)\mathcal{O}_L}{\beta} = \prod_{Q \notin P_L} Q^{m_Q}$$

Hence, P_L does not occur in $\beta\mathcal{O}_L$. Take $\beta'' = \beta' N^P$ and $\alpha'' = \alpha' N$ for $N \in \mathbb{Z}$ such that $\beta'' \in \mathcal{O}_L$ Then:

$$M = L(\alpha'') \qquad (\alpha'')^P = \beta''$$

Now let $\pi = 1 - \zeta_p \in \mathcal{O}_L$ so that $P_L = (\pi)$. Then $\mathbb{F}_{P_L} \cong \mathbb{F}_P$ implies $\beta'' \bmod P_L = m \bmod P_L$ for $m \leq N$. Let $m_0 = m^{-1} \bmod p$, so $\beta'' \to m_0\beta''$ and $\alpha'' \to m_0\alpha''$. Without loss of generality say $\beta'' = 1 \bmod P_L$. Then for some $c \in \mathbb{Z}/p\mathbb{Z}$

$$\beta'' = 1 + c\pi \bmod P_L^2 \qquad \zeta_p = 1 - \pi \bmod P_L^2 \qquad \zeta_p^r = 1 - r\pi \bmod P_L^2 \implies \beta'' = \zeta_p^{-c}\nu$$

where $\nu \equiv 1 \bmod P_L^2$. I claim that $\nu \in (L^\times)^P$, which will imply $M = \mathbb{Q}(\zeta_{p^2})$ and complete the proof. First:

$$\begin{aligned}
(\alpha'')^p &= \beta'' = \zeta_p^{-c}\nu \\
\sigma^{p-1}(\alpha'') &= \alpha''\zeta_p \\
\implies \sigma(\zeta_p) &= \zeta_p^n && n \in (\mathbb{Z}/p\mathbb{Z})^\times \\
\implies \sigma^p(\alpha'') &= \sigma(\sigma^{p-1}(\alpha'')) = \sigma(\alpha''\zeta_p) = \sigma(\alpha'') \cdot \zeta_p^n \\
\implies \sigma^{p-1}((\alpha'')^n) &= (\alpha'')^n\zeta_p^n \\
\implies \sigma^{p-1}\left(\frac{\sigma(\alpha'')}{(\alpha'')^n}\right) &= \frac{\sigma(\alpha'')}{(\alpha'')^n} \\
\implies \frac{\sigma(\alpha'')}{(\alpha'')^n} &\in M^{\langle\sigma^{p-1}\rangle} = L \\
\implies \frac{\sigma(\beta'')}{(\beta'')^n} &\in (L^\times)^P \\
\implies \frac{\sigma(\nu\zeta_p^{-c})}{\nu^n\zeta_p^{-nc}} &\in (L^\times)^p
\end{aligned}$$

Thus $\frac{\sigma(\nu)}{\nu^n} \in (L^\times)^p$.

Next, we claim that $\nu = 1 \bmod P_L^p$. Suppose not. Then let $p^M \| \nu - 1$ where $1 \leq m \leq p-1$, and $\nu = 1 + c\pi^m \bmod P_L^{m+1}$ (where $c \in (\mathbb{Z}/p\mathbb{Z})^\times$). Then by this:

$$\nu^n = 1 + nc\pi^m \bmod P_L^{m+1}$$

hence,

$$\sigma(\pi) = \sigma(1 - \zeta_p) = 1 - \zeta_p^n = (1 - \zeta_p)(1 + \zeta_p + \cdots + \zeta_p^{n-1}) = \pi n \bmod P_L^2$$

implying

$$\sigma(\pi^m) = \pi^m n^m \bmod P_L^{m+1} \implies \sigma(\nu) = 1 + cn^m\pi^m \bmod P_L^{m+1}$$

Note that $n^m \not\equiv n \bmod p$ for $n \in (\mathbb{Z}/p\mathbb{Z})^\times$. Now as a corollary:

$$\frac{\sigma(\nu)}{\nu^m} \equiv 1 + d\pi^m \bmod P_L^{m+1} \qquad d \in \mathbb{Z}/p\mathbb{Z}^\times$$

However,

$$\frac{\sigma(\nu)}{n\nu} = S^p \qquad S \in L$$

where P_L does not occur in S, and:

$$S^p \equiv 1 \bmod P_L \implies S = 1 \bmod P_L$$

Giving us $S = 1 + t$, $P_L \big| t$, so

$$S^P = 1 + pt + \cdots + t^p \equiv 1 \bmod P_L^P$$

a contradiction!

Finally, $L(\sqrt[p]{\nu})/L$ is unramified above P_L. Let

$$F = L(\sqrt[p]{\nu}),\ F \subseteq M(\zeta_{p^2}) \qquad F/Q \text{ abelian}$$

and $I \leqslant \mathrm{Gal}_{\mathbb{Q}}(\mathbb{F})$ where I is the inertia group above P, and $|I| = p-1$, so $F^I/\mathbb{Q}$ is unramified everywhere, namely $F^I = \mathbb{Q}$, so $F = L$. This implies

$$\nu \in (L^\times)^P$$

But then

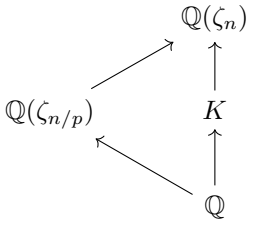
$$M = \mathbb{Q}(\zeta_{p^2})$$

as we sought to show.

Let us use it in an actual example:

Example 50.5.6: Using Kronecker-Weber

Let $K/\mathbb{Q}$ be a galois extension with Galois group $\mathbb{Z}/5\mathbb{Z}$ whose discriminant is only divisible by $5, 11$, and 31. How many such number fields are there?



Proof. By Kronecker Weber, we know that K is an intermediary field of a Cyclotomic extension:

$$K \subseteq \mathbb{Q}(\zeta_n)$$

We may without loss of generailty assume n is minnimal for which this containment makes sense. Since only $5, 11, 31$, divide the discriminant, we know the discriminant of K is of the form:

$$\mathrm{disc}(\mathcal{O}_K) = 5^a 11^b 31^c$$

which also mean only $5, 11, 31$ ramify in K. Now, I claim that only $5, 11, 31$ divide n and no other number those. For the sake of contradiction, let's say $p \big| n$ but $p \notin \{5, 11, 31\}$. By minimality, we have:

Let $I_{\mathfrak{B}}$ be the inertia group (for any prime $\mathfrak{B}$ lying above p). Since $p \nmid \mathrm{disc}(\mathcal{O}_K)$, p is unramified. If p is unramified in $\mathbb{Q}(\zeta_{n/p})$, then since $\mathbb{Q}(\zeta_{n/p}) \subseteq \mathbb{Q}(\zeta_n)$, we get that $\mathbb{Q}(\zeta_{n/p}) \subseteq \mathbb{Q}(\zeta_n)^{I_p} \subseteq \mathbb{Q}(\zeta_n)$

$$K \subseteq \mathbb{Q}(\zeta_n)^{I_{\mathfrak{B}}} \subseteq \mathbb{Q}(\zeta_{n/p})$$

contradicting minimality of n. Hence, we get $n = 5^a 11^b 31^c$. Thus:

$$\mathrm{Gal}_{\mathbb{Q}}(\mathbb{Q}(\zeta_n)) \cong (\mathbb{Z}/n\mathbb{Z})^\times \cong \mathbb{Z}/4\mathbb{Z} \times (\mathbb{Z}/5^{a-1}\mathbb{Z}) \times \mathbb{Z}/10\mathbb{Z} \times (\mathbb{Z}/11^{b-1}\mathbb{Z}) \times \mathbb{Z}/30\mathbb{Z} \times (\mathbb{Z}/31^{c-1}\mathbb{Z})$$

which now become a counting argument of how many subgroups of index 5 there are, counting the number of intermediary subfields, thus completing the proof. □

50.6 *Modules Over Dedekind Domains

(Useful for alg-geo, theory itself is also really nice. Also $\mathcal{O}_K$-modules appear in the next section)

Lemma 50.6.1: all Ideal co-maximal up to Module Isomorphism

Let I, J be fractional ideals of a Dedekind domain R. Then $I \oplus J \cong_R R \oplus IJ$.

***Proof*:**
Step 1: comaximal integral ideals. Let $D, E \subseteq R$ be ideals with $D+E = R$, and write $1 = d_0 + e_0$ with $d_0 \in D$ and $e_0 \in E$. By theorem 9.6.11, $D \cap E = DE$. The R-linear maps

$$D \oplus E \to DE \oplus R \quad (d,e) \mapsto (de_0 - ed_0, d+e) \qquad DE \oplus R \to D \oplus E \quad (c,r) \mapsto (c + rd_0, -c + re_0)$$

are well defined, as $de_0, ed_0 \in DE$ and $c \in DE \subseteq D \cap E$, and they are mutually inverse: using $d_0 + e_0 = 1$, the first composite sends (d,e) to $(d(e_0+d_0), e(d_0+e_0)) = (d,e)$, and the second sends (c,r) to $(c(e_0+d_0), r(d_0+e_0)) = (c,r)$. So $D \oplus E \cong DE \oplus R$.

Step 2: the general case. Choose $y \in K^\times$ with $yJ \subseteq R$ (corollary 50.2.12). By corollary 50.2.21 there is $x \in K^\times$ such that xI is an ideal with $xI + yJ = R$. Multiplication by a nonzero element of K is an R-module isomorphism, so Step 1 gives

$$I \oplus J \cong xI \oplus yJ \cong R \oplus xyIJ \cong R \oplus IJ$$

completing the proof.

Proposition 50.6.2: Ideals Are Projective

Let R be a Dedekind domain and $I \subseteq R$ an ideal. Then I is a projective R-module

***Proof*:**
The zero module is projective. If $I \neq 0$, corollary 50.2.19 gives a nonzero ideal J and $a \neq 0$ with $IJ = aR$, and $aR \cong R$ by multiplication by a. By lemma 50.6.1,

$$I \oplus J \cong R \oplus IJ = R \oplus aR \cong R^2$$

so I is isomorphic to a direct summand of a free module, and it is projective by theorem 17.2.4, completing the proof.

Proposition 50.6.3: IBN equivalent for Dedekind Domains

Let $I_1, ..., I_n$ be fractional ideals of a Dedekind domain R. Then

$$I_1 \oplus I_2 \oplus \cdots \oplus I_n \cong_R \underbrace{R \oplus R \oplus \cdots \oplus R}_{n-1 \text{ times}} \oplus (I_1 I_2 \cdots I_n)$$

Consequently, if $J_1, \ldots, J_n$ are fractional ideals with $I_1 I_2 \cdots I_n = (a) J_1 J_2 \cdots J_n$ for some $a \in K(R)^\times$, that is, if the products lie in the same class of the class group, then

$$I_1 \oplus I_2 \oplus \cdots \oplus I_n \cong_R J_1 \oplus J_2 \oplus \cdots \oplus J_n$$

***Proof*:**
We induct on n, the case $n = 1$ being trivial. For $n \geq 2$, the induction hypothesis and lemma 50.6.1 give

$$I_1 \oplus \cdots \oplus I_n \cong R^{n-2} \oplus (I_1 \cdots I_{n-1}) \oplus I_n \cong R^{n-2} \oplus R \oplus I_1 \cdots I_n$$

For the consequence, multiplication by a is an isomorphism $J_1 \cdots J_n \cong (a) J_1 \cdots J_n = I_1 \cdots I_n$, so both sums are isomorphic to $R^{n-1} \oplus I_1 \cdots I_n$, completing the proof.

The converse also holds, a theorem of Steinitz: if $I_1 \oplus \cdots \oplus I_n \cong J_1 \oplus \cdots \oplus J_m$, then $n = m$ and the products $I_1 \cdots I_n$ and $J_1 \cdots J_m$ differ by a principal ideal. In particular $R^n \oplus I \cong R^n \oplus J$ exactly when $I = (a)J$ for some $a \in K(R)^\times$. This book does not prove the converse.

Theorem 50.6.4: Classifying Torsion-Free Modules Over Dedekind Domain

Let M be a finitely generated torsion-free R-module over a Dedekind domain R of rank $n \geq 1$, in the sense of definition 12.3.16. Then

$$M \cong R^{n-1} \oplus I$$

for a nonzero ideal I of R, where I may be replaced with any ideal J such that $I = (a)J$ (they belong to the same element in the class group). As a consequence, any finitely generated torsion-free module over a Dedekind domain is projective.

***Proof*:**
Let K be the fraction field of R. Elements of K^n are linearly independent over R exactly when they are linearly independent over K, by clearing denominators, so the rank of a submodule $N \subseteq K^n$ is $\dim_K(KN)$, where KN is its K-span.

Step 1: M lies in R^n. Let $y_1, \ldots, y_n \in M$ be linearly independent and let $m_1, \ldots, m_k$ generate M. By maximality of n, each m_j satisfies $c_j m_j = \sum_i r_{ji} y_i$ with $c_j, r_{ji} \in R$ not all zero, and $c_j \neq 0$ as the y_i are independent. For $c = c_1 \cdots c_k \neq 0$, cM lies in the free module $Ry_1 + \cdots + Ry_n \cong R^n$, and multiplication by c is injective on M, as M is torsion-free. So M is isomorphic to a submodule of R^n, and we may assume $M \subseteq R^n \subseteq K^n$, with $KM = K^n$ as M has rank n.

Step 2: splitting off an ideal. We induct on n. If $n = 1$, then $M \subseteq R$ is a nonzero ideal, and $M \cong R^0 \oplus M$. Let $n \geq 2$ and let $\pi\colon R^n \to R$ be the last coordinate. If $\pi(M) = 0$, then $KM \subseteq K^{n-1} \times 0$, contradicting $KM = K^n$. So $I = \pi(M)$ is a nonzero ideal, projective by proposition 50.6.2, and the sequence $0 \to M' \to M \to I \to 0$ with $M' = \ker(\pi|_M)$ splits (theorem 17.2.4), so $M \cong M' \oplus I$. Here M' is torsion-free, and finitely generated, being a quotient of M through this splitting.

Step 3: the rank of M'. Choose $z_0 \in M$ with $a = \pi(z_0) \neq 0$. For $z \in M$, the element $az - \pi(z)z_0$ lies in M', so $z = a^{-1}(az - \pi(z)z_0) + a^{-1}\pi(z)z_0 \in KM' + Kz_0$. Hence $K^n = KM \subseteq KM' + Kz_0$, so $\dim_K KM' \geq n - 1$, and $KM' \subseteq K^{n-1} \times 0$ gives $\dim_K KM' = n - 1$. So M' has rank $n - 1 \geq 1$.

Step 4: conclusion. By the induction hypothesis, $M' \cong R^{n-2} \oplus I'$ for a nonzero ideal I', and by lemma 50.6.1,

$$M \cong R^{n-2} \oplus I' \oplus I \cong R^{n-2} \oplus R \oplus I'I = R^{n-1} \oplus I'I$$

with $I'I$ a nonzero ideal. So for every $n \geq 1$, $M \cong R^{n-1} \oplus I_0$ for a nonzero ideal I_0, namely $I_0 = M$ if $n = 1$ and $I_0 = I'I$ if $n \geq 2$. If $I_0 = (a)J$, then multiplication by $a \neq 0$ is an isomorphism $J \cong I_0$, so I_0 may be replaced by J. Finally, corollary 50.2.19 gives a nonzero ideal J' and $b \neq 0$ with $I_0J' = bR \cong R$, and lemma 50.6.1 gives $I_0 \oplus J' \cong R \oplus I_0J' \cong R^2$, so $R^{n-1} \oplus I_0$ is a direct summand of R^{n+1} and is projective (theorem 17.2.4). A torsion-free module of rank 0 is 0, as any nonzero element is linearly independent, completing the proof.

50.7 *Geometric Idea: 1-Dimensional Schemes

See Neukirch, and put orders here too for their geometric interpretation. I think it is important to include (especially once this chapter becomes its own book) since (to me) this explains why ramification happens. We naturally cannot prove the Riemann-Hurwitz Formula here, but this still is very interesting.

50.7.1 Localization of Dedekind Domains

For the motivation to CFT

50.7.2 Orders: Curves with Singularities

This entire section is completely inspired by Neukirch p.72

should also include how if finite L/K then $\mathrm{Spec}\,(\mathcal{O}_L)$ is the normalization of $\mathrm{Spec}\,(\mathcal{O}_K[\alpha])$ where $L = K(\alpha)$. And I would really love a discussion linking $\mathrm{Spec}\,(\mathcal{O}_L)$ to the "generic point" $\mathrm{Spec}\,(L)$ and to $y - m_{\alpha,K}(x)$ where $m_{\alpha,K}(x)$ is the minimal polynomial of L/K

All smooth 1-dimensional curves correspond to Dedekind domains. However, there are some curves with singularities. These curves are associated to sub-rings of Dedekind domains called *orders*

Definition 50.7.1: Order

Let $K/\mathbb{Q}$ be a number field of degree n. Then an order of K is a subring of $\mathcal{O}_K$ which contains an integral basis of length n. The ring $\mathcal{O}_K$ is called a *maximal order*.

By the above definition, an order is of the form:

$$\mathbb{Z}[\alpha_1, ..., \alpha_n]$$

where $K = \mathbb{Q}(\alpha_1, ..., \alpha_n)$, which motivates why $\mathcal{O}_K$ is the maximal order. It is the maximal ring with this property. This also implies that orders need not be normal, hence an order is a one-dimensional Noetherian integral domain (prime remain maximal as if $a \in \mathfrak{p} \cap \mathbb{Z}$ then $a\mathcal{O} \subseteq \mathfrak{p} \subseteq \mathcal{O}$ that is $\mathfrak{p}$ and $\mathcal{O}$ have the same rank n, and thus $\mathcal{O}/\mathfrak{p}$ is a finite integral domain, showing $\mathfrak{p}$ is maximal) . An example of an order is $\mathbb{Z} = \mathbb{Z}(\sqrt{5})$. Many order's naturally are as "rings of multipliers. For example if $\alpha_1, .., \alpha_n$ is a basis for $K/\mathbb{Q}$ and $M = \sum_i \mathbb{Z}\alpha_i$, then

$$\mathcal{O}_M = \{\alpha \in K \mid \alpha M \subseteq M\}$$

is an order.

It is important that we re-prove the Chinese remainder

Here

As orders are not Dedekind domain in general, *not* all ideals are invertible. This also means that the collection of fractional ideals does not form a group.

Proposition 50.7.2: Invertible Fracitonal Ideals

Let I be a fractional ideal of a Noetherian domain R. Then I is invertible iff its localization at every maximal ideal of R is invertible, equivalently, iff its localization at every prime ideal of R is invertible.

***Proof*:**

Write $K = K(R)$, and for a multiplicative set $S \subseteq R \setminus \{0\}$ and an R-submodule $M \subseteq K$ let $S^{-1}M = M \cdot S^{-1}R \subseteq K$. Write $M_{\mathfrak{p}}$ when $S = R \setminus \mathfrak{p}$. Recall from definition 50.2.9 that $(R : I) = \{x \in K \mid xI \subseteq R\}$, and note $I(R : I) \subseteq R$ always, since $x \in (R : I)$ and $y \in I$ give $xy \in R$. The product $I(R : I)$ is an R-submodule of R, that is an ideal.

First, $(IJ)_S = I_S J_S$ for fractional ideals I and J: an element of $I_S J_S$ is a finite sum $\sum_k (i_k/s_k)(j_k/t_k)$, and putting the terms over the common denominator $\prod_k s_k t_k$ exhibits it in $(IJ)_S$, while the reverse inclusion is immediate. Second, $(R : J)_S = (R_S : J_S)$ for a nonzero fractional ideal J. For $\subseteq$, if $xJ \subseteq R$ then $(x/s)J_S \subseteq R_S$. For $\supseteq$, let $x \in K$ satisfy $xJ_S \subseteq R_S$. Since R is Noetherian, $J = (j_1, \ldots, j_r)$ is finitely generated, and each $xj_k \in R_S$ gives $s_k \in S$ with $s_k x j_k \in R$. With $s = s_1 \cdots s_r$ we get $sxJ \subseteq R$, so $sx \in (R : J)$ and $x \in (R : J)_S$.

Suppose I is invertible, say $IJ = R$ for a fractional ideal J. Then $jI \subseteq R$ for every $j \in J$, so $J \subseteq (R : I)$ and

$$R = IJ \subseteq I(R : I) \subseteq R$$

forcing $I(R : I) = R$. Localising at any prime $\mathfrak{p}$ and applying the two identities gives $I_{\mathfrak{p}}(R_{\mathfrak{p}} : I_{\mathfrak{p}}) = (I(R : I))_{\mathfrak{p}} = R_{\mathfrak{p}}$, so $I_{\mathfrak{p}}$ is invertible. This covers every prime, hence every maximal ideal.

Conversely, suppose $I_{\mathfrak{m}}$ is invertible for every maximal ideal $\mathfrak{m}$. By the paragraph proved above,

$I_{\mathfrak{m}}(R_{\mathfrak{m}} : I_{\mathfrak{m}}) = R_{\mathfrak{m}}$ for every such $\mathfrak{m}$. If the ideal $I(R : I)$ were proper it would lie in some maximal ideal $\mathfrak{m}$, and then

$$R_{\mathfrak{m}} = I_{\mathfrak{m}}(R_{\mathfrak{m}} : I_{\mathfrak{m}}) = (I(R : I))_{\mathfrak{m}} \subseteq \mathfrak{m}R_{\mathfrak{m}} \neq R_{\mathfrak{m}}$$

a contradiction. So $I(R : I) = R$ and I is invertible. Finally, if $I_{\mathfrak{p}}$ is invertible at every prime $\mathfrak{p}$ then in particular at every maximal ideal, so the prime version of the criterion follows from the maximal one.

Example 50.7.3: non-invertible ideal of an order
put this example here

(I want this build up here)

Definition 50.7.4: Picard Group Of An Order

Let $J(\mathcal{O})$ be the collection of invertible ideals and $P(\mathcal{O})$ the fractional principal ideals. Then

$$\operatorname{Pic}(\mathcal{O}) = \frac{J(\mathcal{O})}{P(\mathcal{O})}$$

A lot more to be said.

The Picard group ignore s ideals that are not invertible. Another approach that gives some useful results is to define the following for A Dedekind domain:

$$\operatorname{Div}(\mathcal{O}) = \mathcal{O}_{\mathfrak{p}}\mathbb{Z}\mathfrak{p}$$

Then $\operatorname{Div}(\mathcal{O})$ is isomorphic to the ideal group. For an order, the divisor group shall be a quotient of this group. We would then need to define the divisor elements, which gives the divisor class group/chow group.

50.8 *Profinite Groups

(original title: infinite galois extensions)

I moved this from the galois theory chapter. I actually want to make this its own chapter when I extract these notes into their own book so that the many books that use profinite groups can reference this namely: the class field theory book, the p-adic rep book, and the galois cohomology book.

In this section, we shall explore the case of infinite separable normal extensions L/K. This section uses topological groups [39, Topological Group] and the following facts of point-set topology from *Topology* [39]: Tychonoff's theorem [39, Tychonoff's Theorem], that closed subsets of compact spaces are compact [39, closed subsets of compact spaces are compact], that compact Hausdorff spaces are normal [39, Compact Hausdorff Spaces Are Normal], that continuous images and closures of connected sets are connected [39, Continuous Images of Connected Spaces Are Connected] [39, Connectedness Survives Adding Limit Points], and that a continuous bijection from a compact space onto a Hausdorff space is a homeomorphism [39, making continuous function homeomorphisms]. Most of this material will be important for a course in *Class Field Theory* [77].

In this section, a Galois extension is a normal separable extension, where the finiteness condition is dropped. We may want to keep the galois correspondence between the fixed fields and the subgroups, however there are simply way too many subgroups. Consider

$$\overline{\mathbb{Q}}/\mathbb{Q} \qquad \text{and} \qquad \text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$$

Then the reader should check that there are only countably many intermediary extension of degree 2 corresponding to the extensions of the form $\mathbb{Q}(\sqrt{\alpha})/\mathbb{Q}$ where α is either a prime p, ip, or a finite compositum of such elements. However, there are uncountably many index two subgroups. To see this, consider $\varphi_S : \text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}}) \to \mathbb{Z}/2\mathbb{Z}$ where S is a finite collection of primes where if σ fixes each $\sqrt{p}$. Then $\varphi_S(s) = 0$, and it is 1 otherwise. This is a group-homomorphism, as the composition of two maps that fix each $\sqrt{p}$ for $p \in S$ shall still fix those primes. Furthermore, There are certainly always morphisms τ such that $\varphi_S(\tau) = 1$ for each finite subset S. Thus, each φ_S is a surjective homomorphism, whose kernel is index 2. But then, there are uncountably distinct $\ker(\varphi_S)$. In fact, we do not even need S to be finite (exercise). In this case, we shall even have index two subgroups whose fixed field corresponds to $\mathbb{Q}$!

The reader may feel that there is some simple solutions that can be found, as it seems there are many galois subgroups corresponding to an intermediary. Indeed, we may still recover the galois correspondence if we appropriately limit which subgroups of $\text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ we consider (and more generally which subgroups of $\text{Gal}_K(L)$ we consider). This is done by taking the *Krull topology* on the galois group, which we shall naturally derive by first taking the *profinite topology*. The profinite topology shall make us limit our attention to normal subgroups of finite index (namely, such subgroups shall be open in the profinite topology), while in the Krull topology we shall limit our attention to normal subgroups of finite index which also have a [finite] galois group (namely, such subgroups shall be open in the Krull topology). Both of these topologies are achieved by showing that the infinite galois group, as a topological group, is a profinite group. The main idea is that all of the information of infinite galois extension is in fact fully captured by the finite normal extension, due to the fact galois groups represent the relationship of polynomials (where an infinite galois groups stores the information of infinitely many polynomials).

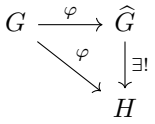
50.8.1 Profinite Groups

In this section, a brief introduction to profinite groups is given. This is not an in-depth coverage, but rather it gives enough information to describe infinite galois theory.

Definition 50.8.1: Profinite Group

Take an inverse system of finite groups with the discrete topology. Then a *profinite group* is a topological group that is the limit of the system. Given any topological group G, we can take its *profinite completion* by taking:

$$\widehat{G} = \varprojlim_N G/N$$



where N ranges over all finite index open normal subgroups ordered by containment.

Any group G can be given a topology by given it the profinite topology given by taking the cosets of finite-index normal subgroups as a basis. The reader should check that if G is a topological group and $\widehat{G}$ is its profinite completion, then the continuous homomorphism $\varphi : G \to \widehat{G}$ can be shown that G is dense in $\widehat{G}$.

Example 50.8.2: Profinite Groups

1. Let G be finite. Then all normal subgroups have finite index and there are finitely many. It follows that $G \cong \widehat{G}$.
2. Let $G = \mathbb{Z}$. Then
$$\widehat{Z} = \varprojlim_n \mathbb{Z}/n\mathbb{Z} \cong \prod_p \mathbb{Z}_p$$
where $\mathbb{Z}_p = \varprojlim_n \mathbb{Z}/p^n\mathbb{Z}$ is the p-adic completion of $\mathbb{Z}$.
3. Take $G = \mathbb{Q}$. Then $\mathbb{Q}$ has only one finite-index normal subgroup, namely itself. Hence $\widehat{\mathbb{Q}} = \{1\}$.

The above examples show that the map $\varphi : G \to \widehat{G}$ could be injective, surjective, both. The map will be injective if the intersections of all finite-index open normal subgroups of G is trivial (where we would then say G is residually finite). The completion comes equipped with a natural universal property where a continuous homomorphism $\varphi : G \to H$ with H a profinite group has a unique continuous homomorphism such that the following diagram commutes:

A word on strongly complete? MIT notes p.275 Remark 26.15

Theorem 50.8.3: Characterizing Profinite Groups

A topological group is profinite if and only if it is a totally disconnected compact group

***Proof*:**

Step 1: profinite groups are compact and totally disconnected. An isomorphism of topological groups preserves both properties, so by definition 50.8.1 we may take $G = \varprojlim_{i\in I} G_i \subseteq P = \prod_{i\in I} G_i$ for an inverse system of finite discrete groups G_i over a directed set I, with transition maps $\varphi_{ji}\colon G_j \to G_i$ for $i \le j$ and projections $p_i\colon P \to G_i$. Each G_i is finite, hence compact, so P is compact by Tychonoff's theorem. The space P is Hausdorff: two distinct points differ in some coordinate i, and the preimages under p_i of the two values are disjoint open sets. For $i \le j$ the set
$$C_{ij} = \{g \in P \mid \varphi_{ji}(p_j(g)) = p_i(g)\}$$
is closed, since its complement is the union, over the pairs $(a, b) \in G_j \times G_i$ with $\varphi_{ji}(a) \neq b$, of the open sets $p_j^{-1}(a) \cap p_i^{-1}(b)$. So $G = \bigcap_{i\le j} C_{ij}$ is closed in P, hence compact, as a closed subset of a compact space. If $C \subseteq G$ is connected, then each $p_i(C)$ is a connected subset of the discrete space G_i, being a continuous image of a connected set, so it is a single point. Points of C therefore agree in every coordinate, and C has at most one point. So G is totally disconnected.

Step 2: a compact totally disconnected group is Hausdorff. Let G be a compact totally disconnected group. The closure of the connected set $\{1\}$ is connected, hence equal to $\{1\}$, so

$\{1\}$ is closed, and so is every $\{g\}$, because left translation is a homeomorphism. Let $x \neq y$ in G. Then $G \setminus \{x^{-1}y\}$ is an open neighbourhood of 1, and continuity of $(a,b) \mapsto ab^{-1}$ at $(1,1)$ gives an open neighbourhood V of 1 with $VV^{-1} \subseteq G \setminus \{x^{-1}y\}$. If $xv = yw$ with $v, w \in V$, then $x^{-1}y = vw^{-1} \in VV^{-1}$, which is impossible. So xV and yV are disjoint open sets containing x and y.

Step 3: every open neighbourhood of 1 *contains a clopen neighbourhood of* 1. Let Y be the intersection of all clopen subsets of G containing 1, a closed set. Suppose $Y = A \cup B$ with A and B disjoint and closed in Y, hence closed in G, and $1 \in A$. A compact Hausdorff space is normal, so there are disjoint open sets $U_A \supseteq A$ and $U_B \supseteq B$. The closed sets $C \setminus (U_A \cup U_B)$, for C clopen with $1 \in C$, have empty intersection, because $Y \subseteq U_A \cup U_B$. By compactness finitely many of them already have empty intersection, and the intersection C of the corresponding clopen sets is clopen, contains 1 and lies in $U_A \cup U_B$. Then $C \cap U_A$ is open, and it equals $C \setminus U_B$, which is closed. So $C \cap U_A$ is a clopen set containing 1, hence $Y \subseteq C \cap U_A$, and $B \subseteq Y \subseteq U_A$. As $B \subseteq U_B$ and $U_A \cap U_B = \emptyset$, B is empty. So Y is connected, and $Y = \{1\}$ because G is totally disconnected. Now let U be an open neighbourhood of 1. The closed sets $C \setminus U$, for C clopen with $1 \in C$, have intersection $Y \setminus U = \emptyset$, so by compactness finitely many of them do, and the intersection of the corresponding clopen sets is a clopen neighbourhood of 1 inside U.

Step 4: every clopen neighbourhood C of 1 *contains an open normal subgroup.* The set C is closed in the compact space G, hence compact. For each $c \in C$, the set C is an open neighbourhood of $c \cdot 1$, so continuity of multiplication at $(c, 1)$ gives open sets $W_c \ni c$ and $V_c \ni 1$ with $W_c V_c \subseteq C$. Finitely many $W_{c_1}, \ldots, W_{c_k}$ cover C, and $V = \bigcap_i \left(V_{c_i} \cap V_{c_i}^{-1}\right)$ is an open neighbourhood of 1 with $V = V^{-1}$ and $CV \subseteq C$. By induction $CV^r \subseteq C$ for every $r \geq 1$, where V^r is the set of products of r elements of V. The union $H = \bigcup_{r \geq 1} V^r$ is a subgroup, being closed under products and, as $V = V^{-1}$, under inverses. It is open, each $V^r = \bigcup_{g \in V^{r-1}} gV$ being a union of translates of V. Since $1 \in C$, $H \subseteq CH \subseteq C$. The left cosets of H are disjoint open sets covering G, so by compactness there are finitely many of them, and H has finite index. The conjugate gHg^{-1} depends only on the coset gH, so $N = \bigcap_{g \in G} gHg^{-1}$ is a finite intersection of open subgroups. It is an open normal subgroup with $N \subseteq H \subseteq C$.

Step 5: G is the limit of its finite quotients. Let $\mathcal{N}$ be the set of open normal subgroups of G, directed by reverse inclusion, as $N_1 \cap N_2 \in \mathcal{N}$ for $N_1, N_2 \in \mathcal{N}$. Each G/N with $N \in \mathcal{N}$ is finite, by the coset argument of Step 4, and carries the discrete topology. The map

$$\Phi \colon G \to \varprojlim_{N \in \mathcal{N}} G/N \qquad g \mapsto (gN)_N$$

is a group homomorphism. It is continuous, because each $G \to G/N$ is: the preimage of any subset of G/N is a union of cosets of the open subgroup N. It is injective: for $g \neq 1$, the set $G \setminus \{g\}$ is an open neighbourhood of 1 by Step 2, it contains a clopen neighbourhood of 1 by Step 3, and that contains some $N \in \mathcal{N}$ by Step 4, so $g \notin N$. It is surjective: let $(x_N N)_N$ be a compatible family. Each coset $x_N N$ is closed, its complement being a union of cosets of the open subgroup N. For $N_1, \ldots, N_k \in \mathcal{N}$ and $N = N_1 \cap \cdots \cap N_k$, compatibility gives $x_N N_i = x_{N_i} N_i$, so $x_N \in x_{N_1} N_1 \cap \cdots \cap x_{N_k} N_k$. By compactness the intersection of all the cosets $x_N N$ contains some g, and then $\Phi(g) = (x_N N)_N$. Finally, $\varprojlim_N G/N$ is Hausdorff, as a subspace of a product of discrete spaces (Step 1), and a continuous bijection from a compact space onto a Hausdorff space is a homeomorphism. So Φ is an isomorphism of topological groups, and G is profinite,

completing the proof.

Corollary 50.8.4: Distinguishing Profinite Completion

Let G be a profinite group. Then G is naturally isomorphic to its profinite completion, or even stronger:

$$G \cong \varprojlim G/U$$

where U ranges over all open normal subgroups ordered by containment.
Moreover G is *strongly complete*, meaning that the natural map from G to the profinite completion of its underlying abstract group is an isomorphism, if and only if every finite index subgroup of G is open

***Proof*:**
By definition 50.8.1 write $G = \varprojlim_{i\in I} G_i \subseteq \prod_i G_i$ for an inverse system of finite discrete groups over a directed index set I. Let $p_i : G \to G_i$ be the projections and $N_i = \ker p_i$, an open normal subgroup since p_i is continuous and G_i is discrete. If $j \geq i$ then the transition map carries $p_j(g)$ to $p_i(g)$, so $N_j \subseteq N_i$. A basic open neighbourhood of 1 in the subspace topology of $\prod_i G_i$ is a finite intersection $\bigcap_{i\in F} N_i$, and by directedness there is j with $j \geq i$ for all $i \in F$, so the N_i form a neighbourhood basis at 1.

By theorem 50.8.3 the group G is compact, so every open subgroup U has finite index: its cosets form an open cover of G by disjoint sets, and a finite subcover must consist of all of them. Any open normal subgroup U is a neighbourhood of 1, hence contains some N_i, so the family $\{N_i\}$ is cofinal among open normal subgroups and $\varprojlim_U G/U = \varprojlim_i G/N_i$. The natural map $G \to \varprojlim_i G/N_i$ is injective because $\bigcap_i N_i = \{1\}$, and it is surjective because a compatible family in $\prod_i G/N_i \cong \prod_i p_i(G)$ is a compatible family in $\prod_i G_i$, hence a point of $\varprojlim_i G_i = G$. It is continuous, since each $G \to G/N_i$ is continuous for N_i open, and a continuous bijection from a compact space to a Hausdorff space is a homeomorphism. So $G \cong \varprojlim_U G/U$ through the natural map, and since every open normal subgroup has finite index, this limit is the profinite completion of the topological group G.

For the second statement, let $\widehat{G}_{\text{abs}} = \varprojlim_N G/N$ where N ranges over *all* finite index normal subgroups of G, and let $\varphi : G \to \widehat{G}_{\text{abs}}$ be the natural map. Every open normal subgroup has finite index, so forgetting the coordinates indexed by the non-open N gives a continuous homomorphism $\psi : \widehat{G}_{\text{abs}} \to \varprojlim_U G/U = G$ with $\psi \circ \varphi = \mathrm{id}_G$.

If every finite index subgroup of G is open, the two index families coincide, $\widehat{G}_{\text{abs}} = \varprojlim_U G/U$, and φ is the isomorphism of the first part. Conversely, suppose φ is an isomorphism. Then $\psi = \varphi^{-1}$ is a continuous bijection, and $\widehat{G}_{\text{abs}}$ is compact, being a closed subgroup of the product of the finite discrete groups G/N, while G is Hausdorff. So ψ, and hence φ, is an isomorphism of topological groups. Let $H \leqslant G$ have finite index and set $N = \bigcap_{g\in G} gHg^{-1}$. The map $g \mapsto gHg^{-1}$ factors through the cosets of the normaliser of H, which contains H and therefore has finite index, so there are finitely many conjugates, each of finite index. Their intersection N again has finite index, because G embeds into the product of the finitely many finite coset spaces, and N is normal by construction. The subgroup $\ker\left(\widehat{G}_{\text{abs}} \to G/N\right)$ is open by construction and its preimage under φ is N, because $G \to \widehat{G}_{\text{abs}} \to G/N$ is the quotient map. Hence N is open, and H, a union of cosets of N, is open as well.

50.8.2 Infinite Galois Theory

Let us now find which topology to put on galois groups. Let us first make sure that the notion of there being a correspondence between subfields and fixed fixed fields of subgroups of galois group is still well-defined

Lemma 50.8.5: Fixed Field Infinite Extension

Let L/K be a galois extension with galois group $G = \mathrm{Gal}_K(L)$ and let F be an intermediate field. Then $H = \mathrm{Gal}_F(L)$ has fixed field F. If moreover F/K is normal, then $H \trianglelefteq G$ is a normal subgroup of G, and there is a short exact sequence:

$$1 \to \mathrm{Gal}_F(L) \to \mathrm{Gal}_K(L) \to \mathrm{Gal}_K(F) \to 1$$

which implies:

$$G/H \cong \mathrm{Gal}_K(F)$$

***Proof*:**
Let $\overline{L}$ be an algebraically closed field containing L, which exists by lemma 19.5.5 and the chain construction before it.

Step 1: extending embeddings. Let E be an intermediate field of L/K and $\rho\colon E \to L$ a field homomorphism fixing K. The extension L/E is algebraic and $\overline{L}$ is algebraically closed, so, regarding $\overline{L}$ as an extension of E through ρ, lemma 19.5.7 gives a field homomorphism $\sigma\colon L \to \overline{L}$ restricting to ρ on E. For $\beta \in L$ with minimal polynomial f over K, $\sigma(\beta)$ is a root of f, because σ fixes K. Since L/K is normal and f has the root β in L, f splits over L (definition 19.5.12), so $\sigma(\beta) \in L$. Moreover σ maps the finite set of roots of f in L injectively into itself, hence onto itself, so $\beta \in \sigma(L)$. Thus σ is an automorphism of L fixing K, that is $\sigma \in G$, and it extends ρ.

Step 2: the restriction map, for normal F/K. Suppose F/K is normal, and let $\sigma \in G$ and $\beta \in F$ with minimal polynomial f over K. As F/K is normal, f splits over F. Since σ fixes K, it maps the finite set of roots of f in F injectively, hence bijectively, to itself. So $\sigma(F) = F$ and $\sigma|_F \in \mathrm{Gal}_K(F)$. The map $G \to \mathrm{Gal}_K(F)$, $\sigma \mapsto \sigma|_F$, is a group homomorphism with kernel $\mathrm{Gal}_F(L) = H$, which is therefore normal in G. It is surjective: given $\tau \in \mathrm{Gal}_K(F)$, Step 1 with $E = F$ and $\rho = \tau$ gives $\sigma \in G$ with $\sigma|_F = \tau$. This is the short exact sequence of the statement, and $G/H \cong \mathrm{Gal}_K(F)$ by theorem 3.5.1.

Step 3: the fixed field of H is F. Every element of H fixes F, so $F \subseteq L^H$. Let $\alpha \in L \setminus F$ and let g be its minimal polynomial over F, which has degree at least 2. It divides the minimal polynomial of α over K, which has distinct roots, as L/K is separable, and splits over L, as L/K is normal. So g has a root $\alpha' \in L$ with $\alpha' \neq \alpha$. By theorem 19.2.27 there is an isomorphism $F(\alpha) \to F(\alpha')$ fixing F and sending α to α', and Step 1 with $E = F(\alpha)$ extends it to some $\sigma \in G$. Then σ fixes F, so $\sigma \in H$, while $\sigma(\alpha) = \alpha' \neq \alpha$. So $\alpha \notin L^H$, and $L^H = F$, completing the proof.

Hence, every normal subextension has (at least one) corresponding normal subgroup. However, there are many normal subgroups whose fixed field F is *not* equal to $\mathrm{Gal}_F(L)$, but is contained in $\mathrm{Gal}_F(L)$

The index two example of $\text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ is the prototypical example, where there are uncountably many index 2 subgroups $H \leqslant \text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ whose fixed field is $\mathbb{Q}$ but naturally H is not the galois subgroup of $\overline{\mathbb{Q}}/\mathbb{Q}$, nor is it the galois group of $\overline{\mathbb{Q}}/K$ for any subextension $K/\mathbb{Q}$. Hence, the following topology limits our attention to the right groups:

Definition 50.8.6: Krull Topology On Galois Group

Let L/K be a Galois (i.e. normal separable) extension with $G = \text{Gal}_K(L)$. Then the *Krull Topology* on G is the basis given by the basis consisting of cosets of the subgroups

$$H_F = \text{Gal}_F(L)$$

where F ranges over finite normal extensions of K in L.

In this topology, every open normal subgroups has finite index, but not every normal subgroup of finite index is open (think $\text{Gal}_{\mathbb{Q}}(\overline{\mathbb{Q}})$ again). Hence, this topology is (strictly) coarser than the porfinite topology, however it is still a profinite group:

Proposition 50.8.7: Galois Group is Profinite Group

Let L/K be a galois extension. Then under the Krull topology, the restriction maps induce a natural isomorphism of topological groups:

$$\text{Gal}_K(L) \cong \varprojlim_F \text{Gal}_K(F)$$

where F ranges over finite galois extension of K in L. Hence, $\text{Gal}_K(L)$ is a profinite group whose open normal subgroups are those of the form $\text{Gal}_F(L)$ for some finite normal extension F/K.

***Proof*:**
Let's first show the map is bijective. For injectivity, for every $\alpha \in L$ it is algebraic over K, and hence liens ins some finite normal subextensions F/K, and so every automorphism in $\text{Gal}_K(L)($ is uniquely determined by all its restrictions to finite normal F/K, showing φ is injective. For surjectivity, given any $(\sigma_F) \in \varprojlim_F \text{Gal}_K(F)$, we may define a corresponding $\sigma \in \text{Gal}_K(L)$ that maps to it by point-wise defining:

$$\sigma(\alpha) := \sigma_F(\vec{\alpha})$$

where F is the normal closure of $K(\alpha)$. This map is well-defined by construction of the inverse limit, giving surjectivity.

For continuity, Letting $G = \text{Gal}_K(L)$ and $H_F = \text{Gal}_F(L)$, we can view φ as the natural continuous map:

$$\varphi : G \to \varprojlim G/H_F$$

Finally, to show the inverse is continuous, we will show the equivalent of φ being an open map, which translates to showing that φ maps open subgroups $H \subseteq G$ (i.e. the basis) to open subsets in $\varprojlim G/H_F$. Taking $H = \text{Gal}_F(L)$, we get:

$$\varphi(H) = \{(\sigma_E) \mid \sigma_{E_{E\cap F}} = \text{id}_{E\cap F}\} = \pi_F^{-1}(\text{id}|_F)$$

as E/K ranges over all finite normal subextension of L/K and π_F is the projection from the limit to $\mathrm{Gal}_K(F)$. Then the singleton set $\{\mathrm{id}|_F\}$ is open in the discrete group $\mathrm{Gal}_K(F)$, and so its inverse is open, completing the proof.

Theorem 50.8.8: Fundamental Theorem of Galois Theory, Infinite Extensions

Let L/K be a galois extension with galois group $G = \mathrm{Gal}_K(L)$ endowed with the Krull topology. Then the maps

$$F \mapsto \mathrm{Gal}_F(L) \qquad H \mapsto L^H$$

define inclusion reversing bijections between subextensions F/K of L/K and closed subgroups H of G. Thus, subextensions of finite degree n correspond to subgroups of finite index n, and normal subextensions F/K correspond to normal subgroups $H \leqslant G$ such that as topological groups:

$$\mathrm{Gal}_K(F) \cong G/H$$

***Proof*:**
First off, recall that every open subgroup is clopen, as the compliment is the union of non-trivial cosets, and so closed subgroups of finite index are open. Next, the correspondence between finite galois subextensions F/K and finite index closed normal subgroups H is given by proposition 50.8.7, and furthermore we have $[F : K] = [G : H]$ as $G/H \cong \mathrm{Gal}_K(F)$ by lemma 50.8.5.

For the correspondence maps, if F/K is any finite subextension with normal closure E, then $H = \mathrm{Gal}(L/F)$ contains the normal subgroup $N = \mathrm{Gal}(L/E)$ with finite index. The subgroup N is open and therefore closed, thus H is closed since it is a finite union of cosets of N. The fixed field of H is F by lemma 50.8.5, thus finite subextensions correspond to closed subgroups of finite index. Conversely, every closed subgroup H of finite index has a fixed field F of finite degree, since the intersection of its conjugates is a normal closed subgroup $N = \mathrm{Gal}(L/E)$ of finite index whose fixed field E contains F and has finite degree. The degrees and indices match because $[G : N] = [G : H][H : N]$ and $[E : K] = [F : K][E : F]$. By the previous argument for finite normal subextensions, $[E : K] = [G : N]$ and $[E : F] = [H : N]$ (for the second equality, replace L/K with L/F and G with H).]

Next, for the closed part, any subextension F/K is the union of its finite subextensions E/K. The intersection of the corresponding closed finite index subgroups $\mathrm{Gal}(L/E)$ is equal to $\mathrm{Gal}(L/F)$, which is therefore closed. Conversely, every closed subgroup H of G is an intersection of basic closed subgroups, all of which have the form $\mathrm{Gal}(L/E)$ for some finite subextension E/K, thus $H = \mathrm{Gal}(L/F)$, where F is the union of the E, completing the proof.

Finally, let F/K be normal and $H = \mathrm{Gal}_F(L)$. By lemma 50.8.5, restriction $\rho\colon G \to \mathrm{Gal}_K(F)$, $\sigma \mapsto \sigma|_F$, is a surjective homomorphism with kernel H, so it induces a group isomorphism $\overline{\rho}\colon G/H \to \mathrm{Gal}_K(F)$. The map ρ is continuous: a basic open set of $\mathrm{Gal}_K(F)$ is a coset $\tau\mathrm{Gal}_E(F)$ with E/K finite normal inside F (definition 50.8.6), and if $\rho(\sigma_0) = \tau$ then $\rho^{-1}(\tau\mathrm{Gal}_E(F)) = \sigma_0\mathrm{Gal}_E(L)$, a basic open set of G, since an element of G fixes E exactly when its restriction to F does. So $\overline{\rho}$ is continuous for the quotient topology on G/H. The group G is compact (proposition 50.8.7 and theorem 50.8.3), so G/H is compact: an open cover of G/H pulls back to an open cover of G, a finite subcover of which maps onto a finite subcover. The group $\mathrm{Gal}_K(F)$ is Hausdorff: if $\tau \neq \tau'$, choose $x \in F$ with $\tau(x) \neq \tau'(x)$ and a finite normal E/K

inside F containing x, the normal closure of $K(x)$. Then the cosets $\tau\mathrm{Gal}_E(F)$ and $\tau'\mathrm{Gal}_E(F)$ are disjoint, their elements sending x to $\tau(x)$ and to $\tau'(x)$ respectively. A continuous bijection from a compact space onto a Hausdorff space is a homeomorphism, as recalled at the start of this section, so $\overline{\rho}$ is an isomorphism of topological groups, completing the proof.

Corollary 50.8.9: Closure in Krull Topology

Let L/K be a galois extension and $H \leqslant \mathrm{Gal}_K(L)$ with fixed field F. Then the closure $\overline{H}$ in the Krull Topology is $\mathrm{Gal}_F(L)$:

$$\overline{H} = \mathrm{Gal}_F(L)$$

***Proof*:**
First, $H \subseteq \mathrm{Gal}_F(L)$ since by definition $\mathrm{Gal}_F(L)$ contains every $\sigma \in \mathrm{Gal}_K(L)$ that fixes F . Next, $\mathrm{Gal}_F(L)$ is closed and is the group characterized by $L^{\mathrm{Gal}_F(L)} = F$ by theorem 50.8.8. Thus

$$H \subseteq \overline{H} \subseteq \mathrm{Gal}_F(L)$$

Then in the bijection presented in theorem theorem 50.8.8, we have that they are equal, completing the proof.

Let us conclude with a result proven by Waterhouse in 1973 that generalizes theorem 20.2.10:

Theorem 50.8.10: Profinite Group Representable By Galois Group

Let G be a profinite group. Then G is isomorphic to the galois group of some galois extension L/K

***Proof*:**
Let $\mathcal{N}$ be the set of open normal subgroups of G and let

$$X = \coprod_{N \in \mathcal{N}} G/N$$

with G acting on each summand by left translation. Each $N \in \mathcal{N}$ has finite index, since G is compact by theorem 50.8.3 and the cosets of N form a cover of G by disjoint open sets. So every G-orbit in X is finite. The action is faithful: if g fixes every point then $g \in N$ for all $N \in \mathcal{N}$, and $\bigcap_N N = \{1\}$ because the natural map $G \to \varprojlim_N G/N$ is injective by corollary 50.8.4. The stabiliser of a point gN is gNg^{-1}, which is open.

Let k be any field and let $L = k(X)$ be purely transcendental over k with one indeterminate x_ξ for each $\xi \in X$. Each $\sigma \in G$ permutes X, hence induces the k-automorphism $x_\xi \mapsto x_{\sigma\xi}$ of L, and faithfulness makes $G \to \mathrm{Aut}_k(L)$ injective. Identify G with its image and put $K = L^G$.

The extension L/K is Galois. Since $k \subseteq K$, we have $L = k(X) \subseteq K(X) \subseteq L$, so $L = K(X)$. For each $\xi \in X$ the orbit $G\xi$ is finite, and the polynomial $\prod_{\eta \in G\xi}(T - x_\eta)$ has coefficients fixed by G, hence in K. Its roots are distinct indeterminates and all lie in L, so x_ξ is separable over K with minimal polynomial splitting in L. Therefore $L = K(X)$ is algebraic, separable and normal over K.

By construction $G \leqslant \mathrm{Gal}_K(L)$ with fixed field K, so G is dense in $\mathrm{Gal}_K(L)$ for the Krull topology

by corollary 50.8.9. The inclusion $\iota : G \to \mathrm{Gal}_K(L)$ is continuous: by definition 50.8.6 it is enough that $\iota^{-1}(\mathrm{Gal}_F(L))$ be open in G for every finite normal subextension F/K, since the preimage of a coset is empty or a coset of that subgroup. Write $F = K(\alpha_1, \ldots, \alpha_r)$. Each α_i is a rational function in finitely many of the x_ξ, so there is a finite $Y \subseteq X$ such that any $\sigma \in G$ fixing Y pointwise fixes every α_i, hence fixes F pointwise. The pointwise stabiliser of Y is a finite intersection of open stabilisers, so it is open, and $\iota^{-1}(\mathrm{Gal}_F(L))$ is a union of its cosets.

Finally, $\iota(G)$ is compact as the continuous image of a compact group, and $\mathrm{Gal}_K(L)$ is Hausdorff because proposition 50.8.7 realises it as a subspace of a product of discrete groups. So $\iota(G)$ is closed, and being dense it is all of $\mathrm{Gal}_K(L)$. Thus ι is a continuous bijection from a compact group to a Hausdorff group, hence an isomorphism of topological groups $G \cong \mathrm{Gal}_K(L)$.

Just like for finite groups where $K = \mathbb{Q}$ is a difficult (as of writing this book unsolved) problem called the *inverse Galois Problem*, there is little control on what base field K we can choose.

Exercise 50.8.1

1. Find $G = \mathrm{Gal}_{\mathbb{F}_p}(\overline{\mathbb{F}}_p)$ recalling that for each degree n, there is only one extension of $\mathbb{F}_p$. Show that there are too many subgroups to correspond to the fixed fields. Define the Krull topology on G.

Part X

Representation Theory

There are many domains of mathematics which have made huge amounts of progress, having very-well understood objects and morphisms, theorems, results, and properties. One of the most well-understood area's of mathematics has become linear algebra, where vector-spaces and linear transformations. One of the goals of this chapter will be do be able to study the following 3 objects where the operations becomes matrix addition and multiplication

1. (Finite) groups as a subgroup of $\mathrm{GL}(V)$, where the group operation becomes the matrix multiplication
2. Associative algebras
3. Lie Algebras

The further advantage of bringing these objects into linear algebra is that many field intersect with it: If the vector-spaces are infinite dimensional, we can make them Hilbert spaces and use tools from analysis. Vector-spaces are at the heart of differential geometry allowing us to use such theories to study groups!

For the reader who is really interested in number theory, section 51.3 shows that matrix algebras have many parallels with some number theory results. The reader who goes onto learn class field theory[28] will to their delight find that these parallels continue. It was observed by Langland[29] that the study of simple k-algebras (algebras with trivial two-sided ideals) can be a higher-dimensional parallel to field extensions and the central results of class field mathematics known as the *Langland's Program*.

(The reader may want to go back to section 12.3 to review about direct sums of modules)

(Also, this entire link is really cool: from wiki. Also has some cool examples of duality!!!)

[28] See [77] for the continuation of this textbook into class field theory

[29] Or at least formalized by Langland, as these ideas were floating around during his time

51

Semisimple Rings and Modules

As mentioned in the introduction, representation theory is all about decomposing structures. In part I, we showed in chapter 3, section 3.7, that all finite groups can uniquely be represented as a series of extensions with simple factors (i.e. G_i/G_{i+1} is simple). The simplest type of composition series would be when G is a direct product of simple groups, which would be in the terminology of exact sequences a series of trivial extensions with simple factors: such a group is sometimes *semi-simple* group[1]. When it came to modules, we found that we may decompose it in different ways depending on what rings acts on it, in particular we saw in chapter 13 that if $R = k$ is a field k, then any k-module is free, and in chapter 14 we saw that if R is a Principal Ideal Domain, where we got that any R-module decompsoed into a free part R-isomorphic to R^k, and a torsion part $R/(a_1) \times \cdots \times R/(a_n)$. It is evident that the ring that acts on the abelian group can have a large impact on it's structure. In this section, we define a new type of ring, which will come to be called a *semi-simple* ring, that will force the module M to *always* be a direct product of *simple modules* (so that we are analysing the "building blocks" of modules).

To define this ring, we first shift focus and start by work with the module itself to find the "simplest" structure it may be[2], and explore in a manner which at the beginning parallels groups: we will look for *simple R-modules*, and direct product of simple modules (since they are the simplest extension of simple module).[3]. After defining such a strucutre, we will define which rings acting on moduels will *always* make the module semi-simple

[1] the term "semi-simple group" is not a completely standard terminology, as direct product of simple groups is not generally very heavily studied, see this

[2] "simple" here means no non-trivial sub-structures that can be used to build an extension, just like for simple groups or simple rings

[3] It might be tempting to say that this means we are exploring projective modules. However, we have yet to establish whether simple modules are free-modules. Are they?

51.1 Decomposing Modules

Definition 51.1.1: Decomposition Terminology

Let M be a nonzero R-module.

1. M is said to be *simple* (or *irreducible*) if the only submodules of M are 0 and M. Otherwise, M is *reducible*
2. M is said to be *indecomposable* if there do not exist submodules $M_1, M_2 \subseteq M$ such that $M = M_1 \oplus M_2$. Otherwise, M is said to be *decomposable*.
3. The module M is said to be *semisimple* (or *completely reducible*) if it is the direct summand of simple modules
4. The module M is said to be semi-indecomposable (or completely indecomposable) if it is a direct summand of indecomposable modules.
5. If M is semisimple, any direct summand of M is called a *constituent* of M (i.e. N is a constituent of M if there exists a submodulde N' such that $M = N \oplus N'$)

A moment should be taken to find the relations between these definitions:

1. Simple modules are semi-simple and indecomposable. The prototypical example of a simple module is a field k over itself.
2. Semi-Simple $\not\Rightarrow$ Simple: take k^2 over k (the 2 dimensional vector-space over k). The cannonical example of a semi-simple module would be vector-spaces, since they are all direct sums of the underlying field, which is a simple k-module.
3. Indecomposable $\not\Rightarrow$ Simple: this statement is equivalent to saying that not all short exact sequence spilt (i.e., not all modules are *projective*, see section 17.2). For a concrete example, let $\mathbb{Z}^2$ be a module over $\mathbb{Z}$ with the action:

$$r \cdot (a, b) = (a + rb, b)$$

   Then it should be checked that it is not simple since $\mathbb{Z} \times \{0\}$ is a submodule, but it is indecomposable[4].
4. Every semi-simple module is a semi-indecomposable module, however the converse is not true: $\mathbb{Z}$ is a semi-indecomposable $\mathbb{Z}$-module (more genreally any module module over a PID is semi-indecomposable due to the Decomposition Theorem from chapter 14), however $\mathbb{Z}$ is not semi-simple a semi-simple $\mathbb{Z}$-module as $p\mathbb{Z}$ is a submodule (the general case will be immediate after lemma 51.1.7)[5]

As stated in the introduction, we want to determine a semi-simple module or semi-simple modules in terms of the ring that is acting on it. The following defintion was made for this purpose:

[4] Hint: Is it possible to write $\mathbb{Z} = n\mathbb{Z} \oplus m\mathbb{Z}$?

[5] This is a version of Krull-Schmidt's theorem for the decomposition of Noetherian or Artinian modules into the direct sum of indecomposable

Definition 51.1.2: Semi-Simple Ring

Let R be a ring. Then R is *semi-simple* if every R-module is semi-simple. Recall that R is *simple* if the only two-sided ideals are (0) and R.

Notice how a semi-simple ring was *not* defined as the direct product of simple rings. In the following proofs, we will show that the definition of semi-simple ring implies that R is the direct product of simple rings, however the converse is not true: there exists simple rings that are *not* semi-simple modules over themselves (and hence not simple R-modules). The problem is that of dimension; we will soon explore the relation between being semi-simple and Noetherian/Artinian. If we impose the condition that R be Noetherian and Artinian, then we are able to say that R is a semi-simple ring if and only if R is the direct product of simple rings.

We next establish many properties of simple and semi-simple modules, and show how closely related they are to the ring acting on them:

Lemma 51.1.3: Simple Module Characterization

Let M be an R-module. Then M is a simple R-module if and only if there exists a maximal left ideal $\mathfrak{m} \subsetneq R$ such that

$$M \cong_R R/\mathfrak{m}$$

***Proof*:**

($\Rightarrow$) Let M be a simple R-module, so $M \neq 0$ and its only submodules are $\{0\}$ and M. Fix $0 \neq x \in M$ and consider the R-module homomorphism

$$\varphi : R \to M \qquad r \mapsto r \cdot x$$

Its image is a nonzero submodule, so $\varphi(R) = M$, and $R/\ker(\varphi) \cong M$, where $\ker(\varphi)$ is a left ideal. The submodules of $R/\ker(\varphi)$ correspond to the left ideals J with $\ker(\varphi) \subseteq J \subseteq R$, so simplicity of M leaves only $J = \ker(\varphi)$ and $J = R$, and $\ker(\varphi) \neq R$ since $M \neq 0$. Thus $\ker(\varphi)$ is a maximal left ideal.

($\Leftarrow$) Let $\mathfrak{m}$ be a maximal left ideal and $M \cong R/\mathfrak{m}$. The submodules of $R/\mathfrak{m}$ correspond to the left ideals J with $\mathfrak{m} \subseteq J \subseteq R$, which are only $\mathfrak{m}$ and R, and $R/\mathfrak{m} \neq 0$. Hence M is simple, as we sought to show.

If R is commutative, a maximal left ideal is a maximal ideal and $R/\mathfrak{m}$ is a field. For noncommutative R, a maximal left ideal need not be two-sided, and $R/\mathfrak{m}$ is then only a left R-module. For instance, the only two-sided ideals of $R = M_n(k)$ are 0 and R (box 51.2.6), while the simple module k^n is $R/\mathfrak{m}$ for the maximal left ideal $\mathfrak{m}$ of matrices with vanishing first column, the kernel of $A \mapsto Ae_1$. Do not confuse the isomorphism in the above statement with a ring isomorphism: the structure of M is isomorphic to the R-module structure of left-multiplication on $R/\mathfrak{m}$. The proof also shows that a simple R-module is cyclic, generated by any of its nonzero elements. If $R = k$ is a field, then M is isomorphic to a 1-dimensional vector-space over k. There do exist noncommutative simple rings that are *not* of the form $M_n(k)$ for a field k, for instance the Hamilton quaternions $\mathbb{H}$, a noncommutative division ring that is a central simple $\mathbb{R}$-algebra of dimension 4 (example 51.3.3).

Using this result, we see that any semi-simple R-module is of the form:

$$M \cong_R \bigoplus_{i \in I} R/\mathfrak{m}_i$$

for maximal left ideals $\mathfrak{m}_i \subseteq R$. In fact, we can further characterize $\mathfrak{m}_i$:

Corollary 51.1.4: Simple Module's And Annihilators

Let M be a simple left R-module. Then $M \cong R/\text{Ann}(m)$ for any nonzero $m \in M$, where $\text{Ann}(m) = \{r \in R \mid rm = 0\}$, and $\text{Ann}(m)$ is a maximal left ideal.

***Proof*:**
For $0 \neq m \in M$, the submodule Rm is nonzero, so $Rm = M$ because M is simple. The map $R \to M$, $r \mapsto rm$, is therefore a surjective homomorphism of left R-modules with kernel $\text{Ann}(m)$, a left ideal, so

$$M \cong_R R/\text{Ann}(m)$$

The submodules of $R/\text{Ann}(m)$ correspond to the left ideals containing $\text{Ann}(m)$, and M is simple, so $\text{Ann}(m)$ is a maximal left ideal, completing the proof.

Since we have seen the limitations of the structure of simple modules, it is also natural to ask if there are any limitations on the structure of the hom-set given two simple modules:

Lemma 51.1.5: Schur's Lemma

Let M and N be simple R-modules, $\varphi : M \to N$ an R-module homomorphism. Then either $\varphi = 0$ or φ is an isomorphism. As a consequence, $\text{End}_R(M)$ is a division ring.

***Proof*:**
Since N is simple, either $\varphi(M) = N$ or $\varphi(M) = 0$. If $\varphi(M) = N$, it has to be that $\ker(\varphi) = 0$, since M is simple, and hence φ would be an isomorphism.

As a consequence, every element in $\text{End}_R(M)$ is either 0 or is a unit, i.e. has a multiplicative inverse, which by definition makes $\text{End}_R(M)$ a divising ring under $(+, \circ)$.

Since $M \cong_R R/\mathfrak{m}$ for some maximal left ideal $\mathfrak{m} \subsetneq R$, we have that $\text{End}_R(R/\mathfrak{m})$ is always a division ring, whether R is commutative or not. In a sense, this can be thought of as "generalization" to proposition 9.4.19, where it was shown that $R/\mathfrak{m}$ is a field if R is commutative.

Notice that if $M = V$ was an 1-dimensional vector-space over k, then $\text{End}_R(V)$ is a known division ring, in particular it's ring-isomorphic to k. If V is a finite dimensional semi-simple module over k, i.e. it is n-dimensional, then $\text{End}_R(V)$ is ring-isomorphic to $M_n(k)$. We might hope for something similar for the structure of $\text{End}_R(M)$ is M is semi-simple. Take a moment to ponder this before reading the next lemma (hint: recall proposition 12.3.36)

Lemma 51.1.6: Hom's of Semisimple Modules

Let M be a semisimple R-module, so that:

$$M = S_1^{\oplus n_1} \oplus S_2^{\oplus n_2} \oplus \cdots \oplus S_k^{\oplus n_k}$$

where each S_i are simple R-modules, $S_i \ncong S_j$. Then as a ring:

$$\mathrm{End}_R(M) \cong_{\mathbf{Ring}} \mathrm{End}_R(S_1^{\oplus n_1}) \oplus \cdots \oplus \mathrm{End}_R(S_k^{\oplus n_k})$$

Furthermore, for each $S_i^{\oplus n_i}$, we have that direct sums "pull out" to become matrices:

$$\mathrm{End}_R(S_i^{\oplus n_i}) \cong_{\mathbf{Ring}} M_{n_i}(\mathrm{End}_R(S)) = M_{n_i}(D_i)$$

where $D = \mathrm{End}_R(S_i)$ and $M_{n_i}(D_i)$ is the matrix ring over the division ring $\mathrm{End}_R(S_i)$.

***Proof*:**
We invoke proposition 12.3.36 to get the result in terms of groups, and then use Schur's lemma and check that the ring operation is compatible:

$$\begin{aligned}
\mathrm{End}_R(M) &= \mathrm{Hom}_R\left(\bigoplus_i S_i^{\bigoplus n_i}, \bigoplus_j S_j^{\bigoplus n_j}\right) \\
&\cong_{\mathbf{Grp}} \bigoplus_{i,j} \mathrm{Hom}_R\left(S_i^{\bigoplus n_i}, S_j^{\bigoplus n_j}\right) \\
&\cong_{\mathbf{Grp}} \bigoplus_{i,j} \mathrm{Hom}_R(S_i, S_j)^{\bigoplus n_i n_j}
\end{aligned}$$

where when $S_i \neq S_j$, by Shur's lemma we must have:

$$\mathrm{Hom}_R(S_i, S_j)^{n_i n_j} = 0$$

Hence we get that $\mathrm{End}_R(M) \cong_{\mathbf{Grp}} \oplus_i \mathrm{Hom}_R(S_i^{n_i}, S_i^{n_i}) = \oplus_i \mathrm{End}_R(S_i^{n_i})$. Next, this map is compatible with the ring structure, since the map:

$$\varphi \to (\varphi|_{S^{n_i}} : S_i^{n_i} \to S_i^{n_i} \subseteq M)$$

is clearly clearly compatible with composition, and hence

$$\mathrm{End}_R(M) \cong_{\mathbf{Ring}} \bigoplus_i \mathrm{End}_R(S_i^{n_i})$$

For part 2, we follow the same steps as for part (1): re-indexing so that $S^n = S_1 \oplus S_2 \oplus \cdots \oplus S_n$ so that $S_i = S_j = S$, we get

$$\mathrm{Hom}_R\left(\bigoplus_i S_i, \bigoplus_j S_j\right) \cong_{\mathbf{Grp}} \bigoplus_{i,j} \mathrm{Hom}_R(S_i, S_j) \overset{!}{=} \bigoplus_{i,j} D \cong_{\mathbf{Grp}} M_n(D)$$

where $\overset{!}{=}$ comes from Shur's lemma with $D = \text{End}_R(S)$ since $S_i = S_j = S$. The last equality comes from the fact that the matrix $M_n(D)$ when treated like a group is simply re-arranging where the addition is happening in $\bigoplus_{i,j} D$. To show that the ring structure is compatible, observe that

$$\varphi \mapsto \varphi_{ji}$$

is the desired map, where

$$\varphi \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix} = \begin{pmatrix} \varphi_{11} & \varphi_{12} & \cdots & \varphi_{1n} \\ \varphi_{21} & \varphi_{22} & \cdots & \varphi_{2n} \\ \vdots & \vdots & \ddots & \cdots \\ \varphi_{n1} & \varphi_{n2} & \cdots & \varphi_{nn} \end{pmatrix} \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_n \end{pmatrix}$$

which is simply a formalization of what the group-isomorphism give us, showing us that composition is compatible, completing the proof. (see this for a more detailed explanation)

Hence, for any semi-simple R-module M, we get that:

$$\text{End}_R(M) \cong_{\mathbf{Ring}} \prod_i M_{n_i}(D_i) \cong_{\mathbf{Ring}} \prod_i \text{End}_R(S_i^{\oplus n_i})$$

and since each S_i is a simple R-module, $S_i \cong_R R/\mathfrak{m}_i$ for an appropriate maximal left ideal $\mathfrak{m}_i \subseteq R$, $\text{End}_R(S_i) \cong \text{End}_R(R/\mathfrak{m}_i)$. Thus:

$$\text{End}_R(M) \cong_{\mathbf{Ring}} \prod_i M_{n_i}(\text{End}_R(R/\mathfrak{m}_i)) = \prod_i M_{n_i}(D_i)$$

If $R = k$ is a field making $M = V$ a vector-sapce over k (say n-dimensonal), then the only simple k-submodule up to isomorphism is k, and so this result reduces to:

$$\text{End}_R(V) \cong_{\mathbf{Ring}} M_n(\text{End}_k(k/(0))) = M_n(k)$$

where $\text{End}_k(k) \cong_{\mathbf{Ring}} k$, aligning with the results we found in secion 13.2. This shows that when generalizing from linear algebra, due to the fact that a ring is non-commutative, we may have several non-isomorphic simple summands, giving us products of several matrix rings. With a better understanding of simple modules and their endomorphisms, we continue by characterizing semi-simple modules:

Lemma 51.1.7: Semi-Simple Module Equivalence

Let M be an R-module. Then the following are equivalent, and M is called *semi-simple* when they hold:

1. M is an external direct sum of simple modules:
$$M \cong \bigoplus_{i \in I} S_i$$
2. M is the internal direct sum of simple submodules:
$$M = \bigoplus_{i \in I} S_i$$
3. If $N \subseteq M$, there exists a complementary submodule, that is there exists another submodule $N' \subseteq M$ such that
$$M = N \oplus N'$$

In particular, if M is semi-simple, every short exact sequence $0 \to N \to M \to M/N \to 0$ splits. Note that semi-simplicity is not assumed: each of the three conditions implies the other two for an arbitrary module, which is what makes (3) a usable criterion for *establishing* semi-simplicity (as in theorem 53.1.9).

***Proof*:**
For (1) $\Rightarrow$ (2), let $\varphi\colon \bigoplus_{i\in I} S_i \to M$ be an isomorphism. The submodules $\varphi(S_i)$ are simple, and every element of M is uniquely a finite sum of elements of the $\varphi(S_i)$, so M is their internal direct sum. For (2) $\Rightarrow$ (1), if $M = \bigoplus_{i\in I} S_i$ internally, then $(s_i)_{i\in I} \mapsto \sum_i s_i$ is an isomorphism from the external direct sum onto M.

For (2) $\Rightarrow$ (3), let $M = \bigoplus_{i\in I} S_i$ and $N \subseteq M$. The submodules $N' \subseteq M$ with $N \cap N' = 0$ form a nonempty set (it contains 0) in which the union of a chain is again such a submodule, so Zorn's lemma gives a maximal one, N'. Suppose $N + N' \neq M$. Since $M = \sum_i S_i$, some S_i is not contained in $N + N'$, so $S_i \cap (N + N')$ is a proper submodule of the simple module S_i, hence
$$S_i \cap (N + N') = 0$$
Then $(S_i + N') \cap N = 0$: if $s + n' \in N$ with $s \in S_i$ and $n' \in N'$, then $s \in S_i \cap (N + N') = 0$, and so $n' \in N \cap N' = 0$. By maximality of N', $S_i + N' = N'$, so $S_i \subseteq N' \subseteq N + N'$, a contradiction. Hence $M = N \oplus N'$.

For (3) $\Rightarrow$ (2), assume every submodule of M has a complement.

Step 1: Every submodule K of M has the same property. Let $L \subseteq K$ and write $M = L \oplus L'$. For $x \in K$ write $x = l + l'$ with $l \in L$ and $l' \in L'$. Then $l' = x - l \in K$, so $K = L \oplus (L' \cap K)$.

Step 2: Every nonzero submodule $N \subseteq M$ contains a simple submodule. Take $x \in N$ nonzero.

The kernel I of $R \to Rx$, $r \mapsto rx$, is a left ideal not containing 1, and Zorn's lemma, applied to the left ideals containing I but not 1 (a union of a chain of them still omits 1), gives a maximal left ideal $\mathfrak{m} \supseteq I$. Under $Rx \cong R/I$, the submodule $\mathfrak{m}x$ of Rx corresponds to $\mathfrak{m}/I$. By Step 1, $Rx = \mathfrak{m}x \oplus L$ for some submodule L, and then

$$L \cong Rx/\mathfrak{m}x \cong (R/I)/(\mathfrak{m}/I) \cong R/\mathfrak{m}$$

which is simple because its submodules correspond to the left ideals between $\mathfrak{m}$ and R. So $L \subseteq Rx \subseteq N$ is a simple submodule.

Step 3: M is an internal direct sum of simple submodules. Call a family of simple submodules of M *independent* if every element of its sum is uniquely a finite sum of elements of its members. Independence is decided by finite subfamilies, so the union of a chain of independent families is independent, and Zorn's lemma gives a maximal independent family $(S_i)_{i\in I}$ (the empty family is independent). Put $N = \sum_{i\in I} S_i = \bigoplus_{i\in I} S_i$. By hypothesis $M = N \oplus N'$ for some N'. If $N' \neq 0$, Step 2 gives a simple submodule $S \subseteq N'$, and $S \cap N = 0$ makes the family $(S_i)_{i\in I}$ together with S independent, against maximality. Hence $N' = 0$ and $M = \bigoplus_{i\in I} S_i$.

Finally, if M is semi-simple and $N \subseteq M$, write $M = N \oplus N'$ by (3). The projection of M onto N along N' is a left inverse of the inclusion $N \to M$, so the sequence $0 \to N \to M \to M/N \to 0$ splits, completing the proof.

This theorem shows that every vector space over k is a semisimple k-module. On the other hand, $\mathbb{Z}$ is *not* a semi-simple $\mathbb{Z}$-module, since $2\mathbb{Z}$ is a submodule with no complement: if $\mathbb{Z} = 2\mathbb{Z} \oplus N'$, then $N' \neq 0$, and for $0 \neq n \in N'$ the element $2n \neq 0$ lies in $2\mathbb{Z} \cap N' = 0$, a contradiction. So not all free modules are semi-simple. We can characterize semi-simple rings by saying that R is semi-simple if and only if every R-module is projective. This also shows us that $\mathbb{Z}$ is not a semi-simple ring: $\mathbb{Z}$ is projective over itself, but any nonzero finite abelian group is a non-projective $\mathbb{Z}$-module. Thus every module over a semi-simple ring is projective. A semi-simple module over an arbitrary ring need not be projective, since $\mathbb{Z}/2\mathbb{Z}$ is a simple $\mathbb{Z}$-module that is not projective, and a module over a semi-simple ring need not be free: even though many examples of semi-simple modules are free modules, we would require the underlying ring to be semi-simple over itself. In fact, it is enough that the underlying ring be a semi-simple module over itself, giving us an easier condition for defining a semi-simple ring.

Corollary 51.1.8: Closure Properties Of Semisimple Modules

Let M be an R-module. Then all submodules and quotient modules of M are semisimple if and only if M is semi-simple. Furthermore, if $(M_i)_{i\in I}$ is a collection of semi-simple modules, then $\bigoplus_{i\in I} M_i$ is a semi-simple module.

***Proof*:**
Every module is a submodule of itself, so if all submodules of M are semi-simple, so is M. Conversely, let M be semi-simple, so that every submodule of M has a complement by lemma 51.1.7.

Submodules. Let $N \subseteq M$ and $L \subseteq N$, and write $M = L \oplus L'$. For $x \in N$ write $x = l + l'$ with $l \in L$ and $l' \in L'$. Then $l' = x - l \in N$, so $N = L \oplus (L' \cap N)$. Thus every submodule of N has a

complement in N, and N is semi-simple by lemma 51.1.7.

Quotients. Let $K \subseteq M$. A submodule of M/K has the form L/K with $K \subseteq L \subseteq M$. Write $M = L \oplus L'$, so that $M/K = L/K + (L' + K)/K$. If $x \in L \cap (L' + K)$, say $x = l' + k$ with $l' \in L'$ and $k \in K$, then $l' = x - k \in L \cap L' = 0$ because $K \subseteq L$, so $x \in K$. Hence $M/K = L/K \oplus (L' + K)/K$. Thus every submodule of M/K has a complement, and M/K is semi-simple by lemma 51.1.7.

Direct sums. If each M_i is the internal direct sum of simple submodules S_{ij}, $j \in J_i$, then $\bigoplus_{i \in I} M_i$ is the internal direct sum of the simple submodules S_{ij} over all i and j, so it is semi-simple by lemma 51.1.7, completing the proof.

These properties of semi-simple modules allow us to characterize semi-simple rings much more easily:

Corollary 51.1.9: Semi-Simple Rings Condition

Let R be a ring. Then R is a semi-simple ring if and only if R is a semi-simple R-module, that is we only need to check that R is a semi-simple R-module for one R-module structure (namely R itself)

***Proof*:**
If R is a semi-simple ring, then every R-module is semi-simple, including R over itself.

Conversely, suppose that R is a semi-simple R-module. Then so is $\bigoplus_{i \in I} R$ for every index set I, by corollary 51.1.8. Let M be an R-module and let $(m_i)_{i \in I}$ be a family of generators of M (for example, all elements of M). Then

$$\bigoplus_{i \in I} R \to M \qquad (r_i)_{i \in I} \mapsto \sum_i r_i m_i$$

is a surjective homomorphism, so M is a quotient of a semi-simple module and is semi-simple by corollary 51.1.8. Thus every R-module is semi-simple, and R is a semi-simple ring by definition, as we sought to show.

Due to this, we get a nice description of semi-simple rings which is even stronger than semi-simple modules:

Lemma 51.1.10: Decomposing Semi-Simple Rings

Let R be a semi-simple ring. Then:

$$R = I_1 \oplus \cdots \oplus I_n$$

for a finite collection of I_k, where I_k are simple left-submodules of R, i.e. *minimal* left ideals[a] of R

[a] These are *left ideals* as we are working with *left* submodules

***Proof*:**
Since R is a semi-simple ring, it is a semi-simple R-module and so by definition:

$$R = \bigoplus_{i \in \mathcal{C}} I_i$$

for simple submodules I_i (i.e. minimal left ideals I_i). To make this a finite sum, since $1 \in R$, we get for an appropraite finite subset $A \subseteq \mathcal{C}$

$$1 \in I_{\alpha_1} + \cdots + I_{\alpha_n}$$

But then, since these are all ideals,

$$R = R \cdot 1 \subseteq I_{\alpha_1} \oplus \cdots \oplus I_{\alpha_n} \subseteq R$$

and hence $R = I_{\alpha_1} \oplus \cdots \oplus I_{\alpha_n}$, completing the proof.

51.1.11 Remark As a consequence of this, any semi-simple ring R is a left-Noetherian/Artinian ring. Interestingly, we will soon show that this also implies that R is a *right*-Noetherian/Artinian ring (see rightNoethArtRemark)

Furthermore, this shows how it is necessary for the condition that R be left-Noetherian/Artinian so that the notion of being semi-simple coincide between the two definitions.

Since we characterized simple R-modules for any ring R to be R-isomorphic to $R/\mathfrak{m}$, and we have given a structure of R if R is a semisimple ring, we can make lemma 51.1.3 more precise:

Corollary 51.1.12: Structure Of Simple Modules Of Semi-Simple Ring

Let R be a semi-simple ring so that $R = I_1 \oplus I_2 \oplus \cdots \oplus I_n$ for minimal left ideal I_k (equivalently, simple left R-modules). Then if M is a simple left R-module,

$$M \cong_{R\textbf{-Mod}} I_i$$

for some $1 \leq i \leq n$.

***Proof*:**
Let M be a simple nonzero left R-module, and consider the R-module homomorphism:

$$\varphi : R \to M \qquad r \mapsto r \cdot x$$

where $x \neq 0$. Since M is simple, it is nonzero, so φ is surjective. Since $R = \bigoplus_i^n I_i$, for some i's

$$\varphi|_{I_i} \neq 0$$

and since $\varphi|_{I_i} = \pi_i \circ \varphi$ we have the R-module homomorphism:

$$\varphi|_{I_i} I_i \to M$$

and since both modules are simple and this is a nonzero homomorphism, by Schur's lemma this map must be an isomorphism, as we sought to show.

Note that there can be multiple I_i's that are isomrophic to M, which we will show in a following theorem.

This shows that any simple R-module over a semi-simple ring R is in fact isomorphic to a simple R-submodule of R (i.e. R-isomorphic to a minimal left ideal of R). Thus, studying simple R-modules over semi-simple rings comes down to studying the ring R itself, and that there are only *finitely many* simple R-modules. Furthermore, we have that $R/(I_1 \oplus \cdots \oplus I_{n-1}) \cong_R I_n$. Here is a good example of where the ring structure of the left hand side cannot exist in the right hand side. For example, if R is commutative, then $R/\mathfrak{m}$ is a field that is R-module isomorphic to a minimal ideal, but ideals cannot be fields (over the same identity[6]). Thus, in the case where R is semi-simple, for a maximal left ideal $\mathfrak{m}$, $R/\mathfrak{m}$ is R-isomorphic to a minimal left ideal of R.

Exercise 51.1.1

1. Let S be a simple module. Show that any nonzero submodule of the injective enveloppe $E(S)$ is indecomposable, but not simple.
2. Show that if M is a simple R-module, then it necessarily has to be cyclic (the converse, however, is not true).
3. Show that $A = \mathbb{Q}[x, y]/(xy - yx - 1)$ is a simple ring, but no a semi-simple ring (this is a special example of an algebra called a *Weyl* Algebra)
4. Let R be a ring, not necessarily commutative, and let $[R, R] = \{rs - sr \mid r, s \in R\}$. Show that the trace map induces an isomorphism

$$\frac{M_n(R)}{[M_n(R), M_n(R)]} \cong \frac{R}{[R, R]}$$

From this perspective, matrix rings are the natural "nonabelian" extension of a ring!

51.2 Artin-Wederburn

We just showed how studying simple and semi-simple R-modules comes down to studying the ring R, especially if the ring R is semi-simple. Thus, it is fruitful to classify semi-simple rings, which leads us to the main classification result for semi-simple rings, namely we build on lemma 51.1.10 and show that we can find more precisely how to represent each minimal left ideal I_i, and furthermore show that this classification is exhaustive, and that any semi-simple ring uniquely breaks down into the result we will show. We will then finish by showing that if we upgrade our ring to k-algebras (that is, we can put a vector-space structure on our ring), we get some stronger results due to the fact we can count dimensions.

[6] $k \times \{0\} \subseteq k \times k$ is an ideal and a field with identity $(1, 0)$

Definition 51.2.1: Opposite Ring

Let R be a ring. Then we define a new ring labelled R^{op} that has the same underlying set and addition operation, whith the multiplication operation $*$ being:

$$x * y = yx$$

where the multiplication yx happens in R

If R is commutative, then $R = R^{\text{op}}$, so the opposite ring carries new information only when R is not commutative.

Proposition 51.2.2: Properties Of Opposite Ring

Let R be a ring and R^{op} its oppposite ring. Then:

1. $(R^{\text{op}})^{\text{op}} = R$
2. $(R \times S)^{\text{op}} = R^{\text{op}} \times S^{\text{op}}$
3. $M_n(R)^{\text{op}} \cong M_n(R^{\text{op}})$ where the isomorphism is $A \mapsto A^t$ (since transposing converts BA into the product whose entries multiply in R^{op})

***Proof*:**
In all three claims the two rings share their underlying set and their addition, so only the multiplications need comparison. Throughout, $*$ denotes an opposite multiplication as in definition 51.2.1.

For (1), write $\star$ for the multiplication of $(R^{\text{op}})^{\text{op}}$, the opposite of the multiplication $*$ of R^{op}. For any $x, y \in R$:

$$x \star y = y * x = xy$$

so $\star$ is the original multiplication of R, and $(R^{\text{op}})^{\text{op}} = R$ as rings.

For (2), both rings have underlying set $R \times S$ with componentwise addition. Multiplying in $(R \times S)^{\text{op}}$ gives

$$(r, s) * (r', s') = (r', s')(r, s) = (r'r, s's)$$

while multiplying in $R^{\text{op}} \times S^{\text{op}}$ gives $(r * r', s * s') = (r'r, s's)$ as well. The two multiplications agree, so the rings are equal.

For (3), let $\tau : M_n(R)^{\text{op}} \to M_n(R^{\text{op}})$ be the transpose map $\tau(A) = A^t$, where $(A^t)_{ij} = A_{ji}$. The map τ is additive, fixes the identity matrix, and is a bijection because it is its own inverse on the underlying set. For multiplicativity, let $A, B \in M_n(R)^{\text{op}}$ and let $*$ denote the multiplication of $M_n(R)^{\text{op}}$, so that $A * B$ is the matrix BA computed in $M_n(R)$. For each pair (i, j):

$$\tau(A * B)_{ij} = (BA)_{ji} = \sum_k B_{jk} A_{ki}$$

Computing $\tau(A)\tau(B)$ in $M_n(R^{\text{op}})$ multiplies the entries in R^{op}:

$$(\tau(A)\tau(B))_{ij} = \sum_k (A^t)_{ik} * (B^t)_{kj} = \sum_k A_{ki} * B_{jk} = \sum_k B_{jk} A_{ki}$$

The two entries agree, so $\tau(A*B) = \tau(A)\tau(B)$ and τ is a ring isomorphism. For noncommutative R the identity $(BA)^t = A^tB^t$ fails inside $M_n(R)$ itself. The computation above succeeds because the entries of $\tau(A)\tau(B)$ are multiplied in R^{op}, which restores the order of each product.

With this, we can make a link between R and R^{op}:

Lemma 51.2.3: Yonneda's Lemma for opposite Rings

Let R be a ring and consider the ring $\text{End}_R(R)$ to be the set of all R-module homomorphisms from R (as an R-module) to itself. Then $\varphi : R^{\text{op}} \to \text{End}_R(R)$, $r \mapsto (x \mapsto xr)$ is a ring isomorphism:

$$R^{\text{op}} \cong_{\textbf{Ring}} \text{End}_R(R)$$

***Proof*:**
Let φ_r be the given map. Let's first check that $\varphi_r \in \text{End}_R(R)$. Then we see that:

$$\begin{aligned}\varphi_r(\lambda x + \lambda y) &= (\lambda x + \lambda y)r \\ &= \lambda(xr) + \lambda(yr) \\ &= \lambda\varphi_r(x) + \lambda\varphi_r(y)\end{aligned}$$

showing that $\varphi_r \in \text{End}_R(R)$. Next, we check that φ is ineed a ring-homomorphism. By the module axioms:

1. $\varphi_1 = \text{id}$, and hence φ sends the identity to the identity.
2. $\varphi_{r+r'} = \varphi_r + \varphi_{r'}$
3. $\varphi_{rr'} = \varphi_{r'} \circ \varphi_r$ (do not forget we are working with R^{op})

Finally, showing bijectivity, for injectivity we see that if $\varphi_r = 0$, then $0 = \varphi_r(1) = r$, and hence $\varphi_r = \varphi_0$. For surjectivity, let $\varphi \in \text{End}_R(R)$. Let's say $\varphi(1) = r$. Then $\varphi(x) = x\varphi(1) = xr$, so $\varphi = \varphi_r$, completing the proof.

In the special case where R is commutative, then $R \cong R^{\text{op}}$, showing that in this case $R \cong \text{End}_R(R)$. Using this, we will use lemma 51.2.3 along with lemma 51.1.6 to upgrade lemma 51.1.10:

Theorem 51.2.4: Artin-Wedderburn, one Direction

Let R be a semisimple ring. Then:

$$R \cong_{\textbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$$

where each D_i is a division ring and $M_{n_i}(D_i)$ is the matrix ring over D_i

The key realization about this theorem is that while the multiplication on the left hand side can "send you" all over the place, the multiplication on the right hand side only sends you back into your particular component. To see this more clearly, let's say R was a k-algebra for a field k so that it has a basis. If R was a semi-simple ring, then that means that when multiplying elements of R (so

figuring out where the basis elements go while multiplying), we can isolate the problem down to the components on the right hand side, and figure out where they go through matrix multiplication!

***Proof*:**
First, lemma 51.1.10 decomposes R into simple R-submodules, that is, minimal left ideals of R,

$$R = I_1 \oplus \cdots \oplus I_n$$

Now, we can always re-order the sums (i.e. $I_1 \oplus I_2 \cong I_2 \oplus I_1$, since $R \cong I_1 \oplus \cdots \oplus I_n$ by proposition 12.3.6). Hence, we will group all the I_i's that belong to the same isomrophism class (as R-modules), letting us re-write R as:

$$R \cong_{\mathbf{Ring}} I_1^{n_1} \oplus \cdots \oplus I_k^{n_k}$$

where $I_i \ncong I_j$ for $i \neq j$. Hence by lemma 51.2.3 and lemma 51.1.6:

$$\begin{aligned} R^{\text{op}} &\cong_{\mathbf{Ring}} \text{End}_R(R) \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k) \end{aligned}$$

where $D_i = \text{End}_R(I_i)$ is a divison ring. Finally, Taking the opposite ring on both sides, we get:

$$\begin{aligned} R &\cong_{\mathbf{Ring}} (R^{\text{op}})^{\text{op}} \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1)^{\text{op}} \times \cdots \times M_{n_k}(D_k)^{\text{op}} \\ &\cong_{\mathbf{Ring}} M_{n_1}(D_1^{\text{op}}) \times \cdots \times M_{n_k}(D_k^{\text{op}}) \end{aligned}$$

and it is clear the D_i^{op} is still a division ring, hence completing the proof.

Thus, if we have a simple-ring then the ring breaks down into the product of matrix rings over division rings. In the special case where $R = k$ is a field, then k has only one minimal ideal, namely itself, and $\text{End}_k(k) \cong M_1(k) \cong k$, and hence we reduce to $k \cong k$. If $R = k^n$ is a product of the same field, then the minimal ideals of R are $R = k \oplus \cdots \oplus k$, so that we get back $k^n \cong_{\mathbf{Ring}} k^n$.

We will now show that the converse of this theorem is true, that the product of matrix rings over division rings is semi simple. We start by showing that matrix ring are simple modules[7].

Proposition 51.2.5: Matrix Ring over Division Rings are semi-simple

Let $R = M_n(D)$ be a matrix ring over a divison ring. Let $C = D^{\oplus n}$ be the left $M_n(D)$-module where the action is left matrix multiplication (imagine C as a column). Then C is a simple $M_n(D)$-module, and

$$M_n(D) \cong_{M_n(D)\text{-}\mathbf{Mod}} C^{\oplus n} = (D^{\oplus n})^{\oplus n}$$

showing that $M_n(D)$ is semisimple ring and $M_n(D) \cong_{\mathbf{Ring}} C^{\oplus n}$

***Proof*:**
Let $R = M_n(D)$ and $C = D^{\oplus n}$ (C for *column*). For notational simplicity, let $E_{ij} \in R$ be the elementary matrix which is 1 in position ij and zero everywehre else. Let $e_i \in C$ be the column

[7] This will be an example of R being both a simple R-module and a simple ring

where it is 1 at position i and zero everywehre else:

$$E_{ij} = \begin{pmatrix} 0 & & & & 0 \\ & \ddots & & \iddots & \\ & & 1 & & \\ & \iddots & & \ddots & \\ 0 & & & & 0 \end{pmatrix} \qquad e_i = \begin{pmatrix} 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{pmatrix}$$

Then $E_{ij}e_k = \delta_{jk}e_i$ where δ_{jk} is the Kronecker Delta:

$$\delta_{jk} = \begin{cases} 1 & j = k \\ 0 & j \neq k \end{cases}$$

Now, we will start by showing that C is a simple $M_n(D)$-module. Since $C = D^{\oplus n}$,

$$C = \bigoplus_i De_i$$

for some basis $e_1, e_2, ..., e_n$. To show that C is simlpe, it is enough to show that for any $0 \neq x \in C$, $C = Rx$ since then any nonzero submodule would in fact be C. Given our above notation, we have that:

$$x = \sum_k d_k e_k$$

for appropriate $d_k \in D$, where at least one of these is nonzero, let's say $d_j \neq 0$. Then consider $E_{ij}x \in Rx$:

$$E_{ij}x = \sum_k \delta_{jk} d_k e_k = d_j e_i$$

since $d_j \neq 0$. Since D is a division ring, we get that $d_j^{-1}e_i \in Rx$, for all $1 \leq i \leq n$. But then, we get:

$$C = \sum De_i \subseteq Rx \subseteq C$$

showing that $C = Rx$ for any $0 \neq x \in C$, showing that C is indeed simple.

Now, we can re-write this ring as the internal direct sum of matrices I_i which are zero outisde the ith column:

$$R = M_n(D) = I_1 \oplus \cdots \oplus I_n$$

$$I_k = \begin{pmatrix} 0 & \cdots & a_{1,k} & \cdots & 0 \\ 0 & & a_{2,k} & & 0 \\ \vdots & & \vdots & & \vdots \\ 0 & & a_{2,n-1} & & 0 \\ 0 & \cdots & a_{n,k} & \cdots & 0 \end{pmatrix}$$

This decomposition works since each I_i is stable under *left* multiplication by elements of $M_n(D)$ (since left multiplication is a *column* transformation, right multiplication would be *row* transformation). Finally, $C \cong_{R\textbf{-mod}} I_i$ by simply moving the column to the right place, and so each I_i is simple. Hence, we have decomposed $M_n(D)$ as a dierct product of simple left $M_n(D)$-modules, and hence $M_n(D)$ is a semisimple $M_n(D)$-module, which by corollary 51.1.9 makes $M_n(D)$ a semi-simple ring. Finally, since $C^{\oplus n}$ represents the n rows of n-length columns, we see that the action of $M_n(D)$ on $C^{\oplus n}$ is identical to that of matrix multiplying elements of $C^{\oplus n}$, which gives us that $M_n(D) \cong_{\textbf{Ring}} C^{\oplus n}$, as we sought to show.

51.2.6 Remark In fact, $M_n(D)$ is a simple ring, meaning the only *two-sided* ideals of R are 0 and R; the above proof can be modified to show this. This gives us a nice class of non-commutative simple rings (since all simple commutative rings are fields).

Notice that it is quite sepcial that the ring opration and the module operation coincided, this because of the special way in which we decompoed the $M_n(D)$-module $M_n(D)$ and by the fact that it is a module over itself. In the previous proposition, we showed that $D^{\oplus n}$ is a simple $M_n(D)$-module. In fact, all simple modules of $M_n(D)$ are isomorphic to $D^{\oplus n}$:

Corollary 51.2.7: Structure of Simple $M_n(D)$-Module

Let $R = M_n(D)$ be a matrix ring over a division ring. Then any simple $M_n(D)$-module is isomorphic to $D^{\oplus n}$.

***Proof*:**
Let M be a simple $M_n(D)$-module. By proposition 51.2.5

$$M_n(D) \cong_{\mathbf{Ring}} D^{\oplus n} \oplus \cdots_{\mathbf{Ring}} \oplus D^{\oplus n}$$

And by corollary 51.1.12,

$$M \cong D^{\oplus n}$$

Corollary 51.2.8: Endomorphism Of Simple $M_n(D)$-Module

Let S be a simple $M_n(D)$-module. Then

$$\mathrm{End}_{M_n(D)}(S) \cong_{\mathbf{Ring}} D^{\mathrm{op}}$$

***Proof*:**
Since S is simple, $S \cong_R D^{\oplus n}$ for some n. Let $\varphi_d : S \to S$, $\varphi_d(x) = x \cdot d$ where $x \cdot d$ is x times dI. Then:

$$\varphi_d(Ax) = (Ax) \cdot d = A(x \cdot d) = A\varphi_d(x)$$

and

$$\varphi_d(x+y) = (x+y) \cdot d = (x+y)dI = xdI + ydI = x \cdot d + y \cdot d = \varphi_d(x) + \varphi_d(y)$$

hence $\varphi_d \in \mathrm{End}_R(S)$. Conversely, if $\varphi \in \mathrm{End}_R(S)$, Since $S \cong D^{\oplus n}$, and

$$D^{\oplus n} \cong \begin{pmatrix} D^{\oplus n} & 0^{\oplus n} & \cdots & 0^{\oplus n} \end{pmatrix}$$

we will treat S as a $M_n(D)$ submodule of $M_n(D)$. Now, since φ is a group homomorphism, we know that:

$$\varphi \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} \varphi_{11} & \cdots & \varphi_{n1} \\ \vdots & \ddots & \vdots \\ \varphi_{n1} & \cdots & \varphi_{nn} \end{pmatrix} \begin{pmatrix} 1 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} \varphi_{11}(1) + \cdots + \varphi_{n1}(1) \\ \vdots \\ 0 \end{pmatrix}$$

hence let $d = \sum_i^n \varphi_{i1}(1)$, and let the right-action on $\text{End}_{M_n(D)}(S)$ be right multiplication by the identity matrix dI. Then: Then for all $x \in S$, we have:

$$\begin{aligned}\varphi\begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} &= \varphi\left(\begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix}\begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 0 \end{pmatrix}\right) \\ &\overset{!}{=} \begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix}\varphi\begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 0 \end{pmatrix} \\ &= \begin{pmatrix} x_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ x_n & \cdots & 0 \end{pmatrix} \cdot d\end{aligned}$$

where $\overset{!}{=}$ comes from the fact that we can treat that matrix as an element of $M_n(D)$, and since φ is an $M_n(D)$-module homomorphism, we can pull it out. But then, the action is completely dependent on on d, an so we have a bijection between right multiplication by $d \in D$ an $M_n(D)$-endomrophisms. It is an easy taks to check that:

$$\varphi_{dd'} = \varphi_{d'} \circ \varphi_d$$

showing that

$$D^{\text{op}} \cong_{\mathbf{Ring}} \text{End}_{M_n(D)}(S)$$

as we sought to show.

The next thing we will need is to show that if R, S are semisimple rings, then so is $R \times S$. Since R and S are semi-simple R-modules and S-modules, if we can show that $R \times S$ is a semi-simple $(R \times S)$-module, we are done. For this to be the case, we must be able to decompose $R \times S$ into simple $(R \times S)$-submodules. Forunately, many universal propeties play in our favour to be able to easily identify simple $(R \times S)$-modules of $R \times S$ given we know the simple R-modules and S-modules.

To see the key idea of the following proof, we define some terms

Definition 51.2.9: Idempotent And Orthogonal Elements

Let R be a ring. Then $e \in R$ is said to be *idempotent* if

$$e^2 = e$$

Furthermore, if e_1, e_2 are idempotent elements in R, if

$$e_1 e_2 = e_2 e_1 = 0$$

then they are said to be *orthogonal*. If e is a nonzero idempotent and cannot be written as the sum of two nonzero orthogonal idempotent elements, then e is said to be a *primitive* idempotent element.

Example 51.2.10: Idempotent Elements

Naturally, for any ring R, $1 \in R$ is an idempotent element.

For a more interesting example the product ring $R \times S$, and take $e = (1,0) \in R \times S$, $f = (0,1) \in R \times S$. Then:

1. $e^2 = e$ and $f^2 = f$ (i.e. they are both *idempotent*)
2. $ef = fe = 0$ (implying also that $ef \in Z(R \times S)$)
3. $e + f = 1$ (i.e. e and f are *not* primitive)

What happens if the number of terms in the product increases?

Next, if M is an R-module an N is an S-module, we can M and N to be $(R \times S)$-module by ignoring what happens to S (resp. R), i.e. think of the action being defined by the following function

$$R \times S \twoheadrightarrow R \to \mathrm{End}_{\mathbf{ab}}(M)$$

and similarly for a S-module N. Hence, we can define $M \oplus N$ as an $(R \times S)$-module. Conversely, if M is an $(R \times S)$-module, then using what we have shown in example 51.2.10, given $e = (1,0)$ and $f = (0,1)$:

$$M = eM + fM$$

Notice that eM is killed by Rf, so it's a $A \cong A \times B/(\{0\} \times B)$-module, and similarly for fM. In other words, idempoent elements characterize the splitting of modules! This gives us the following:

Proposition 51.2.11: Direct Product Decomposition

Let A and B be rings, let $e = (1,0)$ and $f = (0,1)$ be the central idempotents of $A \times B$, and let A-**Mod** $\times$ B-**Mod** be the product category, whose objects are pairs (M, N) of an A-module M and a B-module N, and whose morphisms are pairs of module homomorphisms. For an $(A \times B)$-module P, the submodules eP and fP are an A-module and a B-module through $a \cdot x = (a,0)x$ and $b \cdot y = (0,b)y$. Then the functors

$$A\text{-}\mathbf{Mod} \times B\text{-}\mathbf{Mod} \underset{\psi}{\overset{\varphi}{\rightleftarrows}} (A \times B)\text{-}\mathbf{Mod}$$

defined on objects by

$$\begin{aligned} \varphi(M,N) &= M \oplus N \\ \psi(P) &= (eP, fP) \end{aligned}$$

where $(a,b) \cdot (m,n) = (am, bn)$ on $M \oplus N$, and on morphisms by $\varphi(\alpha, \beta) = \alpha \oplus \beta$ and $\psi(\gamma) = (\gamma|_{eP}, \gamma|_{fP})$, form an equivalence of categories: there are natural isomorphisms $\psi \circ \varphi \cong \mathrm{id}$ and $\varphi \circ \psi \cong \mathrm{id}$.

***Proof*:**

Step 1: φ is a functor. The module axioms for $M \oplus N$ hold componentwise, and $(1,1)$ acts as the identity. For morphisms $\alpha \colon M \to M'$ and $\beta \colon N \to N'$, the map $\alpha \oplus \beta \colon (m,n) \mapsto (\alpha(m), \beta(n))$

is additive and satisfies $(\alpha \oplus \beta)((a,b)(m,n)) = (a\alpha(m), b\beta(n)) = (a,b)(\alpha \oplus \beta)(m,n)$. Identities and composites are preserved componentwise.

Step 2: ψ is a functor. Since e is central, $(a,b)(ep) = e((a,b)p)$, so eP is an $(A \times B)$-submodule of P, and $ex = x$ for $x \in eP$ because $e^2 = e$. The rule $a \cdot x = (a,0)x$ is additive in a and in x, satisfies $(aa') \cdot x = (a,0)(a',0)x = a \cdot (a' \cdot x)$, and $1 \cdot x = ex = x$, so eP is an A-module. The same computation with f makes fP a B-module. If $\gamma\colon P \to P'$ is $(A \times B)$-linear, then $\gamma(ep) = e\gamma(p)$ shows $\gamma(eP) \subseteq eP'$, and $\gamma((a,0)x) = (a,0)\gamma(x)$ shows that $\gamma|_{eP}$ is A-linear. Likewise $\gamma|_{fP}\colon fP \to fP'$ is B-linear, and restriction preserves identities and composites.

Step 3: $\psi \circ \varphi \cong \mathrm{id}$. For (M,N), $e(m,n) = (m,0)$ and $f(m,n) = (0,n)$, so $\psi(\varphi(M,N)) = (M \oplus 0, 0 \oplus N)$, where $a \cdot (m,0) = (am,0)$ and $b \cdot (0,n) = (0,bn)$. Hence $\eta_{(M,N)} = (m \mapsto (m,0),\ n \mapsto (0,n))$ is a pair of module isomorphisms, that is, an isomorphism $(M,N) \to \psi(\varphi(M,N))$. For a morphism (α,β), the map $\psi(\varphi(\alpha,\beta))$ sends $(m,0)$ to $(\alpha(m),0)$ and $(0,n)$ to $(0,\beta(n))$, so $\psi(\varphi(\alpha,\beta)) \circ \eta_{(M,N)} = \eta_{(M',N')} \circ (\alpha,\beta)$, and η is natural.

Step 4: $\varphi \circ \psi \cong \mathrm{id}$. For an $(A \times B)$-module P, define

$$\epsilon_P\colon eP \oplus fP \to P \qquad (x,y) \mapsto x + y$$

For $x \in eP$ and $y \in fP$ we have $(a,b)x = (a,b)ex = (a,0)x$ and $(a,b)y = (0,b)y$, so $\epsilon_P((a,b)(x,y)) = (a,0)x + (0,b)y = (a,b)(x+y)$ and ϵ_P is $(A \times B)$-linear. It is surjective because $p = ep + fp$, as $e + f = 1$. It is injective: if $x + y = 0$, then $0 = e(x+y) = x + efy = x$, using $ex = x$, $y = fy$ and $ef = 0$, and then $y = 0$. For an $(A \times B)$-linear $\gamma\colon P \to P'$,

$$\epsilon_{P'}\big(\varphi(\psi(\gamma))(x,y)\big) = \gamma(x) + \gamma(y) = \gamma(\epsilon_P(x,y))$$

so ϵ is a natural isomorphism $\varphi \circ \psi \to \mathrm{id}$. Steps 3 and 4 show that φ and ψ are mutually inverse equivalences, as we sought to show.

Proposition 51.2.12: Classifying Simple $(A \times B)$-Modules

Let P be a simple $(A \times B)$-module. Then

$$P \cong_{A\times B\text{-Mod}} M \oplus (0) \qquad \text{or} \qquad P \cong_{A\times B\text{-Mod}} (0) \oplus N$$

where M is a simple A-module and N is a simple B-module.

***Proof*:**
By proposition 51.2.11, $P \cong_{A\times B\text{-Mod}} M \oplus N$ where M is an A-module and N is a B-module. BUt then:

$$P \cong_{A\times B\text{-Mod}} (M \oplus (0)) \oplus ((0) \oplus N)$$

since P is simple, one of these has to be zero, and the other one has to be simple.

Corollary 51.2.13: Product Of Semi-Simple Rings

Let R and S be semi-simple rings. Then $R \times S$ is a semi-simple ring. Furtheromre, if $R_1, R_2, ..., R_n$ are the simple R-module up to isomorphism and $S_1, S_2, ..., S_m$ are the simple S-modules, then the simple $R \times S$-modules are of the form:

$$R_i \oplus (0) \qquad (0) \oplus (S_j)$$

***Proof*:**
By proposition 51.2.11, since R is a semi-simple R-module and S is a semi-simple S-module, $R \times S$ is a semi-simple $(R \times S)$-module, and so $R \times S$ is a semi-simple ring. Then by proposition 51.2.12, if $P \subseteq R \times S$ is a simple $(R \times S)$-module, then they it must be of the form:

$$R_i \oplus (0) \qquad (0) \oplus (S_j)$$

Corollary 51.2.14: Structure Of $\prod_i M_{N_i}(D_i)$: Artin Wedderburn part II

Let $R = M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$. Then

1. R is semi-simple
2. There exist exactly k simple R-modules up to isomorphism, each of the form:

$$0 \oplus \cdots \oplus D_i^{\oplus n_i} \oplus \cdots \oplus 0$$

***Proof*:**
The ring R is semi-simpleby corollary 51.2.13 using induction. Furthermore, each $M_{n_i}(D_i)$ has $D_i^{\oplus n_i}$ is it's unique simple $M_{n_i}(D_i)$-module, since there are k matrix rings in the productt, there must be exactly k simple R-modules, as we sought to show.

51.2.15 Remark We can as before get that

$$R^{\text{op}} \cong M_{n_1}(D_1^{\text{op}}) \times \cdots \times M_{n_k}(D_k^{\text{op}})$$

and hence R^{op} is left Noetherian/Artinian, which we know now is true if and only if R is right Noetherian/Artinian (Since a left R^{op})-module is a right R-module). By leftNoethArtRemark, we have that any semisimple ring is left-Noetherian/Artinian, and hence any semisimple ring is both left and right Noetherian/Artinian, even though R is not necesarily commutative!

Thus, we have the following statemnt, were the last thing we need to prove is uniquness

Theorem 51.2.16: Artin-Wedderburn

Let R be a ring. Then R is a semi-simple ring if and only if

$$R \cong_{\textbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$$

where each D_k is a division ring and $M_{n_i}(D_i)$ is the matrix ring over D_i, and each D_i n_i are unique up to isomorphism

***Proof*:**
All that is left to prove is the uniqueness. Let:

$$M_{n_1}(D_1) \oplus \cdots \oplus M_{n_s}(D_s) \cong_{\textbf{Ring}} R \cong_{\textbf{Ring}} M_{n'_1}(D'_1) \oplus \cdots \oplus M_{n_s}(D'_s)$$

By corollary 51.2.14, R has exactly s and t simple module, and so $s = t$. Hence, for any $D_i^{\oplus n_i}$, there must exist a $(D'_i)^{\oplus n'_i}$ such that

$$D_i^{\oplus n_i} \cong_R (D'_i)^{\oplus n'_i}$$

Since $D_i^{\oplus n_i} \cong_R (D'_i)^{\oplus n'_i}$, $\text{End}_{M_{n_i}(D_i)}(D_i^{\oplus n_i}) \cong_{\textbf{Ring}} \text{End}_{M_{n'_i}(D'_i)}((D'_i)^{\oplus n'_i})$. By corollary 51.2.8,

$$D_i^{\text{op}} \cong_{\textbf{Ring}} \text{End}_{M_{n_i}(D_i)}(D_i^{\oplus n_i}) \cong_{\textbf{Ring}} \text{End}_{M_{n'_i}(D'_i)}((D'_i)^{\oplus n'_i}) \cong_{\textbf{Ring}} (D'_i)^{\text{op}}$$

which, taking op on both sides, we see that:

$$D_i \cong_{\textbf{Ring}} D'_i$$

Finally, we need to show that $D^{\oplus n} \cong_R D^{\oplus m}$ implies $n = m$. Treating $D^{\oplus n}$ and $D^{\oplus m}$ as D-modules, then we get that each have a basis of dimension n and m. Importantly, the results of the Replacement Theorem (theorem 13.1.12) applies to divions rings (notice that commutativity was not necessary), and so corollary 13.1.13 and theorem 13.1.8 give us that $n = m$, completing the proof.

This theorem also shows us that if R is a [finitely-generated] semi-simple ring, then R is indeed the direct product of simple rings (since $M_{n_i}(D_i)$ is a simple ring). Notice too that this theorem just gave us the answer to the classification of all *finite simple rings*: namely they would have ot be of the form $M_n(\mathbb{F}_q)$[8] for some finite field of order q (which is a power of some prime p). Contrast this to how hard it is to find all finite simple groups! Furthermore, the finite dimensional assumption was key: the *Weyl Algebra*:

$$W = k\langle x, y\rangle/(xy - yx - 1)$$

is a simple algebra that is not the matrix ring of a division algebra.

Example 51.2.17: Artin Wedderburn

$\text{End}_{M_2(k)}(M_2(k)) = \text{End}_{M_2(k)}((k^2)^{\oplus 2}) = M_2(\text{End}_{M_2(k)}(k^2)) = M_2(k)$

[8]Why is the division ring a field? The answer lies in proposition 9.1.20

Corollary 51.2.18: Artin-Wedderburn For k-Algebras

Let R be a semi-simple k-algebra that is finite-dimensional over a field k. Then

$$R \cong_{k\text{-}\mathbf{Alg}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

where each D_i is a divsion k-algebra, finite dimensional as a k-vector space:

$$\dim_k R = \sum n_i^2 \dim_k(D_i)$$

and has exactly l simple R-modules as we have classified before.

***Proof*:**
By the Artin-Wedderburn theorem, we have that

$$R \cong_{\mathbf{Ring}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

Let's now further assume R is a k-algebra for some field k, so that there is a map $k \hookrightarrow Z(R)$. Then by the above isomorphism:

$$\begin{aligned} k \mapsto Z(R) &\cong Z(M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)) \\ &\cong Z(M_{n_1}(D_1)) \times \cdots \times Z(M_{n_l}(D_l)) \\ &\cong Z(D_1) \times \cdots \times Z(D_l) \end{aligned}$$

where the last one comes form the fact that $Z(M_{n_i}(D_i))$ are the diagonal elements, and $z \mapsto zI$. This shows that D_i each have a natural k-algebra strucure induced by R, and so the above isomrophsim was already a k-algebra isomorphism:

$$R \cong_{k\text{-}\mathbf{Alg}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

Finally, treating $M_{n_i}(D_i)$ as k-vector spaces we have:

$$M_{n_i}(D_i) \cong_{k\text{-}\mathbf{Vect}} D^{\oplus n_i^2}$$

which gives the desired result, completing the proof.

Corollary 51.2.19: Special Case: k Algebraically Closed

Let $k = \overline{k}$ be an algebraically closed field and D a division k-algebra that is finite-dimensional as a k-vector-space. Then $D = k$

***Proof*:**
Suppose $k \subsetneq D$, and pick any $\delta \in D \setminus k$. Then

$$k \subseteq k[\delta] \subseteq D$$

the key thing to observe is that $k[\delta]$ is still commutative!! This is essentially the same reasoning

for why any cyclic group is commutative! Since D is a finite-dimensional vector-sapce over k, some power of δ^n must be a k-linear combination of every smaller term. Since D is a division ring, every δ has an inverse, and so every element of $k[\delta]$ is in fact a unit. Hence $k[\delta]/k$ is an algebraic field extension. However, k is an *algebraically cloased field*, and hence $k[\delta] = k$. Since δ was arbitary, we must have that $D = k$, as we sought to show.

Corollary 51.2.20: Artin-Wedderburn For $\overline{k}$-Algebras

Let R be a semi-simple k-algebra that is finite-dimensional over an algebraically closed field $k = \overline{k}$. Then

$$R \cong_{k\textbf{-Alg}} M_{n_1}(k) \times \cdots \times M_{n_l}(k)$$

so that

$$\dim_k(R) = \sum_i^l n_i^2$$

and R has exactly l simple R-modules as we have classified before.

***Proof*:**
By corollary 51.2.18,

$$R \cong_{k\textbf{-Alg}} M_{n_1}(D_1) \times \cdots \times M_{n_l}(D_l)$$

where each D_i is a division k-algebra that is finite-dimensional over k, and R has exactly l simple modules. By corollary 51.2.19, each D_i is k, so $R \cong_{k\textbf{-Alg}} M_{n_1}(k) \times \cdots \times M_{n_l}(k)$, and $\dim_k(R) = \sum_i n_i^2 \dim_k(k) = \sum_i n_i^2$, as claimed.

As a consequence of this, if R is a semi-simple $\mathbb{C}$-algebra, the simple R-modules are all R-isomorphic to $\mathbb{C}^{n_i}$ for appropriate power n_i. As a final word of warning, it is natural to wonder if all simple rings are of the form $M_n(D_i)$

Exercise 51.2.1

1. Let k be a field, k^n be a direct product of fields a k^n-module over itslef. Let $0 \oplus \cdots \oplus k \oplus \cdots \oplus 0 = k_i \subseteq k^n$. Then $\text{End}_{k^n}(k_i) \cong_{\textbf{Ring}} k$, $\text{End}_{k^n}(k^n) \cong_{\textbf{Ring}} k^n$, and $\text{End}_{k^n}(k^n) \cong_{\textbf{Ring}} M_n(\text{End}_{k^n}(k_i)) \cong_{\textbf{Ring}} M_n(k)$. But that would imply $k^n \cong_{\textbf{Ring}} M_n(k)$ – what's the contradiction?
2. Let k be an algebraically closed field, and let R be a finite-dimensional k-algebra. Let M be a simple R-module. Prove that if r is an element of the centre $Z(R)$ of R, there exists $c \in k$ such that $rm = cm$ for all $m \in M$

51.3 Central Simple Algebras

Definition 51.3.1: Algebra Representation

Let A be a finite dimensional (associative) algebra over k. Then a *representation* of A is a k-homomorphism:

$$\rho : A \to \mathrm{End}_k(V)$$

for some vector space V.

Recall that one definition of an R-module is given by a ring homomorphism $\rho : R \to \mathrm{End}_{\mathbf{Ab}}(M)$ for an abelian group M. If we restrict to k-homomorphisms and k-endomorphisms, we can define the A-module $\rho : A \to \mathrm{End}_k(V)$, hence we can think of representation of and algebra A as a left A-modules. This makes sense, as representation theory can be thought of the study of associative algebras (the study of group representation is the study of group algebras, the study of the representation of lie algebras is universal enveloping algebras, the study of the representation of quiver algebras is the study of path algebras, and so forth). Because of this, we shall see that many of the results for the representation of associative algebras outlined bellow to be familiar to anyone who has taken a basic course in representation theory.

Next, we define the object that shall represent the generalization of number rings:

Definition 51.3.2: Central Simple Algebra

Let A be an algebra over a field k. Then A is called *simple* if it is a simple ring. It is called a *central simple algebra* (CSA) if it is simple, is finite dimensional over k, and its center is k.

The idea behind this definition is that it generalizes field extensions F/k, for we have a distinguished field k, and we are interested in the "algebraic case", hence the extension ought to be finite. Contrasting to fields, a CSA need not be commutative and need be a division ring

Example 51.3.3: Simple and Central Simple Algebras

1. Naturally, $M_n(k)$ is a central simple algebra of dimension n^2
2. It is possible to be simple and have center k but not be finite: the Weyl algebra $k[x, \delta_x]$ is infinite dimensional over k.
3. $\mathbb{C}$ is a central simple algebra over $\mathbb{C}$, but not over $\mathbb{R}$ (as it's center contains more than $\mathbb{R}$
4. Let $A = \mathbb{H}$ be the quaternions (or Hamiltonians). Then this is a CSA over $\mathbb{R}$ with dimension 4. We shall soon define a quaternion algebra, and see that all 4-dimensional central simples algebra's over a field k is a quaternion algebra, and it shall be limited to 2-by-2 matrices or division algebras.

Let us now generalize some of basic representation theory results. Let E be an irreducible representation of A (take for example a minimal left ideal of A).

Lemma 51.3.4: Schur's Lemma - updated

Let E be an irreducible representation of a k-algebra A, and let $K \subseteq \text{End}_k(E)$ be the endomorphisms that commute with the operations of A: it is the centralizer of A in $\text{End}_k(E)$, $K = C_{\text{End}_k(E)}(A)$. Then K is a division ring.

Note that this makes K an A-algebra

***Proof*:**
Take $u \in K$. We want to show that $u^{-1} \in K$. Consider $u^{-1}(0) = V \subseteq E$. For $x \in V$, we have:

$$0 = a \cdot u(x) = u(a \cdot x)$$

hence, V is stable under A, and as $u \neq 0$ we must have $V = 0$ as u is invertible in $\text{End}_k(E)$. It follows that $u^{-1} \in K$.

Notice from this that we may say that the representation E must be faithful (the map must be injective). Indeed, the kernel of this representation would be an ideal of A but

Lemma 51.3.5: Minimal Centralizer of Representations

Let E be a semi-simple an faithful representation of A, $K = C_{\text{End}_k(E)}(A)$, $B = C_{\text{End}_k(E)}(K)$ (i.e. the centralizer of A and K in $\text{End}_k(E)$). Then

$$A = B$$

***Proof*:**
Let $x \in E$ and $b \in B$. We shall show that there exists an $a \in A$ such that $a(x) = b(x)$.

Let $Ax = V \subseteq E$ be a stable subspace. Then V admits a (stable) compliment: $E = V \oplus V^{\perp}$. Let $\pi : E \to V$ be the natural projection map. Then certainly π is A-linear and commutes with K, namely $\pi \in K$. Then:

$$\pi(b(x)) = b(\pi(x)) = b(x)$$

namely, $b(x) \in V = aX$, implying $a(x) = b(x)$, as we sought to show.

Lemma 51.3.6: Generator lemma

Let E be a semi-simple an faithful representation of A, $K = C_{\text{End}_k(E)}(A)$, $B = C_{\text{End}_k(E)}(K)$ (i.e. the centralizer of A and K in $\text{End}_k(E)$). Let $x_1, ..., x_n \in E$ and $b \in B$. Then there exits values $a_i \in A$ such that:

$$ax_1 = bx_1,\ ax_2 = bx_2 \qquad \cdots \qquad ax_n = bx_n$$

***Proof*:**
Let F be the direct sum space of n copies of representation E. Then F is formed of elements $(y_1, ..., y_n)$, $y_i \in E$, on which A acts by

$$a \cdot (y_1, ..., y_n) = (ay_1, ..., ay_n)$$

The representation F is still semi-simple. The centralizer of A in $\mathrm{End}_k(F)$ is formed of matrices (u_{ij}), $u_{ij} \in K$, and it follows that, if we let B operate on F by the formula:

$$b \cdot (y_1, ..., y_n) = (by_1, ..., by_n)$$

the elements of $\mathrm{End}_k(F)$ thus defined will still be in the centralizer of the centralizer of A (in the theory of semi-groups, this is sometimes called the bicommutant). By lemma 51.3.5 applying to the point $x = (x_1, ..., x_n) \in F$, and to $b \in B$ giving us the desired result.

Serre write K_n for $M_n(K)$ for a division ring K, but we shall stick to $M_n(D)$ where our division ring is D instead of K. If D contains k in its center, we have:

$$M_n(D) = M_n(k) \otimes D$$

through $(a_{ij}) \otimes d \mapsto (a_{ij}d)$.

Let A be a k-algebra. Then A acting on itself by left multiplication gives something called the *regular left representation*. If $A = M_n(D)$, it has basis e_{ij}, $1 \leq i, j \leq n$. The elements e_{i,j_0} for a fixed j_0 gives a subspace of $M_n(D)$, say $N_{j_0} \subseteq M_n(D)$. The subspace N_{j_0} is a minimal left ideal (namely, an irreducible representation). Then we see that for any other choice of j_0, say j_1, we get an isomorphic irreducible representation N_{j_1}. The same holds for every finite-dimensional simple k-algebra.

Lemma 51.3.7: Decomposition Of A Simple Algebra Into Left Ideals

Let A be a nonzero finite-dimensional simple k-algebra. Then there are a simple left ideal I of A and elements $a_1, \ldots, a_m \in A$ such that $A = Ia_1 \oplus \cdots \oplus Ia_m$ and $Ia_j \cong I$ as A-modules for every j.

***Proof*:**
Left ideals of A are k-subspaces, since $\lambda x = (\lambda 1)x$ for $\lambda \in k$.

Step 1: A simple left ideal. As $A \neq 0$ is finite-dimensional, it has a nonzero left ideal I of smallest k-dimension among the nonzero left ideals. Every nonzero A-submodule of I is a left ideal of dimension at most $\dim_k I$, hence equal to I, so I is a simple A-module.

Step 2: A is a sum of copies of I. For $a \in A$, the set Ia is a left ideal, and $x \mapsto xa$ is a surjective A-module homomorphism $I \to Ia$. Its kernel is a submodule of the simple module I, so either $Ia = 0$ or $Ia \cong I$. The sum $J = \sum_{a \in A} Ia$ is a left ideal with $Jb \subseteq \sum_{a \in A} I(ab) \subseteq J$ for every $b \in A$, so J is a two-sided ideal, and $J \supseteq I \cdot 1 = I \neq 0$. As A is simple, $J = A$.

Step 3: A direct decomposition. Among the finite families $a_1, \ldots, a_m$ of elements of A such that each Ia_j is nonzero and the sum $Ia_1 + \cdots + Ia_m$ is direct (the empty family is one), choose one with m largest, which is possible because $m \dim_k I \leq \dim_k A$. Let $D = Ia_1 \oplus \cdots \oplus Ia_m$. For $a \in A$ with $Ia \neq 0$, the intersection $Ia \cap D$ is a submodule of the simple module Ia. If it were 0, the sum $D + Ia$ would be direct, and the family $a_1, \ldots, a_m, a$ would contradict the maximality of m. Hence $Ia \subseteq D$ for every $a \in A$, and $A = J = D$. Each Ia_j is nonzero, so $Ia_j \cong I$ by Step 2, as claimed.

Theorem 51.3.8: Representation of Simple Algebra

Let A be a finite-dimensional simple k-algebra. Then every representation of A is isomorphic to a direct sum of irreducible representations.

***Proof*:**
If $A = 0$, every A-module is 0, the empty direct sum, so assume $A \neq 0$.

Step 1: A is a semi-simple ring. By lemma 51.3.7, A is the internal direct sum of the simple submodules Ia_j, so A is a semi-simple A-module by lemma 51.1.7 and a semi-simple ring by corollary 51.1.9.

Step 2: Representations. A representation $\rho\colon A \to \mathrm{End}_k(V)$ is the left A-module V with $a \cdot v = \rho(a)v$, and its subrepresentations are exactly its A-submodules, so its irreducible subrepresentations are its simple submodules. Since A is a semi-simple ring, V is a semi-simple A-module by definition 51.1.2, that is a direct sum of simple modules by lemma 51.1.7. So every representation of A is a direct sum of irreducible representations, as claimed.

Corollary 51.3.9: Representation of Simple Algebra

Let A be a finite-dimensional simple k-algebra. Then:

1. All representations of A are semi-simple (completely reducible in Serre's words)
2. Two representations of A which have the same dimension are isomorphic

***Proof*:**
Part (1) is theorem 51.3.8. For (2) we may assume $A \neq 0$, since otherwise every representation is 0. Let I and $a_1, \ldots, a_m$ be as in lemma 51.3.7, so that $A = Ia_1 \oplus \cdots \oplus Ia_m$ with each $Ia_j \cong I$.

Step 1: Every simple A-module is isomorphic to I. Let S be a simple A-module and $0 \neq s \in S$. The homomorphism $A \to S$, $a \mapsto as$, sends 1 to $s \neq 0$, so its restriction to some Ia_j is nonzero, and this restriction $Ia_j \to S$ is an isomorphism by lemma 51.1.5. Hence $S \cong Ia_j \cong I$.

Step 2: The dimension determines the representation. By part (1) and Step 1, a representation V is isomorphic to a direct sum $\bigoplus_{t \in T} I$ of copies of I, so $\dim_k V = |T| \dim_k I$ with $0 < \dim_k I < \infty$. If $\dim_k V$ is finite, then $|T| = \dim_k V / \dim_k I$, and if it is infinite, then $|T| = \dim_k V$. Two representations of the same dimension are therefore direct sums of the same number of copies of I, hence isomorphic, as claimed.

Let us now turn towards the tensor product of simple algebras.

Lemma 51.3.10: Centralizer of Tensor Product of Algebras

Let A, A' be two k-algebras, B, B' be sub k-algebras of A, A' (respectively) with C, C' their centralizers on A, A' (respectively). Then the centralizer of $B \otimes B'$ in $A \otimes A'$ is $C \otimes C'$.

***Proof*:**
Let us first find the centralizer of $B \otimes 1$. For this, let a_i' be a basis of A'. Any $x \in A \otimes A'$ can be written uniquely in the form:

$$x = \sum_i a_i \otimes a_i' \qquad \text{for appropriate } a_i \in A$$

If x commutes with $b \otimes 1$, then $a_i b = b a_i$ that is $a_i \in C$ for all i. We thus see that the centralizer of $B \otimes 1$ is $C \otimes A'$. Similarly, that of $1 \otimes B'$ is $A \otimes C'$. It follows that the centralizer of $B \otimes B'$ is equal to the intersection of the centralizers of $B \otimes 1$ and $1 \otimes B'$, namely

$$(C \otimes A') \cap (A \otimes C') = C \otimes C'$$

as we sought to show.

Thus, the centre of the tensor product of two algebras is the tensor product of the centre of the two algebras. Applying this to the special case of $A = M_n(k) \otimes D$ for some division ring D, then:

$$Z(A) = k \otimes Z(D)$$

Corollary 51.3.11: Centre of simple algebra is a Field

Let A be a simple k-algebra, finitely generated over k. Then $Z(A)$ is a field.

***Proof*:**
Consider $Z(A)$. As A is a finitely generated k-algebra, $Z(A)$ is a finitely generated k-algebra. For any $0 \neq z \in Z(A)$, consider zA. As z is central,we have that zA is two-sided ideal. As A is simple, it must be that $zA = A$, that is z is there exists a $w \in A$ such that $za = 1$. Therefore, $Z(A)$ is a division ring. It is by definition commutative, and hence it is a field. Since z was an arbitrary nonzero element, $Z(A)$ is a division ring. It is by definition commutative, and hence it is a field.

We shall next require to see the interaction between the tensor product of central simple algebras. We require the following lemma:

Theorem 51.3.12: Ideal Generation Tensor Product

Let A be a k-algebra and K' a left division ring with center k. Then every ideal $N \subseteq A \otimes K'$ is generated (as a left module over K') by its intersection with $A \otimes 1$.

Note that neither A nor K' are assumed finite over k

***Proof*:**
We will first note that we can make K' operate on the left on $A \otimes K'$ by:

$$k'(a \otimes k'') = a \otimes k'k''$$

If N is an ideal of the algebra $A \otimes K'$, it is in particular a K'-module subspace of $A \otimes K'$.

Let a_i be a basis of A over k; the elements $a_i \otimes 1$ equally form a basis of the K'-module $A \otimes K'$. Let x be a primitive element of N with respect to this basis (Bourbaki, Alg.II, paragraph 5):

$$x = \sum_i a_i \otimes k'_i$$

Consider the element $x \cdot m$ ($m \in K'$); we have $x \cdot m \in N$ (N is an ideal), and on the other hand:

$$x \cdot m = \sum_i a_i \otimes k'_i m$$

It then follows from the properties of primitive elements that we have:

$$k'_i m = n k'_i \text{ for all } i \quad (n \in K')$$

Since one of the k'_i is equal to 1, we have $m = n$, and the preceding equality simply means that k'_i commutes with all $m \in K'$, i.e., that $k'_i \in k$. We can then write: $x = a \otimes 1$, by setting: $a = \sum_i k'_i a_i$. We have thus shown that every primitive element x is in $A \otimes 1$; the theorem follows immediately since every vector space is generated by its primitive elements.

Theorem 51.3.13: Tensor Product CSA

Let A, A' be simple k-algebras finitely generated over k, where one of them is a CSA. Then $A \otimes A'$ is a simple k-algebra

***Proof*:**
Suppose that $A' = M_n(k) \otimes K'$ is central, in other words that the center of the left field K' is reduced to k. It will suffice to show that $A \otimes K'$ is a simple algebra. Indeed, if this is demonstrated, $A \otimes K' = M_m(k) \otimes K''$, and $A \otimes A' = M_m(k) \otimes M_n(k) \otimes K'' = M_{mn}(k) \otimes K'' = M_{nm}(K'')$. The algebra $A \otimes A'$ will thus be isomorphic to a matrix algebra for which simplicity is immediately verified. Then the general case of $A \otimes K'$ being simple follow from theorem 51.3.12, completing the proof.

Corollary 51.3.14: Tensor Product of Two CSA's

The tensor product of two CSA is a CSA

***Proof*:**
In the previous proof, it was enough for one of them to be a CSA.

Corollary 51.3.15: Opposite Algebra Tensoring

Let A be a CSA over k and A^{op} the opposite algebar. Then:

$$A \otimes A^{\text{op}} \cong M_{n^2}(k)$$

***Proof*:**
Let us denote by E the algebra A considered as a vector space over k. We can make A act naturally on E by the left or right by multiplication to create a left or right A-module. This amounts to identifying A and A^{op} as sub-algebras of the algebra $\text{End}_k(E)$ of k-endomorphisms of E. Since the algebras A and A^{op} commute in $\text{End}_k(E)$, we can define a canonical homomorphism of $A \otimes A^{\text{op}}$ into $\text{End}_k(E)$ which extends the isomorphisms: $A \to \text{End}_k(E)$ and $A^{\text{op}} \to \text{End}_k(E)$. The algebra $A \otimes A^{\text{op}}$ being simple, this homomorphism is an isomorphism; moreover, as;

$$[A \otimes A^{\text{op}} : k] = [A : k]^2 = n^2 = [\text{End}_k(E) : k]$$

this isomorphism maps $A \otimes A^{\text{op}}$ onto $\text{End}_k(E) = M_{n^2}(k)$, as we sought to show.

51.3.1 Brauer Group

Let A be a CSA over k. As A is simple, we get by Artin-Wedderburn that it is isomorphic to $M_n(D) \cong M_n(k) \otimes D$. For example, if $n = 1$ and $k = \mathbb{R}$ we get (by a classical theorem from algebraic topology) that $A \cong \mathbb{R}$ or $A \cong \mathbb{H}$ (the quaternions). If $n > 1$, we get $M_n(\mathbb{R})$ and $M_n(\mathbb{H})$ (which are no longer division algebras). We see that the division ring is one of the "characterizing" feature of the CSA (the other being its matrix ring), especially that up to Morita-equivalence we get the same category. We thus have the following natural equivalence we may define:

Definition 51.3.16: Brauer Equivalence

Let k-**CSA** be a collection of central simple algebras over k. Then define the equivalence relation $A \sim A'$ where the two are equivalent if and only if their associated division rings are isomorphic.

Proposition 51.3.17: Brauer Group

The Brauer equivalence on a collection of CSA's forms a commutative group under the tensor product. This group will be denoted $\text{Br}(k)$.

In Serre, this group is denoted G_k.

***Proof*:**
By corollary 51.3.14, it is closed under the tensor product, the equivalence class containing k is certainly the identity, and corollary 51.3.15 shows that every equivalence class has an inverse. Associativity and commutativity is a classical result for tensor products.

Example 51.3.18: Brauer Groups

1. Let $k = \overline{k}$. Then $\mathrm{Br}(\overline{k}) = 0$ by corollary 51.2.20.
2. If $k = \mathbb{R}$, then we shall show in the next section that $\mathrm{Br}(\mathbb{R}) = \mathbb{Z}/2\mathbb{Z}$, namely we shall have $\mathbb{R}$ and $\mathbb{H}$, the quaternions.
3. Let k be a finite field. Then $\mathrm{Br}(k) = 0$, as all finite division rings are fields (theorem 19.7.20).
4. If $k = \mathbb{Q}_p$, then $\mathrm{Br}(k) \cong \mathbb{Q}/\mathbb{Z}$ (Serre references Algebren - Chap. VII - 2nd paragarph).
5. If $k = \mathbb{Q}$, $\mathrm{Br}(\mathbb{Q})$ will be a subgroup of

$$\mathbb{Z}/2\mathbb{Z} \oplus (\mathbb{Q}/\mathbb{Z})^{\oplus \mathbb{N}}$$

which can be thought of as a result similar to that in number theory where we study the "global field" $\mathbb{Q}$ by looking at all its localizations (note that $\mathbb{Z}/2\mathbb{Z}$ comes from $\mathrm{Br}(\mathbb{R})$!) Serre references Deuring for the proof (see Sere p.8)

Theorem 51.3.19: Field Extensions and CSA

Let A be a CSA over k, L/k a field extension (either finite or infinite). Then $A \otimes L$ is simple

***Proof*:**
If A is a division ring, then all ideals of $A \otimes L$ will be given with in part with the intersection of the ideals of L, which is simply (0), making $A \otimes L$ simple.

If A is any CSA, write $A \cong M_n(k) \otimes D$. Then:

$$A \otimes L \cong M_n(k) \otimes (D \otimes L) \overset{!}{=} M_n(k) \otimes M_m(D')$$

where for $\overset{!}{=}$, D' is the division ring naturally given by $D \otimes_k L$! But this gives the result.

Corollary 51.3.20: Index of CSA

Let A be a simple, central and finite algebra over k. Then $[A : k]$ is a perfect square.

***Proof*:**
Let L be an algebraically closed extension of k. The algebra $A \otimes L$ can be endowed with an algebra structure over L, and we have:

$$[A \otimes L : L] = [A : k]$$

But $A \otimes L$ is a simple algebra, central over L, and finite over L. It then follows from example 51.3.18[1] that it is a matrix algebra over L, and $[A \otimes L : L]$ is indeed a perfect square.

Looking at the field extension of a k-algebra, it is natural to consider that $- \otimes_k L$ gives a homomorphism

of Brauer groups $\varphi_{k,L} : \mathrm{Br}(k) \to \mathrm{Br}(L)$, namely due to the following result from linear algebra:

$$(A \otimes_k L) \otimes_L (A' \otimes_k L) \cong (A \otimes_k A') \otimes_k L$$

The kernel $\ker \varphi_{k,L}$ consists of all k-algebra's that become trivial (matrix algebras) when extending to L. Serre calls these algebras the algebras that *admit L as a field of decomposition.* (or admit a decomposition by L). More recently, the term *splitting field* is adopted due to the parallels to number theory. Naturally, if $L = \overline{k}$, then every algebra admits a decomposition as $\mathrm{Br}(\overline{k}) = 0$. We only require a finite extension:

Theorem 51.3.21: Splitting Field is Finite

The Brauer group $\mathrm{Br}(k)$ is the union of $\ker \varphi_{k,L}$ going over each L/k where L is a finite field extension. In particular, there exists a finite extension L/k such that for a CSA A over k, $[A \otimes_k L] = [1]$ in $\mathrm{Br}(L)$.

***Proof*:**

By example 51.3.18[1] we have that for a CSA A over $\overline{k}$, $A \otimes_k \overline{k} \cong M_n(D)$. Then the right hand side is generated by finitely many elements of the left hand side. We need only take the elements that map to the generators of the right hand side and to choose the appropriate field elements to get find L/k, as we sought to show.

51.4 Build up to Quaternion Algebras

Theorem 51.4.1: Skolem-Noether Theorem

Let A, B be CSA's over k, and let $f, g : A \to B$ be k-algebra isomorphism. Then there exists a unit $b \in B$ such that:

$$g(a) = bf(a)b^{-1}$$

In particular, every automorphism is an inner automorphism

***Proof*:**

Let's first prove the special case of $B = M_n(k)$. Then the isomorphisms $f, g : A \to M_n(k)$ define actions on k^n, or said differently these define two A-modules (with two different actions): V_f, V_g. Then using f, g we have an A-module isomorphism $g \circ f^{-1} : V_f \to V_g$. But any isomorphism between vector-spaces is representable as (unit) matrix in $M_n(k)$, and so we we get our value by linear algebra.

For the general case, we know that $B \otimes_k B^{\mathrm{op}} \cong M_n(k)$ and $A \otimes_k B^{\mathrm{op}}$ is simple as B^{op} is still simple (use theorem 51.3.13). As $B \otimes_k^B \mathrm{op}$ is a (finite dimensional) matrix algebra, we may apply our special case to:

$$f \otimes 1,\ g \otimes 1 : A \otimes_k B^{\mathrm{op}} \to B \otimes_k B^{\mathrm{op}} \cong M_n(k)$$

which shows that:

$$(f \otimes 1)(a \otimes c) = b(g \otimes 1(a \otimes c)b^{-1}$$

which is true for all $a \in A$ and $c \in B^{\text{op}}$. Thus, it is true for $a = 1$, giving us:

$$1 \otimes c = b(1 \otimes c)b^{-1}$$

for all $c \in B^{\text{op}}$. Thus,

$$b \in Z_{B \otimes_k B^{\text{op}}}(k \otimes B^{\text{op}}) = B \otimes k$$

Hence, as constants move through the tensor we get that $b = b \otimes_k 1$. And so, by setting $z = 1$, we find:

$$f(a) = b' g(a) {b'}^{-1}$$

as we sought to show.

Theorem 51.4.2: Centralizer of Subalgebras

Let A be a CSA over k, $B \subseteq A$ a simple subalgebra, $C = C_A(B)$ the centralizer of B in A. Then C is simple, $B = C_A(C)$, and:

$$[B : k][C : k] = [A : k]$$

***Proof*:**
Let E be B with only the structure of a k-vector space. Then B acts on E via left multiplication; this action isomorphically embeds B into $\text{End}_k(E)$. Then the centralizer of B in $\text{End}_k(E)$ is nothing more than the algebra of right translations by E, that is B^{op}.

Given this, we can consider the simple algebra $A \otimes_k \text{End}_k(E)$. We can now embed B into this tensored algebra in two ways: via $B \otimes 1$ or $1 \otimes B$. Their centralizers are $C \otimes \text{End}_k(E)$ and $A \otimes B^{\text{op}}$ respectively.

By theorem 51.4.1, there exists an inner automorphism of $A \otimes_k \text{End}_k(E)$ mapping $B \otimes 1$ to $1 \otimes B$; it is then a simple algebra exercise to see that this inner automorphism induces a map on the centralizers. As a consequence, as $A \otimes B^{\text{op}}$ is simple, so is $C \otimes \text{End}_k(E)$, which must make C simple.

Furthermore:

$$[C \otimes \text{End}_k(E) : k] = [C : k][B : k]^2 \qquad \text{and} \qquad [A \otimes B^{\text{op}} : k][A : k][B : k]$$

From which we get $[A : k] = [B : k][C : k]$. What's left to show is the centralizer of C in A is B. Say that B' is this centralizer. Then $B \subseteq B'$. Then as $[A : k] = [B : k][C : k]$, we get:

$$[B' : k] = [B : k]$$

But then as they contain we must get $B = B'$, completing the proof.

52

The Jacobson Radical and Non-Semisimple Algebras

The Artin-Wedderburn theorem (theorem 51.2.16) is a complete answer to a narrow question: it classifies the semisimple rings and, in the process, shows that a semisimple k-algebra is nothing more than a finite product of matrix rings over division algebras. When R is semisimple, every module splits into simples, every short exact sequence splits, and the entire representation theory of R collapses onto the finite list of its simple modules. This is the best possible situation, and it is also the exception. The algebras whose representation theory occupies most of this book are precisely the ones that fail to be semisimple: the group algebra $k[G]$ when $\mathrm{char}(k)$ divides $|G|$ (where Maschke's theorem breaks down), the truncated polynomial algebra $k[x]/(x^n)$, universal enveloping algebras of Lie algebras, and the path algebra of a quiver with an oriented cycle. For all of these, some module fails to be a direct sum of simples, some sequence refuses to split, and Wedderburn has nothing to say.

This chapter builds the tools that take over where Wedderburn stops. The first of these, and the subject of the present section, is the *Jacobson radical* $\mathrm{Jac}(A)$: the two-sided ideal that measures, in a single invariant, exactly how far A is from being semisimple. It is the obstruction that vanishes precisely when A is semisimple, and dividing it out always produces a semisimple ring $A/\mathrm{Jac}(A)$ whose simple modules are the same as those of A. In the sections that follow, the radical becomes the engine behind the theory of indecomposable modules and the Krull-Schmidt theorem (which replaces "decomposition into simples" with "decomposition into indecomposables"), and behind the construction of projective covers, which repair the failure of projectivity that semisimplicity had guaranteed for free. The radical is where the non-semisimple story begins.

52.1 The Jacobson Radical

Throughout chapter 51 the simple modules did all the work: a semisimple ring was assembled out of its minimal left ideals, and every module was a direct sum of simples. When a ring is *not* semisimple, the simple modules are still present, but they no longer see everything. Some elements of the ring act as zero on every simple module without being zero themselves, and these elements form an ideal that records the discrepancy. To isolate them, we begin one level down, with modules, and ask which part of a module is invisible to all of its simple quotients.

The maximal submodules of a module M are exactly the kernels of the surjections $M \twoheadrightarrow S$ onto simple modules: a submodule $N \subseteq M$ is maximal precisely when M/N is simple, and every simple quotient of M is of the form M/N for such an N (the classification of simples as quotients by maximal left ideals is lemma 51.1.3). An element lying in every maximal submodule is one that every simple quotient sends to zero. Collecting these gives the radical of a module.

Definition 52.1.1: Radical of a Module

Let M be a left A-module. The *radical* of M, written $\operatorname{rad}(M)$, is the intersection of all maximal submodules of M:

$$\operatorname{rad}(M) = \bigcap_{\substack{N \subseteq M \\ N \text{ maximal}}} N$$

If M has no maximal submodules, the intersection is empty and $\operatorname{rad}(M) := M$ by convention.

Since each maximal submodule is the kernel of a map onto a simple module, an equivalent description is

$$\operatorname{rad}(M) = \bigcap_{\substack{\varphi\colon M \to S \\ S \text{ simple}}} \ker(\varphi)$$

so that $\operatorname{rad}(M)$ is the set of elements killed by *every* homomorphism from M into a simple module. The quotient $M/\operatorname{rad}(M)$ is the largest quotient of M that embeds into a product of simple modules; it is the *semisimple quotient* of M, the part of M that its simple quotients can detect. Everything inside $\operatorname{rad}(M)$ is invisible to them.

Example 52.1.2: The Radical of a Cyclic $\mathbb{Z}$-Module

Take $A = \mathbb{Z}$ and $M = \mathbb{Z}/12\mathbb{Z}$. The maximal submodules of M correspond to the maximal ideals of $\mathbb{Z}$ containing $12\mathbb{Z}$, that is to the primes dividing 12, namely 2 and 3. The corresponding maximal submodules are $2\mathbb{Z}/12\mathbb{Z}$ and $3\mathbb{Z}/12\mathbb{Z}$, with simple quotients $\mathbb{Z}/2\mathbb{Z}$ and $\mathbb{Z}/3\mathbb{Z}$. Their intersection is

$$\operatorname{rad}(\mathbb{Z}/12\mathbb{Z}) = \frac{2\mathbb{Z}}{12\mathbb{Z}} \cap \frac{3\mathbb{Z}}{12\mathbb{Z}} = \frac{6\mathbb{Z}}{12\mathbb{Z}}$$

so $\operatorname{rad}(M) = 6\mathbb{Z}/12\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z}$, and the semisimple quotient is $M/\operatorname{rad}(M) \cong \mathbb{Z}/6\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$. The radical has stripped $\mathbb{Z}/12\mathbb{Z}$ down to its squarefree quotient: the extra factors of 2 and 3 that no simple quotient can see are exactly what lies in $6\mathbb{Z}/12\mathbb{Z}$.

Applying this construction to the ring itself, viewed as a module over itself, produces the central object of the chapter. The radical of A as a left A-module is the intersection of its maximal *left* ideals.

Definition 52.1.3: Jacobson Radical

Let A be a ring. The *Jacobson radical* of A, written $\mathrm{Jac}(A)$, is the radical of A regarded as a left module over itself, that is the intersection of all maximal left ideals of A:

$$\mathrm{Jac}(A) = \mathrm{rad}({}_AA) = \bigcap_{\substack{\mathfrak{m}\subseteq A \\ \mathfrak{m} \text{ maximal left ideal}}} \mathfrak{m}$$

The definition is one-sided: it uses left ideals, and a priori $\mathrm{Jac}(A)$ need only be a left ideal. One of the first surprises is that the resulting set is symmetric, a two-sided ideal that could equally have been defined with maximal *right* ideals. This symmetry, and several other faces of the same object, are the content of the next theorem. Before stating it, recall that an element $u \in A$ is *left-invertible* if there exists $v \in A$ with $vu = 1$.

Theorem 52.1.4: Characterizations of the Jacobson Radical

Let A be a ring and let $a \in A$. The following subsets of A coincide, and their common value is $\mathrm{Jac}(A)$:

1. the intersection of all maximal left ideals of A;
2. the intersection of the annihilators $\mathrm{Ann}_A(S)$ of all simple left A-modules S;
3. the set $\{a \in A \mid 1 - xa \text{ is left-invertible for all } x \in A\}$.

Consequently, $\mathrm{Jac}(A)$ is a two-sided ideal of A, and it is the largest two-sided ideal of A that annihilates every simple left A-module.

The three descriptions look at the same ideal from three angles. The first is the definition. The second recasts it representation-theoretically: $\mathrm{Jac}(A)$ is exactly the set of elements that act as zero on every simple module, which is why it is invisible to the simple representation theory. The third is an intrinsic ring-theoretic criterion that never mentions modules at all, and it is the one that makes the two-sidedness fall out for free, since it is symmetric in a way the definition is not.

***Proof*:**
We prove (1) = (2), then (2) = (3), and finally read off the two-sidedness and maximality statements.

Step 1: (1) = (2). Let J_1 denote the intersection of all maximal left ideals and J_2 the intersection of the annihilators of all simple left modules. If S is a simple left A-module, then for any $0 \neq s \in S$ we have $S = As$ (as As is a nonzero submodule of the simple module S), and by corollary 51.1.4 the map $a \mapsto as$ gives $S \cong A/\mathrm{Ann}_A(s)$ with $\mathrm{Ann}_A(s)$ a maximal left ideal. The annihilator of the whole module is

$$\mathrm{Ann}_A(S) = \bigcap_{0\neq s\in S} \mathrm{Ann}_A(s)$$

an intersection of maximal left ideals, so $J_1 \subseteq \mathrm{Ann}_A(S)$ for every simple S, giving $J_1 \subseteq J_2$. Conversely, if $\mathfrak{m}$ is any maximal left ideal, then $S = A/\mathfrak{m}$ is a simple left module and $\mathrm{Ann}_A(S) \subseteq \mathfrak{m}$ (since $\mathrm{Ann}_A(S)$ kills the coset $1 + \mathfrak{m}$, so $\mathrm{Ann}_A(S) \cdot 1 \subseteq \mathfrak{m}$). Hence $J_2 \subseteq \mathfrak{m}$ for every maximal left ideal $\mathfrak{m}$, giving $J_2 \subseteq J_1$. Thus $J_1 = J_2$.

Step 2: (2) $\subseteq$ (3). Let $a \in J_2$, so a annihilates every simple left module, and fix $x \in A$. We must show $1 - xa$ is left-invertible. If not, then $A(1-xa)$ is a proper left ideal, hence contained in some maximal left ideal $\mathfrak{m}$ (using that $1 \notin A(1-xa)$ and Zorn's lemma). The quotient $S = A/\mathfrak{m}$ is simple, so a annihilates it: $a \cdot (1 + \mathfrak{m}) = 0$, meaning $a \in \mathfrak{m}$. But $xa \in \mathfrak{m}$ as well, since $\mathfrak{m}$ is a left ideal, and $1 - xa \in \mathfrak{m}$ since $1 - xa \in A(1-xa) \subseteq \mathfrak{m}$. Adding, $1 = (1-xa) + xa \in \mathfrak{m}$, contradicting that $\mathfrak{m}$ is proper. Hence $1 - xa$ is left-invertible for every x, so $a \in J_3$, the set in (3).

Step 3: (3) $\subseteq$ (2). Let $a \in J_3$, and suppose toward a contradiction that a does *not* annihilate some simple left module S. Then $as \neq 0$ for some $s \in S$, and since As is a nonzero submodule of the simple module S we have $As = S$. In particular $s \in As$, so $s = xas$ for some $x \in A$, giving $(1-xa)s = 0$. By hypothesis $1 - xa$ is left-invertible, say $v(1-xa) = 1$; applying v gives $s = v(1-xa)s = 0$, contradicting the choice of s. Hence a annihilates every simple module, so $a \in J_2$.

Combining the three steps, $J_1 = J_2 = J_3 = \mathrm{Jac}(A)$.

Step 4: two-sidedness and maximality. As the intersection of the left ideals $\mathrm{Ann}_A(S)$, description (2) shows $\mathrm{Jac}(A)$ is a left ideal. But each $\mathrm{Ann}_A(S)$ is in fact a two-sided ideal: if $a \in \mathrm{Ann}_A(S)$ and $b \in A$, then for all $s \in S$ we have $(ab)s = a(bs) = 0$, so $ab \in \mathrm{Ann}_A(S)$. An intersection of two-sided ideals is two-sided, so $\mathrm{Jac}(A)$ is a two-sided ideal. Finally, if I is any two-sided ideal annihilating every simple left module, then $I \subseteq \mathrm{Ann}_A(S)$ for every simple S, hence $I \subseteq \bigcap_S \mathrm{Ann}_A(S) = \mathrm{Jac}(A)$; thus $\mathrm{Jac}(A)$ is the largest such ideal, completing the proof.

The left-invertibility criterion (3) deserves a second look, because it is what makes the radical robust. It says a lies in the radical exactly when $1 - xa$ can never be turned into a non-unit by any left multiplier x. A standard manipulation upgrades "left-invertible" to "two-sided invertible" for these particular elements: if $a \in \mathrm{Jac}(A)$ and $v(1-xa) = 1$, then $v = 1 + vxa = 1 - (-vx)a$, and since $a \in \mathrm{Jac}(A)$ the element v is itself left-invertible by the same criterion; a left-invertible element with a left-invertible left inverse is a unit. So for $a \in \mathrm{Jac}(A)$ the element $1 - xa$ is a two-sided unit for every x, and by the right-handed version of the whole theorem $1 - ax$ is a unit as well. This is the working form of the radical: $\mathrm{Jac}(A)$ is the set of elements a such that $1 - xay$ is a unit for all $x, y \in A$, and it is exactly this that will drive Nakayama's lemma below.

Description (2) also settles the two-sided nature of the radical without any of the asymmetry of the original definition, and it makes precise the sense in which the radical is invisible to representation theory. If A is semisimple, every module is a sum of simples, so an element killing all simples kills everything: $\mathrm{Jac}(A) = 0$. The content of the non-semisimple theory is that $\mathrm{Jac}(A)$ can be nonzero, and it is this ideal that the simple modules fail to detect.

Before turning to that theory, the radical of a ring is anchored by two computations. The first is the archetype of a local non-semisimple algebra.

Example 52.1.5: The Radical of a Truncated Polynomial Algebra

Let k be a field and let $A = k[x]/(x^n)$ with $n \geq 1$, writing $\bar{x}$ for the image of x. This is a commutative local ring: an element $f(\bar{x}) = c_0 + c_1\bar{x} + \cdots + c_{n-1}\bar{x}^{n-1}$ is a unit if and only if $c_0 \neq 0$, since when $c_0 = 0$ the element is nilpotent ($\bar{x}^n = 0$ forces $f(\bar{x})^n = 0$), and when $c_0 \neq 0$ one inverts using the geometric series, which terminates because $\bar{x}^n = 0$:

$$(c_0 + \bar{x}g)^{-1} = c_0^{-1}\big(1 + c_0^{-1}\bar{x}g\big)^{-1} = c_0^{-1}\sum_{j=0}^{n-1}(-c_0^{-1}\bar{x}g)^j$$

The non-units are therefore exactly the elements with $c_0 = 0$, which is the ideal $(\bar{x})$. In a commutative ring the maximal ideals are the maximal left ideals, and here there is a single maximal ideal, namely $(\bar{x})$, because $A/(\bar{x}) \cong k$ is a field while any element outside $(\bar{x})$ is a unit. Hence

$$\mathrm{Jac}(A) = (\bar{x}) = \{c_1\bar{x} + c_2\bar{x}^2 + \cdots + c_{n-1}\bar{x}^{n-1} \big| c_i \in k\}$$

This ideal is nilpotent: $(\bar{x})^n = (\bar{x}^n) = 0$, so already $\mathrm{Jac}(A)^n = 0$. The quotient $A/\mathrm{Jac}(A) = A/(\bar{x}) \cong k$ is a field, hence semisimple, which is the general phenomenon established in theorem 52.1.9. The single simple A-module is $k = A/(\bar{x})$, and $\bar{x}$ acts on it as zero, confirming that $\mathrm{Jac}(A) = (\bar{x})$ annihilates every simple module.

The second computation is the model of a non-commutative, non-local radical, where the one-sided origin of the definition is easiest to see in matrices.

Example 52.1.6: The Radical of Upper-Triangular Matrices

Let k be a field and let $A = T_n(k)$ be the ring of $n \times n$ upper-triangular matrices over k. Write $N \subseteq A$ for the strictly upper-triangular matrices (zero on and below the diagonal). The claim is $\mathrm{Jac}(A) = N$.

N annihilates every simple module. For each $1 \le i \le n$ there is a one-dimensional A-module $S_i = k$ on which an upper-triangular matrix $a = (a_{pq})$ acts by its ith diagonal entry, $a \cdot v = a_{ii}v$; this is a ring homomorphism $A \to k$ because the (i,i) entry of a product of upper-triangular matrices is the product of the (i,i) entries. The S_i are pairwise non-isomorphic simple A-modules. Any strictly upper-triangular matrix has all diagonal entries zero, so it acts as 0 on each S_i; thus $N \subseteq \mathrm{Ann}_A(S_i)$ for all i, and $N \subseteq \mathrm{Jac}(A)$ by theorem 52.1.4.

Nothing outside N lies in the radical. If $a \in A \setminus N$, some diagonal entry a_{ii} is nonzero, so a acts invertibly on S_i, and a does not annihilate the simple module S_i. By part (2) of theorem 52.1.4, $a \notin \mathrm{Jac}(A)$. Combining, $\mathrm{Jac}(A) = N$.

As a check on the intrinsic criterion, N is nilpotent with $N^n = 0$ (each multiplication by a strictly upper-triangular matrix pushes nonzero entries one further diagonal above the main diagonal), so for $a \in N$ the element $1 - xa$ has the form $1 -$ (nilpotent) and is a unit via the terminating geometric series $\sum_{j \ge 0}(xa)^j$. The quotient is $A/N \cong k^n$, the diagonal matrices, which is semisimple, and there are exactly n simple modules $S_1, \ldots, S_n$, matching the n factors of k^n.

The two examples share a feature: in each, $\mathrm{Jac}(A)$ turned out to be nilpotent, and the geometric series that inverts $1 - xa$ terminated precisely because a power of the radical vanished. This is not special to small examples. For the finite-dimensional and, more generally, left Artinian algebras that concern us, the radical is always nilpotent. The route to that fact runs through Nakayama's lemma, which converts the invertibility criterion into a statement about modules being forced to zero.

The lemma answers a question that recurs throughout module theory: if multiplying a module by the radical does not shrink it, must the module already be zero? The commutative version, over a local ring or with a general ideal contained in the radical, is proved in the companion volume [20] and will not be re-derived here; the module form over an arbitrary ring is the form needed here, and its proof uses only the invertibility criterion from theorem 52.1.4.

Lemma 52.1.7: Nakayama's Lemma

Let A be a ring and M a finitely generated left A-module.

1. If $\mathrm{Jac}(A)\,M = M$, then $M = 0$.
2. If $N \subseteq M$ is a submodule with $M = N + \mathrm{Jac}(A)\,M$, then $N = M$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

1. Suppose $M \neq 0$ and $JM = M$. Since M is finitely generated, choose a generating set $m_1, \ldots, m_r$ with r minimal, so no fewer than r elements generate M; as $M \neq 0$ we have $r \geq 1$. From $M = JM$ we may write the last generator as

$$m_r = \sum_{i=1}^{r} a_i m_i \qquad \text{with } a_i \in J$$

   Isolating m_r gives $(1 - a_r)m_r = \sum_{i=1}^{r-1} a_i m_i$. Because $a_r \in J = \mathrm{Jac}(A)$, the element $1 - a_r$ is a unit (the working form of theorem 52.1.4: $1 - a_r$ is left-invertible, and for radical elements this upgrades to a two-sided inverse). Multiplying on the left by $(1 - a_r)^{-1}$ expresses m_r as an A-combination of $m_1, \ldots, m_{r-1}$, so these $r-1$ elements already generate M, contradicting the minimality of r. Hence $M = 0$.

2. Apply part (1) to the finitely generated module M/N. Its finite generation is inherited from M (the images of generators of M generate the quotient). The hypothesis $M = N + JM$ gives, in the quotient, $M/N = J\,(M/N)$, since the image of JM is $J(M/N)$ and the image of N is 0. By part (1), $M/N = 0$, that is $N = M$, completing the proof.

The finite-generation hypothesis is not optional. Over the local ring $A = \mathbb{Z}_{(p)}$ (integers localized at p, whose radical is $p\mathbb{Z}_{(p)}$) the module $M = \mathbb{Q}$ satisfies $pM = M$ yet $M \neq 0$; it fails to be finitely generated, and the minimal-generator argument has nothing to grip. Part (2) is the form used in practice: it says that generators of $M/\mathrm{Jac}(A)M$ lift to generators of M. Once $\mathrm{Jac}(A)M$ is known (below) to be a "small" submodule, this becomes the statement that a minimal generating set of M is detected by the semisimple quotient $M/\mathrm{Jac}(A)M$, which is the seed of the theory of projective covers in a later section.

We now specialize to the setting where the radical is best behaved. A ring A is *left Artinian* if it satisfies the descending chain condition on left ideals; every finite-dimensional algebra over a field is left Artinian, since a descending chain of left ideals is a descending chain of subspaces and dimension cannot drop forever. In this setting the radical is not only an intersection of maximal left ideals but a nilpotent ideal, and it is the largest one.

Theorem 52.1.8: The Radical Is Nilpotent for Artinian Rings

Let A be a left Artinian ring. Then $\mathrm{Jac}(A)$ is nilpotent: there exists $m \geq 1$ with $\mathrm{Jac}(A)^m = 0$. Moreover, $\mathrm{Jac}(A)$ contains every nilpotent left ideal and every nilpotent two-sided ideal of A, so it is the largest nilpotent one-sided or two-sided ideal.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

Step 1: J is nilpotent. The descending chain of two-sided ideals

$$J \supseteq J^2 \supseteq J^3 \supseteq \cdots$$

is a descending chain of left ideals, so by the descending chain condition it stabilizes: there is m with $I := J^m = J^{m+1} = J\,I$. Suppose for contradiction that $I \neq 0$. Consider the set Σ of left ideals $L \subseteq A$ with $IL \neq 0$; it is nonempty because $I \cdot I = J^{2m} = I \neq 0$ shows $I \in \Sigma$ (using $J^{2m} = (J^m)^2 = I \cdot I$ and $J^{2m} = J^m = I$ since the chain stabilized). By the descending chain condition, Σ has a minimal element L_0. Choose $x \in L_0$ with $Ix \neq 0$; then $Ix \subseteq L_0$ is a left ideal with $I(Ix) = I^2x = Ix \neq 0$ (as $I^2 = I$), so $Ix \in \Sigma$, and minimality forces $Ix = L_0$. In particular $x \in L_0 = Ix$, so $x = ax$ for some $a \in I \subseteq J$. Then $(1-a)x = 0$, and since $a \in J$ the element $1 - a$ is a unit, giving $x = 0$ and hence $Ix = 0$, a contradiction. Therefore $I = J^m = 0$.

Step 2: J contains every nilpotent one-sided or two-sided ideal. Let I be a nilpotent left ideal, say $I^t = 0$. For any $a \in I$ and any $x \in A$, the element xa lies in I (a left ideal absorbs left multiplication), so $(xa)^t \in I^t = 0$; thus xa is nilpotent. A nilpotent element y with $y^t = 0$ makes $1 - y$ a unit, with inverse the terminating sum $1 + y + y^2 + \cdots + y^{t-1}$. Hence $1 - xa$ is a unit, in particular left-invertible, for every $x \in A$, so $a \in \mathrm{Jac}(A)$ by part (3) of theorem 52.1.4. This holds for every $a \in I$, so $I \subseteq J$. A nilpotent two-sided ideal is in particular a nilpotent left ideal, so the same conclusion applies, completing the proof.

For a left Artinian ring, then, "the Jacobson radical" and "the largest nilpotent ideal" name the same object; the two definitions of the radical current in the literature (intersection of maximal left ideals versus largest nilpotent ideal) agree exactly when A is Artinian. The nilpotence is what powers the terminating geometric series seen in the truncated-polynomial and upper-triangular examples, and it is the property that fails for general rings. It also gives a concrete way to detect non-semisimplicity: a single nonzero nilpotent element of a two-sided ideal already forces the radical to be nonzero. This is exactly the obstruction that appears for modular group algebras.

Having pinned down $\mathrm{Jac}(A)$ as a nilpotent ideal, the pieces are in place for the structural payoff. Dividing A by its radical removes precisely the elements that the simple modules could not see, and what remains is semisimple.

Theorem 52.1.9: Semisimplicity of the Quotient by the Radical

Let A be a left Artinian ring. Then $A/\mathrm{Jac}(A)$ is a semisimple ring, and hence Artin-Wedderburn (theorem 51.2.16) applies to it. Moreover, the simple left A-modules are exactly the simple left $A/\mathrm{Jac}(A)$-modules: every simple A-module is annihilated by $\mathrm{Jac}(A)$ and so factors through $A/\mathrm{Jac}(A)$, and every simple $A/\mathrm{Jac}(A)$-module is a simple A-module via the quotient map $A \twoheadrightarrow A/\mathrm{Jac}(A)$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$ and $\bar{A} = A/J$.

Step 1: $\bar{A}$ is semisimple. By corollary 51.1.9 it suffices to show that $\bar{A}$ is semisimple as a left module over itself, that is that $\mathrm{rad}(\bar{A}) = 0$. The maximal left ideals of $\bar{A}$ are exactly the images $\mathfrak{m}/J$ of the maximal left ideals $\mathfrak{m}$ of A (which all contain $J = \mathrm{Jac}(A)$), by the correspondence

theorem. Their intersection is

$$\operatorname{Jac}(\bar{A}) = \bigcap_{\mathfrak{m} \supseteq J} \mathfrak{m}/J = \Big(\bigcap_{\mathfrak{m}} \mathfrak{m}\Big) \Big/ J = J/J = 0$$

So $\operatorname{Jac}(\bar{A}) = 0$. It remains to convert this into semisimplicity, which is where the Artinian hypothesis is spent: $\bar{A}$ is Artinian (a quotient of the Artinian ring A), and for an Artinian ring $\operatorname{Jac}(\bar{A}) = 0$ forces $\bar{A}$ to be semisimple. Concretely, since $\bar{A}$ is Artinian we may pick finitely many maximal left ideals $\mathfrak{m}_1/J, \dots, \mathfrak{m}_r/J$ whose intersection is already 0 (take a minimal finite subintersection, which exists by the descending chain condition and equals the full intersection $\operatorname{Jac}(\bar{A}) = 0$). The map

$$\bar{A} \longrightarrow \bigoplus_{i=1}^{r} \bar{A}/(\mathfrak{m}_i/J)$$

is injective, since its kernel is $\bigcap_i (\mathfrak{m}_i/J) = 0$. Each summand $\bar{A}/(\mathfrak{m}_i/J)$ is a simple $\bar{A}$-module, so $\bar{A}$ embeds as a submodule of a semisimple module and is therefore semisimple by corollary 51.1.8. Thus $\bar{A}$ is a semisimple $\bar{A}$-module, and by corollary 51.1.9 a semisimple ring. Artin-Wedderburn now applies to $\bar{A}$.

Step 2: the simple modules coincide. Let S be a simple left A-module. By part (2) of theorem 52.1.4, $J = \operatorname{Jac}(A)$ annihilates every simple A-module, so $JS = 0$. Hence the A-action on S factors through the quotient $\bar{A} = A/J$: setting $(\bar{a})s := as$ is well-defined because J acts as zero. The A-submodules and $\bar{A}$-submodules of S are the same subsets (a subgroup of S is A-stable if and only if it is $\bar{A}$-stable, since the actions agree), so S is simple as an $\bar{A}$-module precisely because it is simple as an A-module.

Conversely, let T be a simple left $\bar{A}$-module. Pulling back the action along the surjection $\pi\colon A \twoheadrightarrow \bar{A}$, that is defining $a \cdot t := \pi(a)\, t$, makes T an A-module. Its A-submodules are exactly its $\bar{A}$-submodules (again the two actions have the same invariant subgroups, because π is surjective), so T is simple as an A-module. These two passages are mutually inverse, so the simple A-modules and the simple $\bar{A}$-modules are identified, as we sought to show.

This is the structural role of the radical: it is the exact obstruction one divides out to recover the Wedderburn world. The simple modules of A are unchanged by the passage to $A/\operatorname{Jac}(A)$, so the finite list of simples that a semisimple ring enjoys is available for *any* Artinian ring, read off from its semisimple quotient. What the radical takes away is not the simples but the way they fit together: over A the simples can be glued into indecomposable modules that do not split, and the gluing data lives in $\operatorname{Jac}(A)$. The theorem says that for an Artinian A there are finitely many simple A-modules, one for each simple factor of the Wedderburn decomposition of $A/\operatorname{Jac}(A)$, and this is the starting point for the character theory and the block theory developed later.

The special case $\operatorname{Jac}(A) = 0$ returns to chapter 51.

Corollary 52.1.10: Semisimplicity via the Radical

Let A be a left Artinian ring. Then A is semisimple if and only if $\operatorname{Jac}(A) = 0$.

***Proof*:**
If A is semisimple, then by corollary 51.1.9 it is a semisimple left module over itself, so its radical (the intersection of its maximal left ideals) is 0; that is, $\mathrm{Jac}(A) = \mathrm{rad}({}_AA) = 0$. Indeed, a semisimple module is a direct sum of simples, and its radical, the intersection of maximal submodules, is 0: writing $A = \bigoplus_i I_i$ as a sum of minimal left ideals (lemma 51.1.10), each $\bigoplus_{j\neq i} I_j$ is a maximal submodule, and their intersection is 0.

Conversely, if $\mathrm{Jac}(A) = 0$, then $A = A/\mathrm{Jac}(A)$, and by theorem 52.1.9 the quotient $A/\mathrm{Jac}(A)$ is semisimple; hence A itself is semisimple, completing the proof.

The corollary makes the radical the precise measure of the failure of semisimplicity: A is semisimple exactly when the measurement returns zero, and Artin-Wedderburn (theorem 51.2.16) describes what A looks like in that case, namely a product $M_{n_1}(D_1) \times \cdots \times M_{n_k}(D_k)$. For a general Artinian A, the same product describes $A/\mathrm{Jac}(A)$ rather than A, and the difference between A and this product is stored in the nilpotent ideal $\mathrm{Jac}(A)$. The truncated-polynomial algebra $k[x]/(x^n)$ with $n \geq 2$ is the simplest case where the measurement is nonzero: its radical $(\bar{x})$ is a nonzero nilpotent ideal, so it is not semisimple, even though its semisimple quotient is the field k.

The most consequential source of non-semisimple algebras in representation theory is the group algebra $k[G]$ when the characteristic of k divides the order of the group. Maschke's theorem guarantees semisimplicity precisely when $\mathrm{char}(k) \nmid |G|$; the radical detects, and measures, the failure in the opposite case.

Example 52.1.11: The Radical of a Modular Group Algebra
Let $G = \mathbb{Z}/p\mathbb{Z}$ be cyclic of order p and let k be a field. Writing g for a generator, the group algebra is

$$k[G] \cong k[t]/(t^p - 1)$$

via $g \mapsto t$, since g has order p. The structure of $\mathrm{Jac}(k[G])$ depends entirely on whether $\mathrm{char}(k)$ divides $|G| = p$.

The modular case $\mathrm{char}(k) = p$. In characteristic p the Frobenius identity gives $t^p - 1 = (t-1)^p$, so

$$k[G] \cong k[t]/\big((t-1)^p\big) \cong k[s]/(s^p) \qquad (s := t-1)$$

the last isomorphism being the change of variable $s = t - 1$. This is precisely the truncated polynomial algebra of example 52.1.5 with $n = p$, so its radical is

$$\mathrm{Jac}(k[G]) = (s) = (g-1)$$

the ideal generated by $g - 1$, which is the augmentation ideal (the kernel of the augmentation map $k[G] \to k$ sending $g \mapsto 1$). It is nilpotent, $(g-1)^p = g^p - 1 = 0$, and nonzero, so $k[G]$ is not semisimple: Maschke's theorem fails exactly because $p = \mathrm{char}(k)$ divides $|G|$. The unique simple $k[G]$-module is the trivial module k, on which g acts as the identity, so $g - 1$ acts as zero, confirming $\mathrm{Jac}(k[G]) = (g-1)$ annihilates the only simple module.

The coprime case $\mathrm{char}(k) \nmid p$. If the characteristic does not divide p, then the polynomial $t^p - 1$ is separable (its derivative pt^{p-1} is nonzero and shares no root with it), so it has no repeated factors. Over a field containing a primitive pth root of unity ζ it splits as $t^p - 1 = \prod_{i=0}^{p-1}(t - \zeta^i)$, and the Chinese remainder theorem gives

$$k[G] \cong \prod_{i=0}^{p-1} k[t]/(t - \zeta^i) \cong k^p$$

a product of p copies of k, which is semisimple with radical $\mathrm{Jac}(k[G]) = 0$. (Over a field without the roots of unity, $t^p - 1$ still factors into distinct irreducible separable factors and $k[G]$ is a product of finite separable field extensions of k, again semisimple with zero radical.) This is Maschke's theorem in the coprime case, seen through the radical: separability of $t^p - 1$ is exactly the condition $\mathrm{char}(k) \nmid |G|$, and it forces $\mathrm{Jac}(k[G]) = 0$.

The contrast in the two cases is the whole point of the chapter in miniature. When $\mathrm{char}(k) \nmid |G|$ the group algebra is semisimple, its radical is zero, and the representation theory of G over k is governed by Wedderburn and character theory. When $\mathrm{char}(k) \mid |G|$ the radical becomes a nonzero nilpotent ideal, the group algebra acquires indecomposable modules that are not simple, and one enters modular representation theory, where the radical, the indecomposables, and the projective covers built in the following sections are the working tools.

52.2 Indecomposable Modules and Krull-Schmidt

The previous chapter rested on a single organizing principle: over a semisimple ring, every module splits into simple pieces, and Artin-Wedderburn turns that splitting into a matrix description of the ring itself. The trouble is that semisimplicity is a strong hypothesis. The ring $k[x]/(x^2)$ is a two-dimensional k-algebra, and the module $k[x]/(x^2)$ over itself has a proper nonzero submodule $(x)/(x^2)$, yet that submodule has no complement: there is no way to write $k[x]/(x^2) = (x)/(x^2) \oplus N$. So this module does not break into simples at all. Once the semisimple world is left behind, the simple modules stop being the building blocks, and the decomposition theory of lemma 51.1.7 collapses.

What survives is a weaker notion of "building block". A module that cannot be split into two nonzero summands is *indecomposable* (definition 51.1.1), and every module of finite length is at least a finite direct sum of indecomposables, for the trivial reason that one keeps splitting until nothing splits further. The content of this section is that this crude decomposition is in fact canonical: the list of indecomposable summands, taken up to isomorphism, is uniquely determined by the module. This is the Krull-Schmidt theorem, and it is the correct replacement for the semisimple decomposition when simples are no longer available. The engine driving uniqueness is a structural fact about the endomorphism ring of an indecomposable module of finite length, that it is a *local ring*, which is itself a consequence of Fitting's lemma. So the section runs Fitting's lemma to the local-ring theorem to Krull-Schmidt, each result feeding the next.

Throughout, A is an algebra over a field k (the arguments need only that modules have finite length, so the results apply verbatim to modules of finite length over any ring). Modules are left modules. The starting point is worth isolating, since it is the gap between this chapter and the last. A simple module is indecomposable, because a simple module has no proper nonzero submodule at all, let alone a complemented one. The converse fails, and it fails already in dimension two: the $k[x]$-module $k[x]/(x^2)$ has the unique proper nonzero submodule $(x)/(x^2)$, so it is not simple, but that submodule is not a summand (any complement would have to be one-dimensional and x-stable, and $(x)/(x^2)$ is the only such subspace), so the module is indecomposable. An indecomposable module of finite length can therefore sit strictly between "simple" and "decomposable", and it is exactly this middle ground that Krull-Schmidt organizes.

The first tool is a splitting result for a single endomorphism. Given $\varphi \in \mathrm{End}_A(M)$, the iterated kernels $\ker(\varphi) \subseteq \ker(\varphi^2) \subseteq \cdots$ increase and the iterated images $\mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^2) \supseteq \cdots$ decrease. When M has finite length, both chains must stabilize, and Fitting's lemma says that at a common stabilization point the module splits into the eventual kernel and the eventual image.

Lemma 52.2.1: Fitting's Lemma

Let M be an A-module of finite length and let $\varphi \in \mathrm{End}_A(M)$. Then there exists a positive integer n such that

$$M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$$

Consequently, if M is indecomposable, then every $\varphi \in \mathrm{End}_A(M)$ is either nilpotent or an automorphism.

***Proof*:**
Write $\ell = \ell(M)$ for the length of M, which is finite by hypothesis.

Step 1: The kernel and image chains stabilize. The submodules $\ker(\varphi^i)$ form an increasing chain and the submodules $\mathrm{im}(\varphi^i)$ form a decreasing chain:

$$\ker(\varphi) \subseteq \ker(\varphi^2) \subseteq \cdots \qquad \mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^2) \supseteq \cdots$$

A module of finite length is both Noetherian and Artinian, so an increasing chain of submodules cannot strictly ascend more than ℓ times and a decreasing chain cannot strictly descend more than ℓ times. Setting $n = \ell$ makes both chains stationary from index n onward: for all $m \geq n$,

$$\ker(\varphi^m) = \ker(\varphi^n) \qquad \mathrm{im}(\varphi^m) = \mathrm{im}(\varphi^n)$$

Indeed, once the kernel chain repeats, it is stationary forever after: if $\ker(\varphi^i) = \ker(\varphi^{i+1})$ and $x \in \ker(\varphi^{i+2})$, then $\varphi(x) \in \ker(\varphi^{i+1}) = \ker(\varphi^i)$, so $x \in \ker(\varphi^{i+1}) = \ker(\varphi^i)$, giving $\ker(\varphi^{i+2}) = \ker(\varphi^{i+1})$; iterating shows $\ker(\varphi^j) = \ker(\varphi^i)$ for all $j \geq i$. A chain that strictly increased past step ℓ would produce more than ℓ strict inclusions, violating finite length, so the first repeat occurs by step ℓ. The same bound applies to the image chain, and $n = \ell$ dominates both stabilization thresholds.

Step 2: The two submodules intersect trivially. Fix n as above and take $y \in \ker(\varphi^n) \cap \mathrm{im}(\varphi^n)$. Write $y = \varphi^n(x)$ for some $x \in M$. Then $\varphi^n(y) = 0$ gives $\varphi^{2n}(x) = 0$, so $x \in \ker(\varphi^{2n}) = \ker(\varphi^n)$ by the stabilization of the kernel chain. Hence $y = \varphi^n(x) = 0$, and $\ker(\varphi^n) \cap \mathrm{im}(\varphi^n) = 0$.

Step 3: The two submodules span M. Take any $z \in M$. Since $\mathrm{im}(\varphi^n) = \mathrm{im}(\varphi^{2n})$, the element $\varphi^n(z) \in \mathrm{im}(\varphi^n)$ also lies in $\mathrm{im}(\varphi^{2n})$, so $\varphi^n(z) = \varphi^{2n}(w)$ for some $w \in M$. Then

$$z = \varphi^n(w) + \big(z - \varphi^n(w)\big)$$

where $\varphi^n(w) \in \mathrm{im}(\varphi^n)$, and the second term lies in $\ker(\varphi^n)$ because $\varphi^n(z - \varphi^n(w)) = \varphi^n(z) - \varphi^{2n}(w) = 0$. Thus $M = \ker(\varphi^n) + \mathrm{im}(\varphi^n)$, and together with Step 2 this gives the internal direct sum $M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$.

Step 4: The dichotomy for indecomposable M. Suppose now that M is indecomposable. The decomposition $M = \ker(\varphi^n) \oplus \mathrm{im}(\varphi^n)$ forces one of the two summands to be M and the other to be 0. If $\ker(\varphi^n) = M$, then $\varphi^n = 0$, so φ is nilpotent. If instead $\ker(\varphi^n) = 0$ and $\mathrm{im}(\varphi^n) = M$, then φ is injective, since $\ker(\varphi) \subseteq \ker(\varphi^n) = 0$, and φ is surjective, since $\mathrm{im}(\varphi) \supseteq \mathrm{im}(\varphi^n) = M$. An injective and surjective endomorphism is an automorphism. In either case φ is nilpotent or an automorphism, completing the proof.

The decomposition in Fitting's lemma is the "eventual kernel" and "eventual image" of φ, and

it works for any single endomorphism of any finite-length module, indecomposable or not. The sharp consequence appears only in the indecomposable case: an indecomposable module of finite length admits no interesting endomorphisms in the sense that the only two behaviors available to a $\varphi \in \mathrm{End}_A(M)$ are "eventually kills everything" (nilpotent) and "moves everything bijectively" (automorphism). There is no room in between, precisely because any intermediate behavior would produce a nontrivial Fitting decomposition and split the module. This is the mechanism that will make the endomorphism ring so rigid.

To see the dichotomy in a case where it can be checked by hand, take the endomorphism given by multiplication by x on $M = k[x]/(x^3)$. Multiplication by x has kernel $(x^2)/(x^3)$ and image $(x)/(x^3)$, which are not complementary. But the lemma is about a *power*: φ^3 is multiplication by $x^3 = 0$, so $\ker(\varphi^3) = M$ and $\mathrm{im}(\varphi^3) = 0$, giving the trivial decomposition $M = M \oplus 0$. This is the nilpotent branch of the dichotomy, and indeed multiplication by x is nilpotent. Multiplication by $1 + x$, on the other hand, is invertible (with inverse $1 - x + x^2$), landing in the automorphism branch. Every element of $\mathrm{End}_{k[x]}(M)$ is one or the other.

The endomorphism ring $\mathrm{End}_A(M)$ of an indecomposable finite-length module is close to being a division ring but not quite: Schur's lemma (lemma 51.1.5) gave a division ring only for *simple* M, and indecomposable is weaker. The right substitute is that $\mathrm{End}_A(M)$ is a *local ring*. A ring is local when its non-units form a two-sided ideal, equivalently when it has a unique maximal left ideal; the intuition is that "being a non-unit" is closed under addition, so failures of invertibility do not conspire to produce an invertible element. Fitting's lemma is exactly what closes the non-units under addition here, because a non-unit of $\mathrm{End}_A(M)$ is precisely a nilpotent endomorphism, and controlling sums of nilpotents is where the argument lives.

Theorem 52.2.2: Endomorphism Rings of Indecomposables are Local

Let M be a nonzero indecomposable A-module of finite length. Then $\mathrm{End}_A(M)$ is a local ring: the set of non-units of $\mathrm{End}_A(M)$ is a two-sided ideal, and it consists exactly of the nilpotent endomorphisms of M.

***Proof*:**

Write $E = \mathrm{End}_A(M)$ and let $\mathfrak{m} \subseteq E$ be the set of endomorphisms that are not units, that is, not automorphisms of M.

Step 1: The non-units are the nilpotents. By lemma 52.2.1, every $\varphi \in E$ is either an automorphism or nilpotent, and these are mutually exclusive (a nilpotent $\varphi \neq 0$ kills some nonzero element, and $\varphi = 0$ is not invertible since $M \neq 0$). Hence $\mathfrak{m}$ is exactly the set of nilpotent endomorphisms.

Step 2: $\mathfrak{m}$ is closed under left and right multiplication by E. Let $\varphi \in \mathfrak{m}$, so φ is not an automorphism, and let $\psi \in E$ be arbitrary. If $\psi\varphi$ were an automorphism, then φ would be injective (as $\psi\varphi$ is) and ψ surjective; an injective endomorphism of a finite-length module is bijective (its image has the same length as M, hence equals M), so φ would be an automorphism, a contradiction. Thus $\psi\varphi \in \mathfrak{m}$. Symmetrically, if $\varphi\psi$ were an automorphism, then φ would be surjective, hence bijective by the length argument, again contradicting $\varphi \in \mathfrak{m}$. So $\varphi\psi \in \mathfrak{m}$, and $\mathfrak{m}$ absorbs multiplication on both sides.

Step 3: $\mathfrak{m}$ is closed under addition. This is the step that uses indecomposability. Let $\varphi, \psi \in \mathfrak{m}$ and suppose, for contradiction, that $\varphi + \psi$ is an automorphism. Set

$$\alpha = (\varphi + \psi)^{-1}\varphi \qquad \beta = (\varphi + \psi)^{-1}\psi$$

so that $\alpha+\beta=(\varphi+\psi)^{-1}(\varphi+\psi)=\mathrm{id}_M$. By Step 2, $\mathfrak{m}$ absorbs left multiplication, so $\alpha,\beta\in\mathfrak{m}$; in particular α is nilpotent, say $\alpha^r=0$. From $\beta=\mathrm{id}_M-\alpha$ the standard geometric-series identity gives an inverse for β:

$$(\mathrm{id}_M-\alpha)\big(\mathrm{id}_M+\alpha+\alpha^2+\cdots+\alpha^{r-1}\big)=\mathrm{id}_M-\alpha^r=\mathrm{id}_M$$

so $\beta=\mathrm{id}_M-\alpha$ is an automorphism of M. But $\beta\in\mathfrak{m}$ means β is not an automorphism, a contradiction. Hence $\varphi+\psi\in\mathfrak{m}$.

Step 4: Conclusion. Steps 2 and 3 show $\mathfrak{m}$ is a two-sided ideal of E, and Step 1 identifies it as the set of non-units. A ring whose non-units form a two-sided ideal is local: any element outside $\mathfrak{m}$ is a unit, so $\mathfrak{m}$ is the unique maximal left ideal (a proper left ideal contains no units, hence lies in $\mathfrak{m}$). Therefore $E=\mathrm{End}_A(M)$ is local, as we sought to show.

The theorem sharpens Schur's lemma in exactly the direction needed. For a simple module, lemma 51.1.5 gave a division ring, where every nonzero element is a unit. For an indecomposable module of finite length, one gets the next best thing: a local ring, where the non-units are corralled into a single ideal and every element outside it is a unit. The residue $\mathrm{End}_A(M)/\mathfrak{m}$ is a division ring, and one can think of the local ring as a division ring with a nilpotent "fuzz" $\mathfrak{m}$ attached. The content used below is the geometric series in Step 3, which turns "id_M minus a nilpotent" into a unit; this is what will let one element of a decomposition be swapped for another in the exchange argument below.

The running example makes the local structure explicit.

Example 52.2.3: The Endomorphism Ring of a Truncated Polynomial Module
Fix $n\geq 1$ and let $M=k[x]/(x^n)$, viewed as a module over $A=k[x]$ (equivalently over $k[x]/(x^n)$, which acts through the same operators). This module is indecomposable of length n: its submodules are exactly the ideals $(x^j)/(x^n)$ for $0\leq j\leq n$, forming a single chain

$$0=(x^n)/(x^n)\subseteq(x^{n-1})/(x^n)\subseteq\cdots\subseteq(x)/(x^n)\subseteq M$$

and a chain of submodules has no way to split off a complementary summand (a decomposition $M=M_1\oplus M_2$ with both $M_i\neq 0$ would give two submodules neither containing the other).

Every A-endomorphism of M is multiplication by some polynomial: since M is generated by the image of 1, a homomorphism φ is determined by $\varphi(1)=\overline{f(x)}$, and then $\varphi(\overline{g})=\overline{gf}$. So

$$\mathrm{End}_A(M)\cong k[x]/(x^n)$$

as rings, the isomorphism sending φ to $\varphi(1)$. This is a local ring with maximal ideal $\mathfrak{m}=(x)/(x^n)$: an element $\overline{f}=\overline{a_0+a_1x+\cdots+a_{n-1}x^{n-1}}$ is a unit if and only if $a_0\neq 0$ (with inverse computed by the geometric series when $a_0=1$), and it is nilpotent if and only if $a_0=0$. The non-units are precisely the nilpotents, matching theorem 52.2.2, and $\mathrm{End}_A(M)/\mathfrak{m}\cong k$ is the residue division ring (here a field, since A is commutative).

The local endomorphism ring is now used to prove the main theorem. Existence of a decomposition into indecomposables is easy, by induction on length; the content is uniqueness. The classical route to uniqueness is an *exchange argument*: given two decompositions of the same module, one shows that each indecomposable summand of the first can be swapped into the second, one at a time, without changing the ambient module, and the local endomorphism rings are exactly what make each swap

possible. The theorem is due to Krull and Schmidt for finite groups and finite-length modules, with Azumaya's extension to any module that is a direct sum of submodules with local endomorphism rings.

Theorem 52.2.4: Krull-Schmidt(-Azumaya)

Let M be a nonzero A-module of finite length. Then:

1. M is a finite direct sum of indecomposable submodules,
$$M = M_1 \oplus M_2 \oplus \cdots \oplus M_r$$
with each M_i indecomposable.
2. This decomposition is unique up to isomorphism and reordering: if
$$M = M_1 \oplus \cdots \oplus M_r = N_1 \oplus \cdots \oplus N_s$$
are two decompositions into indecomposable submodules, then $r = s$ and there is a permutation σ of $\{1, \dots, r\}$ with $M_i \cong N_{\sigma(i)}$ for every i.

***Proof*:**

1. *Existence.* Argue by induction on the length $\ell(M)$. If M is indecomposable, then $M = M$ is already such a decomposition, with one summand. Otherwise $M = M_1 \oplus M_2$ with both M_i nonzero, and then $\ell(M_1), \ell(M_2) < \ell(M)$ because length is additive over direct sums and both summands are nonzero (hence of positive length). By the inductive hypothesis each M_i is a finite direct sum of indecomposables, and concatenating the two lists expresses M as a finite direct sum of indecomposables. The base case $\ell(M) = 1$ is a simple, hence indecomposable, module. This proves existence.
2. *Uniqueness.* Suppose
$$M = M_1 \oplus \cdots \oplus M_r = N_1 \oplus \cdots \oplus N_s$$
with all M_i and N_j indecomposable of finite length, so each $\mathrm{End}_A(M_i)$ and $\mathrm{End}_A(N_j)$ is local by theorem 52.2.2. Induct on r. The strategy is to exchange M_1 for one of the N_j, peel it off both sides, and apply the inductive hypothesis to what remains.

   Let $\iota_i \colon M_i \hookrightarrow M$ and $\pi_i \colon M \twoheadrightarrow M_i$ be the inclusion and projection for the first decomposition, and $\iota'_j \colon N_j \hookrightarrow M$, $\pi'_j \colon M \twoheadrightarrow N_j$ those for the second. These satisfy
$$\sum_{i=1}^{r} \iota_i \pi_i = \mathrm{id}_M \qquad \sum_{j=1}^{s} \iota'_j \pi'_j = \mathrm{id}_M$$
   Restricting the second identity to M_1 and projecting back to M_1 gives, in $\mathrm{End}_A(M_1)$,
$$\mathrm{id}_{M_1} = \pi_1 \Big(\sum_{j=1}^{s} \iota'_j \pi'_j \Big) \iota_1 = \sum_{j=1}^{s} (\pi_1 \iota'_j)(\pi'_j \iota_1)$$
   Now $\mathrm{End}_A(M_1)$ is local, so its non-units form an ideal and cannot sum to the unit id_{M_1}; at least one summand $(\pi_1 \iota'_j)(\pi'_j \iota_1)$ must be a unit of $\mathrm{End}_A(M_1)$. After reindexing the N_j

we may assume this happens for $j = 1$: the composite

$$\theta = (\pi_1\iota_1')(\pi_1'\iota_1)\colon M_1 \longrightarrow M_1$$

is an automorphism of M_1, where $\pi_1'\iota_1\colon M_1 \to N_1$ and $\pi_1\iota_1'\colon N_1 \to M_1$.

Exchange step. Consider the maps

$$f = \pi_1'\iota_1\colon M_1 \to N_1 \qquad g = \pi_1\iota_1'\colon N_1 \to M_1$$

so $gf = \theta$ is an automorphism of M_1. Then f is a split monomorphism, with left inverse $\theta^{-1}g$, since $(\theta^{-1}g)f = \theta^{-1}(gf) = \mathrm{id}_{M_1}$. The endomorphism $e = f\theta^{-1}g\colon N_1 \to N_1$ is then idempotent:

$$e^2 = f\theta^{-1}(gf)\theta^{-1}g = f\theta^{-1}\theta\theta^{-1}g = f\theta^{-1}g = e$$

and its image is $\mathrm{im}(f)$ (from $ef = f\theta^{-1}gf = f$), so $N_1 = \mathrm{im}(e) \oplus \ker(e) = \mathrm{im}(f) \oplus \ker(e)$ is the splitting associated to the idempotent e. But N_1 is indecomposable and $\mathrm{im}(f) \neq 0$ (since f is injective and $M_1 \neq 0$), which forces $\mathrm{im}(f) = N_1$, making f surjective as well. Hence $f\colon M_1 \to N_1$ is an isomorphism, and in particular

$$M_1 \cong N_1$$

Peeling off the summand. It remains to remove M_1 and N_1 from the two decompositions and match the rest. Set $M' = M_2 \oplus \cdots \oplus M_r$, so $M = M_1 \oplus M'$ and M' is the kernel of the projection $\pi_1\colon M \to M_1$. The claim is

$$M = N_1 \oplus M'$$

viewing $N_1 = \iota_1'(N_1) \subseteq M$ as the submodule it names in the second decomposition. The key observation is that the restriction of π_1 to N_1 is an isomorphism onto M_1: on N_1 this restriction is $\pi_1\iota_1' = g$, and $g = \theta f^{-1}$ is a composite of the automorphism θ with the isomorphism f^{-1}, hence itself an isomorphism $N_1 \to M_1$. Granting that $\pi_1|_{N_1}\colon N_1 \to M_1$ is an isomorphism, the claim follows:

- *Trivial intersection.* If $y \in N_1 \cap M'$, then $\pi_1(y) = 0$ because $M' = \ker(\pi_1)$, and $\pi_1|_{N_1}$ is injective, so $y = 0$. Thus $N_1 \cap M' = 0$.
- *Spanning.* Given $z \in M$, set $a = \pi_1(z) \in M_1$. Since $\pi_1|_{N_1}$ is onto M_1, choose $y \in N_1$ with $\pi_1(y) = a$. Then $\pi_1(z - y) = a - a = 0$, so $z - y \in \ker(\pi_1) = M'$, and $z = y + (z - y) \in N_1 + M'$.

Hence $M = N_1 \oplus M'$, establishing the claim.

Induction. Quotienting $M = N_1 \oplus M'$ by the summand N_1 gives $M/N_1 \cong M'$, and quotienting the original $M = N_1 \oplus N'$ by the same submodule N_1 gives $M/N_1 \cong N'$. Therefore

$$M' \cong N'$$

Now M' carries the decomposition $M_2 \oplus \cdots \oplus M_r$ into $r - 1$ indecomposables, and the isomorphism $M' \cong N'$ transports the decomposition $N_2 \oplus \cdots \oplus N_s$ onto M' as a second decomposition into indecomposables. Applying the inductive hypothesis to M', whose first decomposition has $r - 1$ summands, yields $r - 1 = s - 1$, so $r = s$, together with a bijection matching $M_2, \ldots, M_r$ against $N_2, \ldots, N_s$ up to isomorphism. Combined with $M_1 \cong N_1$ from the exchange step, this produces the permutation σ with $M_i \cong N_{\sigma(i)}$ for all i. The base case $r = 1$ has $M = M_1$ indecomposable, forcing $s = 1$ and $N_1 = M$, completing the induction and the proof.

The theorem says that the finite-length representation theory of *any* algebra, semisimple or not, has canonical building blocks: the indecomposable modules. Over a semisimple algebra these are the simple modules and Krull-Schmidt recovers the decomposition of lemma 51.1.7, but the statement here needs no semisimplicity. What it does need is finite length, and the two places that hypothesis enters are worth marking. Finite length gave the Fitting decomposition (via the ascending and descending chain conditions), which produced the local endomorphism rings; and finite length is what let "injective endomorphism" upgrade to "automorphism" at several points. Drop finiteness and uniqueness can fail. A concrete failure: over the ring $R = \mathbb{R}[x, y, z]/(x^2 + y^2 + z^2 - 1)$ of real polynomial functions on the 2-sphere, the module R^3 splits both as $R \oplus P$, where P is the (indecomposable, non-free) module of tangent vector fields, and as $R \oplus R \oplus R$; the two decompositions have non-isomorphic summands, so uniqueness is lost once the summands are no longer of finite length. Krull-Schmidt is thus not a formality but a theorem with content tied to its hypotheses.

The exchange argument also explains *why* the answer is unique, not just *that* it is. The reason each M_i has a unique isomorphism partner is that when the identity of M_1 is written as a sum of composites through the N_j, locality of $\mathrm{End}_A(M_1)$ forbids the sum from being "spread out" among non-units; one composite must already be invertible, and that single composite pins down the partner. Locality is doing the work that a division ring did in the simple case, and it is the exact amount of structure required.

Reading off the multiplicities gives the invariant form of the theorem that is used in practice.

Corollary 52.2.5: Uniqueness of Multiplicities

Let M be a nonzero A-module of finite length. For each isomorphism class of indecomposable module I, the number of summands isomorphic to I appearing in a decomposition of M into indecomposables is independent of the decomposition. That is, writing

$$M \cong I_1^{\oplus m_1} \oplus I_2^{\oplus m_2} \oplus \cdots \oplus I_t^{\oplus m_t}$$

with the I_j pairwise non-isomorphic indecomposables, the classes $I_1, \ldots, I_t$ and the multiplicities $m_1, \ldots, m_t$ are uniquely determined by M.

***Proof*:**
By theorem 52.2.4, any two decompositions of M into indecomposables have the same number of summands and are matched by a permutation σ respecting isomorphism type. Grouping the summands of a decomposition by isomorphism class, the multiplicity of a class I is the number of indices i with $M_i \cong I$. Since σ carries each M_i to an $N_{\sigma(i)} \cong M_i$ and is a bijection, it restricts to a bijection between the summands isomorphic to I in the first decomposition and those isomorphic to I in the second. Hence the two decompositions assign I the same multiplicity, and this holds for every isomorphism class I. The set of classes that occur and their multiplicities are therefore invariants of M, completing the proof.

The multiplicities m_j are the numbers one computes when decomposing a representation, and the corollary is what guarantees the computation has a well-defined answer regardless of the method used to obtain it. In the language of the Grothendieck-style count, M determines a formal $\mathbb{N}$-linear combination $\sum_j m_j[I_j]$ of indecomposable classes, and two modules are isomorphic if and only if these combinations agree. This is the precise sense in which the indecomposables are a basis for the finite-length modules of A.

The full classification is transparent for $A = k[x]/(x^n)$, where the indecomposables can be listed and the uniqueness of multiplicities checked against an explicit computation.

Example 52.2.6: Modules over the Truncated Polynomial Algebra $k[x]/(x^n)$

Fix $n \geq 1$ and let $A = k[x]/(x^n)$. A finite-dimensional A-module is the same datum as a finite-dimensional k-vector space V together with a k-linear operator T, the action of the class of x, satisfying $T^n = 0$, so that T is nilpotent of nilpotency index at most n. Being finite-dimensional over k, every such module has finite length, so Krull-Schmidt applies.

The indecomposables. Since A is a quotient of the principal ideal domain $k[x]$, the structure theorem for finitely generated modules over $k[x]$ describes every finite-length A-module as a direct sum of cyclic modules $k[x]/(x^m)$. Only the exponents $1 \leq m \leq n$ occur, because x^n annihilates the module. Each

$$J_m := k[x]/(x^m) \qquad 1 \leq m \leq n$$

is indecomposable: as in example 52.2.3, its submodules form the single chain $0 \subseteq (x^{m-1}) \subseteq \cdots \subseteq (x) \subseteq J_m$, which admits no splitting into two nonzero summands. So the indecomposable A-modules are exactly

$$J_1, J_2, \ldots, J_n$$

up to isomorphism, with $\dim_k J_m = m$; these are the Jordan blocks for the nilpotent operator, J_m being a single Jordan block of size m with eigenvalue 0. There are precisely n of them.

A decomposition and its uniqueness. Take $n = 3$ and the module $M = A \oplus J_1$, that is, $V = k^4$ with the operator

$$T = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

a single Jordan block of size 3 in the top-left together with a 1×1 zero block. As an A-module,

$$M \cong J_3 \oplus J_1$$

with multiplicities $m_3 = 1$, $m_1 = 1$, and $m_2 = 0$. corollary 52.2.5 asserts these multiplicities are forced by M, and they can be read off invariantly from the ranks of powers of T, which do not depend on any chosen decomposition. The number of Jordan blocks of size at least j equals $\operatorname{rank}(T^{j-1}) - \operatorname{rank}(T^j)$, so the multiplicity of J_m is

$$m_m = \operatorname{rank}(T^{m-1}) - 2\operatorname{rank}(T^m) + \operatorname{rank}(T^{m+1})$$

Here $\operatorname{rank}(T^0) = \operatorname{rank}(\mathrm{id}) = 4$, $\operatorname{rank}(T) = 2$, $\operatorname{rank}(T^2) = 1$, and $\operatorname{rank}(T^3) = 0$. Substituting,

$$m_1 = 4 - 2 \cdot 2 + 1 = 1, \qquad m_2 = 2 - 2 \cdot 1 + 0 = 0, \qquad m_3 = 1 - 2 \cdot 0 + 0 = 1$$

recovering $M \cong J_3 \oplus J_1$. Since the ranks $\operatorname{rank}(T^j)$ are intrinsic to the operator T (hence to the module M), the multiplicities are intrinsic too, exactly as Krull-Schmidt predicts. Any presentation of M as a direct sum of J_m's, arrived at by any change of basis, must yield one copy of J_3, one copy of J_1, and no copy of J_2.

52.3 Idempotents, Projective Covers, and the Regular Representation

The Artin–Wedderburn theorem told us how to read off the simple modules of a semisimple algebra: they are exactly the summands of the regular module A, because a semisimple A splits as a direct sum of minimal left ideals and each minimal left ideal is simple. Once A is not semisimple this picture breaks. The regular module A still decomposes into indecomposable summands (the algebra is finite-dimensional, so a dimension count forces any module to be a finite direct sum of indecomposables), but those summands are no longer simple. They are the *indecomposable projective modules*, and the simple modules sit one level down, as their tops. This section builds the dictionary that replaces the semisimple one: the summands of A are cut out by a decomposition $1 = e_1 + \cdots + e_n$ of the identity into primitive orthogonal idempotents, each summand Ae_i is an indecomposable projective covering a single simple module, and the whole configuration is governed, through the quotient $A/\mathrm{Jac}(A)$, by the semisimple theory of chapter 51.

Throughout this section A is a finite-dimensional algebra over a field k (so in particular A is left Artinian and $\mathrm{Jac}(A)$ is nilpotent). Modules are left modules. The tool that transports information from the semisimple quotient $A/\mathrm{Jac}(A)$ back up to A is the lifting of idempotents, so that is where we begin.

The projection $\pi\colon A \to A/\mathrm{Jac}(A)$ collapses the radical. A decomposition of $A/\mathrm{Jac}(A)$ into a sum of simple summands is a statement about idempotents in $A/\mathrm{Jac}(A)$, and to pull such a decomposition back to A we need to produce idempotents in A that reduce to the given ones. The obstruction is that a preimage of an idempotent need not be idempotent. The nilpotence of $\mathrm{Jac}(A)$ removes the obstruction: a Newton-style correction converts any element that is idempotent modulo $\mathrm{Jac}(A)$ into a genuine idempotent lying over it.

Theorem 52.3.1: Lifting Idempotents Modulo the Radical

Let A be a finite-dimensional k-algebra and write $J = \mathrm{Jac}(A)$. Let $\pi\colon A \to A/J$ be the quotient map.

1. If $\bar{e} \in A/J$ satisfies $\bar{e}^2 = \bar{e}$, then there exists an idempotent $e \in A$ with $\pi(e) = \bar{e}$.
2. If $\bar{e}_1, \ldots, \bar{e}_m \in A/J$ are pairwise orthogonal idempotents with $\bar{e}_1 + \cdots + \bar{e}_m = \bar{1}$, then there exist pairwise orthogonal idempotents $e_1, \ldots, e_m \in A$ with $\pi(e_i) = \bar{e}_i$ and $e_1 + \cdots + e_m = 1$.

***Proof*:**

Since A is left Artinian, $J = \mathrm{Jac}(A)$ is nilpotent by theorem 52.1.8; fix N with $J^N = 0$.

Step 1: Lifting a single idempotent. Choose any $a \in A$ with $\pi(a) = \bar{e}$. Then $a^2 - a \in J$, since $\pi(a^2 - a) = \bar{e}^2 - \bar{e} = 0$. The idea is to correct a inside the coset $a + J$ until the error $a^2 - a$ is pushed into higher and higher powers of J, where it eventually vanishes. Set

$$e = 3a^2 - 2a^3$$

which lies in $a + J$, since $e - a = (3a^2 - 2a^3) - a = -(2a - 1)(a^2 - a) \in J$, so $\pi(e) = \bar{e}$. A direct

computation gives

$$e^2 - e = (3a^2 - 2a^3)^2 - (3a^2 - 2a^3) = (a^2 - a)^2\,(4a^2 - 4a - 3)$$

Writing $u = a^2 - a \in J$, this says $e^2 - e \in (u^2) \subseteq J^2$. Thus the operation $a \mapsto 3a^2 - 2a^3$ sends an element whose defect $a^2 - a$ lies in J^r to an element whose defect lies in J^{2r}, while staying in the same coset modulo J. Starting from $a_0 = a$ with defect in J^1 and iterating,

$$a_{t+1} = 3a_t^2 - 2a_t^3$$

produces $a_t \in a + J$ whose defect $a_t^2 - a_t$ lies in J^{2^t}. Once $2^t \geq N$ we have $a_t^2 - a_t \in J^N = 0$, so $e := a_t$ is a genuine idempotent with $\pi(e) = \bar{e}$. This proves (1).

Step 2: Lifting an orthogonal family. We argue by induction on m. For $m = 1$ the statement is $e_1 = 1$, which is immediate. Suppose the result holds for families of size $m-1$, and let $\bar{e}_1, \dots, \bar{e}_m$ be pairwise orthogonal idempotents summing to $\bar{1}$. Apply the inductive hypothesis to the shorter orthogonal family $\bar{e}_1, \dots, \bar{e}_{m-2}, \bar{e}_{m-1} + \bar{e}_m$ (its members are pairwise orthogonal idempotents summing to $\bar{1}$, since $\bar{e}_{m-1}$ and $\bar{e}_m$ are orthogonal). This yields pairwise orthogonal idempotents $e_1, \dots, e_{m-2}, f \in A$ lifting them, with $e_1 + \cdots + e_{m-2} + f = 1$ and $\pi(f) = \bar{e}_{m-1} + \bar{e}_m$.

It remains to split f. Consider the algebra fAf, which has identity element f. Its radical is $\mathrm{Jac}(fAf) = fJf$, and the reduction $fAf \to fAf/fJf$ identifies with the corner $\bar{f}(A/J)\bar{f}$ of the semisimple algebra A/J, where $\bar{f} = \bar{e}_{m-1} + \bar{e}_m$. In that corner, $\bar{e}_{m-1}$ and $\bar{e}_m$ are orthogonal idempotents summing to the identity $\bar{f}$. Applying part (1) inside the finite-dimensional algebra fAf to the idempotent $\bar{e}_{m-1} \in fAf/fJf$ produces an idempotent $e_{m-1} \in fAf$ with $\pi(e_{m-1}) = \bar{e}_{m-1}$. Set $e_m = f - e_{m-1}$. Then e_m is idempotent, since

$$e_m^2 = (f - e_{m-1})^2 = f - 2e_{m-1} + e_{m-1} = f - e_{m-1} = e_m$$

using $fe_{m-1} = e_{m-1}f = e_{m-1}$ (because $e_{m-1} \in fAf$) and $e_{m-1}^2 = e_{m-1}$; moreover $\pi(e_m) = \bar{f} - \bar{e}_{m-1} = \bar{e}_m$, and $e_{m-1}e_m = e_{m-1}f - e_{m-1}^2 = e_{m-1} - e_{m-1} = 0$, with $e_m e_{m-1} = 0$ symmetrically. Finally $e_{m-1}, e_m \in fAf$ are orthogonal to each of $e_1, \dots, e_{m-2}$, since f is, and $e_1 + \cdots + e_{m-2} + e_{m-1} + e_m = e_1 + \cdots + e_{m-2} + f = 1$. This completes the induction and the proof.

The polynomial $3a^2 - 2a^3$ is the second Newton iterate for the equation $x^2 - x = 0$; the quadratic doubling of the exponent is exactly Newton's quadratic convergence, made to terminate by nilpotence rather than to converge by a metric. The content of the theorem is that the arithmetic of idempotents in A is completely controlled by the arithmetic of idempotents in the semisimple quotient $A/\mathrm{Jac}(A)$: any way of splitting the identity in $A/\mathrm{Jac}(A)$ lifts to a way of splitting it in A, so the summand structure of the regular module is governed from below by Artin–Wedderburn. The next result turns this into a decomposition of A itself.

Before stating it, recall the mechanism from example 51.2.10: an idempotent $e \in A$ produces a direct sum decomposition $A = Ae \oplus A(1-e)$ of the regular module, because every $a \in A$ writes uniquely as $a = ae + a(1-e)$ with $ae \in Ae$ and $a(1-e) \in A(1-e)$. More generally an orthogonal decomposition $1 = e_1 + \cdots + e_n$ gives $A = Ae_1 \oplus \cdots \oplus Ae_n$. The summand Ae_i is indecomposable precisely when e_i cannot be split further, which is the meaning of *primitive*. Pushing the splitting as far as it will go decomposes the regular module into indecomposables.

Theorem 52.3.2: Primitive Idempotent Decomposition of the Regular Module

Let A be a finite-dimensional k-algebra. Then the identity admits a decomposition

$$1 = e_1 + e_2 + \cdots + e_n$$

into pairwise orthogonal primitive idempotents, and correspondingly the regular module decomposes as

$$A = Ae_1 \oplus Ae_2 \oplus \cdots \oplus Ae_n$$

where each Ae_i is an indecomposable projective left A-module. For an idempotent $e \in A$ with $e \neq 0$, the summand Ae is indecomposable if and only if e is primitive, if and only if the corner algebra eAe has no idempotents other than 0 and e.

***Proof*:**

Step 1: Idempotent decompositions correspond to direct-sum decompositions. Let $e \in A$ be an idempotent. Direct summands of the module Ae correspond to idempotents of its endomorphism ring: if $Ae = P \oplus Q$, the projection onto P along Q is an idempotent $\varepsilon \in \mathrm{End}_A(Ae)$, and conversely an idempotent $\varepsilon \in \mathrm{End}_A(Ae)$ splits $Ae = \varepsilon(Ae) \oplus (1-\varepsilon)(Ae)$. By the same computation as in lemma 51.2.3, the map $eAe \to \mathrm{End}_A(Ae)$ sending eae to right multiplication $x \mapsto x(eae)$ is a ring isomorphism

$$\mathrm{End}_A(Ae) \cong (eAe)^{\mathrm{op}}$$

The idempotents of $(eAe)^{\mathrm{op}}$ are the idempotents of eAe. So Ae decomposes nontrivially if and only if eAe has an idempotent other than 0 and $e = 1_{eAe}$. Writing such an idempotent as g and its complement $e - g$ (which is idempotent and orthogonal to g, by the computation in Step 2 of theorem 52.3.1), the decomposition $Ae = Ag \oplus A(e-g)$ corresponds to the refinement $e = g + (e-g)$ of e into orthogonal idempotents. Thus e is primitive (cannot be written as a sum of two nonzero orthogonal idempotents) if and only if eAe has no idempotent besides $0, e$, if and only if Ae is indecomposable. This proves the final three-way equivalence.

Step 2: The decomposition terminates. Start from 1. If 1 is primitive, take $n = 1$. Otherwise $1 = f + f'$ with f, f' nonzero orthogonal idempotents, giving $A = Af \oplus Af'$ with both summands nonzero. Since A is finite-dimensional and the summands Af, Af' are proper (each has strictly smaller k-dimension than A, as the other is nonzero), repeating the splitting on any summand that is still decomposable strictly decreases dimension at each step and so must stop. When it stops, every summand Ae_i is indecomposable, so by Step 1 each e_i is primitive. The resulting $e_1, \ldots, e_n$ are pairwise orthogonal (an idempotent split off from a corner Ae is orthogonal to every idempotent orthogonal to e) and sum to 1.

Step 3: Projectivity. Each Ae_i is a direct summand of the free module A, hence projective. A direct summand of a free module is projective because the splitting $A = Ae_i \oplus A(1-e_i)$ exhibits Ae_i as a retract of A, and retracts of free modules satisfy the lifting property defining projectivity. The general statement is proved in the companion volume, [21, Equivalencies for Projective Modules]. This gives the decomposition of A into indecomposable projectives, completing the proof.

The decomposition $A = \bigoplus_i Ae_i$ is the non-semisimple replacement for the Wedderburn splitting of a semisimple algebra into minimal left ideals. In the semisimple case each Ae_i was already simple, and the e_i were the matrix units picking out columns of the matrix blocks (proposition 51.2.5). In

general each Ae_i is only indecomposable, and it will turn out to have a whole composition series rather than length one. The indecomposable summands that appear are the objects the rest of the section studies, so they deserve a name.

Definition 52.3.3: Indecomposable Projective Module

Let A be a finite-dimensional k-algebra and $1 = e_1 + \cdots + e_n$ a decomposition of the identity into primitive orthogonal idempotents. The indecomposable projective left A-modules are the summands

$$P_i = Ae_i$$

Its *radical* is $\operatorname{rad}(P_i) = \operatorname{Jac}(A)\, P_i$, and its *top* (or *head*) is the quotient

$$\operatorname{top}(P_i) = P_i/\operatorname{rad}(P_i) = Ae_i/\operatorname{Jac}(A)Ae_i$$

The module P_i is called the *projective cover* of its top; the top is a simple module.

The claim that the top is simple is the hinge of the whole correspondence, so we verify it at once. Reducing modulo $\operatorname{Jac}(A)$ turns the primitive idempotent e_i into a primitive idempotent $\bar{e}_i \in A/\operatorname{Jac}(A)$, and over the semisimple algebra $A/\operatorname{Jac}(A)$ a primitive idempotent cuts out a simple module.

Example 52.3.4: The Top of Ae_i

Let $A = k[x]/(x^3)$, a local algebra with $\operatorname{Jac}(A) = (x)/(x^3)$. Here 1 is the only nonzero idempotent (a commutative local ring has no idempotents besides 0 and 1), so the identity decomposition is trivial, $n = 1$ and $e_1 = 1$, giving a single indecomposable projective $P_1 = A$. Its radical is $\operatorname{rad}(P_1) = \operatorname{Jac}(A)\, A = (x)/(x^3)$, and its top is

$$P_1/\operatorname{rad}(P_1) = \big(k[x]/(x^3)\big)\big/\big((x)/(x^3)\big) \cong k[x]/(x) = k$$

a one-dimensional, hence simple, module. So the single projective $P_1 = A$ (of dimension 3) covers the single simple module k (of dimension 1); the two extra dimensions live in the radical $\operatorname{rad}(P_1)$, whose composition factors are again copies of k. This is the smallest example in which a projective indecomposable is strictly larger than the simple it covers.

The passage $P_i \mapsto \operatorname{top}(P_i)$ from indecomposable projectives to simple modules, and its reverse, is the organizing principle of non-semisimple representation theory. Simple modules are visible in the semisimple quotient $A/\operatorname{Jac}(A)$, where Artin–Wedderburn counts them; primitive idempotents in A are the summands of the regular module; and lifting idempotents connects the two. The following theorem assembles these into a single correspondence.

Theorem 52.3.5: Simples, Indecomposable Projectives, and Primitive Idempotents

Let A be a finite-dimensional k-algebra, and let $1 = e_1 + \cdots + e_n$ be a decomposition of the identity into primitive orthogonal idempotents. There are mutually inverse bijections among the following three finite sets:

1. isomorphism classes of simple left A-modules;
2. isomorphism classes of indecomposable projective left A-modules;
3. conjugacy classes of primitive idempotents of A, where e and e' are conjugate if $e' = ueu^{-1}$ for a unit $u \in A^\times$.

The bijection from (2) to (1) sends $P_i \mapsto S_i := P_i/\mathrm{rad}(P_i)$; the bijection from (3) to (2) sends the class of e_i to $P_i = Ae_i$. If A is split, that is every A-linear endomorphism of a simple A-module is a scalar (for instance if $k = \bar{k}$), the number of classes equals the number of blocks in the Artin–Wedderburn decomposition of $A/\mathrm{Jac}(A)$, and

$$A/\mathrm{Jac}(A) \cong M_{d_1}(k) \times \cdots \times M_{d_r}(k), \qquad d_i = \dim_k S_i$$

where $S_1, \dots, S_r$ are the simple modules and P_i appears $d_i = \dim_k S_i$ times in $A = \bigoplus_i P_i^{\oplus m_i}$.

***Proof*:**

Write $J = \mathrm{Jac}(A)$ and $\bar{A} = A/J$, which is semisimple by theorem 52.1.9.

Step 1: Simple modules are the same for A and $\bar{A}$. A simple A-module S is annihilated by J: the submodule $JS \subseteq S$ is either 0 or S, and $JS = S$ is impossible by Nakayama's lemma (lemma 52.1.7, applied to the cyclic module S: $JS = S$ would force $S = 0$). Hence $JS = 0$ and S is an $\bar{A}$-module; conversely every $\bar{A}$-module is an A-module through $\pi\colon A \to \bar{A}$. Since a submodule for A is the same as a submodule for $\bar{A}$ on a module killed by J, simplicity is preserved in both directions. Thus the simple A-modules are exactly the simple $\bar{A}$-modules, and by corollary 51.1.12 there are finitely many, one for each Wedderburn block of $\bar{A}$.

Step 2: $\mathrm{top}(P_i)$ is simple, and $P_i \mapsto \mathrm{top}(P_i)$ lands in (1). Reducing the decomposition $1 = e_1 + \cdots + e_n$ modulo J gives $\bar{1} = \bar{e}_1 + \cdots + \bar{e}_n$, a decomposition into orthogonal idempotents of $\bar{A}$. Applying the right-exact functor $\bar{A} \otimes_A -$ (equivalently reducing mod J) to $P_i = Ae_i$ gives

$$P_i/JP_i = Ae_i/JAe_i \cong \bar{A}\bar{e}_i$$

as $\bar{A}$-modules. Now $\bar{e}_i$ is primitive in $\bar{A}$: an orthogonal splitting $\bar{e}_i = \bar{g} + \bar{h}$ in $\bar{A}$ would lift, by theorem 52.3.1 applied inside the corner e_iAe_i, to an orthogonal splitting of e_i in A, contradicting primitivity of e_i. Over the semisimple algebra $\bar{A}$ a primitive idempotent generates a simple module, since $\bar{A}\bar{e}_i$ is an indecomposable summand of the semisimple module $\bar{A}$ and indecomposable semisimple means simple. Hence $\mathrm{top}(P_i) = P_i/\mathrm{rad}(P_i) = \bar{A}\bar{e}_i =: S_i$ is simple.

Step 3: The map (2) $\to$ (1) is a bijection. Distinct indecomposable projectives have distinct tops: if $Ae_i \cong Ae_j$ as A-modules then reducing mod J gives $\bar{A}\bar{e}_i \cong \bar{A}\bar{e}_j$, so $S_i \cong S_j$; conversely if $S_i \cong S_j$ then the two primitive idempotents $\bar{e}_i, \bar{e}_j$ generate isomorphic simple summands of $\bar{A}$, hence are conjugate in $\bar{A}$ (two primitive idempotents of a semisimple algebra generating isomorphic simples lie in the same Wedderburn block and differ by an inner automorphism), and a conjugating unit lifts to a unit of A because $\pi\colon A^\times \to \bar{A}^\times$ is surjective (an element of A

mapping to a unit of $\bar{A}$ is itself a unit, since J is nilpotent: if $\bar{a}$ is invertible then a has a left and right inverse modulo the nilpotent ideal J, and $1 + J \subseteq A^\times$). Conjugate idempotents give isomorphic projectives $Ae_i \cong Ae_j$ via right multiplication by the conjugating unit. So $P_i \cong P_j$ if and only if $S_i \cong S_j$, giving a bijection between (2) and (1). Every simple module arises as some S_i: a simple $\bar{A}$-module is a summand of $\bar{A} = \bigoplus_i \bar{A}\bar{e}_i$, hence isomorphic to some $\bar{A}\bar{e}_i = S_i$.

Step 4: Conjugacy classes of primitive idempotents. By the last paragraph, $Ae_i \cong Ae_j$ as modules if and only if e_i and e_j are conjugate in A: one direction lifts a conjugation, the other reduces an isomorphism to a conjugation via $\mathrm{End}_A(A) \cong A^{\mathrm{op}}$ (lemma 51.2.3), under which a module isomorphism $Ae_i \to Ae_j$ is right multiplication by an element u with $ue_iu^{-1} = e_j$. Thus the class of e_i under conjugacy corresponds to the isomorphism class of P_i, giving the bijection between (3) and (2).

Step 5: The split case. When $k = \bar{k}$, the algebra A is split: a simple module S is a quotient of A, hence finite-dimensional, so $\mathrm{End}_A(S)$ is a finite-dimensional division k-algebra by lemma 51.1.5, equal to k by corollary 51.2.19.

Now let A be split. By corollary 51.2.18 applied to the semisimple algebra $\bar{A}$, we have $\bar{A} \cong \prod_{l=1}^{r} M_{d_l}(D_l)$ with each D_l a finite-dimensional division k-algebra, and $\bar{A}$ has exactly r simple modules, the column modules $D_l^{\oplus d_l}$ of the blocks, on which the other blocks act by zero. By Step 1 these are the simple A-modules, and their A-endomorphisms are their $M_{d_l}(D_l)$-endomorphisms, which form the ring D_l^{op} by corollary 51.2.8. The split hypothesis gives $\dim_k D_l = 1$, so $D_l = k$ and the simple modules are $S_l = k^{d_l}$, with $\dim_k S_l = d_l$.

For the multiplicities, let $P_1, \dots, P_r$ be indecomposable projectives with $\mathrm{top}(P_i) = S_i$ (Step 3), and let m_i be the number of j with $Ae_j \cong P_i$, so that $A = \bigoplus_i P_i^{\oplus m_i}$. By Step 3, m_i is also the number of j with $\bar{A}\bar{e}_j \cong S_i$. For simple modules S and T, the space $\mathrm{Hom}_{\bar{A}}(S, T)$ is one-dimensional if $S \cong T$ and zero otherwise, by lemma 51.1.5 and the split hypothesis. So for any decomposition of $\bar{A}$ into finitely many simple submodules, $\dim_k \mathrm{Hom}_{\bar{A}}(S_i, \bar{A})$ is the number of summands isomorphic to S_i. The decomposition $\bar{A} = \bigoplus_j \bar{A}\bar{e}_j$ of Step 2 gives the number m_i. The decomposition of $\bar{A} \cong \prod_l M_{d_l}(k)$ in which each block $M_{d_l}(k)$ is the direct sum of its d_l columns, each isomorphic to k^{d_l}, gives the number d_i. So $m_i = d_i = \dim_k S_i$, as we sought to show.

The correspondence is the reason the count of simple modules is finite and computable: it equals the number of Wedderburn blocks of $A/\mathrm{Jac}(A)$, which Artin–Wedderburn hands us. In the semisimple case the three sets coincide with the columns of the matrix blocks and the map $P_i \mapsto S_i$ is the identity; the passage to a general finite-dimensional algebra keeps the same indexing set but separates the projective P_i from the simple S_i it covers. The word “cover” is precise, and the next definition makes it so. A cover should be the most economical projective surjecting onto a module, with no wasted projective sitting over the radical.

Definition 52.3.6: Superfluous Submodule and Projective Cover

Let A be a ring and M an A-module. A submodule $L \subseteq M$ is *superfluous* (or *small*) if for every submodule $N \subseteq M$ the equality $L + N = M$ forces $N = M$. A surjection $f\colon P \to M$ is *essential* if $\ker f$ is superfluous in P.
A *projective cover* of M is a projective module P together with an essential surjection $f\colon P \to M$; that is, f is surjective, P is projective, and $\ker f$ is superfluous in P.

The condition that $\ker f$ be superfluous is what pins the cover down. Any module has a surjection from a projective (a free module surjects onto it), but without the superfluous condition one could pad the source with a free summand mapping to zero and never have a canonical choice. Superfluousness forbids exactly this padding: no proper submodule of P maps onto M, so P is as small a projective as can surject onto M. Over a finite-dimensional algebra the radical gives a ready source of superfluous submodules, and this makes covers exist and be unique.

Theorem 52.3.7: Existence of Projective Covers

Let A be a finite-dimensional k-algebra and M a finitely generated (equivalently, finite-length) left A-module. Then M has a projective cover $f\colon P \to M$, unique up to isomorphism over M. For a simple module $S = S_i$, the projective cover is the indecomposable projective $P_i = Ae_i$ with its quotient map $P_i \twoheadrightarrow P_i/\mathrm{rad}(P_i) = S_i$.

***Proof*:**
Write $J = \mathrm{Jac}(A)$.

Step 1: JP is superfluous in a finitely generated P. Let P be finitely generated and suppose $JP + N = P$ for a submodule $N \subseteq P$. Then $J \cdot (P/N) = (JP + N)/N = P/N$, so the finitely generated module P/N satisfies $J \cdot (P/N) = P/N$. Nakayama's lemma (the module form, lemma 52.1.7; concretely, using the nilpotence of J: if $J^N = 0$ and $JQ = Q$ then $Q = JQ = J^2Q = \cdots = J^NQ = 0$) forces $P/N = 0$, i.e. $N = P$. Hence JP is superfluous in P.

Step 2: Construction of the cover. The top $\bar{M} = M/JM$ is a module over the semisimple algebra $\bar{A} = A/J$, hence semisimple: $\bar{M} \cong \bigoplus_i S_i^{\oplus c_i}$ for multiplicities $c_i \geq 0$. Set

$$P = \bigoplus_i P_i^{\oplus c_i}$$

with each $P_i = Ae_i$ the indecomposable projective covering S_i. Then $P/JP = \bigoplus_i (P_i/JP_i)^{\oplus c_i} = \bigoplus_i S_i^{\oplus c_i} = \bar{M}$, so the projection $P \to P/JP = \bar{M}$ agrees with $M \to \bar{M}$ on tops. Because P is projective, the surjection $M \twoheadrightarrow \bar{M}$ lifts through $P \to \bar{M}$ to a homomorphism $f\colon P \to M$ with $M \to \bar{M}$ equal to $P \xrightarrow{f} M \to \bar{M}$. The image $f(P)$ satisfies $f(P) + JM = M$ (their images in $\bar{M}$ agree and equal all of $\bar{M}$), and JM is superfluous in M by Step 1 applied to M; hence $f(P) = M$ and f is surjective.

Step 3: f is essential. Let $K = \ker f$. Suppose $K + N = P$ for a submodule N. Then $f(N) = f(P) = M$, so $N + JP \supseteq N + \ker(P \to \bar{M})$ surjects onto $\bar{M} = P/JP$, giving $N + JP = P$; since JP is superfluous (Step 1), $N = P$. Thus K is superfluous and $f\colon P \to M$ is a projective cover.

Step 4: Uniqueness. Let $f\colon P \to M$ and $f'\colon P' \to M$ be two projective covers. Projectivity of P'

lifts f' through f to $g\colon P' \to P$ with $fg = f'$. Then $f(g(P')) = f'(P') = M$, so $g(P') + \ker f = P$; since $\ker f$ is superfluous, $g(P') = P$ and g is surjective. As P' is projective, the surjection g splits, $P' = \ker g \oplus P''$ with $P'' \cong P$; but $\ker g \subseteq \ker f' = \ker(fg)$ is superfluous in P' and a superfluous direct summand is zero (a summand L with complement C satisfies $L + C = P'$, forcing $C = P'$ hence $L = 0$). So g is an isomorphism over M.

Step 5: The simple case. For $M = S_i$ the top $\bar{M} = S_i$ has $c_i = 1$ and all other multiplicities 0, so the construction returns $P = P_i$ with $f\colon P_i \twoheadrightarrow P_i/\mathrm{rad}(P_i) = S_i$, the stated cover, completing the proof.

The theorem certifies the terminology in definition 52.3.3: $P_i \to S_i$ really is *the* projective cover, and every finite-length module is covered by an explicit direct sum of the P_i read off from its top. Uniqueness makes the assignment $M \mapsto P(M)$ well defined and turns the correspondence of theorem 52.3.5 into a computational tool: to find the projective cover of any module, compute its top $M/\mathrm{Jac}(A)M$, decompose that semisimple module into simples, and sum the corresponding P_i. What the projective P_i contributes beyond the simple top S_i is recorded in its composition series, and tabulating those multiplicities across all i produces the central numerical invariant of the algebra.

Definition 52.3.8: Cartan Matrix of an Algebra

Let A be a finite-dimensional k-algebra with simple modules $S_1, \dots, S_r$ and indecomposable projectives $P_1, \dots, P_r$, indexed so that $P_i/\mathrm{rad}(P_i) = S_i$. The *Cartan matrix* of A is the $r \times r$ matrix $C = (C_{ij})$ of nonnegative integers

$$C_{ij} = [P_i : S_j]$$

the multiplicity of the simple module S_j among the composition factors of a composition series of P_i.

The multiplicities $[P_i : S_j]$ are well defined by the Jordan–Hölder theorem, which guarantees the composition factors of a finite-length module are independent of the chosen composition series. The Cartan matrix measures how far A is from semisimple in a single array: when A is semisimple every $P_i = S_i$ has length one, so $C_{ij} = \delta_{ij}$ is the identity matrix, and any off-diagonal or large diagonal entry records simples fused together by the radical. The diagonal entry $C_{ii} = [P_i : S_i]$ is at least 1 (the top contributes one copy of S_i), and $C_{ii} > 1$ signals a self-extension living in the radical. The next example computes the whole apparatus of this section for the smallest non-semisimple algebra with two non-isomorphic simple modules, so that the Cartan matrix is not diagonal.

Before the example, one further point for completeness: the entire theory has a dual half. Everything above was built from the regular module A as a source of projectives; dualizing over k turns projectives into injectives and covers into envelopes.

52.3.9 Remark: The Dual Theory of Injective Envelopes Dual to a projective cover is an *injective envelope*: an injective module E with an essential injection $M \hookrightarrow E$, meaning every nonzero submodule of E meets the image of M nontrivially. Over a finite-dimensional algebra A these exist and are unique, and the duality $D = \mathrm{Hom}_k(-, k)$ carries left A-modules to right A-modules (equivalently left A^{op}-modules), exchanging projective covers of A-modules with injective envelopes of A^{op}-modules. The indecomposable injective A-modules are thus $D(e_i A)$, and each has a simple *socle* (its largest semisimple submodule) rather than a simple top; the socle plays for injectives the role the top plays for projectives. The general theory of injective and projective modules over a ring, including existence of injective envelopes via injective hulls, is developed in the companion volume [21]; the present section uses only the projective side.

Example 52.3.10: Projective Covers over the Upper-Triangular Algebra $T_2(k)$
Let

$$A = T_2(k) = \left\{ \begin{pmatrix} a & b \\ 0 & c \end{pmatrix} : a, b, c \in k \right\}$$

the algebra of 2×2 upper-triangular matrices over a field k, a three-dimensional k-algebra. We work out its idempotents, indecomposable projectives, simple modules, projective covers, and Cartan matrix.

Idempotents. The matrix units

$$e_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad e_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$$

are orthogonal idempotents with $e_1 + e_2 = 1$. Each is primitive: the corner algebra $e_1 A e_1 = k\, e_1 \cong k$ has no idempotents but $0, e_1$, and likewise $e_2 A e_2 \cong k$, so by theorem 52.3.2 both Ae_1 and Ae_2 are indecomposable. Thus $1 = e_1 + e_2$ is a primitive orthogonal decomposition and there are two indecomposable projectives.

The radical. The Jacobson radical is the strictly upper-triangular part,

$$\mathrm{Jac}(A) = \begin{pmatrix} 0 & k \\ 0 & 0 \end{pmatrix}$$

a one-dimensional nilpotent ideal with $\mathrm{Jac}(A)^2 = 0$, and the quotient is

$$A/\mathrm{Jac}(A) \cong \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \cong k \times k$$

a product of two copies of k, confirming via theorem 52.3.5 that there are exactly two simple modules, both one-dimensional.

The indecomposable projectives. Left multiplication by A on e_i gives, with $E_{12} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$,

$$P_1 = Ae_1 = \begin{pmatrix} k & 0 \\ 0 & 0 \end{pmatrix}, \qquad P_2 = Ae_2 = \begin{pmatrix} 0 & k \\ 0 & k \end{pmatrix}$$

so $\dim_k P_1 = 1$ and $\dim_k P_2 = 2$, and indeed $\dim_k A = 1 + 2 = 3 = \dim_k P_1 + \dim_k P_2$, consistent with $A = P_1 \oplus P_2$.

The simple modules and covers. The tops are

$$S_1 = P_1/\mathrm{rad}(P_1) = P_1/\mathrm{Jac}(A)P_1 = P_1 \cong k, \qquad S_2 = P_2/\mathrm{rad}(P_2) = P_2/\mathrm{Jac}(A)P_2 \cong k$$

Here $\mathrm{Jac}(A)P_1 = 0$, so $P_1 = S_1$ is already simple and is its own projective cover, an essential surjection $P_1 \xrightarrow{\cong} S_1$. For P_2, the radical $\mathrm{Jac}(A)P_2 = \left(\begin{smallmatrix} 0 & k \\ 0 & 0 \end{smallmatrix}\right)$ is one-dimensional, and

$$\mathrm{rad}(P_2) = \begin{pmatrix} 0 & k \\ 0 & 0 \end{pmatrix} \cong S_1, \qquad P_2/\mathrm{rad}(P_2) \cong S_2$$

So P_2 is a length-two module with a nonsplit exact sequence

$$0 \to S_1 \to P_2 \to S_2 \to 0$$

and the quotient map $P_2 \twoheadrightarrow S_2$ is the projective cover of S_2, with kernel $\mathrm{rad}(P_2) = S_1$ superfluous in P_2 (it lies inside $\mathrm{Jac}(A)P_2$). The two simple modules S_1 and S_2 are not isomorphic, since e_1 and e_2 act as 1 on one and 0 on the other; the algebra is not semisimple, as $\mathrm{Jac}(A) \neq 0$.

The Cartan matrix. Reading off composition factors: P_1 has the single factor S_1, while P_2 has factors S_2 (its top) and S_1 (its radical). Hence

$$[P_1 : S_1] = 1, \quad [P_1 : S_2] = 0, \quad [P_2 : S_1] = 1, \quad [P_2 : S_2] = 1$$

and the Cartan matrix is the upper-triangular integer matrix

$$C = \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

Its determinant is 1 and its off-diagonal entry $C_{21} = 1$ records the single copy of S_1 that the radical of P_2 contributes: the exact numerical trace of the failure of $T_2(k)$ to be semisimple, where the Cartan matrix would have been the identity.

53

Representation of Finite Groups

All modules will be left R-modules for a not necessarily commutative ring R. Furthermore, all actions will be non-trivial actions unless specified otherwise.

53.1 Representations of Finite Groups

Similarly to how we studied groups and by how they acted on themselves through group-actions (ex. how a group acted on itself by conjugation gave us Sylow's Theorem), we will now try to study groups using *linear algebra*. Many really difficult results in classical group theory will become much easier when studied through this new "representation" of groups (and hence why it is called *representation theory*). Furthermore, vector-spaces afford many more structures than a module structures (ex. a complex vector-space is the starting point for the Nullstellensatz, Complex Geometry, Analysis, and much more!) Hence, one large advantage of Representation theory will be the intersection of many mathematical disciplines which contribute towards our study (and they all feed back on each other).

In this part of the book, G will always be a finite group[1], and k will always be a field. The module-theoretic set-up of this section works over any field, but the results that follow do not: Maschke's theorem and everything downstream of it need $\mathrm{char}(k) \nmid |G|$, and the character theory of section 53.2 needs $k = \mathbb{C}$. Each result states the hypothesis it needs, and section 53.5$\star$ takes up what happens when $\mathrm{char}(k)$ divides $|G|$. We write $\mathrm{Aut}_{k\text{-}\mathbf{Vect}}(V) = \mathrm{GL}(V)$ for the automorphisms of the k-vector space V. Once a basis is chosen and $\dim(V) = n < \infty$, this is isomorphic to $\mathrm{GL}_n(k)$, the group of invertible $n \times n$ matrices over k.

[1] Not sure about where to address infinite groups

Definition 53.1.1: Representation

Let G be a finite group and V a vector space over k. Then a *linear representation* is any homomorphism $\varphi : G \to \mathrm{GL}(V)$. The *degree* of the representation is the dimension of V. A *matrix representation* of G is any homomorphism $\varphi : G \to \mathrm{GL}_n(k)$

Usually, when we say representation we will mean *linear representation*. If a vector-space V has a representation of G, we will often call it a G-representation. To be as rigorous as possible we would say we have a representation of G on V over k, if the context requires it. Just like for group actions, a representation is *faithful* if it is injective. Representations need not be faithful, and most are not: the trivial representation, the sign representation of S_n, and anything inflated from a proper quotient all have kernel.

As usual, we can curry or uncurry an action[2]: we can take $\varphi : G \to \mathrm{GL}(V)$ and make it $G \times V \to V$ where $g : V \to V$ with $v \mapsto g \cdot v$ is linear over k for all g. It is left for the curious to see that this is indeed the proper uncurrying of this action.

Using the definition of $\varphi : G \to \mathrm{GL}(V)$, it is easy to define a representation homomorphism mirroring the definition of group-actions and modules (which are ring actions on abelian groups):

Definition 53.1.2: Representation Homomorphism

Let V, W be two vectors spaces over k with a linear representation by G. Then $\varphi : V \to W$ a *representation homomorphism* if φ k-linear and for any $g \in G$:

$$\varphi(g \cdot v) = g \cdot \varphi(v)$$

such a homomorphism will be called G-linear.

From this perspective, it might be hard to see how our previous discussion on semi-simple rings might give us any insight. We thus introduce a perspective better suited to the results of chapter 51: every representation of G on V over k is in bijective correspondence with all $k[G]$-modules over V, where $k[G]$ represents the *group ring* as seen in section 9.2. This second perspective will also make it easier to define a couple of examples, and so we will delay giving examples till the correspondence has been established. As a reminder, a group ring $k[G]$ over a ring k (which in our case will always be a field) is the set of all formal sums:

$$\sum_{g_i \in G} a_i g_i$$

where addition and multiplication are defined in the natural way[3]:

$$\sum_i^n a_i g_i + \sum b_i g_i = \sum_i (a_i + b_i) g_i$$

$$\left(\sum_i^n a_i g_i \right) \left(\sum b_i g_i \right) = \sum_\ell^n \left(\sum_{\substack{i,j \\ g_i g_j = g_\ell}} a_i b_j \right) g_\ell$$

[2] See remark 4.1.3

[3] A word on this really being a natural way?

Another common notation for group rings is kG, where the brackets are dropped. Several facts about group rings are used below:

1. The group G naturally injects into $k[G]$ by identifying g_i with $1g_i$ which is the formal sum $\sum_j \delta_{ij} g_j$ (where δ_{ij} is the Kronecker delta).
2. The field k naturally injects in $k[G]$ by corresponding an element $a \in k$ with $ag_1 = ae$ where $g_1 = e$ is the identity. If it is clear from context, we will sometimes simply write $a \in k[G]$ if it is understood $a = ae = ag_1$.
3. There is a natural k action on $k[G]$ defined by
$$b \cdot \left(\sum_i a_i g_i \right) = \sum_i (ba_i) g_i$$
due to this, $k[G]$ is a vector space over k with the elements of G as a basis, and hence is finite dimensional if $|G| < \infty$.
4. By definition, The elements of k identified as kg_1 commute with all the elements of $k[G]$, hence it is in the center of $k[G]$: $k \subseteq Z(k[G])$. Thus, $k[G]$ is in fact a k-algebra.
5. The group ring is left adjoint to the unit-group functor $A \mapsto A^\times$ from k-algebras to groups, that is $\mathrm{Hom}_{k\text{-}\mathbf{Alg}}(k[G], A) \cong \mathrm{Hom}_{\mathbf{Grp}}(G, A^\times)$, hence is free with respect to groups, justifying the name "formal sum" for it's elements.

Using these, we show how representations of G on V over k correspond to $k[G]$-modules: let $\varphi : G \to \mathrm{GL}(V)$ be a representation, with $G = \{g_1, g_2, ..., g_n\}$. Thus, each $\varphi(g_i)$ is linear transformation (in particular an automorphism). Define the $k[G]$ action on V by defining:

$$\left(\sum_i^n a_i g_i \right) \cdot v = \left(\sum_i^n a_i \varphi(g_i) \right)(v) = \sum_i^n a_i \varphi(g_i)(v)$$

Then this defines a $k[G]$-module (as should be verified if it does not seem like it). A particular reminder for those who are checking that $\varphi(g_i g_j) = \varphi(g_i) \circ \varphi(g_j)$, since φ is a group homomorphism onto $\mathrm{GL}(V)$ under composition. Notice how this action in fact extends the action of k on $k[G]$ since $a \cdot v = av$ (similarly to how the $F[x]$ action extended the action of F on V in section 14.3).

Conversely, let's say V is an $k[G]$-module. Seeking to make V a vector space over k and finding a group homomorphism $\varphi : G \to \mathrm{GL}(V)$, the first thing is that V is already a K vector-space by limiting to the action of $k \subseteq k[G]$. Furthermore, for each $g \in G$, we can obtain a map $\varphi : V \to V$ by defining:

$$\varphi(g)(v) = g \cdot v$$

Then $\varphi(g)$ is a linear transformation: for $\alpha, \beta \in k$, $v, w \in V$

$$\begin{aligned} \varphi(g)(\alpha v + \beta w) &= g \cdot (\alpha v + \beta w) \\ &= \alpha(g \cdot v) + \beta(g \cdot w) \\ &= \alpha\varphi(g)(v) + \beta\varphi(g)(w) \end{aligned}$$

and by the associativity axiom of modules, we get

$$\varphi(g_i g_j)(v) = (\varphi(g_i) \circ \varphi(g_j))(v)$$

Thus, $\varphi : G \to \mathrm{GL}(V)$ is indeed a group homomorphism, and we have:

$$\left\{ V \text{ an } k[G]\text{-module} \right\} \rightleftarrows \left\{ \begin{array}{c} V \text{ a vector space over } k \\ \text{and} \\ \varphi : G \to \mathrm{GL}(V) \text{ a representation} \end{array} \right\}$$

Note that this also means that this also shows that linear representations also have kernel objects, since modules have kernels. Hence, the kernel of a G-representation homomorphism between V and W is G-invariant.

Definition 53.1.3: Affording Representation

Let V be a $k[G]$-module. Then given the previous discussion, we say that V *affords* the representation φ of G.

Given this new perspective, we can also characterize sub-actions. If we have a $k[G]$-module V, then a $k[G]$-submodule $W \subseteq V$ would have to be a k-submodule, and hence a subspace, but it also has to be closed under the action of g on W, i.e. $g \cdot W \subseteq W$. Hence, any $k[G]$-submodule is a G-stable subspace of V. Conversely, if $W \subseteq V$ is G-stable, then it is closed under the action of G and is a subspace, and hence a $k[G]$-submodule. Hence

$$\left\{ W \subseteq V \text{ a } k[G]\text{-submodule} \right\} \rightleftarrows \left\{ W \subseteq V \text{ a } G\text{-stable subspace} \right\}$$

Next, we should know when two representations are equivalent. Recall that when studying a linear transformation T on V to itself, a basis for V can be found that gives a "canonical form" to the matrix representation of T. Changing basis for V kept V the same, but changed the matrix representation of T up to similarity (i.e. changed the isomorphism from $\mathrm{GL}(V)$ to $\mathrm{GL}_n(k)$). The following is the analogous term:

Definition 53.1.4: Equivalent Representation

Let φ and ψ be two representations of G over k. Then we say these two represetnations are *equivalent* (or *similar*) if the $k[G]$-module affording them are isomorphic as modules. If two representations are not equivalent, they are called *inequivalent* (or *not similar*).

When the field is known[a], if V and W are equivalent (i.e. isomorphic as $k[G]$-modules), then we write $V \cong_G W$.

[a] In most cases, the field will be $\mathbb{C}$

Note that two different representations can mean two different vector-spaces over k. If $\varphi : G \to \mathrm{GL}(V)$ and $\psi : G \to \mathrm{GL}(W)$ are equivalent representations, it would make sense if there is a relation between V and W. If $T : V \to W$ is the $k[G]$-module isomorphism between them, It is a k-module isomorphism, and hence $V \cong W$ as vector spaces, implying $\dim(V) = \dim(W)$. Furthermore, by definition of T, $T(g \cdot v) = g \cdot T(v)$. By definition of the action, we have that $T(\varphi(g)(v)) = \psi(g)(T(v))$, i.e.

$$T \circ \varphi(g) = \psi(g) \circ T \quad \Leftrightarrow \quad T \circ \varphi(g) \circ T^{-1} = \psi(g) \qquad \forall g \in G$$

That is, T is the *simultaneous change of basis* for all $\varphi(g)$, $g \in G$. In terms of matrices, there must exist a fixed invertible matrix P such that for all $g \in G$,

$$P\varphi(g)P^{-1} = \psi(g)$$

The function T (or matrix P) are said to *intertwine* φ and ψ (it gives the rules on how to relate φ and ψ).

Example 53.1.5: Representations

1. Let G be any finite group, V any 1 dimensional vector-space over k. Define the $k[G]$-module structure on V by
$$g \cdot v = v$$
for all $g \in G$, $v \in V$. This called the *trivial representation* of G. This module affords the representation $\varphi : G \to \mathrm{GL}(V)$ by $\varphi(g) = I$ (the corresponding matrix representation from G to $\mathrm{GL}_1(k)$ sends $g \mapsto I$).

2. Let G be any finite group and k any field. Let $V = k[G]$ and consider it as a $k[G]$-module over itself. Then $\dim_k(V) = |G| = n$, with the basis being the elements of G. Then we see that each $g \in G$ permute the basis elements:
$$g \cdot g_i = gg_i = g_j \in G$$
Thus, the matrix representation for the action by the element g is an $n \times n$ matrix with 1 in the ij component if $g \cdot g_j = g_i$ (hence n 1's) and zero everywhere else. This representation of g is called the *regular representation* of G. Note how the underlying field did not matter: the coefficients in the matrices can only ever by 1 or 0, and we would simply say "Let φ be the regular representation of G" without specifying which field the group-ring is.

3. Let $G = S_n$ ($n \in \mathbb{N}_{>0}$) and k be any field. Then let V be a vector-space over k of dimension n, $(e_1, e_2, ..., e_n)$ a basis for V, and define the action:
$$\sigma \cdot e_i = e_{\sigma(i)}$$
that is, σ permute the basis of V. Through this, we see that we afford a faithful representation $\varphi : S_n \hookrightarrow \mathrm{GL}(V)$. Furthermore, since any finite group is a subgroup of S_n for an appropriate n, we see that a group of order n we can define $\varphi : G \to S_n \to \mathrm{GL}(V)$, giving another perspective on how to embed any finite group into a matrix group. Notice too how we made a $k[G]$-module given the action of a $k[S_n]$-module. This is called the *permutation representation* of G.

   Note that this means that *any* finite groups acts on a vector space, and by using this construction we see that any finite group G of size n can be embedded into $\mathrm{GL}_n(k)$ showing how much structure the matrix groups embody.

4. Generlizing the last result, if $\psi : H \to \mathrm{GL}(V)$ is any representation and $\varphi : G \to H$ is a group homomorphism, then $\psi \circ \varphi$ is a representation of G on V.

5. Recall that in section 20.1.3 we defined a *group character* to be a homomorphism from G to $L^\times$. This is in fact a 1-dimensional representation of G, since $\mathrm{GL}_1(L) = L^\times$. For a concrete

example, let $G = C_n$ be the cyclic group of order n and $\zeta_n \in \mathbb{C}^\times$ a *primitive* nth root of unity, and let a be a generator of G. Then the map:

$$\chi : G \to \mathbb{C}^\times \qquad a^i \mapsto \zeta_n^i$$

is a faithful representation of G (primitivity is what makes it faithful).

6. Let $G = D_4$, the dihedral group of order 8 (we write $|D_n| = 2n$). We already have the regular representation of dimension 8 and permutation representation of dimension 8, but can we do better? In fact we can. In order to see this, let's first write out D_4 in terms of generators and relations:

$$D_4 = \langle r, s \mid r^4 = s^2 = 1,\ rs = sr^{-1} \rangle$$

Let $k = \mathbb{R}$ and consider $\mathrm{GL}_2(\mathbb{R})$. Matrices satisfying these relations determine a representation of degree 2. It is faithful precisely when their images generate a group of order 8, which one checks directly for the matrices below. This can be laborious, but with some work we can find:

$$r \mapsto \begin{pmatrix} \cos(2\pi/4) & -\sin(2\pi/4) \\ \sin(2\pi/4) & \cos(2\pi/4) \end{pmatrix} \qquad s \mapsto \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

Let $G = Q_8$. We will show how different fiels can produce different represetnations. First, recall the following two generator and relation set for Q_8:

$$Q_8 = \langle i, j \mid i^4 = j^4 = 1,\ i^2 = j^2,\ i^{-1}ji = j^{-1} \rangle$$

$$Q_8 = \langle i, j, k \mid i^2 = j^2 = k^2 = ijk \rangle$$

Working over $\mathbb{C}$ in $\mathrm{GL}_2(\mathbb{C})$, we can use the first representation an find:

$$i \mapsto \begin{pmatrix} \sqrt{-1} & 0 \\ 0 & -\sqrt{-1} \end{pmatrix} \qquad j \mapsto \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

can you find one if $k = \mathbb{R}$ and $\mathrm{GL}_4(\mathbb{R})$? (Hint: think of the quaternions $\mathbb{H}$)

7. Let $H \trianglelefteq G$ which is further an *elementary* abelian p-group for some prime p (that is, abelian of exponent p). Without exponent p the scalar action below is not well defined. Then $V = H$ is a vector-space over $\mathbb{F}_p$ with the action of $a \cdot v = v^a$. Then define the action of G on H by conjugation: $g \cdot h = ghg^{-1}$. This action is well-defined since $gh^a g^{-1} = (ghg^{-1})^a$. The kernel of this action is $C_G(H)$. Such an action is called a *module representation*.

8. Let V be the $k[S_n]$-module which affords the permutation representation. We will find 2 S_n-invariant subspaces: Let $N \subseteq V$ be the subspace defined by:

$$N = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 = \cdots = \alpha_n\}$$

Then this a subspace that is also S_n-invariant. As practice, show that if $n \geq 3$, then N is the unique 1-dimension subspace which is S_n-stable. This submodule is called the *trace* submodule of V.

Another natural S_n-stable subspace is the following: take $I \subseteq V$ such that

$$I = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 + \cdots + \alpha_n = 0\}$$

notice that $I = \ker(\varphi)$ where $\varphi : V \to \mathbb{C}$, $\varphi(\alpha_1 e_1 \alpha_2 e_2 \cdots \alpha_n e_n) = \sum_i \alpha_i$, and so I is $n-1$ dimensional. Since φ is called the *augmentation map* (was in section 7.3 of D&F), I is called the *augmentation module*.

9. If V is a regular representation of G so that $V = k[G]$, then V has the same two natural G-invariant subspaces:

$$N = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 = \cdots = \alpha_n\}$$
$$I = \{\alpha_1 e_1 + \cdots + \alpha_n e_n \mid \alpha_1 + \cdots + \alpha_n = 0\}$$

these are both in fact *two-sided ideals*, even if G is not abelian. Since they appear naturally, they are usually given a name: N is called the *trace ideal* and I is called the *augment ideal*.

Corollary 53.1.6: Schur's Lemma For Representations

Let V, W be irreducible G-representations (over $\mathbb{C}$) with represetnations ρ_V and ρ_W. Then:

1. If $V \ncong_G W$, then there does not exist a non-trivial G-linear map between V and W
2. Let's say $V = W$, are finite dimensional vecor-spaces with $\rho_V = \rho_W$, then the only non-trivial G-linear maps from V to W are scalars: $\lambda I : V \to W$, $\lambda I(v) = \lambda v$.

***Proof*:**

1. Since V and W are irreducible G-representations, they are simple $k[G]$-modules, and hence we apply the original Schur's lemma.
2. Let $V = W$ of the same dimension with matching actions $\rho_V = \rho_W$, and let $f : V \to W$. Since f is a linear transformation over $\mathbb{C}$, there always exists an eigenvalue, say λ so that $f(x) = \lambda x$. Consider:
$$\varphi = f - \lambda I$$
so that $\varphi(x) = 0$. Since the difference of two G-linear maps is G-linear, then $\ker(\varphi)$ is a G-invariant subspace. But V is irreducible, and $\ker(\varphi) \neq 0$ since it contains the nonzero eigenvector x, and hence must be all of V, and so $\varphi(V) = 0$, telling us that $0 = f(x) - \lambda I(x)$, i.e.
$$f(x) = \lambda x$$
completing the proof.

Recall that if V is a simple R-module over a semi-simple ring R, then $\mathrm{End}_R(V) \cong_{\mathbf{Ring}} D^{\mathrm{op}}$ is a division ring, and that any finite-dimensional division $\mathbb{C}$-algebra is in fact equal to $\mathbb{C}$. This lemma now gives an explicit isomorphism between these two!

Since we are working over a vector-space, it is often convenient when possible to bring in an inner product that give further relations between our objects. The key the following inner product is that it is invariant on G-actions:

Definition 53.1.7: G-Invariant Inner Product

Let $k = \mathbb{R}$ or $\mathbb{C}$ and let V be a finite-dimensional $k[G]$-module. (An inner product presupposes an ordering or a conjugation on the scalars, so this definition is not available over a general field.) Then a *G-invariant inner product* is an inner product $\langle \cdot, \cdot \rangle$ along with the additional property of:

$$\langle g \cdot v, g \cdot w \rangle = \langle v, w \rangle$$

Instead of giving examples of this inner product, we will soon show that when G is finite and $|G|$ is invertible in k, any inner product on V can be averaged into a G-invariant one (hint: can you see how to use the "averaging" idea in Machke's Theorem to do so? The answer is given in corollary 53.1.12, page 1604).

Now, the study of linear representations in themseves can difficult; we are essentially studying all possible $\mathbb{C}[G]$-module. We would rather be able to decompose them into smaller pieces, and show that any represetnation of G is some how build form these simpler pieces (similarly to our exploration of semi-simple modules). The rest of this chapter is dedicated to seeing if we can bring Artin-Wedderburn's theorem and all of it's consequences to understanding linear representations of finite groups:

Definition 53.1.8: Decomposing Representations

A representation is called *simple, reducible, indecomposable, decomposable*, or *semisimple* if the $k[G]$-module affording it has the corresponding property

Recall that indecomposable in general does not imply irreducible. The example under definition 51.1.1 could is in fact a representation of $\mathbb{Z}$ defined by:

$$n \mapsto \begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$$

which is reducible (since it is in block upper-triangular form) but indecomposable: $\text{span}(e_1)$ is the only invariant line, so no basis puts it in block-diagonal form. Notice that any 1-dimensional representation is automatically an irreducible, since any $k[G]$-submodule of k would be a k-subspace of k, but k is already irreducible as vector-space over k.

To get an idea of how $k[G]$-submodules interact with the definitions above, let V be an n-dimensional representation of G affording the represetnation ρ, and $W \subseteq V$ an m-dimensional $k[G]$-submodule (i.e. m-dimensional G-invariant subspace) with $0 \neq m \neq n$. Then choosing a basis $\{w_1, w_2, ..., w_m\}$ for W, we can extend it to a basis $\{w_1, w_2, ..., w_m, v_{m+1}, ..., v_n\}$. Since W is G-invariant, for any $w \in W$, $\rho(g)(w) \in W$. In matrix representation, $\varphi(g)(w^i) = \rho^i_j w^j$, and the coefficients of $v^{m+1}, ..., v_n$ are zero. Hence we get the matrix representation of $\rho(g)$ as:

$$\begin{pmatrix} \alpha(g) & \beta(g) \\ 0 & \gamma(g) \end{pmatrix}$$

Notice too that:

$$\begin{aligned}\begin{pmatrix}\alpha(gh) & \beta(gh)\\ 0 & \gamma(gh)\end{pmatrix} &= \rho(gh)\\ &= \rho(g)\rho(h)\\ &= \begin{pmatrix}\alpha(g) & \beta(g)\\ 0 & \gamma(g)\end{pmatrix}\begin{pmatrix}\alpha(h) & \beta(h)\\ 0 & \gamma(h)\end{pmatrix}\\ &= \begin{pmatrix}\alpha(g)\alpha(h) & \alpha(g)\beta(h)+\beta(g)\gamma(h)\\ 0 & \gamma(g)\gamma(h)\end{pmatrix}\end{aligned}$$

which shows that α and γ are themselves representations. The converse is immediate and needs no computation: if every matrix is block upper triangular in a given basis, the span of the first m basis vectors is G-invariant. As an example of this, let V be the permutation representation of S_3. Then the set of all vectors that are invariant to the action of $G = S_3$ is $V^G = \text{span}(e_1 + e_2 + e_3)$. Let $W = \text{span}(e_1 + e_2 + e_3)$. Since $G \curvearrowright W$ is of the form $g \cdot w = w$, we see that W is in fact the *trivial representation*. Since V is semi-simple, we have that $V = V^G \oplus U$ for some G-stable complement U. Making some new basis for V, say $(e_1 + e_2 + e_3, e_2, e_3)$, we see that $S_3 \curvearrowright V$ will have matrix representations that are of the above form:

$$\begin{pmatrix}1 & * & *\\ 0 & * & *\\ 0 & * & *\end{pmatrix}$$

If V were irreducible, then no such basis would exist. If $V = U \oplus W$, then we would get a block diagonal form. It turns out that all representations of *finite* groups over a field of characteristic zero, or of characteristic not dividing $|G|$, are block-diagonal, i.e. are semisimple. (Finiteness is essential: the representation of $\mathbb{Z}$ displayed above is over $\mathbb{C}$ and is not semisimple.)

Theorem 53.1.9: Maschke's Theorem

Let G be a finite group and let k be a field whose characteristic does not divide $|G|$ or $\text{char}(k) = 0$. Then if V is a $k[G]$-module, it is a semi-simple $k[G]$-module.

The condition that $\text{char}(k) \nmid |G|$ is equivalent to $|G|$ being invertible in k, which is what the proof below divides by. Note how this theorem is "surprising": a finite group G certainly cannot be reduced to a direct sum of simple groups, only built from them as iterated extensions, and (as of writing this book) we do not know how to construct all finite groups via such extensions. Hence, having a very computable decomposition into irreducible representations provides a very potent tool to analyze the structure of finite groups.

***Proof*:**
We will use lemma 51.1.7[3] to show that for any $U \subseteq V$, there exists a complement W such that $V = U \oplus W$.

We will find a projection onto U: $\pi : V \to U$. Thus, we need to show it has the following properties:

1. $\pi(u) = u$ for all $u \in U$
2. $\pi(\pi(v)) = \pi(v)$ for all $v \in V$[a]

To see why this is sufficient, let $\pi\colon V \to U$ be a $k[G]$-module homomorphism with these properties. Let $W = \ker(\pi)$. Then $W \subseteq V$ is a submodule, and W is a complement of U. First, let $v \in U \cap W$. Then since $v \in U$, $\pi(v) = v$ and since $v \in W$, $\pi(v) = 0$, hence $v = 0$, meaning $U \cap W = 0$. Next, let $v \in V$ be an arbitrary element, and write $v = \pi(v) + (v - \pi(v))$. By definition, $\pi(v) \in U$, and by the 2nd property:

$$\pi(v - \pi(v)) = \pi(v) - \pi(\pi(v)) = \pi(v) - \pi(v) = 0$$

and hence $v - \pi(v) \in W$. Hence $v \in U + W$, and so $V = U + W$, hence $V \cong U \oplus W$. Hence, it suffices to find an $k[G]$-module projection π.

Let $U \subseteq V$ be a $k[G]$-submodule. Then it is already a k-subspace, and so it has a vector-space direct sum complement $W_0 \subseteq V$ (take a basis β for U, extend it to a basis $\mathcal{B}$ for V, then take $\mathcal{B} - \beta$) Thus, $V = U \oplus W_0$ as a vector-space. However, W_0 need not be G-stable (i.e. a $k[G]$-submodule), for example $G = C_2$ on $\mathbb{R}^2$ with the reflection across $y = x$ which has the G-subspace $y = x$ and complement spanned by $(1, 0)$, which is not G-invariant. Let $\pi_0\colon V \to U$ be the vector-space projection map:

$$\pi_0(u + w_0) = u$$

To find a G-stable complement, we average π_0 over G:

$$g\pi_0 g^{-1} : V \to U \qquad g\pi_0 g^{-1}(v) = g \cdot \pi_0(g^{-1} \cdot v)$$

Since π_0 maps V to U, and U is a $k[G]$-submodule, U is stable under this G-action, hence $g\pi_0 g^{-1}$ is well-defined. Note that both g and g^{-1} act as k-linear transformations, so $g\pi_0 g^{-1}$ is a k-linear transformation. Furthermore, if $u \in U$, then so must $g^{-1}u$, so by definition of π_0, $\pi_0(g^{-1}u) = g^{-1}u$. Thus, for all $g \in G$:

$$g\pi_0 g^{-1}(u) = u$$

hence, $g\pi_0 g^{-1}$ is also a vector-space projection of V onto U!

Let $n = |G|$, and viewing n as an element of k ($n = 1 + \cdots + 1$), since $\mathrm{char}(k) \nmid |G|$ we have $n \neq 0$, i.e. $n \in k^\times$. Thus, n has an inverse in k, meaning we can define:

$$\pi = \frac{1}{n} \sum_{g \in G} g\pi_0 g^{-1}$$

We can immediately deduce that π has the following properties:

1. By definition, π is still k-linear from V to U.
2. Restricting π to U would restrict each summand in the definition of π, and so as we have pointed out earlier each summand would be the identity map. Hence, we get $1/n$ times n copies of u, meaning $\pi|_U = \mathrm{id}$
3. π is well-defined, hence $\pi(v) \in U$, and since π restricts to the identity on U we get $\pi(\pi(v)) = \pi(v)$, i.e. $\pi^2 = \pi$

It remains to show that π is in fact a $k[G]$-module homomorphism (i.e. is $k[G]$ linear). It suffices to show that for any $h \in G$, $\pi(hv) = h\pi(v)$. This is simply a computation:

$$\begin{aligned}
\pi(hv) &= \frac{1}{n}\sum_{g\in G} g\pi_0(g^{-1}hv) \\
&= \frac{1}{n}\sum_{g\in G} h(h^{-1}g)\pi_0(g^{-1}hv) \\
&\overset{!}{=} \frac{1}{n}\sum_{\substack{x=h^{-1}g \\ g\in G}} h(x\pi_0(x^{-1}v)) \\
&= h\frac{1}{n}\sum_{\substack{x=h^{-1}g \\ g\in G}} (x\pi_0(x^{-1}v)) \\
&= h\pi(v)
\end{aligned}$$

where $\overset{!}{=}$ is the reindexing $x = h^{-1}g$, valid because left translation by h^{-1} is a bijection of G, so as g runs over G so does x. Hence, π is indeed a $k[G]$-homomorphism, and so it is a projection map, completing the proof.

[a] In fact, this is implied by 1

Thus, if we take any representation V over k of G, and consider the $k[G]$-module, then we know through $k[G]$ and G being finite and k a field (so V is a vector-space) that there are only *finitely many* simple $k[G]$-modules (i.e. finitely many irreducible representations of G), meaning we only have a finite number of "building blocks" from which we can build) any representation for G! Even better, the way we put together irreducible representation is through direct sums the simplest of ways of putting together algebraic objects! Then through the Artin-Wedderburn decomposition of $k[G]$ we obtain the list of irreducibles, and Maschke's theorem decomposes any representation V of G into them, giving us a simple finite list of irreducible representations per finite group! Note that if $p = \mathrm{ch}(k) > 0$ and $p \big| |G|$, then $k[G]$ is *not* semisimple, or if G is infinite, it need not be semi-simple

Example 53.1.10: Non-Semisimple Group Rings

For the infinite case, the action of $\mathbb{Z}$ on k^2 presented above is a non-semisimple $k[\mathbb{Z}]$-module. For finite groups, cyclic groups already exhibit both behaviors. Let $G = C_n$ be cyclic of order n, generated by g.

1. The k-algebra map $k[a] \to k[C_n]$, $a \mapsto g$, is surjective because g generates C_n, and its kernel contains $a^n - 1$. Both $k[a]/(a^n - 1)$ and $k[C_n]$ have dimension n over k, with bases $1, a, \ldots, a^{n-1}$ and $1, g, \ldots, g^{n-1}$, so the induced map $k[a]/(a^n - 1) \to k[C_n]$ is an isomorphism.
2. Suppose $\mathrm{char}(k) \nmid n$. The derivative na^{n-1} of $a^n - 1$ is nonzero and shares no root with $a^n - 1$, so $a^n - 1 = f_1 \cdots f_r$ with $f_1, \ldots, f_r$ distinct monic irreducible polynomials, which are pairwise coprime in the principal ideal domain $k[a]$. The Chinese Remainder Theorem theorem 9.6.11 gives
$$k[C_n] \cong k[a]/(f_1) \times \cdots \times k[a]/(f_r)$$
a product of fields. A field is M_1 of a division ring, so this is an Artin-Wedderburn decomposition of $k[C_n]$, and $k[C_n]$ is semisimple by theorem 51.2.16.

3. Suppose $\text{char}(k) = p$. In $k[C_p]$ the element $g - 1$ is nonzero, while $(g-1)^p = g^p - 1 = 0$ because the binomial coefficients $\binom{p}{i}$ vanish in k for $0 < i < p$. A product of fields has no nonzero nilpotent elements, so $k[C_p]$ is not a product of fields. Since $k[C_p]$ is commutative, each factor $M_{n_i}(D_i)$ of an Artin-Wedderburn decomposition of it would be commutative, which forces $n_i = 1$ (as $E_{12}E_{21} \neq E_{21}E_{12}$ when $n_i \geq 2$) and D_i a field. Hence $k[C_p]$ is not semisimple, by theorem 51.2.16.

If $k = \mathbb{C}$, then Maschke's Theorem always applies, and we can further use Artin Wedderburn over closed k-algebras (corollary 51.2.20) to deduce a relatively simple structure! Hence, from now on, we will always have $k = \mathbb{C}$, meaning all of our representations of finite groups will be over the complex vector-field of finite dimension.

Corollary 53.1.11: Matrix Representation Consequences

Let G be finite, let V be finite dimensional, and let $\rho : G \to \text{GL}(V)$ be a representation over a field k where $\text{char}(k) \nmid |G|$. Then there exists a basis for V such that for all $g \in G$, the matrix $\rho(g)$ is of block-diagonal form:

$$\begin{pmatrix} \rho_1(g) & & & \\ & \rho_2(g) & & \\ & & \ddots & \\ & & & \rho_m \end{pmatrix}$$

where ρ_i is an irreducible representation of G, $1 \leq i \leq m$.

***Proof*:**
Let V be the $k[G]$-module representing ρ. By Maschke's Theorem, we may write $V = U_1 \oplus \cdots \oplus U_m$. where U_i is simple $k[G]$-module. For each U_i, choose a basis β_i. Let $\beta = \bigcup_i^m \beta_i$. then each matrix representation of $\rho(g)$ is of the form in the corollary, with $\rho(g)|_{U_i} = \rho_i(g)$, completing the proof.

Corollary 53.1.12: Defining G-Invariant Inner Product

Let $k = \mathbb{R}$ or $\mathbb{C}$, let G be finite, let V be a finite-dimensional $k[G]$-module, and let $\langle \cdot, \cdot \rangle$ be any inner product on V. Then this inner product induces a G-invariant inner product

***Proof*:**
If $\langle \cdot, \cdot \rangle$ is an inner product, then:

$$\langle v, w \rangle_G = \frac{1}{|G|} \sum_{g \in G} \langle gv, gw \rangle$$

is a well-defined inner product (as can be checked), and for any $h \in G$

$$\begin{aligned}\langle hv, hw\rangle_G &= \frac{1}{|G|}\sum_{g\in G}\langle ghv, ghw\rangle \\ &= \frac{1}{|G|}\sum_{x=gh\in G}\langle xv, xw\rangle \\ &= \langle v, w\rangle_G\end{aligned}$$

In other words, there is always an inner product on our space in which the group actions keeps all elements of the same length and the same angle between them, showing how we can interpret a group as somehow rotating and reflecting an object in a vector-space. Now that we know any represetnation of G is composed in some way by finitely many irreducible representations, it would be useful to be able to quickly deduce the Artin-Wedderburn decomposition of $\mathbb{C}[G]$:

Proposition 53.1.13: Properties Of Representations

Let $k = \mathbb{C}$ and G be finite. Let $S_1, S_2, ..., S_r$ be the irreducible G-representations (up to isomorphism). Then:

1. the number of irreducible G-representations is equal to the number of conjugacy classes in G
2. For every finite-dimensional representation V of G,

   $$V \cong S_1^{\oplus \ell_1} \oplus \cdots \oplus S_r^{\oplus \ell_r}$$

   where the $\ell_i \geq 0$ are uniquely determined, namely $\ell_i = \dim_{\mathbb{C}} \operatorname{Hom}_{\mathbb{C}[G]}(S_i, V)$. (An irreducible need not occur at all: the trivial representation of S_3 has $\ell_2 = \ell_3 = 0$.)
3. $\mathbb{C}[G] \cong \bigoplus_{i=1}^{r} \left(S_i^{\oplus \dim_k S_i}\right)$ as regular representation
4. $|G| = \sum(\dim_k S_i)^2$

***Proof*:**

part (3) and (4) come from corollary 51.2.20.

For part (1), we first use Artin-Wedderburn to conclude that $Z(\mathbb{C}[G]) = \prod_i^r \mathbb{C}$, so $\dim_{\mathbb{C}}(Z(\mathbb{C}[G])) = r$, so the dimension of the center is equal to the number of irreducible G-representations.

Now, let $\mathcal{K}_1, ..., \mathcal{K}_s$ represent the conjugacy classes (recall they partition G). Define:

$$\sigma_i = \sum_{g\in\mathcal{K}_i} g$$

Note that any pair of elements σ_i and σ_j have no common terms since the conjugacy classes partition G. Furthermore, by definition, for any $g \in G$, $g\sigma_i g^{-1} = \sigma_i$, and so $\sigma_i \in Z(\mathbb{C}[G])$. If the σ_i's form a basis for $Z(\mathbb{C}[G])$, then we would have $s = r$. As a $\mathbb{C}$-vector-space, they are already linearly independent since the group elements from a basis, so it suffices to show they

span. If $\sum_{g\in G}\lambda_g g \in Z(\mathbb{C}[G])$. Then by definition for all $h \in G$,

$$\begin{aligned}
&\Leftrightarrow\ h\left(\sum_{g\in G}\lambda_g g\right) = \left(\sum_{g\in G}\lambda_g g\right)h \\
&\Leftrightarrow\ \left(\sum_{g\in G}\lambda_g g\right) = h^{-1}\left(\sum_{g\in G}\lambda_g g\right)h \\
&\Leftrightarrow\ \sum_{g\in G}\lambda_g g = \left(\sum_{g\in G}\lambda_g (h^{-1}gh)\right) \\
&\overset{!}{\Leftrightarrow}\ \sum_{g\in G}\lambda_g g = \sum_{g\in G}\lambda_{hgh^{-1}} g \\
&\Leftrightarrow \lambda_{hgh^{-1}} = \lambda_g \qquad \forall g \in G
\end{aligned}$$

since h arbitrary, we see that the coefficients of elements in the same conjugacy class remain with an element that's in that conjugacy class. Equivalently, the function $G \to \mathbb{C}$, $g \mapsto \lambda_g$ is constant on conjugacy classes. Thus:

$$Z(\mathbb{C}[G]) = \text{span}\left\{\sum_{g\in G} f([g])g\right\}$$

where f is a function from the conjugacy classes of G to $\mathbb{C}$. Hence $s = r$.

for (2), Since $\mathbb{C}[G]$ is a semi-simple ring, V is a semi-simple $\mathbb{C}[G]$-module, giving us existence of the decomposition by AW. For uniqueness, first note that:

$$\text{End}_{\mathbb{C}[G]}(S_i) = \mathbb{C}$$

since $\mathbb{C}$ is the only [finite-dimensional?] division $\mathbb{C}$-algebra. Then, we get by Schur's lemma:

$$\text{Hom}_{\mathbb{C}[G]}(S_i, V) \overset{\text{Schur}}{\cong} \text{Hom}_{\mathbb{C}[G]}(S_i, S_i)^{\oplus l_i} \cong \mathbb{C}^{l_i}$$

Corollary 53.1.14: Abelian Groups And Degree 1 Decomposition

1. If A is a *finite* abelian group, then every irreducible complex representation of A is 1-dimensional (i.e. a homomorphism from A to $\mathbb{C}^\times$), and A has $|A|$ inequivalent irreducible complex representations.
2. The number of inequivalent (irreducible) 1-dimensional complex representations of any finite group G is equal to $|G/G'|$

***Proof*:**

1. Since A is abelian, so is $\mathbb{C}[A]$. By the Artin-Wedderburn decomposition, it must be a product of matrices, which since $\mathbb{C}[A]$ abelian is so must each matrix ring, which is only

true if and only if $n_i = 1$. Then, by corollary 51.2.20, $\mathbb{C}[A]$ is a product of fields. It follows that any irreducible representation (i.e. simple $\mathbb{C}[A]$-module) is 1-dimensional. Conversely, if A were not abelian, $\mathbb{C}[A]$ cannot be a product of fields, hence one of the dimensions of the matrix rings *must* be greater than 1

2. Let G be an arbitrary group. We want to show that there is a bijective correspondence between the 1-dimension representations of G and the 1-dimensional representations of G/G'. $\rho : G/G' \to \mathbb{C}^\times$ is a 1-dimensional representations of G/G', then we have the natural map $G \to G/G'$, which shows that each 1-dimensional representations of G/G' is also a 1-dimensional representations of G. Convexly, if f $\rho : G \to \mathbb{C}^\times$ is a 1-dimensional representations of G, then by the universal property, this factors through:

$$\begin{array}{ccc} G/G' & \longrightarrow & \mathbb{C}^\times \\ \uparrow & \nearrow & \\ G & & \end{array}$$

showing that any 1-dimensional representation of G is associated to a 1-dimensional representations of G/G', showing there cannot be more 1-dimensional representations of G than there are of G/G', completing the proof.

A more general technique can be adopted from this proof: If $H \trianglelefteq G$ and V is an irreducible representation of G/H, then V is an irreducible representation of G.

Example 53.1.15: Decomposition Of Modules

1. DnF p. 847, and a bit about $\dim(V) = 1$ example right under definition

Finally, for those who read chapter 50, the following results are a glimpse at how representation theory is a "generalization" of number theory. First, if $H \leqslant G$ is a subgroup and (ρ, V) is an irreducible representation, $\rho|_H$ breaks up into the direct sum of representations, not necessarily of the same size or multiplicity. This is similar to how for a prime $\mathfrak{p} \subseteq F$ it may split to multiple primes with varying inertia degree and ramification numbers in a finite separable extension L/F. If L/F is furthermore normal (and hence Galois) then all the inertia degree's and ramification numbers match. In a similar vein:

Theorem 53.1.16: Clifford's Theorem

G be a group, $N \trianglelefteq G$ a normal subgroup, K a field, $\pi : G \to \mathrm{GL}_n(K)$ be an irreducible representation. Then the restriction $\pi|_N$ breaks up into a direct sum of irreducible representations of N of equal dimensions (i.e. it is semisimple and each representation is of the same dimension). These irreducible representations of N lie in one orbit for the action of G by conjugation on the equivalence classes of irreducible representations of N (i.e. they are isotypic components with the same multiplicity).

***Proof*:**
Write V for the space of π and let $W \subseteq V$ be an irreducible N-subrepresentation.

Step 1: $V|_N$ is semisimple. For $g \in G$ the subspace gW is N-stable, because N is normal: for $n \in N$ one has $n(gW) = g(g^{-1}ng)W = gW$, using $g^{-1}ng \in N$. It is irreducible over N, since $w \mapsto gw$ carries N-subrepresentations of W bijectively onto N-subrepresentations of gW, and the representation it affords is $n \mapsto \pi_W(g^{-1}ng)$, the conjugate π_W^g. In particular all the gW have the same dimension as W. Now $\sum_{g\in G} gW$ is stable under N by the above and under G because $h\sum_g gW = \sum_g (hg)W$, so it is a non-zero subrepresentation of the irreducible V and therefore equals V. A sum of irreducible subrepresentations is semisimple, so $V|_N$ is semisimple and all its irreducible constituents have $\dim W$.

Step 2: one orbit, with equal multiplicities. For an irreducible representation U of N let $V_U \subseteq V$ be its isotypic component in $V|_N$. If $g \in G$ then $v \mapsto gv$ carries V_U onto V_{U^g}, where $U^g(n) = U(g^{-1}ng)$: it is a bijection by Step 1 applied to each constituent, and it is an isomorphism of vector spaces, so V_U and V_{U^g} have equal dimension and hence U and U^g occur with equal multiplicity. Consequently G permutes the isotypic components, and the sum of those lying in a single G-orbit of isomorphism classes is a G-subrepresentation. It is non-zero, so it is all of V: the classes occurring form exactly one orbit, and the multiplicities agree across it, completing the proof.

Exercise 53.1.1

1. If χ_1 and χ_2 are both 1 dimensional representations, then $\chi_1 \cong \chi_2 \Leftrightarrow \chi_1 = \chi_2$. Use the property of equivalent representations to see this.
2. Let V be a non-trivial irreducible G-representation (i.e. not $\chi(g) = 1$ for all $g \in G$). Show that there are $\dim_{\mathbb{C}}(V^G) = 0$
3. By Caley's Theorem, all finite groups are linear. Do there exists infinite non-linear groups? (Hard: Do there exists finitely generated non-linear groups?)
4. Show that if ρ is irreducible and $N \trianglelefteq G$ is normal, and N fixes some *nonzero* vector $v \in V$, then N acts trivially on all of V.

53.2 Character Theory

We know now we can decompose a G-representation V into the direct sum of r different types of irreducible G-modules. How do we now proceed to find these? These can be quite unwieldy: if we have a 10 or 100-dimensional representation of a group G, then we have a matrix with 100 and 10′000 entries! We would then have to multiply these and figure out what relations they have between each other, quite a hassle! Furthermore, how do we do this in such way that is independent of equivalent representations? A convenient basis might be nice, but to find a nice basis for every $\rho(g) \in \rho(G)$, we'd have to find a basis that can *simultaneously* diagonalize every element in $\rho(G)$! If there was some invariant we can find on a representation that we can use to keep track of the decomposition information between representations that is invariant of representation, that would be useful to this endevaour. The following does exactly this (Move the discussion of trace here to build-up to it? Give some of D&F examples to demonstrate it does get quite ugly sometimes?)

Definition 53.2.1: Class Function and Character

Let G be finite and let V be a finite-dimensional representation of G over an arbitrary field F. Then

1. A function $f : G \to F$ that is constant on conjugacy classes is called a *class function* of G
2. If φ is a representation of G afforded by the $F[G]$-module V, then a function:

$$\chi_V : G \to F \qquad g \mapsto \text{tr}(g : V \to V) = \text{tr}(\varphi(g))$$

is called the *character* of φ, where $\text{tr}(\varphi(g))$ is the trace of φ with respect to some basis for V. A character is called *irreducible* if φ is irreducible (and reducible oherwise). The *degree* of a character is the degree of any representation affording it.

For ease of reference, recall these properties of the trace:

1. $\text{tr}(A + B) = \text{tr}(A) + \text{tr}(B)$ an $\text{tr}(cA) = c\text{tr}(A)$
2. $\text{tr}(A) = \text{tr}(A^t)$
3. $\text{tr}(AB) = \text{tr}(BA)$

Note that in general, a character is *not* a homomorphism from G into the additive or multiplicative structure of k. Since $\text{tr}(AB) = \text{tr}(BA)$, $\text{tr}(ABA^{-1}) = \text{tr}(B)$, we see that the trace (and hence the character) is independent of choice of basis, and so equivalent representations have the same character, meaning the character is indeed an invariant. Furthermore, for any representation φ of G,

$$\varphi(g^{-1}xg) = \varphi(g)^{-1}\varphi(x)\varphi(g)$$

hence, we can take the trace and use the 3rd property above to show that characters an an example of *class functions*. Furthermore, since the trace is linear, we can extend the domain of a character to be the trace over any element in $\mathbb{C}[G]$. If $F = \mathbb{C}$, then the collection of class function's form a complex vector-space, since the sum of two class functions is a class function, and multiplying by a scalar $z \in \mathbb{C}$ does not change that a class function is invariant.

Example 53.2.2: Character

1. Given the trivial representation of G (i.e. any 1-dim vector space where $g \mapsto I$), then if φ is the representating affording the trivial representation, it has $\chi_\varphi(g) = 1$ for all g. This is called the *trivial character*.
2. If we have a degree 1-representation, then the character and the representation are the same. Thus for abelian group, complex representations and their characters are the same. For example, take the representation $\varphi : C_p \to \mathbb{C}^\times$, $\varphi(a^i) = \zeta_p^i$. Then:

$$\chi(a^i) = \zeta_p^i$$

3. Let $\Pi : G \to S_n$ be a permutation representation of G and φ the linear of G of degree n on V where:

$$\varphi(g)(e_i) = e_{\Pi(g)(i)}$$

with respect to the given basis, $\varphi(g)$ has 1 in the ii-entry if $\Phi(g)$ fixes i, and zero otherwise. Thus, we can say that the character χ is:

$$\chi(g) = \#\{\text{number of fixed points of } g \text{ on } \{1, 2, ..., n\}\}$$

The character of the representation attached to any permutation action is called the *permutation character*. The case where G acts on itself by left multiplication gives the regular character below.

4. Consider any regular representation of G, φ. Then the character is:

$$\chi(g) = \begin{cases} 0 & g \neq 1 \\ |G| & g = 1 \end{cases}$$

This character is called the *regular character* of G (note how this character is not a group homomorphism into k or $k^\times$)

5. Take the representation $\varphi : D_n \to \mathrm{GL}_2(\mathbb{R})$ from example 53.1.5. Then:

$$\chi(r) = 2\cos(2\pi/n) \qquad \chi(s) = 0 \qquad \chi(1) = 2$$

where the last one is since $1 \in G$ must map to the identity matrix $I \in \mathrm{GL}_2(\mathbb{R})$.

From now on, all our representation will be complex.

Lemma 53.2.3: Properties Of Character

Let $\rho_V : G \to \mathrm{GL}(V)$ be a complex representation. Then:

1. $\chi_V(1) = \dim_{\mathbb{C}}(V)$
2. $\rho_V(g)$ is diagonalizable for all $g \in G$ and $\chi(g)$ is integral over the integers: $\chi(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$
3. If $g \in G$ has order n, then $\chi_V(g)$ is a sum of $\dim(V)$ number of nth roots of 1
4. $|\chi_V(g)| \leq \chi_V(1)$ for all $g \in G$
5. $\chi_V(g^{-1}) = \overline{\chi_V(g)}$

***Proof*:**

1. We showed this in the above examples.
2. The criterion we need from linear algebra is that $A \in M_n(\mathbb{C})$ is diagonlizable if and only if the minimal polynomial has no repeated roots, which can be implied if $M^k = I$ for some k, which it certainly is in our case since every element is finite.

3. If $g^n = 1$, then $\rho_V(g)^n = 1$, so by (2)

$$\rho_V(g) \sim \begin{pmatrix} z_1 & & \\ & \ddots & \\ & & z_k \end{pmatrix}$$

where $z_i^n = 1$ for all $1 \leq i \leq k$. Furthermore, this shows that these trace values in the matrix representation are always integral over the integers, being the sum of integral elements.

4. $$|\chi_V(g)| = \left|\sum z_i\right| \leq \sum |z_i| = \dim_{\mathbb{C}}(V) = \chi_V(1)$$

5. Since $\rho_V(g^{-1}) = \rho_V(g)^{-1}$ and

$$\rho_V(g)^{-1} \sim \begin{pmatrix} z_1^{-1} & & \\ & \ddots & \\ & & z_k^{-1} \end{pmatrix}$$

$\chi_V(g^{-1}) = \sum_i z_i^{-1}$, but $\|z_i\| = 1$, so $z_i^{-1} = \overline{z_i}$, so

$$\chi_V(g^{-1}) = \sum_i z_i^{-1} = \sum_i \overline{z_i} = \overline{\chi_V(g)}$$

Now, if we have some G-representation V, it has some character χ. In the following, we will show how we can always break-down a character to be the sums of characters on the irreducible G-representations:

Proposition 53.2.4: Linearly Independent Characters

Let G be a finite group and V a semi-simple $k[G]$-module, and φ the representation that V affords. Part (1) holds over any field. Part (2) requires $k = \mathbb{C}$ (or an algebraically closed field of characteristic 0), and is *false* over a splitting field of characteristic p dividing $|G|$, where the irreducible characters are fewer than the conjugacy classes. Then:

1. The character of V is the sum of the characters of the components appearing in the direct sum decomposition.
2. The irreducible characters of G are linearly independent set in the set of class functions. Furthermore, the irreducible characters of G form a basis of the vector-space of class functions.

***Proof*:**
For the 1st point, By the Artin-Wedderburn decoposition, we have:

$$V \cong (S_1)^{n_1} \oplus \cdots \oplus (S_k)^{n_k}$$

where S_i are simple $k[G]$-modules (irreducible G-representations). If we focus on the case where

$M = S_1 \oplus S_2$, then we can choose a basis for S_1 and S_2 which will give us:

$$\varphi(g) = \begin{pmatrix} \varphi_1(g) & 0 \\ 0 & \varphi_2(g) \end{pmatrix}$$

where φ_1, φ_2 are the representations afforded by M_1 and M_2 respectively. Then if ψ_1 and ψ_2 are the characters of φ_1 and φ_2 an χ is the character of φ then we get:

$$\chi = \psi_1 + \psi_2$$

using induction get's us the result.

For the 2nd point, first notice that the class functions defined by being 1 on a conjugacy class and 0 otherise forms a basis for class functions of dimension r. It thus suffices to sho that the r irreducible characters are independent. To that end, define:

$$\widetilde{\chi_V} : \mathbb{C}[G] \to \mathbb{C} \qquad x \mapsto \text{tr}(x : V \to V)$$

Note that this map is $\mathbb{C}$-linear since $\mathbb{C}$ commutes with $\mathbb{C}[G]$, and $\widetilde{\chi_V}|_G = \chi_V$. Now, say $S_1, ..., S_r$ are simple $\mathbb{C}[G]$-modules and:

$$\sum_i^r \lambda_i \chi_{S_i} = 0 \qquad \lambda_i \in \mathbb{C}$$

Then this is equivalent to:

$$\sum_i^r \lambda_i \widetilde{\chi_{S_i}}(g) = 0 \qquad \forall g \in G$$

and since the maps are $\mathbb{C}$-linear, by linearity:

$$\sum_i^r \lambda_i \widetilde{\chi_{S_i}}(x) = 0 \qquad \forall x \in \mathbb{C}[G]$$

which by plugging into the definition we get:

$$\sum_i^r \lambda_i \text{tr}(x : S_i \to S_i) = 0 \qquad \forall x \in \mathbb{C}[G]$$

Next, by Artin Wederburn, we have the decomposition:

$$C[G] \cong M_{n_1}(\mathbb{C}) \times \cdots \times M_{n_r}(\mathbb{C})$$

where each $M_{n_i}(\mathbb{C}) \cong S_i^{\oplus n_i}$, with $S_i = \mathbb{C}^{\oplus n_i}$. Using this, take the element:

$$x_i = (0, ..., I, ..., 0)$$

where I is the identity matrix[a]. Then $x_i : S_j \to S_j$ is 0 if $i \neq j$, and the identity marix if $i = j$. Thus, the trace is:

$$\text{tr}(x_i : S_j \to S_j) = \begin{cases} 0 & i \neq j \\ n_j & i = j \end{cases}$$

and since n_j is at least 1, we must have that

$$\lambda_1 = \cdots = \lambda_r = 0$$

where we took advantage of the fact we are in characeristic 0

[a] If the field had finite characteristic, it is better to take the elementary matrix E_{11}

53.2.5 Remark We can prove this directly without using Artin-Wedderburn, which we will

Corollary 53.2.6: Detecting Isomorphic Representations Using Characters

Let $k = \mathbb{C}$ and let V_1, V_2 be representations that are semi-simple modules. (Characteristic 0 is needed: over $\overline{\mathbb{F}}_2$ the trivial $\mathbb{Z}/3$-module T and $T^{\oplus 3}$ have the same character, since $3 = 1$ in k, but are not isomorphic.)

1. Every character of G is uniquely of the form

$$\sum_i^r \lambda_i \chi_i \qquad \lambda_i \in \mathbb{Z}_{\geq 0}$$

   where χ_i are irreducible characters.

2. the representations V_1 and V_2 are isomorphic if and only if $\chi_{V_1} = \chi_{V_2}$

***Proof*:**

1. This comes straight from the fact that irreducible characters form a basis, and that any G-representation V will be some direct sum of a finite list of known simple G-modules
2. If $V_1 \cong_G V_2$, there is a single change of basis P intertwining the two actions, so that if A and B are basis matrices, $A = PBP^{-1}$. But the trace is independent of conjugation, and so the characters are the same. For the othe way around, treating a representation as a $k[G]$-module, then by Machke's theorem, we *know* the list simple $k[G]$-modules and the actions of $k[G]$ on them. Since any $k[G]$-module can be broken down into a direct summand of simlpe $k[G]$-modules, and the two chracters are the same, the list of $k[G]$-modules and their multiplicity are the same.

Thus, we have translated the problem of finding the irreducible representations of a group G to finding the irreducible characters of G! Since a character of a representation is determined by the irreducible characters, we give a way to systematize the tracking of irreducible characters:

Definition 53.2.7: Character Table

Let $\varphi : G \to \mathrm{GL}(V)$ be a representaiton of G an χ_V it's character. Then we call the *character table* a table with the rows being irreducible characters and columns being an element in the conjugacy class. Common practice is to make the first column the identity conjugacy class and the first row the trivial representation

Example 53.2.8: Character Table

Consider $G = S_3$ Then we can start creating it's character table:

	e	$(1\ 2)$	$(1\ 2\ 3)$
1	1	1	1
χ_{sgn}	1	-1	1
$\vdots$	$\vdots$	$\vdots$	$\vdots$

Since G has 3 conjugacy classes, exactly 3 irreducible characters of G. How would we go about finding it? The comning propositions work towards this.

To be able to find the missing character, and more generally find new characters for a character table, we may look to construct new character given old one, and hope that we break down those characters into a linear combination of irreducible characters. In a sense, we are finding a way to create represetnations without doing it "by hand". We will do this in two way: the first is by taking advatange of group-actions, since are relatively easy to define and their representations are matrices with 1's and 0's. Since all groups embed into a symmetric group, this can be done systematically. We then see how to work directly with known representations to create new representations.

Definition 53.2.9: Precaution Representation

Let G act on a finite set X. Define $\mathbb{C}X$ to be the set of formal sums:

$$\mathbb{C}X = \left\{ \sum_{x \in X} \lambda_x x \;\middle|\; \lambda_x \in \mathbb{C} \right\}$$

So that we get a $\mathbb{C}$-vector space with $\dim_{\mathbb{C}}(\mathbb{C}X) = |X|$. Then we can make this a G-represetnation by defining:

$$g \cdot \left(\sum \lambda_x x \right) = \sum \lambda_x (g \cdot x)$$

The 3 usual permutation representations are $G \curvearrowright G$ by left multiplication (which gives the regular representation) or conjugation, and $G \curvearrowright \{*\}$ trivially (which gives the trivial representation).

Lemma 53.2.10: Character Of Permutation Representation

Let G act on X, $G \curvearrowright X$. Then

$$\chi_{\mathbb{C}X}(g) = \#\{x \in X \mid gx = x\}$$

***Proof*:**
FIx $g \in G$. Then the set of x's is a basis for the representation. To make the computation simpler, we will find a convinient order for them. In particular, by choosing any $x_1 \in X$, we can find the orbit of the element:

$$x_1 \xrightarrow{g} x_2 \longrightarrow \cdots \longrightarrow x_k \qquad x_{k+1} \xrightarrow{g} \cdots$$

so the basis representation will look like:

$$\begin{pmatrix} 0 & & & \\ 1 & 0 & & \\ & & \ddots & \\ 0 & 1 & & \\ & & 1 & 0 \end{pmatrix}$$

so we get that the trace is 0 if the order of the orbit is greater than 1, hence:

$$\chi_{\mathbb{C}X}(g) = \#\{g\text{-orbits of size } 1\}$$

An immediate consequence of this is that we have another way of computing the character of the regular representation

$$\chi_{\mathbb{C}G}(g) = \begin{cases} |G| & g = e \\ 0 & g \neq e \end{cases}$$

which makes sense, since the $\dim_{\mathbb{C}}(\mathbb{C}G) = |G|$.

Next, we turn towards a more systematic way of constructing characters by creating them out of pervious ones, that is, given some representations V and W of a group G, we can make new representations by creating new representations from V and G:

Definition 53.2.11: Constructing Representations from smaller ones

Let V, W be G-representations. Then

1. we can make a $V \oplus W$ representation by:

$$g \cdot (v, w) = (g \cdot v, g \cdot w) \ [(\rho_V(g)v, \rho_W(g)w)]$$

2. we can make $V \otimes_{\mathbb{C}} W$ a representations by:

$$g \cdot (v \otimes w) \mapsto (gv) \otimes (gw)$$

3. we can make $\mathrm{Hom}_{\mathbb{C}}(V, W)$ a representations by:

$$g \cdot f : V \to W \quad v \mapsto g \cdot f(g^{-1} \cdot v)$$

4. we can make $V^* = \mathrm{Hom}_{\mathbb{C}}(V, \mathbb{C})$ a representaiton by:

$$g \cdot f : V \to \mathbb{C}, \ v \mapsto f(g^{-1} \cdot v)$$

Note that the last construction is the same as the 3rd if we take $\mathbb{C}$ as the trivial representation. Before we show what the character's of these new representations are, we first find a relatively simpler way of representing the hom representation of V and W:

Lemma 53.2.12: Hom-Tensor Representation Dual

Let V, W be G representations. Then:

$$\mathrm{Hom}_{\mathbb{C}}(V, W) \cong_G V^* \otimes_{\mathbb{C}} W$$

as G-representations.

Note that this is not true in general, even for vector-spaces. It is important that the spaces are finite-dimensional. This is a different statement from the hom-tensor adjunction of theorem 15.3.9, not a strengthening of it: the adjunction holds for arbitrary modules, whereas the lemma here needs $\dim_{\mathbb{C}} V < \infty$. It is the more usable description for the case of finite-dimensional vector-spaces.

***Proof*:**
By the universal property:

$$\theta : V^* \otimes_{\mathbb{C}} W \to \mathrm{Hom}_{\mathbb{C}}(V, W) \qquad \lambda \otimes w \mapsto (v \mapsto \lambda(v)w)$$

you should check that this is well-define (note that it is bilinear).

Now, pick basis $e_1, e_2, ..., e_n$ for V, $f_1, f_2, ..., f_m$ for W, and the natural dual $e_1^*, ..., e_n^*$ for V^*. Then we get a basis for $V^* \otimes W$:

$$(e_i^* \otimes f_j) \qquad 1 \leq i \leq n,\ 1 \leq j \leq m$$

Now, notice that:

$$\theta(e_i^* \otimes f_j) \qquad v \mapsto e_i^*(v) f_j \sim \begin{pmatrix} 0 & \cdots & 0 & \cdots & 0 \\ \vdots & & \vdots & & 0 \\ 0 & & 1 & & 0 \\ \vdots & & \vdots & & \vdots \\ 0 & \cdots & 0 & \cdots & 0 \end{pmatrix} = E_{ij}$$

which is the matrix whose only nonzero entry is a 1 in the position sending the basis vector e_i to f_j, and zero everywhere else. This is clearly a basis, hence θ sends a basis to a basis, and hence θ is a vector-space isomorphism. We next check that θ is G-linear:

$$\begin{aligned} \theta(g \cdot (\lambda \otimes w)) &= \theta(g\lambda \otimes gw) \\ &\equiv v \mapsto (g\lambda)(v)gw \\ &= v \mapsto (g\lambda)(g^{-1}v)w \\ &= g(\lambda(g^{-1}v)w) \\ &\equiv g(\theta(\lambda \otimes w)g^{-1}v) \\ &= g \cdot \theta(\lambda \otimes w) \end{aligned}$$

Lemma 53.2.13: Creating New Characters

1. $\chi_{V\oplus W} = \chi_V + \chi_W$
2. $\chi_{V\otimes W} = \chi_V \cdot \chi_W$
3. $\chi_{\mathrm{Hom}_{\mathbb{C}}(V,W)} = \overline{\chi_V}\chi_W$
4. $\chi_{V^*} = \overline{\chi_V}$

***Proof*:**

1. obvious
2. It is enough to show that if $f : V \to V$ and $g : W \to W$ are linear functions, then:
$$\mathrm{tr}(f \otimes h) = \mathrm{tr}(f)\mathrm{tr}(h)$$
Now if we pick basis (e_i) for V and (f_j) for W, then $f(e_i) = \sum a_{ij}e_j$ and $h(f_k) = \sum b_{lk}f_l$. Then:
$$(f \otimes h)(e_i \otimes f_k) = \left(\sum_j a_{ij}e_j\right) \otimes \left(\sum_l b_{lk}f_l\right) = \sum_{j,l} a_{ij}b_{lk}(e_j \otimes f_l)$$
The diagonal coefficient, that of $e_i \otimes f_k$ itself, is $a_{ii}b_{kk}$, so summing over the basis gives $\mathrm{tr}(f \otimes h) = \sum_{i,k} a_{ii}b_{kk} = (\sum_i a_{ii})\,(\sum_k b_{kk}) = \mathrm{tr}(f)\mathrm{tr}(h)$
3. Recall that for $f \in V^*$,
$$(gf)(v) = f(g^{-1} \cdot v)$$
that is
$$\rho_{V^*}(g)(f) = f \circ \rho_V(g^{-1})$$
that is, it is the transpose:
$$\rho_{V^*}(g) = (\rho_V(g^{-1}))^t$$
So, since the transpose matrix has the same trace, we have
$$\chi_{V^*}(g) = \chi_V(g^{-1}) = \overline{\chi_V(g)}$$
we then apply lemma 53.2.12 and part (3)to get:
$$\chi_{\mathrm{Hom}_{\mathbb{C}}(V,W)} = \overline{\chi_V} \cdot \chi_W$$
4. $\chi_{V^*} = \chi_{\mathrm{Hom}(V,\mathbb{C})} = \overline{\chi_V} \cdot 1 = \overline{\chi_V}$.

With this, we can create new characters! However, we have yet to establish how we may find the irreducible components of these chracters. For example, if we take $V \otimes V$, we may find that $\chi_{V\otimes V}$ is a linear combination of some characters already present in our table, but then we have a left-over part. How would we determine if the left-over is irreducible? We will show this by defining an *inner product* on the vector-space of class functions, and show that the irreducible form an *orthogonal basis*!

Definition 53.2.14: Inner Product On Class functions

Let $\chi_1, \chi_2 : G \to \mathbb{C}$ be class functions. Then define:

$$\langle \chi_1, \chi_2 \rangle = \frac{1}{|G|} \sum_{g \in G} \chi_1(g)\overline{\chi_2(g)} \in \mathbb{C}$$

Then this is a [Hermitian] *inner product*.

It should be verified that this is indeeed an inner product. Since class functions are by definition constant on conjugacy classes, we only need to run through representatives of conjgacy classe times the order of each conjugacy class:

$$\langle \chi_1, \chi_2 \rangle = \frac{1}{|G|} \sum_{\substack{\mathcal{K} \in \text{conj}(G) \\ g \in \mathcal{K}}} |\mathcal{K}| \chi_1(g)\overline{\chi_2(g)} \in \mathbb{C}$$

where we pick a single represetnative $g \in \mathcal{K}$ and sum over the number of conjugacy classes, i.e. $|\text{conj}(G)|$. Looking a the inner product like this is desirable to make computation easier (ex. if taking the inner product of a character with itself, we take the *modulus* squared $|\chi(g)|^2$ of each entry in a row (the modulus matters: character values need not be real), multiply by the size of it's conjugcay class). Notice how this inner product mirrors the G-invariant inner product we induced in corollary 53.1.12 if we let $\langle \cdot, \cdot \rangle$ be the usual conjugate dot product on $\mathbb{C}^n$. (TBD)

Lemma 53.2.15: Inner Product With Trivial Character

Let V be a G-representation. Then if $\mathbb{1}$ is the trivial representation,

$$\langle \chi_V, \chi_{\mathbb{1}} \rangle = \dim_{\mathbb{C}}(V^G)$$

where $V^G = \{v \in V \mid g \cdot v = v \ \forall g \in G\}$ is the subspace fixed by G.

***Proof*:**

Define the linear map $\pi : V \to V$ where

$$v \mapsto \frac{1}{|G|} \sum_{g \in G} g \cdot v$$

then:

$$\pi|_{V^G} = \text{id}$$

and

$$\text{im}(\pi) \subseteq V^G$$

which implies $\pi^2 = \pi$, i.e. a projection. By linear linear algebra:

$$V = \ker(\pi) \oplus \text{im}(\pi)$$

where on the kernel, $\pi = 0$, and on the image $\pi = \text{id}$. Thus,

$$\frac{1}{|G|} \sum_g \chi_V(g) = \frac{1}{|G|} \sum_g \text{tr}(g : V \to V) = \text{tr}(\pi) = \dim_{\mathbb{C}}(V^G)$$

but the left hand side is $\langle \chi_V, \chi_{\mathbb{1}} \rangle$, completing the proof.

Corollary 53.2.16: Row Orthogonality

If V and W are any representations of G, then

$$\langle \chi_V, \chi_W \rangle = \dim_{\mathbb{C}}(\hom_{\mathbb{C}[G]}(W, V))$$

In particualr, if V an W are irreducible, then

$$\langle \chi_V, \chi_W \rangle = \begin{cases} 1 & V \cong W \\ 0 & \text{otherwise} \end{cases}$$

that is, irreducible character's are orthogonal to each other.

***Proof*:**
We reduce to the previous lemma:

$$\begin{aligned} \langle \chi_V, \chi_W \rangle &= \frac{1}{|G|} \sum_{g \in G} \chi_V(g) \overline{\chi_W(g)} \\ &= \frac{1}{|G|} \sum_{g \in G} \chi_{\mathrm{Hom}_{\mathbb{C}}(W,V)}(g) \\ &= \langle \chi_{\mathrm{Hom}_{\mathbb{C}}(W,V)}, 1 \rangle \\ &= \dim_{\mathbb{C}}(\mathrm{Hom}_{\mathbb{C}}(W, V)^G) \end{aligned}$$

Note that $f \in \mathrm{Hom}_{\mathbb{C}}(W, V)$ is G-invariant, so $g \cdot f = gfg^{-1} = f$ for all $g \in G$ (recall the definition of $g \cdot f$ on $\mathrm{Hom}_{\mathbb{C}}(W, V)$). Thus this is true iff

$$gf = fg$$

Thus

$$gf(w) = f(gw) \qquad \forall g \forall w \in W$$

so f is $\mathbb{C}[G]$-linear so f is in the $\mathrm{Hom}_{\mathbb{C}[G]}(W, V)$.

There is also a more concrete proof worth remarking: since characters are linear combination's of irreducible characters, the direct product of irreducible modules translates to the sum of an irreducible character with the multiplicity of the irreducible module afording the representation being the multiplicity of the ireducibile characters. Hence:

$$\begin{aligned} \langle \chi_V, \chi_W \rangle &= \langle \sum_i m_i \chi^{(i)}, \sum_j m_j \chi^{(j)} \rangle \\ &= \sum_{i,j} m_i n_j \langle \chi^{(i)}, \chi^{(j)} \rangle \end{aligned}$$

where we have now reduced it to $\langle \chi^{(i)}, \chi^{(j)} \rangle$. Expanding the inner product and using the hom-set definition, we can apply Schur's Lemma and get:

$$\langle \chi^{(i)}, \chi^{(j)} \rangle = \delta_{ij}$$

Thus, our formula becomes:

$$\begin{aligned}\langle \chi_V, \chi_W \rangle &= \langle \sum_i m_i \chi^{(i)}, \sum_j n_j \chi^{(j)} \rangle \\ &= \sum_{i,j} m_i n_j \langle \chi^{(i)}, \chi^{(j)} \rangle \\ &= \sum_{i,j} m_i n_j \delta_{ij} = \sum_i m_i n_i\end{aligned}$$

To find $\langle \chi^{(i)}, \chi^{(i)} \rangle$ for an irreducible character, seeing it through multiplicites, then we know that an irreducible character corresponds to an irreducible representation of multiplicity one. (This is a mnemonic, not an independent proof: the identity $\langle \chi_V, \chi_V \rangle = \sum_i m_i^2$ is itself a consequence of the orthonormality established above.) So if in particular:

$$\langle \chi^{(i)}, \chi^{(i)} \rangle = m_i^2 = 1 \cdot 1 = 1$$

Thus, the irreducible character produce and orthogonal basis of class functions!

Corollary 53.2.17: Consequence of Orthogonality

Let $V = \bigoplus_i^r S_i^{l_i}$ where each S_i irreducible and $S_i \ncong S_j$. Then

1. the multipliity of l_i of S_i is: $l_i = \langle \chi_V, \chi_{S_i} \rangle$
2. $\langle \chi_V, \chi_V \rangle = \sum_i l_i^2$
3. $\hom_G(W, V) \cong \hom_G(V, W)^*$

***Proof*:**

1. Use the Artin-Wedderburn decomposition and the fact that direct sums of modules becomes sums of characters
2. this is just taking advantage of the summing formula
3. This is taking advantage of the fact that $\langle \chi, \psi \rangle = \overline{\langle \psi, \chi \rangle}$.

The second line is useful enough to be given it's own name:

Definition 53.2.18: Character Norm

Let V be a G-representation and let $\langle \cdot, \cdot \rangle$ be the inner product on the class functions of G. Then for any class function $\psi = \sum_i \lambda_i \chi_i$,

$$\|\psi\| = \left(\sum_i |\lambda_i|^2 \right)^{1/2} = \langle \psi, \psi \rangle^{1/2}$$

We will use all this informaiton to deduce new characters:

Example 53.2.19: Orthogonality Relation
Let's go back to our table for S_3:

	e	$(1\ 2)$	$(1\ 2\ 3)$
1	1	1	1
χ_{sgn}	1	-1	1
$\vdots$	$\vdots$	$\vdots$	$\vdots$

Since S_3 has 3 conjugacy classes, it can at most have one more irreducible character. What can this character be? We may start by looking at the degree-three permutation representation of S_3, the one on $\mathbb{C}X$ for $X = \{1, 2, 3\}$ with its natural action, and take its character χ_V. Then:

$$\langle \chi_V, 1 \rangle = 1$$
$$\langle \chi_V, \chi_{\text{sng}} \rangle = 0$$

showing the permutation character χ_V has one copy of the trivial representation (which makes sense, since S_3 is transitive on X, so the fixed space is spanned by the single vector summing the basis). Since

$$\chi_V(e) = 3 \qquad \chi_V((1\ 2)) = 1 \qquad \chi_V((1\ 2\ 3)) = 0$$

then we can take a "compliment" character by subtracting the trivial character, which defines a character which gives:

$$\chi^{\perp}(e) = 2 \qquad \chi^{\perp}(1\ 2) = 0 \qquad \chi^{\perp}(1\ 2\ 3) = -1$$

So, if there were to be another irreducible character, it would be of this form. But does there exist a degree 2 irreducible representation with this character? There is: the class function $(2, 0, -1)$ has norm $\langle \chi^{\perp}, \chi^{\perp} \rangle = (1 \cdot 4 + 3 \cdot 0 + 2 \cdot 1)/6 = 1$, so it is irreducible. Counting also confirms it: we saw that the number of irreducible representations is equal to the number of conjugacy classes, meaning the number of characters must be equal to the number of irreducible representations.

More generally, there can be a few approaches to finding it. One is to tensor two characters we know and see if it is irreducible, or one of it's linear components is irreducible. Another is to find the compliment of a represetnation of an existing character (since $k[G]$-modules are semi-simple). This compliment method is in general less desirable, and usually harder, but is managable if working with permutation representations.To demonstrate, let V be the degree three permutation representation of S_3[a] with basis $\{e_1, e_2, e_3\}$. Then if $\mathbb{1}$ is the trivial action, $V^{\mathbb{1}} = \text{span}(e_1 + e_2 + e_3)$, Thus, by Machke's theorem, $V^{\mathbb{1}}$ has a compliment. To see it, we simply have to extend $e_1 + e_2 + e_3$ to a basis whose last two vectors span its orthogonal complement, for example $(e_1 + e_2 + e_3, e_2 - e_1, e_3 - e_1)$ (these last two are not orthogonal to each other, but they do span the complement). Then we can calculate what the action ρ does on this basis. For example:

$$\begin{aligned}\rho(1\ 2)(e_1 + e_2 + e_3) &= e_1 + e_2 + e_3 \\ \rho(1\ 2)(e_2 - e_1) &= e_1 - e_2 = -(e_2 - e_1) \\ \rho(1\ 2)(e_3 - e_1) &= e_3 - e_2 = -(e_2 - e_1) + (e_3 - e_1)\end{aligned}$$

If we write out ρ for an element in each conjugacy class, we will find that its trace will be

$$\chi^{\perp}(e) = 2 \qquad \chi^{\perp}((1\ 2)) = 0 \quad \chi^{\perp}((1\ 2\ 3)) = -1$$

showing we have found the desired irreducible representation! Finally, each irreducible occurs in the regular representation with multiplicity equal to its degree (proposition 53.1.13), so $\mathbb{C}S_3 \cong \mathbb{1} \oplus \text{sgn} \oplus (V^\perp)^{\oplus 2}$ as representations, of dimension $1+1+4=6$. As algebras Artin-Wedderburn gives $\mathbb{C}S_3 \cong \mathbb{C} \times \mathbb{C} \times M_2(\mathbb{C})$

Now that we know the character table for S_3, we can construct any other character of representations of S_3, and hence any other representation of S_3. For example, we know that $V^\perp \otimes V^\perp$ has as character $\chi_{V^\perp} \cdot \chi_{V^\perp}$. Using this, we can compute that:

$$\begin{aligned}\langle V^\perp \otimes V^\perp, \mathbb{1}\rangle &= 1\\ \langle V^\perp \otimes V^\perp, \text{sgn}\rangle &= 1\\ \langle V^\perp \otimes V^\perp, V^\perp\rangle &= 1\end{aligned}$$

showing that

$$\chi_{V^\perp \otimes V^\perp} = \chi_{\mathbb{1}} + \chi_{\text{sgn}} + \chi_{V^\perp}$$

[a] This is the representation on $\mathbb{C}X$ for $X = \{1,2,3\}$ with its natural S_3-action, not the regular representation, which has degree $|S_3| = 6$.

Recall from linear algebra that if the rows are orthogonal in a square matrix, then so would be the column (and vice-versa). We bring to light this relation for the character table. As in linear algebra, it comes down to proper normalizing of a different basis: recall the class functions $\delta_{\mathcal{K}} : G \to \mathbb{C}$ where:

$$\delta_{\mathcal{K}}(g) = \begin{cases} 1 & g \in \mathcal{K} \\ 0 & \text{otherwise} \end{cases}$$

this naturally forms a basis for the class equations too. The following theorem will also show how to go between this basis and the irreducible character basis:

Theorem 53.2.20: Column Orthogonality

If $\chi_1, \chi_2, ..., \chi_r$ are the irreducible characters of G and $g_1, g_2, ..., g_r$ represent the conjugacy classes of G, then

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \delta_{st}\frac{|G|}{|\text{conj}(g_s)|}$$

which by Orbt-stabalizer,

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \delta_{st}|C_G(g_s)|$$

If $g_s, g_t \in \text{conj}(g)$, then we get that

$$\sum_i \chi_i(g_s)\overline{\chi_i(g_t)} = \sum_i |\chi_i(g_s)|^2 = |C_G(g_s)|$$

in particular, we must have:

$$\sum_i |\chi_i(e)|^2 = |G|$$

***Proof*:**
Define $f_s : G \to \mathbb{C}$,

$$g \mapsto \begin{cases} 1 & g \in \text{conj}(g_s) \\ 0 & \text{otherwise} \end{cases}$$

which is natural basis for the class functions. since it's a class function, we know we can write it as the sum of orhtogonal ireducibile characters:

$$f_s = \sum_i^r \lambda_{is}\chi_i \qquad \lambda_{is} \in \mathbb{C}$$

since these are orthornormal, we know that:

$$\lambda_{is} = \langle f_s, \chi_i \rangle$$

so computing:

$$\begin{aligned} \lambda_{is} &= \langle f_s, \chi_i \rangle \\ &= \frac{1}{|G|} \sum_{g \in G} f_s(g)\overline{\chi_i(g)} \\ &= \frac{1}{|G|} \sum_{g \in \text{conj}(g_s)} \overline{\chi_i(g)} \\ &= \frac{|\text{conj}(g_s)|}{|G|}\overline{\chi_i(g_s)} \end{aligned}$$

so

$$f_s = \frac{\text{conj}(g_s)|}{|G|} \sum_i^r \overline{\chi_i(g_s)}\chi_i$$

we know evaluate at g_t.

Since both the rows and columns of a character table are all orthogonal to each other, the character table is in fact invertible!

Example 53.2.21: Using Column Orthogonality
Let $G = S_4$. We want to find it's character table. We first pick what conjugacy classes to index the columns by, say:

conj. class	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
size	1	6	8	3	6

Next, we can immediately deduce that $\chi_{\mathbb{1}}$ and χ_{sgn} are irreducible characters, giving us the current begining of a character table:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	−1	1	1	−1

To find more characters, we can first take the pemutation character of $\mathbb{C}X$. The character of each conjugacy class is the number of fixed points, giving us:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{C}X}$	4	2	1	0	0

We can see that the trivial character is part of linear decomposition of $\chi_{\mathbb{C}X}$, since:

$$\langle \chi_{\mathbb{C}X}, \chi_{\mathbb{1}} \rangle = \big(1(4\cdot 1) + 6(2\cdot 1) + 8(1\cdot 1) + 3(0\cdot 1) + 6(0\cdot 1)\big)/24 = 24/24 = 1$$

and so $\chi_{\mathbb{C}X} - \chi_{\mathbb{1}}$ is a 3 dimensional character, let's label this χ_3. Then $\|\chi_3\|^2 = 1$, showing that it's irreducible, hence we expand our table:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
$\chi_{\mathbb{C}X} - \chi_{\mathbb{1}} = \chi_3$	3	1	0	-1	-1

To find the next character, we can multiply χ_{sgn} and χ_3 (note we can do χ_3 with itself, but it will be 9 dimensional, which we will show in the next proposition cannot be an irreducible representation). Let$\chi_4 = \chi_{\text{sgn}} \cdot \chi_3$. Then $\|\chi_4\|^2 = 1$, meaning it's irreducible, and so we add another row to our table:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	1	0	-1	-1
$\chi_{\text{sng}} \cdot \chi_3 = \chi_4$	3	-1	0	-1	1

Finally, since $|G| = \sum_i \chi_i(e)^2$, we can deduce that $\chi_5(e) = 2$. We cannot do this same trick exactly for the other columns since we will get the value up to a complex number z with $\|z\| = 1$. To find the rest of the character values, we can either use column orthogonality For example, to find $\chi_5(1\ 2)$, noticet that the inner product of the first and second column is:

$$1\cdot 1 + (-1)\cdot 1 + 3\cdot 1 + 3\cdot(-1) = 0$$

and so $\chi_5((1\ 2))$ must be 0. For the next column, we'd get:

$$1\cdot 1 + 1\cdot 1 + 3\cdot 0 + 3\cdot 0 = 2$$

and so, since $\chi_5(1)\chi_5((1\ 2\ 3)) = 2\chi_5((1\ 2\ 3))$ must cancel this 2, we get that $\chi_5((1\ 2\ 3)) = -1$. Continuing this way, we get that the rest of the table will be:

	1	6	8	3	6
	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	1	0	-1	-1
χ_4	3	-1	0	-1	1
χ_5	2	0	-1	2	0

We can verify this is indeed irreducible by taking $\|\chi_5\|^2 = 1$.

Another method would be to use the regular representation, where we get:

$$\chi_{\mathbb{C}[G]} = \sum_i \chi_i(1)\chi_i$$

These can be verified by taking advantage of the fact that the "column norm" $\sum_i |\chi_i(g)|^2$ should give you $|C_G(g)|$, which is $|G|$ divided by the class size printed on top of the table. For $g = (1\ 2)$, for instance, the column gives $1+1+1+1+0 = 4 = 24/6$.

As a fun aside, the representation with character χ_4 is the rotation action on a cube: if $C \subseteq \mathbb{R}^3$ is the set of vertices of a cube, then χ_4 is the character of the action of S_4 on $\mathbb{R}^3$ by all rotations preserving C, where S_4 permutes the four long diagonals. A transposition acts as a 180° edge rotation and a 4-cycle as a 90° face rotation, with traces -1 and 1, matching the row. It is χ_4 and not χ_3 because a rotation has determinant 1, and $\det \chi_3 = \text{sgn}$.

Notice how the dimension of each irreducible representation divided the order of the group. This is in fact true in general. It is not a trivial fact, the only "order" information we have shown so far is that the sums of the squares of the dimensions of the ireducibile representation sum to $|G|$. It is also relatively eays to show that if $W \subseteq V$ is an irreducible $\mathbb{C}[G]$-module then $(\dim W)^2 \leq |G|$, which is immediate from part (4) above. The following is thus a much stronger result:

Proposition 53.2.22: Dimension Theorem of Irreducible Representations

Let V be an irreducible G-representation. Then:

$$\dim_{\mathbb{C}}(V) \mid |G|$$

that is, the dimension of V divides the order of G.

***Proof*:**
Let $g_1, g_2, ..., g_r$ be representatives of the conjugacy class. Recall the following trick from proposition 53.1.13:

$$e_i = \left(\sum_{g \in \text{conj}(g_i)} g \right) \in Z(\mathbb{C}[G])$$

Note that e_i in fact lies in $e_i \in Z(\mathbb{Z}[G])$, since $ge_ig^{-1} = e_i$ (by definition), and so extending linearly all $xe_ix^{-1} = e_i$. Now we have a commutative ring that is a finitely generated $\mathbb{Z}$-module (one way to see this is as we have done in proposition 53.1.13, another way is to notice that $\mathbb{Z}[G]$ is a finitely generated $\mathbb{Z}$-module and $\mathbb{Z}$ is Noetherian, so the center is finitely generated)

Thus, by proposition 26.1.4, $\mathbb{Z} \subseteq Z(\mathbb{Z}[G])$ is an *integral extension*. Next, we have a ring homomorphism:

$$\varphi : Z(\mathbb{C}[G]) \to \text{End}_{\mathbb{C}[G]}(V) \overset{!}{\cong} \mathbb{C} \qquad z \mapsto (z : V \to V)$$

where $\overset{!}{=}$ comes from corollary 51.2.19 and Schur's lemma, and $z(v) = zv$. Hence each $z \in Z(\mathbb{C}[G])$ acts on V as a scalar $\varphi(z) \in \mathbb{C}$, that is as $\varphi(z) \cdot I$. (Note this scalar may well be 0, for instance whenever $\chi_V(g_i) = 0$, so φ does *not* land in $\text{GL}(V)$.) Acting by a scalar is all we need, and it is exactly the restriction of the original G-action ρ to $Z(\mathbb{C}[G])$. Hence $\rho(e_i) = \lambda_i I$ for appropriate

$\lambda_i = \varphi(e_i)$, meaning $\chi(e_i) = \text{tr}(e_i : V \to V) = n\varphi(e_i)$ where $n = \dim(V)$ since by what we have just shown, $\varphi(e_i)$ acts as scalar multiplication on the representation V.

Now, since $e_i \in Z(\mathbb{C}[G])$ is integral over $\mathbb{Z}$, $\varphi(e_i) \in \mathbb{C}$ is integral over $\mathbb{Z}$, that is $\varphi(e_i) \in \overline{\mathbb{Z}}^{\mathbb{C}} \subseteq \mathbb{C}$ (i.e. $\varphi(e_i)$ is algebraic). Next, we can express $\chi(e_i)$ in a different way:

$$\sum_{g \in \text{conj}(g_i)} \chi_V(g) = |\text{conj}(g_i)| \cdot \chi_V(g_i) = \chi(e_i)$$

so:

$$\frac{\text{conj}(g_i)}{n} \chi_V(g_i) = \varphi(e_i) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

which is telling us that if we divide it by n, we still get an algebraic integer! Taking a nice linear combination and multiplying by $\overline{\chi_V(g_i)}$ we get:

$$\sum_i^r \frac{\text{conj}(g_i)}{n} \chi_V(g_i) \overline{\chi_V(g_i)}$$

Then we have just shown that $\frac{\text{conj}(g_i)}{n} \chi_V(g_i)$ is an algebraic integer, and $\overline{\chi_V(g_i)}$ is an algebraic integer (being the sum of roots of unity). Now, notice this is the form of the inner product, giving us:

$$\frac{|G|}{n} \langle \chi_V, \chi_V \rangle = \frac{|G|}{n} \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

as a V irreducible. Thus, we have that $\frac{|G|}{n}$ is some algebraic integer. We further have that it is certainly a rational number ($|G|, n \in \mathbb{N}$), but then we have:

$$\frac{|G|}{n} \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} \overset{!}{=} \mathbb{Z}$$

where $\overset{!}{=}$ comes from the fact that if R is a Unique Factorization Domain, $\alpha \in \text{Frac}(R)$, α is integral over R if and only if $\alpha \in R$, completing the proof.

This will make the computation of characters of abelian groups paticularly simple! (see rep theory of finite groups: An introductory Appraoch p. 47!)

Exercise 53.2.1

1. Let G act on the n-dimensional vector-space V by basis permutation. Show that $\dim(V^G)$ equals the number of orbits of G.

53.2.1 More Character Tables

In this section, we go over a few more exmaples of character tables in order to see some techniques used to find them. For any abelian, group, the character table is straight forward. As a really simple example, consider $\mathbb{Z}/3\mathbb{Z}$:

	1	1	1
	0	1	2
χ_0	1	1	1
χ_1	1	ζ_3	ζ_3^2
χ_2	1	ζ_3^2	ζ_3

If we take $\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$, we will get a 9 by 9 table. The table bellow fills in a few of the characters (note that these were found by taking $\chi_i(g_i)\chi_j(g_j)$)

	1	1	1	1	1	1	1	1	1
$\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$	$(0,0)$	$(1,0)$	$(2,0)$	$(0,1)$	$(1,1)$	$(2,1)$	$(0,2)$	$(1,2)$	$(2,2)$
$\chi_{(0,0)}$	1	1	1	1	1	1	1	1	1
$\chi_{(1,0)}$	1	ζ_3	ζ_3^2	1	ζ_3	ζ_3^2	1	ζ_3	ζ_3^2
$\chi_{(1,1)}$	1	ζ_3	ζ_3^2	ζ_3	ζ_3^2	1	ζ_3^2	1	ζ_3
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$

Note that the root ζ_3 might change if we take the direct product of cyclic groups of differnet orders, for example the character table of $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$ has roots of unity of order 3 and 6 (as you can verify).

More generally, if G is abelian, we break G down into a product of cyclic groups and construct the table like above. Thus, we focus on non-abelian groups. We have already found the character table for S_3:

S_3	e	(1 2)	(1 2 3)
$\chi_{\mathbb{1}}$	1	1	1
χ_{sgn}	1	-1	1
$\chi^{\perp}$	2	0	-1

and the character table for S_4:

	1	6	8	3	6
S_4	1	(1 2)	(1 2 3)	(1 2)(3 4)	(1 2 3 4)
$\chi_{\mathbb{1}}$	1	1	1	1	1
χ_{sgn}	1	-1	1	1	-1
χ_3	3	1	0	-1	-1
χ_4	3	-1	0	-1	1
χ_5	2	0	-1	2	0

Next, let $G = D_4$. Then: $D' = \{e, r^2\}$, so G has 4 degree 1-irreducible representations. We also found in example 53.1.5 that D_4 has a degree 2 irreducible representation. These are all of the representations, sinc $1 + 1 + 1 + 1 + 2^2 = 8$. To find the 1-dimensional irreducible representations, notice that $D_4/D_4' \cong \mathbb{Z}_2 \times \mathbb{Z}_2$, meaning we can find the irreducible representations of $\mathbb{Z}/2\mathbb{Z}$, which are:

$\mathbb{Z}/2\mathbb{Z}$	0	1
χ_0	1	1
χ_1	1	-1

and take the tensor product to create:

$\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$	$(0,0)$	$(1,0)$	$(0,1)$	$(1,1)$
$\chi_{(0,0)}$	1	1	1	1
$\chi_{(1,0)}$	1	-1	1	-1
$\chi_{(0,1)}$	1	1	-1	-1
$\chi_{(1,1)}$	1	-1	-1	1

and using this, we can complete the table for D_4:

D_4	e	r	r^2	σ	σr
χ_1	1	1	1	1	1
χ_2	1	1	1	-1	-1
χ_3	1	-1	1	1	-1
χ_4	1	-1	1	-1	1
χ_5	2	0	-2	0	0

More generally, for D_n, the character table will conssite of characters of degree 1 and 2.

Let's now let $G = Q_8$. Taking the presentation:

$$Q_8 = \langle i, j | i^4 = 1,\ i^2 = j^2,\ i^{-1}ji = j^{-1} \rangle$$

with $k = ij$ and $i^2 = -1$, we get the conjugacy classes can be represented by $1, -1, i, j, k$, with sizes 1, 1, 2, 2, 2. Since $Q_8/Q_8' \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$, there are 4 degree 1 characters. The final irreducible character thus *must* have degree 2; let's label if χ_5. We have in fact explicitely found this character before in example 53.1.5, but we can find it without actually manually finding a representation. Let φ be an irreducible representation of degree 2. Since $-1 \in Z(Q_8)$, by Schur's lemma $\varphi(-1)$ is a 2×2 scalar matrix of order 2, hence it is $\pm I$, and so $\chi_5(-1) = \pm 2$. Next, if $\chi_5(i) = a$, $\chi_5(j) = b$, and $\chi_5(k) = c$, then since χ_5 is orthogonal, we have that:

$$1 = \langle \chi_5, \chi_5 \rangle = \frac{1}{8}(2^2 + (\pm 2)^2 + 2a\overline{a} + 2b\overline{b} + 2c\overline{c})$$

and since $a\overline{a}, b\overline{b}, c\overline{c} \in \mathbb{R}_{\geq 0}$, they must all be zero. Furthermore, we must have that:

$$0 = \langle \chi_1, \chi_5 \rangle = \frac{1}{8}\big(2 + (\pm 2) + 0 + 0 + 0\big)$$

implying that $\chi_5(-1) = -2$. Thus, we have that the character table is:

Q_8	1	i	-1	j	k
χ_1	1	1	1	1	1
χ_2	1	1	1	-1	-1
χ_3	1	-1	1	1	-1
χ_4	1	-1	1	-1	1
χ_5	2	0	-2	0	0

Notice that this character table is identical to the character table of D_4. Hence, identical character tables does not imply isomorphic groups! Finally, we could have found the last row of the above table by applying column orthogonality to find the missing values, once we knew $\chi_5(1) = 2$.

Next, let $G = A_4$. Since we found the character table for S_4, we can use it it to find the character table of A_4. We first note that A_4 has 4 conjugacy classes (represented by 1, (1 2)(3 4), (1 2 3) and (1 3 2)), and $[A_4 : A_4'] = 3$, meaning A_4 has 3 chacacters of degree 1, and the only other character must be of degree 3. Next, using the orthogonality relation, notice that χ_3 in the table for S_4 when restricted to A_4 is still irreducible (this is certainly not generally the case, for ex. the degree 2 representaiton of S_3 will become reducible since any proper subgroup of S_3 is abelian). Overall, we get:

A_4	1	(1 2)(3 4)	(1 2 3)	(1 3 2)
χ_1	1	1	1	1
χ_2	1	1	ζ_3	ζ_3^2
χ_3	1	1	ζ_3^2	ζ_3
χ_4	3	-1	0	0

Finally, we will do the character table for S_5:

S_5	1	(1 2)	(1 2 3)	(1 2 3 4)	(1 2 3 4 5)	(1 2)(3 4)	(1 2)(3 4 5)
χ_1	1	1	1	1	1	1	1
χ_2	1	-1	1	-1	1	1	-1
χ_3	4	2	1	0	-1	0	-1
χ_4	4	-2	1	0	-1	0	1
χ_5	5	-1	-1	1	0	1	-1
χ_6	5	1	-1	-1	0	1	1
χ_7	6	0	0	0	1	-2	0

TBD

53.2.2 Burnside's Theorem

We now move towards Burnside's Theorem, which shows that any group of order $p^a q^b$ for primes p, q and numbers $a, b \in \mathbb{N}$ is a solvable group! This proof is relatively simple in the context of representation theory, but it took over 70 years before a proof was found using just group theory! This is a good example of the power perspective: simply switching to the context of representation theory and seeing groups as embedded into $GL(V)$ let us prove a claim that from another perspective is much much harder!

Lemma 53.2.23: Burnside build-up Lemma

Suppose that V is an irreducible representation is of dimension n (i.e. $\chi_V(1) = n$). If $\gcd(n, |\text{conj}(g)|) = 1$, then:

$$|\chi_V(g)| = 0 \text{ or } n$$

***Proof*:**
By the above proof, we have:

$$\frac{|\text{conj}(g)|}{n}\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

where $\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$ as well, so by Bézout ($1 = an + b|\text{conj}(g)|$, using $\gcd(n, |\text{conj}(g)|) = 1$)

$$\frac{1}{n}\chi_V(g) \in \overline{\mathbb{Z}}^{\mathbb{C}}$$

Let $\alpha = \frac{1}{n}\chi_V(g)$. Furthermore, notice that:

$$|\alpha| = \left|\frac{\chi_V(g)}{\chi_V(1)}\right| \leq 1$$

Now, let N be the Galois closure of $\mathbb{Q}(\alpha)/\mathbb{Q}$ and write $\Gamma = \text{Gal}(N/\mathbb{Q})$ for its Galois group (not to be confused with the group G of the lemma). Let

$$\beta = \prod_{\sigma \in \Gamma} \sigma(\alpha)$$

Then certainly β is in the fixed field of the Galois group, $\beta \in N^{\Gamma} = \mathbb{Q}$. Notice that each $\sigma(\alpha)$ satisfies the same monic polynomials as that of α, and so $\sigma(\alpha) \in \overline{\mathbb{Z}}^{\mathbb{C}}$, and so $\beta \in \overline{\mathbb{Z}}^{\mathbb{C}}$, but then $\beta \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} = \mathbb{Z}$.

Now, recall that:

$$\alpha = \frac{\chi_V(g)}{n} = \frac{\zeta_1 + \zeta_2 + ... + \zeta_n}{n}$$

which are roots of unity, which means that:

$$\sigma(\alpha) = \frac{\sigma(\zeta_1) + \cdots + \sigma(\zeta_n)}{n}$$

so $|\sigma(\zeta_1)| \leq 1$, so $|\beta| \leq 1$. Since β is an integer, we either get that $|\beta| \in \{0, 1\}$, If $|\beta| = 0$, then $\alpha = 0$, and if $|\beta| = 1$, then $|\alpha| = 1$, and so plugging back into our original equation we get that:

$$\chi_V \in \{0, n\}$$

as we sought to show.

We can also treat this lemma as another check that we have given the correct character table (verify it for the character table of S_4 we found in example 53.2.21).

Theorem 53.2.24: Burnside's Theorem

Let $p \neq q$ be prime numbers, $a, b \in \mathbb{N}$. If $|G| = p^a q^b$, then G is solvable.

Notice how this immediately implies that a non-abelian simple group must have at least three distinct prime divisors, so its order is at least $2 \cdot 3 \cdot 5 = 30$. The true minimum is 60, attained by A_5. There is in fact no simple group of order 30. Recall also that if $|G| = p^a$, then we would need that $a = 1$ (namely, any p-group has a non-trivial center)

***Proof*:**
Take the composition series:

$$1 = G_0 \trianglelefteq G_1 \trianglelefteq \cdots \trianglelefteq G_k = G$$

where G_i/G_{i-1}. Then we will show that if G is simple, then G is *abelian*. For the sake of contradiction, suppose that G is non-abelian and simple with order $p^a q^b$ (where we may as well assume $a, b \in \mathbb{N}_{>0}$). Let $\chi_1, \chi_2, ..., \chi_r$ be the irreducible representation for the group G, and $\chi_1 = \chi_{\mathbb{1}}$. Let $Z_i = \{g \in G \mid |\chi_i(g)| = \chi_i(1)\}$. By the equality case of the triangle inequality this says exactly that $\rho_i(g)$ acts as a scalar, so Z_i is the kernel of $G \to \mathrm{PGL}(V_i)$ and in particular

$$Z_i \trianglelefteq G$$

Fix i and suppose $Z_i = G$. Then G acts by scalars on V_i, so every subspace of V_i is a subrepresentation and hence $\dim V_i = 1$. So χ_i is a homomorphism

$$\chi_i : G \to \mathbb{C}^\times$$

with $\ker \chi_i \trianglelefteq G$. Since G is simple, either $\ker \chi_i = 1$, in which case G embeds in the abelian group $\mathbb{C}^\times$ and is abelian, a contradiction; or $\ker \chi_i = G$, in which case χ_i is trivial and $i = 1$. Thus, it must be that:

$$Z_i = 1 \qquad \forall i > 1$$

Now, take the sylow q-subgroup Q: (notice we are using that $a, b > 0$)

$$1 \subsetneq Q \subsetneq G$$

So Q is a q-group, and so has a non-trivial center: $Z(Q) \neq 1$. Take $h \in Z(Q) \setminus \{e\}$. Hence $Q \leqslant C_G(h)$. , so $[G : C_G(h)] \big| [G : Q] = p^a$, where $[G : C_G(h)] = |\mathrm{conj}(h)$. Now recall we have shown that:

$$\chi_i(1) \big| |G| = p^a q^b$$

Now, if $p \nmid \chi_i(1)$, then by the previous line we have that $\chi_i(1) \big| q^b$. So, $\gcd(\chi_i(1), |\mathrm{conj}(h)|) = 1$, and so by lemma 53.2.23

$$\chi_i(h) = 0 \qquad \text{or} \qquad \chi_i(1)$$

But if $|\chi_i(h)| = \chi_i(1)$, $h \in Z_i$, and so $i = 1$

So, if $p \nmid \chi_i(1)$ and $i > 1$, then $\chi_i(h) = 0$. Using this, we can get our contradiction: as h is not the trivial element, we get:

$$\begin{aligned}
0 &= \sum_i \overline{\chi_i(h)} \chi_i(1) \\
&= \sum_i \chi_i(h) \chi_i(1) && \text{(conjugating, as each } \chi_i(1) \text{ is real)} \\
&\overset{!}{=} 1 + \sum_{\substack{i>1 \\ p \big| \chi_i(1)}} \underbrace{\chi_i(1)}_{\in p\mathbb{Z}} \underbrace{\chi_i(h)}_{\in \overline{\mathbb{Z}}^{\mathbb{C}}} \\
&= 1 + p\alpha && \text{some } \alpha \in \overline{\mathbb{Z}}^{\mathbb{C}}
\end{aligned}$$

where the one in the $\overset{!}{=}$ equality came from when $i = 1$. Thus,

$$\alpha = -1/p \in \overline{\mathbb{Z}}^{\mathbb{C}} \cap \mathbb{Q} = \mathbb{Z}$$

a contradiction, completing the proof.

(huge list of character tables: commented)

53.3 Induced Representation

This is another way of constructing representations. We saw that if $H \leqslant G$ and V is a G representation, then we can make V an H-representation through the inclusion map $H \hookrightarrow G \to \mathrm{GL}(V)$. We may ask if we may go the other way: given an H representation W, can we find a G-representation? If φ is the representations afforded by H, can we find a Φ such that $\Phi|_H = \varphi$? It turns out we cannot: take $A_3 \subseteq S_3$ and consider a faithful representation of degree 1 (recall it's a cyclic group). Then notice that any 1 dimensional representations of S_3 will have to have A_3 in it's kernel, meaning we cannot extend the action of A_3 to an action of S_3. A little more generally, if we let G be a simple group, $H \leqslant G$, and φ a representation of H where $\ker(\varphi)$ is a proper nontrivial subgroup of H, then if we somehow extend the representation φ of H to Φ of G, then $\ker(\Phi) \cap H = \ker(\varphi)$, so $\ker(\Phi)$ is nontrivial (it contains $\ker\varphi$) and proper (else $\ker\varphi = H$), contradicting that G is simple. So instead, we will not be extending representation from H to G, but *inducing* a representation in a natural way. This method of inducing a representation will work even in the two above cases, meaning an induced representation will not always be an extension.

Let $H \leqslant G$, and consider some H-representation V, which can be represented as a $k[H]$-module V. Recall that we can "extend scalars" and define a new $k[G]$-module:

$$k[G] \otimes_{k[H]} V$$

This is extension of scalars along the inclusion $k[H] \hookrightarrow k[G]$.

Definition 53.3.1: Induced Representation

Let $H \leqslant G$ of a finite group G and let V be a $k[H]$-module affording the representation φ. Then the $k[G]$-module $k[G] \otimes_{k[H]} V$ is called the *induced module* of V, the representation is called the *induced representation*, and if χ is the character of φ, then the character of the induced representation is called the *induced character*, and is written as $\mathrm{Ind}_H^G(\chi)$.

Another intuition behind defining the induced module is the following: If W is an H-representation, then let our new module be:

$$\mathrm{Ind}_H^G(W) = \{f \in \mathrm{Hom}_{\mathbf{Set}}(G, W) \mid f(hg) = h \cdot f(g),\ \forall g \in G, h \in H\}$$

Then $\mathrm{Ind}_H^G(W)$ is clearly a complex vector space under pointwise addition and scalar multiplication, and the G-action on this space would be:

$$\gamma \cdot f : G \to W \qquad g \mapsto f(g\gamma)$$

It should be verified that this is indeed G-linear. In this case, we get that:

$$\mathrm{Ind}_H^G(W) = \mathrm{Hom}_{\mathbb{C}[H]}(\mathbb{C}[G], W)$$

This second construction is the *coinduced* module, and it is a genuinely different functor from the induced module $k[G] \otimes_{k[H]} V$ in general. The two agree precisely because $[G : H]$ is finite: $k[G]$ is free of finite rank as a right $k[H]$-module, and for a finitely generated free module the natural map

$k[G] \otimes_{k[H]} V \to \mathrm{Hom}_{k[H]}(k[G], V)$ is an isomorphism. Since G is finite throughout this section, we may and do use the two interchangeably, and we take the tensor construction of definition 53.3.1 as the definition of record. The dimension of $\mathrm{Ind}_H^G(W)$ is

$$\dim_{\mathbb{C}}(\mathrm{Ind}_H^G(W)) = [G : H] \dim_{\mathbb{C}}(W)$$

with the $\mathbb{C}$-vector space isomorphism being:

$$\mathrm{Ind}_H^G(W) \to W^{\oplus [G:H]} \qquad f \mapsto f(g_1), ..., f(g_{[G:H]})$$

where we treat $G = \coprod_i Hg_i$ for the *right* cosets Hg_i (the equivariance $f(hg) = hf(g)$ makes f constant-up-to-H on right cosets, so those are the ones its values are indexed by). Note that every block and character formula later in this section is indexed by *left* cosets g_iH instead, matching the tensor model $k[G] = \bigoplus_i g_i k[H]$. The two indexings are exchanged by $g \mapsto g^{-1}$, and we will say which is meant wherever it matters. By letting $g_1 = e$ being the identity, there is a natural canonical map:

$$\mathrm{Ind}_H^G(W) \to W \qquad f \mapsto f(e)$$

This motivates the following adjoint of the restriction functor:

Theorem 53.3.2: Frobenius Reciprocity

Let $H \leqslant G$. Then if V is a G-representation and W and H-representation, then:

$$\mathrm{Hom}_G(V, \mathrm{Ind}_H^G W) \cong_{\mathbb{C}} \mathrm{Hom}_H(V|_H, W)$$

where $V|_H$ is the restriction of the action to H

***Proof*:**
We will explicitly construct inverse bijections Φ from left to right and Θ from right to left.
Let $\alpha : \mathrm{Ind}_H^G(W) \to W$, $f \mapsto f(1)$. Then α is H-linear. Then let

$$\Phi(f) = \alpha \circ f$$

Then $\Phi(f)$ is H-linear (check $\mathbb{C}$-linearity of Φ). For the other way, let $\psi : V|_H \to W$ be H-linear,

$$\Theta(\psi) : V \to \mathrm{Ind}_H^G(W) \qquad v \mapsto (g \mapsto \psi(gv))$$

Then this is well-defined. What's left is to check they are inverses of each other

53.3.3 Left Vs Right Adjoint This proof shows that induction is right-adjoint to restriction. It is also *left* adjoint: for a finite group, $\mathrm{Hom}_G(\mathrm{Ind}_H^G W, V) \cong \mathrm{Hom}_H(W, V|_H)$ as well. A pair of functors (F, U) where F is both left and right adjoint to U is sometimes called a *Frobenius pairing*, and this is exactly what the coincidence of induction and coinduction at finite index buys.

The two-sided adjunction is special to finite index. For an infinite group the tensor construction $k[G] \otimes_{k[H]} -$ is left adjoint to restriction and the coinduced module $\mathrm{Hom}_{k[H]}(k[G], -)$ is right adjoint, and these are different functors. In the smooth representation theory of locally profinite groups the convention is that Ind denotes the coinduced (right adjoint) functor and c-Ind, *compact induction*, denotes the left adjoint (see [34]).

Corollary 53.3.4: Frobenius Reciprocity On Characters

Let G be finite, $k = \mathbb{C}$, and $H \leqslant G$. Let χ be the character of a G-representation V and ψ the character of an H-representation W. Then:

$$\langle \chi|_H, \psi \rangle_H = \langle \chi, \mathrm{Ind}_H^G(\psi) \rangle_G$$

***Proof*:**

Both sides count the same dimension. First note that for representations A, B of a finite group over $\mathbb{C}$ we have $\dim_{\mathbb{C}} \mathrm{Hom}(A, B) = \dim_{\mathbb{C}} \mathrm{Hom}(B, A)$: by corollary 53.2.16 these are $\langle \chi_B, \chi_A \rangle$ and $\langle \chi_A, \chi_B \rangle$, and writing A and B in terms of irreducibles (theorem 53.1.9) both equal $\sum_i a_i b_i$ for the multiplicities a_i, b_i.

Now apply corollary 53.2.16 to each side:

$$\langle \chi, \mathrm{Ind}_H^G(\psi) \rangle_G = \dim_{\mathbb{C}} \mathrm{Hom}_G(\mathrm{Ind}_H^G W, V) = \dim_{\mathbb{C}} \mathrm{Hom}_G(V, \mathrm{Ind}_H^G W)$$

using the symmetry just noted, and this last space is $\mathrm{Hom}_H(V|_H, W)$ by theorem 53.3.2. Applying the symmetry and corollary 53.2.16 once more,

$$\dim_{\mathbb{C}} \mathrm{Hom}_H(V|_H, W) = \dim_{\mathbb{C}} \mathrm{Hom}_H(W, V|_H) = \langle \chi|_H, \psi \rangle_H$$

as claimed.

Example 53.3.5: Induced Representations

1. $\mathrm{Ind}_G^G(W) = W$
2. $\mathrm{Ind}_{\{e\}}^G(\mathbb{C}) = \mathbb{C}[G]$
3. $\mathrm{Ind}_H^G(\mathbb{1}) = \mathbb{C}[G/H]$

Another way of thinking of this result is that if V is an irreducible representation of G and W is an irreducible representation of H, then the number of times V occurs in $\mathrm{Ind}_H^G(W)$ is equal to the number of times W occurs in $V|_H$.

Proposition 53.3.6: Properties Of Induced Representation

Let $K \leqslant H \leqslant G$, W be an K-representation, $\mathrm{Ind}_K^H(W)$ the induced H representation, $\mathrm{Ind}_H^G(\mathrm{Ind}_K^H(W))$ the induced G-representation. Then:

1. If χ, χ' are characters of K-representations,
$$\mathrm{Ind}_K^H(\chi + \chi') = \mathrm{Ind}_K^H(\chi) + \mathrm{Ind}_K^H(\chi')$$
2. Induction is transitive:
$$\mathrm{Ind}_H^G(\mathrm{Ind}_K^H(W)) = \mathrm{Ind}_K^G(W)$$

***Proof*:**
For (1), let W_1, W_2 be K-representations affording χ, χ'. Tensoring is additive in its second argument, so

$$k[H] \otimes_{k[K]} (W_1 \oplus W_2) \cong \big(k[H] \otimes_{k[K]} W_1\big) \oplus \big(k[H] \otimes_{k[K]} W_2\big)$$

as $k[H]$-modules, and the character of a direct sum is the sum of the characters.

For (2), the point is associativity of the tensor product together with $k[H] \otimes_{k[H]} k[G] \cong k[G]$ as $(k[G], k[H])$-bimodules. Explicitly,

$$\mathrm{Ind}_H^G\big(\mathrm{Ind}_K^H(W)\big) = k[G] \otimes_{k[H]} \big(k[H] \otimes_{k[K]} W\big) \cong \big(k[G] \otimes_{k[H]} k[H]\big) \otimes_{k[K]} W \cong k[G] \otimes_{k[K]} W = \mathrm{Ind}_K^G(W)$$

where the first isomorphism is associativity and the second is the unit isomorphism. Each map is $k[G]$-linear because G acts by left multiplication on the leftmost factor throughout, which every map above respects.

Theorem 53.3.7: Computing Induced Representation

Let $H \leqslant G$ of a finite group G, and $g_1, g_2, ..., g_m$ be representatives for distinct left cosets of H in G. Let V be an H-representation of degree n. Then the induced G-representation $W = k[G] \otimes_{k[H]} V$ is an nm degree representation, and if Φ repersented the induced representation, then there exists a basis for W such that W affords the matrix representation defined for each $g \in G$ by:

$$\Phi(g) = \begin{pmatrix} \varphi(g_1^{-1} g g_1) & \cdots & \varphi(g_1^{-1} g g_m) \\ \vdots & \vdots & \cdots \\ \varphi(g_m^{-1} g g_1) & \cdots & \varphi(g_m^{-1} g g_m) \end{pmatrix}$$

where each $\varphi(g_i^{-1} g g_j)$ is an $n \times n$ block, with $\varphi(g_i^{-1} g g_j) = 0$ if $g_i^{-1} g g_j \notin H$.

***Proof*:**
First, $k[G]$ is a free right $k[H]$-module with decomposition:

$$k[G] = g_1 k[H] \oplus \cdots \oplus g_m k[H]$$

Since tensor products commute with direct sums, we get:

$$W = k[G] \otimes_{k[H]} V \cong (g_1 \otimes V) \oplus \cdots \oplus (g_m \otimes V)$$

Since k is in the center of $k[G]$, the above isomorphism is also a k-vector space isomorphism. Thus, if $v_1, v_2, ..., v_n$ is a basis for V, then $\{g_i \otimes v_j \mid 1 \leq i \leq m,\ 1 \leq j \leq n\}$ is a basis for W, and hence $\dim_k(W) = nm$.

To show $\Phi(g)$ is of the given form, order the basis into m of size n as:

$$g_1 \otimes v_1, g_1 \otimes v_2, ..., g_1 \otimes v_n, g_2 \otimes v_1, ..., g_m \otimes v_n$$

Using this order, we can compute the matrix $\Phi(g)$ for each g acting on W given this basis. Fixing j and g, let i be the unique index with $gg_j \in g_i H$ and write $gg_j = g_i h$ with $h \in H$. Then for every k:

$$g(g_j \otimes v_k) = gg_j \otimes v_k = g_i h \otimes v_k = g_i \otimes hv_k = \sum_{t=1}^{n} a_{tk}(h)(g_i \otimes v_t)$$

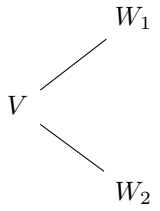
where a_{tk} is the t, k coefficient of the matrix h acting on V with respect to the basis $v_1, v_2, ..., v_n$. Notice that the action of g on W maps the jth block of n basis vectors of W to the ith block of basis vectors, and then has the matrix $\varphi(h)$ as that block. Since $h = g_i^{-1} g g_j$, this fully describes $\Phi(g)$, as we sought to show.

Corollary 53.3.8: Computing The Induced Character

Let $H \leqslant G$ where G is a finite group, V be an H-representation with character χ, and $\mathrm{Ind}_H^G(\chi)$ the induced character. Then:

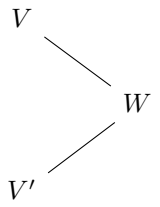
$$\mathrm{Ind}_H^G(\chi)(g) = \sum_{i=1}^{m} \chi(g_i^{-1} g g_i) \qquad \text{for all } g \in G$$

where $g_1, \ldots, g_m$ is a complete set of representatives for the left cosets of H in G, $m = [G : H]$, and $\chi(g_i^{-1} g g_i) := 0$ if $g_i^{-1} g g_i \notin H$. (The right-hand side does not depend on the chosen representatives: replacing g_i by $g_i h$ conjugates $g_i^{-1} g g_i$ by $h \in H$, which preserves membership in H and leaves χ unchanged, χ being a class function on H.) Hence, $\mathrm{Ind}_H^G(\chi)(g) = 0$ if g is not conjugate of some element in H in G, in particular if $H \trianglelefteq G$ then $\mathrm{Ind}_H^G(\chi)$ is zero on all elements $G - H$.



***Proof*:**
Let φ be the representation afforded by V. By theorem 53.3.7, $k[G] \otimes_{k[H]} V$ has a basis in which g acts by the block matrix $\Phi(g)$ whose (i, j) block is $\varphi(g_i^{-1} g g_j)$, the block being zero when $g_i^{-1} g g_j \notin H$. By definition 53.3.1, $\mathrm{Ind}_H^G(\chi)(g)$ is the trace of $\Phi(g)$, which is the sum of the traces of the diagonal blocks $\varphi(g_i^{-1} g g_i)$. Each of these traces is $\chi(g_i^{-1} g g_i)$ when $g_i^{-1} g g_i \in H$ and 0 otherwise, which gives the formula. If g is conjugate to no element of H, every $g_i^{-1} g g_i$ lies outside H and the sum is 0. If $H \trianglelefteq G$ and $g \notin H$, then $g_i^{-1} g g_i \notin H$ for every i, since $g_i^{-1} g g_i \in H$ would give $g \in g_i H g_i^{-1} = H$, so $\mathrm{Ind}_H^G(\chi)(g) = 0$, as claimed.

Proposition 53.3.9: Induced Index Two Induced Representation



Let $H \leqslant G$ where $[G : H]$ has index two[a] (ex. $A_n \leqslant S_n$ or $C_n \leqslant D_{2n}$). Then if V is a finite-dimensional irreducible representation of G, either $V|_H$ is irreducible or $V|_H = W_1 \oplus W_2$ where $W_1 \ncong W_2$, are both ireducibile, and have the same dimension. Moreover, the second option implies that $V \cong V \otimes \chi$ where $\chi : G \twoheadrightarrow G/H \cong \{\pm 1\}$ (i.e. a 1-dimensional representation)

[a]Recall that this makes H a normal subgroup

In the case where $V|_H$ is not irreducible, we can imagine it splitting into a diagram like so:

while in the case where $V|_H$ is irreducible, what we actually have (and did not have time to prove), is that we have *two* irreducible representation's of G (V and V') that both get restricted to W:

and then the induced representation of W is the direct sum of V and V'.

***Proof*:**
Let $W \subseteq V|_H$ be an irreducible H-representation. Then Since $H \trianglelefteq G$, gW is is an H-stable space: gW is some subspace of V (it satisfies the subspace axioms since the action is linear), and for any $h \in H$, $h \cdot gW = hgW = g(g^{-1}hg)W = gW$, since $g^{-1}hg \in H$ by normality of H and W is H-stable. Now, gW is irreducible: the map $w \mapsto gw$ is a k-linear bijection $W \to gW$ satisfying $h(gw) = g((g^{-1}hg)w)$, so it intertwines the H-action up to conjugation. Since $g^{-1}Hg = H$ by normality, it carries H-submodules to H-submodules in both directions, so gW is irreducible. Finally, the structure of gW only depends on that of the coset gH

Thus, fix $\gamma \in G \setminus H$ so that

$$\sum_{g \in G} gW = W + \gamma W \subseteq V$$

where the $\subseteq$ comes from the fact that this is a sum of two subspaces. Now, notice that the left hand side is a G-stable space which is nonzero, and V is irreducible so has no proper nonzero G-stable subspace. Therefore we actually have the equality:

$$W + \gamma W = V$$

meaning the $H + gH = G$ is parallelled in the action! We now have two possibilities: either $W = \gamma W$, and so $V|_H = W$, and we have $\dim V = \dim W$ (which is case (a)).

On the other hand, if $W \neq \gamma W$, then $W \cap \gamma W = (0)$ (since they are both irreducible), and so $V = W \oplus \gamma W$ (i.e. direct sum as H-representations), and so V is the direct sum of two irreducible H-representations.

Now, by Frobenius reciprocity, we get:

$$\langle W, V|_H \rangle_H = \langle \mathrm{Ind}_H^G(W), V \rangle_G$$

Since W occurs in $V|_H$ by definition, we get that $1 \leq \langle W, V|_H \rangle_H$, while since V is irreducible and, continuing in case (b), $\dim \mathrm{Ind}_H^G(W) = [G : H] \dim W = 2 \dim W = \dim V$, the representation V can occur at most once, so $\langle \mathrm{Ind}_H^G(W), V \rangle_G \leq 1$, and hence:

$$1 = \langle W, V|_H \rangle_H = \langle \mathrm{Ind}_H^G(W), V \rangle_G = 1$$

Thus, from the first one, we get that $W \ncong \gamma W$ (or else the left hand side would be equal to 2), and we must have $V = \mathrm{Ind}_H^G(W)$ (or else the right hand side would be equal to something greater than 1)

If part (b) holds, then

$$(V \otimes \chi)|_H \cong V|_H$$

and

$$V \cong \mathrm{Ind}_H^G(W) \cong V \otimes \chi$$

Conversely, if $V \cong V \otimes \chi$, then $\chi_V(g) = \chi_V(g)\chi(g)$ for all $g \in G$. Since $\chi(g) = -1$ for $g \notin H$, this gives $\chi_V(g) = -\chi_V(g)$, so $\chi_V(g) = 0$ for all $g \notin H$. And so:

$$\|\chi_{V|_H}\|_H^2 = 2\|\chi_V\|_G^2$$

and so $\langle \chi_{V|_H}, \chi_{V|_H} \rangle_H = 2$, which rules out a single irreducible (norm 1) and $W \oplus W$ (norm 4), forcing $V|_H = W_1 \oplus W_2$ with $W_1 \ncong W_2$ irreducible, as we sought to show.

Theorem 53.1.16 says that the constituents of $\pi|_N$ form a single G-orbit. Once induction is available, that orbit description turns into a construction: the representation is induced from the subgroup stabilizing one of the classes. This is the form in which Clifford's theorem is normally applied.

Corollary 53.3.10: Clifford Induction From the Stabilizer

Let G be a group, $N \trianglelefteq G$, K a field, and let (π, V) be an irreducible representation of G on a finite-dimensional K-space. Let $W \subseteq V$ be an irreducible N-subrepresentation, let

$$H = \{g \in G \mid \pi_W^g \cong \pi_W\}, \qquad \pi_W^g(n) = \pi_W(g^{-1}ng)$$

be the stabilizer of its class, and let V_W be the π_W-isotypic component of $V|_N$. Then $N \subseteq H$, the subspace V_W is an irreducible H-subrepresentation, and

$$V \cong \mathrm{Ind}_H^G V_W$$

If $\pi|_N$ has more than one isomorphism class among its constituents, then $H \neq G$ and π is induced from a proper subgroup.

***Proof*:**
That $N \subseteq H$ is immediate, since $\pi_W^n \cong \pi_W$ for $n \in N$ by conjugating the isomorphism. Since V is finite dimensional, $V|_N$ has finitely many constituents, so the orbit below is finite and $[G : H]$ is finite. No finiteness of G itself is needed anywhere. By theorem 53.1.16 the classes occurring in $V|_N$ form one G-orbit, and $g \mapsto (U \mapsto U^g)$ is a left action, so the orbit is in bijection with G/H and $gV_W = V_{\pi_W^g}$ depends only on the coset gH. Summing the isotypic decomposition of the semisimple $V|_N$ over that orbit,

$$V = \bigoplus_{gH \in G/H} gV_W$$

This decomposition exhibits V as an induced representation. By definition 53.3.1 the induced representation is $\operatorname{Ind}_H^G V_W = K[G] \otimes_{K[H]} V_W$. The map

$$\Theta \colon K[G] \otimes_{K[H]} V_W \longrightarrow V, \qquad g \otimes v \longmapsto gv$$

is well defined, because $gh \otimes v$ and $g \otimes hv$ both go to ghv for $h \in H$, and it is G-equivariant by construction. It is surjective, since its image contains every gV_W and those span V by the display. Finally $\dim_K K[G] \otimes_{K[H]} V_W = [G : H] \dim_K V_W$, which is $\dim_K V$ by the display again, so Θ is an isomorphism.

Irreducibility of V_W over H. If $V_0 \subseteq V_W$ were a non-zero proper H-subrepresentation then $\bigoplus_{gH} gV_0$ would be a non-zero proper G-subrepresentation of V, the sum being direct and G-stable because V_0 is H-stable and gV_0 depends only on gH. That contradicts irreducibility of V.

For the last sentence, suppose more than one isomorphism class occurs in $\pi|_N$. The classes are in bijection with G/H, so $[G : H] > 1$ and H is proper, completing the proof.

53.4 *Application to Harmonic Analysis

In this section, we take a brief moment to explore the representation of locally compact abelian groups, such as $\mathbb{R}$. This section will assume some understanding of topological groups, and is mainly to motivate for the reader the connection between the representation theory of this chapter with *Fourier analysis* and more broadly *Harmonic analysis*.

Every group G is always a topological group with the discrete topology (see appendix C.4). The group G is finite iff it is a compact discrete group. Many groups of interest are either compact (like the torus or compact lie groups), or locally compact (like the real line). The representation theory of these groups rely on the correct framing of the representation in the finite case. For the case of infinite dimension *non-abelian* groups, the build-up is a good deal too complicated for this expository section[4], however many of the major ideas for the abelian are simple enough to exposit, and even better naturally motivate the Fourier transform and abstract harmonic analysis through the lens of representation theory.

Let G be a finite abelian group so that all complex irreducible representations are 1-dimensional, and hence characters and necessarily a homomorphism. As G is finite, say $n = |G|$, then $\chi(g^n) = \chi(e) = 1$

[4] see [41] for the EYNTKA series on geometric representation theory

for all $g \in G$, and so $\chi^n = \text{id}$, showing that $\chi : G \to \mathbb{C}^*$ restricts to a map $\chi : G \to S^1$. This shows that all characters are *unitary representations*. All characters for a finite group are necessarily unitary representations, while for non-finite groups there can be non-unitary representations[5]. Such groups which have a (general) representation theory that doesn't generalize as well as infinite unitary representations (many representations are indecomposable but not irreducible, for the details see the companion Lie groups notes). Thus, for this sections we stick to maps to S^1 with the natural multiplication structure as the subgroup of $\mathbb{C}^*$: label this collection $\hat{G} = \text{Hom}_{\mathbf{Ab}}(G, S^1)$. As the codomain is a group, $\text{Hom}_{\mathbf{Ab}}(G, S^1)$ has a group structure given by point-wise multiplication.

Definition 53.4.1: Pontryagin Group

Let G be locally compact abelian group. Then the *Pontryagin dual* of G is the group:

$$\text{Hom}_{\mathbf{Top}}(G, S^1)$$

of *continuous* homomorphisms, with the operation being point-wise multiplication and the compact-open topology. The topology is what makes $\widehat{G}$ itself locally compact abelian, and so what makes the double dual $\widehat{\widehat{G}}$ meaningful; for finite G it is discrete and can be ignored.

This is just another way of representing the characters of the group. Let us stick to the special case where G is a finite abelian group and re-frame the previous theory using the Pontryagin group:

Proposition 53.4.2: Pontryagin Dual

Let G be a finite abelian group, $\hat{G} = \text{Hom}_{\mathbf{Ab}}(G, S^1)$ the group of characters under point-wise multiplication. Then there is an isomorphism:

$$G \cong \widehat{G}$$

Furthermore, there is a natural isomorphism:

$$G \cong \hat{\hat{G}}$$

If G is infinite, it is rarely the case that $G \cong \widehat{G}$ (think $\widehat{L^p} \cong L^q$). Indeed when G is compact and infinite it never is, since $\widehat{G}$ is then discrete. What is most important is that $\widehat{G}$ contains the necessary information to recover G, as the double-dual recovers G. The operation $\widehat{(-)}$ passes back and forth between a group and a unitary representation, and since the representations in play are unitary, that collection is itself a group[6]. The passage between the two is thus:

$$\text{Group} \overset{\widehat{(-)}}{\rightleftarrows} \text{Unitary Rep.}$$

[5] $\text{SL}_2(\mathbb{R})$ acting on $\mathbb{R}^2$ need not be unitary

[6] the collection of representations also form a ring called the *representation ring* and has fascinating ties to K-theory and intersection theory, but it is again too much for this section and the connections are discussed in [13, Part II] of the EYTNKA series

***Proof*:**
As G is finite abelian,

$$G \cong \mathbb{Z}/n_1\mathbb{Z} \times \mathbb{Z}/n_2\mathbb{Z} \times \cdots \times \mathbb{Z}/n_k\mathbb{Z}$$

where $n_1 \big| n_2 \big| \cdots \big| n_k$. Choose generators, $a_1, ..., a_k$. Define the indicator characters on the generators:

$$\chi_i(a_j) = \begin{cases} e^{\frac{2\pi i}{n_i}} & i = j \\ 1 & i \neq j \end{cases}$$

These certainly generate $\hat{G}$. Define the map on the generators:

$$\Phi(a_i) = \chi_i$$

This is an isomorphism.

For the double-dual, take the natural map (distinct from the Φ above):

$$\Psi(g_i) = \mathrm{ev}_{g_i}$$

where as usual $\mathrm{ev}_{g_i}(\chi) = \chi(g_i)$. This is easy to check that is an isomorphism, completing the proof.

Now, to study a space is to study all the (continuous) functions on it. Here the space is a finite abelian group. Let G have the discrete topology so that the set of continuous functions from G to $\mathbb{C}$ is all set functions. The goal is a $\mathbb{C}$-algebra isomorphism between $\mathbb{C}[G]$ and $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$. These two sets are clearly bijective via the natural mapping:

$$\sum_i a_i g_i \mapsto (g_i \mapsto a_i)$$

And this map preserves addition if addition is defined point-wise in the hom-set:

$$\begin{aligned} &\Phi\left(\sum_i a_i g_i + \sum_i b_i g_i\right) \\ &= \Phi\left(\sum_i (a_i + b_i) g_i\right) \\ &\mapsto (g_i \mapsto a_i + b_i) \\ &= (g_i \mapsto a_i) + (g_i \mapsto b_i) \\ &= \Phi\left(\sum_i a_i g_i\right) + \Phi\left(\sum_i b_i g_i\right) \end{aligned}$$

But it does *not* preserve multiplication if the operation is pointwise multiplication:

$$\begin{aligned}
&\Phi\left(\sum_{g\in G} a_i g \sum_{g\in G} b_i g\right) \\
&= \Phi\left(\sum_{g\in G}\sum_{g_k g_\ell = g} (a_k b_\ell) g\right) \\
&\mapsto (g_i \mapsto \sum_{g_k g_\ell = g_i} (a_k b_\ell)) \\
&\neq (g_i \mapsto a_i b_i) \\
&= (g_i \mapsto a_i)\cdot(g_i \mapsto b_i) \\
&= \Phi\left(\sum_i a_i g_i\right)\cdot\Phi\left(\sum_i b_i g_i\right)
\end{aligned}$$

This is because the points g_i act on each other. There is a natural multiplication function defined on $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ called *convolution*:

Definition 53.4.3: Convolution

Let $p, q \in \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$. Then their *convolution* is define pointwise as:

$$(p * q)(g) = \sum_{g_i g_j = g} p(g_i) q(g_j) = \sum_{h\in G} p(h) q(h^{-1} g)$$

Lemma 53.4.4: Isomorphism With Convolution

Let G be a finite abelian group. Then:

$$(\mathbb{C}[G], +, \cdot) \cong_{k\text{-}\mathbf{Alg}} (\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$$

where the left hand side is the usual group ring and the right hand side has convolution as multiplication

***Proof*:**
The first two lines of the multiplication calculation above evaluate $\Phi(x\cdot y)$ at g_i as $\sum_{g_k g_\ell = g_i} a_k b_\ell$, which is exactly $(\Phi(x) * \Phi(y))(g_i)$ for the convolution just defined; additivity and bijectivity were checked above.

Now, $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$ is a $|G|$-dimensional $\mathbb{C}$ vector-space with the natural basis given by the indicator function:

$$\delta_h(g) = \begin{cases} 1 & g = h \\ 0 & g \neq h \end{cases}$$

Namely for any $f : G \to \mathbb{C}$ there is a unique decomposition given the functionals defined by each $g \in G$:

$$f = \sum_{h\in G} f(h)\delta_h \qquad \text{so that} \qquad f(g) = \sum_{h\in G} f(h)\delta_h(g) = f(g)\cdot 1 = f(g)$$

The key feature of this basis is that it acts like evaluation when taking the inner product. Define:

$$\langle f, g\rangle = \sum_{h\in G} f(h)\overline{g(h)}$$

Then $\{\delta_g\}_{g\in G}$ is an orthogonal basis and:

$$\langle f, \delta_{g_i}\rangle = f(g_i)\cdot\overline{\delta_{g_i}(g_i)} = f(g_i)\cdot 1 = f(g_i) = a_i$$

This is a special case of the Riesz representation theorem: every linear functional here is inner-product representable, and ev_{g_i} is represented by δ_{g_i}. This inner product can be thought as expressly chosen so that the collection δ_{g_i} forms an orthonormal basis, or conversely given this standard inner product, the indicator function will always be an orthonormal basis. Now $\hat{G}$ also has $|G|$ elements, so the characters are at least the right number to be a second basis, but they are a different family of functions from the δ_g, not the image of them under any isomorphism, and nothing so far says they are independent, let alone orthogonal. The key insight of Fourier analysis is that they are!

Proposition 53.4.5: Character Form Orthogonal Basis: Fourier Basis

The characters $\widehat{G}$ form an orthogonal basis for $\text{Hom}_{\mathbf{Top}}(G, \mathbb{C})$. Normalizing by $1/\sqrt{|G|}$ forms an orthonormal basis.

***Proof*:**
If $i = j$:

$$\begin{aligned}\langle \chi_i, \chi_i\rangle &= \sum_{g\in G}\chi_i(g)\overline{\chi_i(g)}\\ &= \sum_{g\in G}|\chi_i(g)|^2\\ &= \sum_{g\in G}1^2\\ &= |G|\end{aligned}$$

if $i \neq j$, Then as $\overline{\chi_j} = \chi_j^{-1}$ (as we are mapping to the unit circle), we get that $\chi' = \chi_i\chi_j^{-1}$ is a non-trivial character, so there is some h such that $\chi'(h) \neq 1$. Let

$$\langle \chi_i, \chi_j\rangle = S = \sum_{g\in G}\chi'(g)$$

Then:

$$\chi'(h)S = \chi'(h)\sum_{g\in G}\chi'(g) = \sum_{g\in G}\chi'(h)\chi'(g) = \sum_{g\in G}\chi'(hg)$$

As $hG = G$, this is just a re-arranging of terms, hence:

$$\chi'(h)S = \sum_{g\in G}\chi'(g) = S \qquad \text{so} \qquad S(\chi'(h) - 1) = 0$$

Now, by assumption $\chi'(h) \neq 1$, so $\chi'(h) - 1 \neq 0$, so as $\mathbb{C}$ is an integral domain it must be that $S = 0$, implying:

$$\langle \chi_i, \chi_j\rangle = 0$$

as we sought to show.

This inner product can be thought of as extracting the "phase" information.

Example 53.4.6: Phase-Space Basis

Let $G = \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z} = \{(0,0),(1,0),(0,1),(1,1)\}$. A character $\chi : G \to \mathbb{C}^*$ is determined by its values on the generators $g_1 = (1,0)$ and $g_2 = (0,1)$. Since both generators have order 2, necessarily $\chi(g_1)^2 = \chi(g_1^2) = \chi(0,0) = 1$ and likewise for g_2. Thus, the character's values on the generators must be either 1 or -1. This gives $2 \times 2 = 4$ possible characters, indexed by pairs $(k_1, k_2) \in \{0,1\}^2$.

The four characters χ_{k_1,k_2} are defined by their values on the generators:

$$\chi_{k_1,k_2}(1,0) = (-1)^{k_1} \qquad \text{and} \qquad \chi_{k_1,k_2}(0,1) = (-1)^{k_2}$$

From this, the value for any element $(a,b) \in G$ is $\chi_{k_1,k_2}(a,b) = (-1)^{k_1 a + k_2 b}$.

This gives the following character table, which explicitly lists the functions that form our new "basis":

$\hat{G}$	**(0,0)**	**(1,0)**	**(0,1)**	**(1,1)**
χ_{00}	1	1	1	1
χ_{10}	1	-1	1	-1
χ_{01}	1	1	-1	-1
χ_{11}	1	-1	-1	1

The orthogonality relation from proposition 53.4.5 can be checked directly. Computing $\langle \chi_{10}, \chi_{11} \rangle$:

$$\begin{aligned}
\langle \chi_{10}, \chi_{11} \rangle &= \sum_{g \in G} \chi_{10}(g)\overline{\chi_{11}(g)} \\
&= \chi_{10}(0,0)\chi_{11}(0,0) + \chi_{10}(1,0)\chi_{11}(1,0) + \chi_{10}(0,1)\chi_{11}(0,1) + \chi_{10}(1,1)\chi_{11}(1,1) \\
&= (1)(1) + (-1)(-1) + (1)(-1) + (-1)(1) \\
&= 1 + 1 - 1 - 1 = 0
\end{aligned}$$

Using the above example, let us change perspectives on how to interpret this change of basis. The function $f : G \to \mathbb{C}$ takes the "points" $g \in G$ and maps them (continuously) to the complex numbers, and those points are evaluated by the Riesz representation of f against the indicator functions that form an orthonormal basis. But the characters give another orthogonal basis for $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ against which the inner product can be taken, orthonormal once scaled by $1/\sqrt{|G|}$. The characters $\chi \in \hat{G}$ may thus be read as points in their own right: points carrying "phase" information rather than the "location" information that the indicator functions carry. This motivates the following definition:

Definition 53.4.7: Fourier Transform (Gelfand Transform)

Let G be a finite abelian group with the discrete topology. Then the *Fourier transform* is:

$$(\widehat{-}) : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \to \mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C}) \qquad f \mapsto (\chi \mapsto \langle f, \chi \rangle)$$

where the image of f is often written as:

$$\hat{f}(\chi) = \langle f, \chi \rangle = \sum_{g \in G} f(g)\overline{\chi(g)}$$

The name *Gelfand transform* comes from the fact that the Fourier transform is traditionally about real periodic functions, or Lebesgue measurable functions. It wasn't until later that Pontryagin, van Kampen, Weil and Gelfand generalized it to the context of locally compact abelian groups, where the above is the special case where G is finite.

Now, certainly as vector spaces $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \cong_{\mathbb{C}} \mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C})$ mapping:

$$(g \mapsto \langle f, \delta_g \rangle) \mapsto (\chi \mapsto \langle f, \chi \rangle)$$

But does this map preserve the inner product, and more so can the convolution product of $\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ be preserved given the appropriate choice of product on $\mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C})$? The answer is yes, and can be thought of as the corner-stone result of harmonic analysis on discrete abelian groups:

Theorem 53.4.8: Fourier Reciprocity

The map given in definition 53.4.7 is a $\mathbb{C}$-algebra isomorphism,

$$(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *) \cong (\mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C}), +, \cdot)$$

with $\cdot$ in $(\mathrm{Hom}_{\mathbf{Top}}(\hat{G}, \mathbb{C}), +, \cdot)$ being point-wise multiplication. It scales the inner product by $|G|$, so the normalisation $\mathcal{U}(f) = \frac{1}{\sqrt{|G|}}\hat{f}$ is unitary.

Recall that unitary means $\langle \hat{f}, \hat{g} \rangle = \langle f, g \rangle$. In a conventional real analysis course:

- the $\mathbb{C}$-algebra homomorphism is called the *Convolution Theorem*,
- the unitary property is called *Plancherel's Theorem*,
- invertibility (i.e. bijectivity) is called the *Fourier Inversion Theorem*.

***Proof*:**

1. *1. Linearity:* Let $f, h \in \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})$ and $a, b \in \mathbb{C}$.

$$\begin{aligned}
\widehat{af+bh}(\chi) &= \langle af+bh, \chi\rangle && \text{by definition}\\
&= \sum_{g\in G}(af+bh)(g)\overline{\chi(g)}\\
&= a\sum_{g\in G} f(g)\overline{\chi(g)} + b\sum_{g\in G} h(g)\overline{\chi(g)} && \text{by linearity of sums}\\
&= a\langle f,\chi\rangle + b\langle h,\chi\rangle\\
&= a\hat{f}(\chi) + b\hat{h}(\chi)
\end{aligned}$$

Since this holds for all $\chi \in \hat{G}$, the transform is a linear map.

2. $\mathbb{C}$-algebra Homomorphism (The Convolution Theorem): We must show that the Fourier transform converts convolution into pointwise multiplication.

$$\begin{aligned}
\widehat{f*h}(\chi) &= \langle f*h, \chi\rangle\\
&= \sum_{k\in G}(f*h)(k)\overline{\chi(k)} && \text{by definition of inner product}\\
&= \sum_{k\in G}\left(\sum_{g\in G} f(g)h(g^{-1}k)\right)\overline{\chi(k)} && \text{by definition of convolution}\\
&= \sum_{g\in G} f(g)\sum_{k\in G} h(g^{-1}k)\overline{\chi(k)} && \text{swapping order of summation}
\end{aligned}$$

Let $\ell = g^{-1}k$, so $k = g\ell$. As k runs over G, so does ℓ. The inner sum becomes:

$$\sum_{\ell\in G} h(\ell)\overline{\chi(g\ell)} = \sum_{\ell\in G} h(\ell)\overline{\chi(g)\chi(\ell)} = \overline{\chi(g)}\sum_{\ell\in G} h(\ell)\overline{\chi(\ell)} = \overline{\chi(g)}\hat{h}(\chi)$$

Substituting this back into the main expression:

$$\begin{aligned}
\widehat{f*h}(\chi) &= \sum_{g\in G} f(g)\left(\overline{\chi(g)}\hat{h}(\chi)\right)\\
&= \hat{h}(\chi)\sum_{g\in G} f(g)\overline{\chi(g)}\\
&= \hat{h}(\chi)\hat{f}(\chi)
\end{aligned}$$

Thus, $\widehat{f*h} = \hat{f}\cdot\hat{h}$, proving the map is an algebra homomorphism.

3. Isomorphism (The Fourier Inversion Theorem): We show the map is invertible by constructing its inverse. Let $\mathcal{F}(f) = \hat{f}$. We claim the inverse is given by $\mathcal{F}^{-1}(\hat{f})(g) =$

$\frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi(g)$.

$$\begin{aligned}
\frac{1}{|G|}\sum_{\chi\in\hat{G}}\hat{f}(\chi)\chi(g) &= \frac{1}{|G|}\sum_{\chi\in\hat{G}}\left(\sum_{h\in G} f(h)\overline{\chi(h)}\right)\chi(g) && \text{by definition of } \hat{f}\\
&= \frac{1}{|G|}\sum_{h\in G} f(h)\sum_{\chi\in\hat{G}}\chi(g)\overline{\chi(h)} && \text{swapping order of summation}\\
&= \frac{1}{|G|}\sum_{h\in G} f(h)\sum_{\chi\in\hat{G}}\chi(gh^{-1})
\end{aligned}$$

The inner sum is an example of the *Second Orthogonality Relation* and is a standard exercise the reader should do. In particular, the sum of all characters evaluated at a group element (giving all powers of a certain root of unity) is $|G|$ if the element is e and 0 otherwise. Thus $\sum_{\chi\in\hat{G}}\chi(gh^{-1}) = |G|\delta_{g,h}$.

$$\frac{1}{|G|}\sum_{h\in G} f(h)(|G|\delta_{g,h}) = \sum_{h\in G} f(h)\delta_{g,h} = f(g)$$

Since we can recover f uniquely from $\hat{f}$, the map is an isomorphism.

4. Unitary Property (Plancherel's Theorem): Note that here is where the transform picks up a factor of $|G|$, and so where the normalising constant is forced. Let us calculate the inner product for the given definition.

$$\begin{aligned}
\langle\hat{f},\hat{h}\rangle_{\hat{G}} &= \sum_{\chi\in\hat{G}}\hat{f}(\chi)\overline{\hat{h}(\chi)}\\
&= \sum_{\chi\in\hat{G}}\left(\sum_{g\in G} f(g)\overline{\chi(g)}\right)\overline{\left(\sum_{k\in G} h(k)\overline{\chi(k)}\right)}\\
&= \sum_{\chi\in\hat{G}}\left(\sum_{g\in G} f(g)\overline{\chi(g)}\right)\left(\sum_{k\in G}\overline{h(k)}\chi(k)\right)\\
&= \sum_{g\in G}\sum_{k\in G} f(g)\overline{h(k)}\sum_{\chi\in\hat{G}}\chi(k)\overline{\chi(g)} && \text{re-arranging terms}\\
&= \sum_{g\in G}\sum_{k\in G} f(g)\overline{h(k)}(|G|\delta_{g,k}) && \text{by Second Orthogonality}\\
&= |G|\sum_{g\in G} f(g)\overline{h(g)}\\
&= |G|\langle f,h\rangle_G
\end{aligned}$$

This proves *Plancherel's Theorem.* To make the map strictly unitary, one must normalize the transform. If we define the unitary transform $\mathcal{U}(f) = \frac{1}{\sqrt{|G|}}\hat{f}$, then it follows immediately that $\langle\mathcal{U}(f),\mathcal{U}(h)\rangle = \langle f,h\rangle$, completing the proof.

Example 53.4.9: Fourier Transform

Take $G = \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ from example 53.4.6. Now for the Fourier transform of a concrete function. Let $f = \delta_{(1,0)}$, so that $f(1,0) = 1$ and is zero elsewhere. This is a basis vector in the standard "position" basis, and its coordinates in the character basis come from computing $\hat{f}(\chi) = \langle f, \chi \rangle$ for each character.

$$\begin{aligned}\hat{f}(\chi) = \langle \delta_{(1,0)}, \chi \rangle &= \sum_{g \in G} \delta_{(1,0)}(g)\overline{\chi(g)} \\ &= 1 \cdot \overline{\chi(1,0)} + 0 + 0 + 0 = \chi(1,0)\end{aligned}$$

The character table gives this value for each χ:

- $\hat{f}(\chi_{00}) = \chi_{00}(1,0) = 1$
- $\hat{f}(\chi_{10}) = \chi_{10}(1,0) = -1$
- $\hat{f}(\chi_{01}) = \chi_{01}(1,0) = 1$
- $\hat{f}(\chi_{11}) = \chi_{11}(1,0) = -1$

Thus, the original function $f = \delta_{(1,0)}$, which is a spike at one point in the "position" basis, has been transformed into a new function $\hat{f}$ on $\hat{G}$ with values $(1, -1, 1, -1)$.

Recall the inversion formula from the proof of theorem 53.4.8: $f(g) = \frac{1}{|G|} \sum_{\chi \in \hat{G}} \hat{f}(\chi)\chi(g)$ (here $|G| = 4$). Let's check the value at $g = (1,0)$:

$$\begin{aligned}f(1,0) &= \frac{1}{4}\left(\hat{f}(\chi_{00})\chi_{00}(1,0) + \hat{f}(\chi_{10})\chi_{10}(1,0) + \hat{f}(\chi_{01})\chi_{01}(1,0) + \hat{f}(\chi_{11})\chi_{11}(1,0)\right) \\ &= \frac{1}{4}\left((1)(1) + (-1)(-1) + (1)(1) + (-1)(-1)\right) \\ &= \frac{1}{4}(1+1+1+1) = 1\end{aligned}$$

Now the value at $g = (0,1)$, which should be 0:

$$\begin{aligned}f(0,1) &= \frac{1}{4}\left(\hat{f}(\chi_{00})\chi_{00}(0,1) + \hat{f}(\chi_{10})\chi_{10}(0,1) + \hat{f}(\chi_{01})\chi_{01}(0,1) + \hat{f}(\chi_{11})\chi_{11}(0,1)\right) \\ &= \frac{1}{4}\left((1)(1) + (-1)(1) + (1)(-1) + (-1)(-1)\right) \\ &= \frac{1}{4}(1-1-1+1) = 0\end{aligned}$$

This now connects to representation theory. So far, for a finite abelian group G, the Fourier transform has been established as a unitary $\mathbb{C}$-algebra isomorphism between the algebra of functions on G with convolution, $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), *)$, and the algebra of functions on the dual group $\hat{G}$ with pointwise multiplication. The representation theory perspective shows that Fourier analysis is the simplest case of an Artin-Wedderburn decomposition. The key is to view the $\mathbb{C}$-group algebra $\mathbb{C}[G]$ with the natural G-action given by left multiplication (convolution), namely $\rho : G \to \mathrm{GL}(\mathbb{C}[G])$ given by:

$$\rho(g) : f \mapsto g * f$$

From this viewpoint, the study of the $\mathbb{C}$-algebra $(\mathbb{C}[G], +, *)$ and the $\mathbb{C}[G]$-module $\mathbb{C}[G]$ is the same thing that is the study of the regular representation of G. Now, this representation can be broken down into the direct sum of 1-dimensional irreducible representations. Namely, for a finite abelian group, the set of irreducible representations is exactly the dual group: $\mathrm{Irr}(G) = \widehat{G}$, giving:

$$\mathbb{C}[G] \cong \bigoplus_{\chi \in \widehat{G}} V_\chi$$

where each V_χ is a 1-dimensional subspace corresponding to the character χ.

This decomposition is made concrete by the Fourier transform. The Fourier Inversion Formula, $f = \frac{1}{|G|} \sum_{\chi \in \hat{G}} \hat{f}(\chi)\chi$, is the literal expression of this decomposition. It writes the function f as a sum of components, where each term $\hat{f}(\chi)\chi$ is the projection of f onto the 1-dimensional irreducible subspace V_χ. Then the fourier coefficient $\hat{f}(\chi)$ is the coordinate of f in the irreducible component corresponding to χ.

The projection functions $p_\chi = \frac{1}{|G|} \sum_{g \in G} \overline{\chi(g)} g$ can be constructed inside $\mathbb{C}[G]$, and project onto the irreducible subspace V_χ. Convolving any function f with p_χ annihilates all other "frequency components", leaving the part of f that lies in V_χ.

Hence, the Fourier basis is *the* basis that diagonalizes the natural action of the group on its own algebra of functions.

If G is a *non-abelian* finite group, the identification $\mathrm{Irr}(G) = \hat{G}$ breaks and with it the simple transform: $\mathrm{Hom}(G, S^1)$ remains a group, but it only sees the abelianisation $\widehat{G^{\mathrm{ab}}}$, while the object one wants, $\mathrm{Irr}(G)$, carries no natural group structure. However, the representation theory perspective remains: the generalized Fourier transform (given by the *Peter-Weyl Theorem*) decomposes a function f on the group into a sum of *matrix coefficients* corresponding to these higher-dimensional matrix representations.

53.4.1 Generalization to Locally Compact Abelian Groups

What happens for abelian groups like $(\mathbb{R}, +)$, $(\mathbb{Z}, +)$, or the circle group $(S^1, \cdot)$? These are examples of *Locally Compact Abelian (LCA)* groups. Moving from the finite to the infinite setting means replacing finite sums with integrals, and integrating on an arbitrary group first requires a notion of "volume" or "measure". The shape of the answer is already visible in the finite case: read the delta functions δ_h as *measures*, and every f becomes a sum of weighted point masses. The right object, then, is a measure on the group that the group operation cannot see. The essential new ingredient is the *Haar measure*. For any LCA group G, there exists a measure μ that gives a consistent way to integrate functions on the group.

Definition 53.4.10: Haar Measure

A *Haar measure* on an LCA group G is a measure μ on the Borel σ-algebra of G that is left-translation-invariant. That is, for any measurable set $E \subseteq G$ and any element $g \in G$:

$$\mu(gE) = \mu(E)$$

This measure is unique up to a positive scaling constant. For abelian groups, it is also right-translation-invariant.

See [82] for details on how to construct such a measure on any LCA that is unique up to scaling. This measure is the direct generalization of taking the order of the group.

Example 53.4.11: Haar Measure

1. For a finite group with the discrete topology, the Haar measure is the counting measure, and $\mu(G) = |G|$.
2. For $(\mathbb{R}, +)$, the Haar measure is the standard Lebesgue measure dx.
3. For $(S^1, \cdot)$, the Haar measure can be taken as $d\theta$.
4. For $(\mathbb{Z}, +)$, the Haar measure is again the counting measure.

In the infinite case points can no longer be represented by indicator functions; the *Dirac delta distributions* take on that role instead. See [80] for the theory of distributions.

With the Haar measure in hand, the main objects of study can be redefined by replacing every sum over G with an integral with respect to $d\mu$.

1. *The Group Algebra $L^1(G)$:* The space of all functions becomes too large. The natural replacement for the convolution algebra $\mathbb{C}[G]$ is the space of absolutely integrable functions, $L^1(G, d\mu)$. For two functions $f, h \in L^1(G)$, their convolution is defined by the integral:

$$(f * h)(g) = \int_G f(x)h(x^{-1}g)d\mu(x)$$

   This space $(L^1(G), +, *)$ forms a Banach algebra.

2. *The Dual Group $\widehat{G}$:* It was proven that the correct codomain should be S^1. The dual group is the set of all *continuous* group homomorphisms into S^1.

$$\widehat{G} = \mathrm{Hom}_{\mathbf{Top}}(G, S^1)$$

   The dual group $\widehat{G}$ is itself an LCA group. It is crucial to note that, unlike the finite case, $G \cong \widehat{G}$ is the exception rather than the rule, holding for $\mathbb{R}$ but failing for $\mathbb{Z}$ and S^1:

$$\widehat{\mathbb{R}} \cong \mathbb{R}, \qquad \widehat{\mathbb{Z}} \cong S^1, \qquad \widehat{S^1} \cong \mathbb{Z}$$

   This highlights why it is essential to treat $\hat{G}$ as a distinct space. The theory that governs this relationship is *Pontryagin Duality*, which states that the double-dual is canonically isomorphic to the original group: $\widehat{\widehat{G}} \cong G$.

3. *The Fourier Transform:* The definition of the Fourier transform is the direct analogue of the finite case, replacing the sum with an integral. For a function $f \in L^1(G) \cap L^2(G)$, its Fourier transform is a function $\hat{f}$ on the dual group $\hat{G}$:

$$\hat{f}(\chi) = \int_G f(g)\overline{\chi(g)}d\mu(g)$$

   Similarly, the inner product that defines the Hilbert space structure on $L^2(G)$ is:

$$\langle f, h\rangle = \int_G f(g)\overline{h(g)}d\mu(g)$$

With these definitions, the entire suite of theorems proven in the finite case carries over:

Theorem 53.4.12: Fourier Reciprocity on LCA Groups

Let G be an LCA group with Haar measure μ. Then there exists a unique Haar measure ν on the dual group $\widehat{G}$ for which the following hold. (Unlike the finite case these are statements about two different maps: $L^2(G) \to L^2(\widehat{G})$ is a unitary isomorphism, while $L^1(G) \to C_0(\widehat{G})$ is an injective algebra map that is not onto.)

1. *The Fourier Inversion Theorem:* For a sufficiently well-behaved function f (e.g., $f \in L^1 \cap L^2$ such that $\hat{f} \in L^1$), the original function can be recovered by an integral over the dual group:
$$f(g) = \int_{\widehat{G}} \hat{f}(\chi)\chi(g)d\nu(\chi)$$
2. *Plancherel's Theorem:* The Fourier transform extends uniquely from $L^1 \cap L^2$ to a unitary isomorphism of Hilbert spaces, $\mathcal{F} : L^2(G, \mu) \to L^2(\widehat{G}, \nu)$. This means it preserves the inner product:
$$\langle \hat{f}, \hat{h} \rangle_{L^2(\widehat{G})} = \langle f, h \rangle_{L^2(G)}$$
3. *The Convolution Theorem:* For $f, h \in L^1(G)$, the Fourier transform maps convolution to pointwise multiplication:
$$\widehat{f * h}(\chi) = \hat{f}(\chi) \cdot \hat{h}(\chi)$$

***Proof*:**
This is the Pontryagin duality theorem; a full proof via the Gelfand transform belongs to the harmonic analysis of locally compact abelian groups and is not reproduced in this starred section.

The correspondence between the finite and general LCA settings can be summarized as follows:

Finite Abelian Case	**LCA Case**
Group G	LCA Group G
Order $\lvert G \rvert$	Haar Measure μ
Group Algebra $\mathbb{C}[G]$	Banach Algebra $L^1(G, \mu)$
Hilbert Space $\mathrm{Hom}(G, \mathbb{C})$	Hilbert Space $L^2(G, \mu)$
Summation $\sum_{g \in G}$	Integration $\int_G d\mu(g)$
Dual Group $\widehat{G} = \mathrm{Hom}(G, \mathbb{C}^\times)$	Dual Group $\widehat{G} = \mathrm{Hom}_{\mathbf{Top}}(G, S^1)$
Inner Product $\sum f(g)\overline{h(g)}$	Inner Product $\int f(g)\overline{h(g)}d\mu(g)$
Fourier Transform $\sum f(g)\overline{\chi(g)}$	Fourier Transform $\int f(g)\overline{\chi(g)}d\mu(g)$

53.4.2 The Algebraic-Geometric Meaning of the Dual Group

In algebraic geometry, a fundamental principle is that the geometry of a space can be recovered from its algebra of functions. For an affine space k^n over an algebraically closed k, the corresponding

algebra is the polynomial ring $k[x_1, \dots, x_n]$, and the Nullstellensatz makes the points of the space correspond to the maximal ideals of this algebra. (Over a non-closed field the correspondence fails: $(x^2+1) \subseteq \mathbb{R}[x]$ is maximal and is no point of $\mathbb{R}^1$.) Specifically, for any point $p = (a_1, \dots, a_n) \in k^n$, the evaluation map:

$$\mathrm{ev}_p : k[x_1, \dots, x_n] \to k \qquad f \mapsto f(p)$$

is an algebra homomorphism whose kernel, $m_p = (x_1 - a_1, \dots, x_n - a_n)$, is a maximal ideal. The quotient $k[x_1, \dots, x_n]/m_p \cong k$ recovers the value of the function at that point.

A similar setup is now in place for a finite abelian group G, with the convolution algebra $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), *, +)$ taking the role of the function algebra. A natural question arises: can we recover the "points" of our space from the maximal ideals of this algebra? Let's first attempt a direct analogy, assuming the points are the elements of the group G itself. For a point $g_i \in G$ there is a point-evaluation map, which is linear:

$$\mathrm{ev}_{g_i} : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \to \mathbb{C} \qquad f \mapsto f(g_i)$$

The kernel of this map is the vector subspace of functions that are zero at g_i. However, for this subspace to be an ideal, it must be closed under convolution. Let $f \in \ker(\mathrm{ev}_{g_i})$ (so $f(g_i) = 0$) and let h be any function in our algebra. Consider their convolution:

$$(h * f)(g_i) = \sum_{k \in G} h(k) f(k^{-1} g_i)$$

The value of f at other points, $f(k^{-1}g_i)$, can be non-zero, and in fact the subspace really does fail to be an ideal. Take $G = \mathbb{Z}/2\mathbb{Z} = \{e, a\}$ and $g_i = e$. Then $\delta_a \in \ker(\mathrm{ev}_e)$, but $\delta_a * \delta_a = \delta_{a^2} = \delta_e$, which is 1 at e. So the kernel of the point-evaluation map is *not* an ideal with respect to convolution. This implies the points of G do not correspond to the maximal ideals of its convolution algebra.

The key insight is that the correct "geometric points" for the convolution algebra are not the elements of G, but the characters of the dual group $\widehat{G}$.

Proposition 53.4.13: Characters and Maximal Ideals

Let G be a finite abelian group. The maximal ideals of the convolution algebra $(\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}), +, *)$ are in bijective correspondence with the characters $\chi \in \widehat{G}$.

***Proof*:**

For each character $\chi \in \widehat{G}$, define a Fourier evaluation map:

$$\widehat{\mathrm{ev}}_\chi : \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \to \mathbb{C} \qquad f \mapsto \hat{f}(\chi)$$

This map takes a function and returns its Fourier coefficient at the frequency χ. By 53.4.8 $\widehat{\mathrm{ev}}_\chi$ is a $\mathbb{C}$-algebra homomorphism. Since $\widehat{\mathrm{ev}}_\chi$ is a surjective algebra homomorphism onto a field ($\mathbb{C}$), its kernel, which we denote by I_χ, is a maximal ideal:

$$I_\chi = \ker(\widehat{\mathrm{ev}}_\chi) = \{f \in \mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C}) \,|\, \hat{f}(\chi) = 0\}$$

By the First Isomorphism Theorem for rings, we have:

$$\mathrm{Hom}_{\mathbf{Top}}(G, \mathbb{C})/I_\chi \cong \mathbb{C}$$

This shows that every character $\chi \in \widehat{G}$ defines a maximal ideal. Conversely, after applying the Fourier transform we get the usual multiplication and ring structure, and then an approach similar to the Gelfand-Kolmogorov theorem gives the desired result.

> For the infinite case the same picture holds with one caveat: $L^1(G, \mu)$ is non-unital unless G is discrete, carrying only an approximate identity, so it is the maximal *modular* ideals that correspond to the homomorphisms into $\mathbb{C}$ (via the *Gelfand-Mazur Theorem*, which identifies the quotient by such an ideal with $\mathbb{C}$).

Thus, with the convolution algebra $\mathbb{C}[G]$ as our primary object, the natural geometric space that emerges is not the group G itself, but its Pontryagin dual, $\widehat{G}$. The Fourier transform is the mechanism that allows us to evaluate the functions of our algebra at the points of this "true" underlying space. This perspective, generalized by Gelfand, is the foundation of non-commutative geometry.

Concepts	**Classical Algebraic Geometry**
Algebra	Polynomial Ring $(k[x_1, \ldots, x_n], \cdot)$
Product	Polynomial Multiplication

53.5⋆ Modular Representations and the Failure of Semisimplicity

⋆ *Optional. This section is an aside; nothing later in the book depends on it.*

Two chapters have approached $k[G]$ from opposite sides. Chapter 53 has assumed throughout that $\mathrm{char}(k) \nmid |G|$, where theorem 53.1.9 makes every module semisimple and the character theory of section 53.2 computes what the modules are. Chapter 52 built machinery for algebras where semisimplicity fails: the radical $\mathrm{Jac}(A)$ measuring the failure, Krull-Schmidt replacing simple summands by indecomposable ones, and projective covers replacing the projections that no longer exist. The group algebra $k[G]$ with $\mathrm{char}(k) = p$ dividing $|G|$ is the object that machinery was built for, and this section applies it.

There is a temptation to read theorem 53.1.9 as having settled the characteristic-p case. The condition $p \big| |G|$ does say exactly when semisimplicity fails,[7] and example 52.1.11 computed the resulting radical for $G = \mathbb{Z}/p\mathbb{Z}$ down to the last element. What the theorem does not say is what replaces the semisimple picture when it fails, and that question, for a general finite group, is open. The subject

[7] Theorem 53.1.9 gives one direction. The other is quick: the element $\nu = \sum_{g \in G} g$ satisfies $h\nu = \nu = \nu h$ for every $h \in G$, so $k\nu$ is a two-sided ideal, and $\nu^2 = |G|\nu = 0$ when p divides $|G|$. Since $k[G]$ is finite dimensional it is left Artinian, so a nonzero nilpotent ideal forces $\mathrm{Jac}(k[G]) \neq 0$ by theorem 52.1.8, and $k[G]$ is not semisimple by corollary 52.1.10.

devoted to it is *modular representation theory*, treated in *Modular Representation Theory* [36]. The word *modular* here refers to reduction modulo a prime and has nothing to do with modular forms or with the modular arithmetic of $\mathbb{Z}/n\mathbb{Z}$.

It is worth being precise about what is open, because the framework is not. Krull-Schmidt (theorem 52.2.4) applies to $k[G]$ for any field, so the regular module has a decomposition into indecomposable summands that is unique up to isomorphism and reordering, theorem 52.3.5 matches those summands with the simple modules, and theorem 52.3.7 identifies them as the projective covers. The structural questions are answered. What is not known, for a general G and p, are the *invariants*: the dimensions and characters of the simple $k[G]$-modules. Determining them for the symmetric groups is a well-known open problem. Worse, the indecomposable modules themselves are unclassifiable for most groups, in a sense theorem 53.5.7 below makes precise.

We begin with the coarsest decomposition of $k[G]$, which costs nothing beyond chapter 52 and already organizes everything that follows.

Definition 53.5.1: Block of an Algebra

Let A be a finite-dimensional k-algebra and let $Z(A)$ denote its centre. A *block idempotent* of A is a primitive idempotent of the algebra $Z(A)$, and for such an idempotent b the two-sided ideal $B = bA$ is called a *block* of A.

The word *block* is overworked, and three of its meanings have already appeared in this book. A Jordan block is a matrix in the normal form of example 52.2.6; the Artin-Wedderburn factors $M_{n_i}(D_i)$ of a semisimple algebra are called blocks in the statement of theorem 52.3.5; and definition 53.5.1 is the sense used from here on. The last two agree on semisimple algebras, where the block idempotents are exactly the identity elements of the Artin-Wedderburn factors, so no earlier statement changes meaning. They diverge as soon as $\mathrm{Jac}(A) \neq 0$, which is the case this section is about.[8]

Theorem 53.5.2: Block Decomposition

Let A be a finite-dimensional k-algebra. Then the identity has a decomposition

$$1 = b_1 + b_2 + \cdots + b_m$$

into pairwise orthogonal primitive idempotents of $Z(A)$, and this decomposition is unique up to reordering. The corresponding blocks give a direct sum decomposition

$$A = b_1 A \oplus b_2 A \oplus \cdots \oplus b_m A$$

of A into two-sided ideals, each of which is a k-algebra with identity element b_i. Every indecomposable left A-module M satisfies $M = b_i M$ for exactly one index i, and every block contains at least one simple module in this sense.

***Proof*:**
Existence. The centre $Z(A)$ is a commutative k-algebra, and it is finite dimensional because A is. Applying theorem 52.3.2 to the algebra $Z(A)$ gives a decomposition $1 = b_1 + \cdots + b_m$ of its

[8]The eponym is also overworked. Richard Brauer's name attaches both to the block theory of this section and to the Brauer group of section 51.3. The two objects are unrelated.

identity, which is the identity of A, into pairwise orthogonal primitive idempotents of $Z(A)$.

The decomposition of A. Each b_i is central, so $b_iA = Ab_i$ is a two-sided ideal, and it is closed under multiplication with b_i acting as a two-sided identity on it. Since the b_i are orthogonal with sum 1, every $a \in A$ satisfies $a = \sum_i b_i a$ with $b_i a \in b_i A$, and if $\sum_i b_i a_i = 0$ then multiplying by b_j gives $b_j a_j = 0$ for each j. The sum is therefore direct.

Uniqueness. Let $1 = c_1 + \cdots + c_l$ be a second such decomposition. For each i we have $b_i = \sum_j b_i c_j$, and each $b_i c_j$ is an idempotent of $Z(A)$ because b_i and c_j are commuting idempotents. These are pairwise orthogonal, since $(b_i c_j)(b_i c_{j'}) = b_i c_j c_{j'} = 0$ for $j \neq j'$. Primitivity of b_i forces exactly one summand to be nonzero, so $b_i = b_i c_j$ for a unique j, which is to say $b_i \leq c_j$ in the sense that $b_i c_j = b_i$. Running the same argument with the roles reversed gives, for that j, a unique i' with $c_j = c_j b_{i'}$. Then $b_i = b_i c_j$ and $c_j = c_j b_{i'}$ give $b_i b_{i'} = b_i c_j b_{i'} = b_i c_j = b_i \neq 0$, and orthogonality of distinct b's forces $i' = i$, whence $b_i = b_i c_j = c_j b_i = c_j$. So $i \mapsto j$ is a bijection matching the two decompositions.

Modules. Let M be an indecomposable left A-module. Each $b_i M$ is a submodule, because b_i is central: for $a \in A$ we have $a(b_i m) = b_i(am)$. The identity acts as the identity map on M, so $M = \sum_i b_i M$, and the sum is direct by the same orthogonality computation as above. Indecomposability leaves exactly one nonzero summand, so $M = b_i M$ for exactly one i.

Each block has a simple module. The map $A \to b_i A$, $a \mapsto b_i a$, is a surjective ring homomorphism, since b_i is a central idempotent, and it carries 1 to the identity b_i of $b_i A$. Now $b_i A$ is a nonzero finite-dimensional algebra, so it has a maximal left ideal and hence a simple module S. Pulling back along the surjection makes S a simple A-module with $b_i S = S$.

The theorem says that the study of $k[G]$-modules splits, with no loss and no overlap, into m independent problems, one per block. This is the first thing one does with a modular group algebra, and it is why the literature speaks of the representation theory "of a block".

The blocks of $k[G]$ can be located without factoring the algebra, which is what makes them computable. Each block idempotent b_i is central, so multiplication by b_i is an endomorphism of any A-module, and on a simple module it is either 0 or the identity because it is idempotent. A simple module is indecomposable, so theorem 53.5.2 gives $S = b_i S$ for exactly one index i: one block idempotent acts as the identity on S and the rest act as zero, which is what it means for S to belong to that block. Suppose now that k is a splitting field for G, so that $\mathrm{End}_{k[G]}(S) = k$ for every simple S. Then Schur's lemma makes every central element act on S by a scalar, and the resulting k-algebra map $\omega_S : Z(k[G]) \to k$ is called the *central character* of S. By the previous paragraph ω_S determines the block of S, since it returns 1 on that block's idempotent and 0 on the others. Now the class sums $\sigma_1, \ldots, \sigma_s$, one for each conjugacy class of G, form a k-basis of $Z(k[G])$ over any field: each σ_i is central because conjugation permutes each class, the σ_i are linearly independent because the group elements are, and $\sum_g \lambda_g g$ is central exactly when $g \mapsto \lambda_g$ is constant on conjugacy classes. That is the computation carried out inside the proof of proposition 53.1.13, which used nothing about the characteristic of the field. Every b_i is therefore a k-combination of class sums, so two simple modules whose central characters agree on every class sum lie in the same block. The criterion is a statement about the simple modules in characteristic p, which are themselves the unknowns. What turns block-finding into arithmetic with the ordinary character table is Brauer's refinement, which runs the test on the *ordinary* irreducible characters instead. For an ordinary irreducible χ and a class sum σ_C with representative g_C, the relevant scalar is

$$\omega_\chi(\sigma_C) = \frac{|C|\,\chi(g_C)}{\chi(1)}$$

an algebraic integer. Ordinary irreducible characters are sorted into blocks of $k[G]$ because the block idempotents lift from $k[G]$ to $R[G]$ once a p-modular system is fixed (definition 53.5.4), and two ordinary irreducibles lie in the same block when these scalars agree for every class modulo a maximal ideal above p. The division by $\chi(1)$ is not optional: for a simple module of dimension 1 a class sum acts by the plain sum of the scalars, and dropping the normalization for a character of higher degree gives the wrong answer. Example 53.5.3 uses the degree-1 shortcut precisely because both of its simple modules are one dimensional and are reductions of ordinary representations.

For a semisimple algebra the decomposition is the Artin-Wedderburn one and nothing is gained. The content is in the opposite direction: when $\mathrm{Jac}(A) \neq 0$ a single block can carry many simple modules, and untangling them is the work.

Example 53.5.3: The Blocks of $k[S_3]$ in Characteristic 3

Let k be a field with $\mathrm{char}(k) = 3$ and let $G = S_3$, so $p = 3$ divides $|G| = 6$ and theorem 53.1.9 does not apply. The centre $Z(k[S_3])$ has the three class sums as a basis:

$$\sigma_1 = e, \qquad \sigma_2 = (1\ 2) + (1\ 3) + (2\ 3), \qquad \sigma_3 = (1\ 2\ 3) + (1\ 3\ 2)$$

Write $N = \{e, (1\ 2\ 3), (1\ 3\ 2)\}$ for the normal subgroup of order 3, generated by $c = (1\ 2\ 3)$, and let I be the ideal of $k[S_3]$ generated by $c - 1$, which is two-sided because N is normal. By the computation of example 52.1.11 with $p = 3$ we have $(c-1)^3 = c^3 - 1 = 0$, so I is nilpotent. For any simple $k[S_3]$-module S the subset IS is a submodule, and nilpotency of I forces $IS \neq S$, so $IS = 0$ and N acts trivially on S. The simple $k[S_3]$-modules are therefore exactly the simple modules of

$$k[S_3/N] \cong k[\mathbb{Z}/2\mathbb{Z}]$$

inflated along the quotient map. Since $\mathrm{char}(k) = 3$ does not divide 2, theorem 53.1.9 makes $k[\mathbb{Z}/2\mathbb{Z}]$ semisimple, and $t^2 - 1 = (t-1)(t+1)$ has distinct roots, so $k[\mathbb{Z}/2\mathbb{Z}] \cong k \times k$. Hence $k[S_3]$ has exactly two simple modules, both of dimension 1: the trivial module $\mathbb{1}$ and the sign module sgn. In particular both are absolutely simple, so k is a splitting field and the central characters above are defined.

To locate them we compute central characters. Both simple modules are one dimensional, so a group element g acts on S by the scalar $\chi_S(g)$ and a class sum acts by the sum of those scalars over the class. The three-cycles are even permutations, so

$$\omega_{\mathbb{1}}(\sigma_2) = 3 \cdot 1 = 0, \qquad \omega_{\mathrm{sgn}}(\sigma_2) = 3 \cdot (-1) = 0, \qquad \omega_{\mathbb{1}}(\sigma_3) = \omega_{\mathrm{sgn}}(\sigma_3) = 2 \cdot 1 = 2$$

all computed in k, where $3 = 0$, and $\omega(\sigma_1) = 1$ for both. The two central characters agree on every class sum, so $\mathbb{1}$ and sgn lie in the same block. Every block contains a simple module by theorem 53.5.2, so there is no room for a second: $k[S_3]$ has exactly one block, itself.

This is the phenomenon the section is about. In characteristic 0 the algebra $\mathbb{C}[S_3]$ splits into three Artin-Wedderburn factors, one per irreducible character of example 53.2.8, and each factor is a matrix algebra that can be understood on its own. In characteristic 3 the algebra does not split at all, and the two simple modules are bound together in a single block, so the algebra is indecomposable as an algebra.

Having fixed the coarse decomposition, we turn to the numerical invariants. The first was already defined in general in definition 52.3.8, and the group algebra is its intended application: the Cartan matrix of $k[G]$ has entries $C_{ij} = [P_i : S_j]$, the multiplicity of the simple module S_j among the

composition factors of the projective cover of S_i. In characteristic 0 this matrix is the identity, because $P_i = S_i$ for a semisimple algebra, and it carries no information. In characteristic p it records how far the projectives are from the simples.

Computing it from the definition means knowing the projective modules, which is exactly what one does not have at the outset. The second invariant is what makes it accessible, and it is the one Brauer's program is built on. It compares characteristic p with characteristic 0 directly. Doing this properly requires a p-modular system: a complete discrete valuation ring R with residue field k of characteristic p and fraction field F of characteristic 0, chosen large enough that both $F[G]$ and $k[G]$ split. A finitely generated $F[G]$-module then contains an R-lattice stable under G, and reducing that lattice modulo the maximal ideal produces a $k[G]$-module. The composition factors of the reduction do not depend on which lattice was chosen, a theorem of Brauer and Nesbitt, and this independence is what makes the following definition well posed.

Definition 53.5.4: Decomposition Matrix

Let (F, R, k) be a splitting p-modular system for G, let $T_1, \dots, T_s$ be the simple $F[G]$-modules and $S_1, \dots, S_r$ the simple $k[G]$-modules. The *decomposition matrix* of G at p is the $s \times r$ matrix $D = (d_{ij})$ of nonnegative integers where d_{ij} is the multiplicity of S_j as a composition factor of the reduction, modulo the maximal ideal of R, of a full G-stable R-lattice in T_i. The lattice must be full, meaning that it spans T_i over F, or the reduction has the wrong dimension. The reduction is taken modulo the maximal ideal of R and not modulo p, because R is typically ramified over $\mathbb{Z}_p$, in which case the two differ.

The rows of D are indexed by the ordinary irreducible characters, which section 53.2 computes, and the columns by the modular simple modules, which are the unknowns. Each row records how one ordinary irreducible breaks up when reduced. This is Brauer's idea in one sentence: the characteristic-0 theory is completely understood, so the characteristic-p theory should be reachable by reduction, and D is the matrix that records the reduction. What makes the idea pay is that D determines the Cartan matrix of definition 52.3.8 outright.

Theorem 53.5.5: Cartan Matrix, Decomposition Matrix, and p-Regular Classes

Let (F, R, k) be a splitting p-modular system for G, with decomposition matrix D and Cartan matrix C. Then

$$C = D^{\mathsf{T}} D$$

In particular C is symmetric. Moreover the number of simple $k[G]$-modules equals the number of p-regular conjugacy classes of G, where a conjugacy class is p-regular when the order of its elements is prime to p.

We state these without proof. The first is a statement about the three Grothendieck groups attached to (F, R, k) and the maps c, d and e between them, the configuration known as the *cde triangle*: the relation $C = D^{\mathsf{T}} D$ is the matrix form of the factorization $c = de$ together with the fact that e is the transpose of d over a splitting system. The second is a separate theorem of Brauer, proved without the triangle. Developing that machinery needs the theory of lattices over a complete discrete valuation ring and the Brauer characters built from it, which is where [36] begins. Complete treatments are in Serre's *Linear Representations of Finite Groups* [90, Part III] and Webb's *A Course in Finite Group Representation Theory* [100, Chs. 9 and 10].

The counting statement is already enough to check the earlier computation. The 3-regular classes of S_3 are those whose elements have order prime to 3, namely $\{e\}$ and the class of transpositions, so there are two of them, matching the two simple modules found in example 53.5.3. It also puts the characteristic-0 count of proposition 53.1.13 in context: over $\mathbb{C}$ the number of simple modules is the number of *all* conjugacy classes, and passing to characteristic p discards exactly the classes of order divisible by p.

Example 53.5.6: The Decomposition and Cartan Matrices of S_3 at $p = 3$

The ordinary irreducible characters of S_3 are the trivial character $\chi_{\mathbb{1}}$, the sign character χ_{sgn}, and a character $\chi^{\perp}$ of degree 2. The first two are read off example 53.2.8, and $\chi^{\perp}$ is constructed in example 53.2.19 as the character of the complement $V^{\perp}$ of the trivial summand in the permutation representation, with $\chi^{\perp}(e) = 2$, $\chi^{\perp}((1\ 2)) = 0$ and $\chi^{\perp}((1\ 2\ 3)) = -1$. The two simple $k[S_3]$-modules are $S_1 = \mathbb{1}$ and $S_2 = \mathrm{sgn}$, both of dimension 1, as computed in example 53.5.3. Take the p-modular system $(F, R, k) = (\mathbb{Q}_3, \mathbb{Z}_3, \mathbb{F}_3)$, which is splitting for S_3: all three ordinary irreducibles are realizable over $\mathbb{Q}$, the degree-2 one by the explicit rational basis of example 53.2.19, and they stay irreducible after extending scalars to $\mathbb{C}$, so they are absolutely irreducible. Both modular simples are one dimensional, hence absolutely simple, so theorem 53.5.5 applies.

Reducing modulo 3, the trivial and sign representations are already defined over k and remain simple, so they contribute the rows $(1, 0)$ and $(0, 1)$. The representation $V^{\perp}$ reduces to a module M of dimension 2. Both simple modules are one dimensional, so M has exactly two composition factors, each S_1 or S_2. Taking determinants of the matrices of the group action identifies which. A permutation matrix has determinant the sign of the permutation, so the degree-three permutation representation has determinant sgn, and its trivial summand contributes 1, leaving $\det V^{\perp} = \mathrm{sgn}$. The determinant is a polynomial with integer coefficients in the matrix entries, so it commutes with reducing those entries modulo the maximal ideal, giving $\det M = \mathrm{sgn}$ as a character valued in k. In a basis adapted to a composition series the matrices are block triangular, so the determinant of a module is the product of the determinants of its composition factors, and the two factors of M have determinants multiplying to sgn. Two copies of S_1 would give $\mathbb{1}$ and two copies of S_2 would give $\mathrm{sgn}^2 = \mathbb{1}$, and $\mathrm{sgn} \neq \mathbb{1}$ over k because $\mathrm{char}(k) = 3 \neq 2$. So the factors are one S_1 and one S_2, giving the row $(1, 1)$. Hence

$$D = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix} \qquad \text{and} \qquad D^{\mathsf{T}} D = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$$

so by theorem 53.5.5 the Cartan matrix of $k[S_3]$ is

$$C = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$$

Reading the entries back: $C_{11} = [P_1 : S_1] = 2$ and $C_{12} = [P_1 : S_2] = 1$, so the projective cover of the trivial module has three composition factors and dimension 3. That is a check on the whole computation, since theorem 52.3.5 gives $k[S_3] = P_1 \oplus P_2$ with each P_i appearing $\dim_k S_i = 1$ time, and $3 + 3 = 6 = \dim_k k[S_3]$.

Two features of C are general. It is symmetric, which holds for any group algebra over a splitting field and fails for finite-dimensional algebras at large. And $\det C = 4 - 1 = 3$ is a power of p, which is also always true. Here it happens to equal the order of a Sylow 3-subgroup of S_3.

Note what the computation used: the ordinary character table, which is classical, and one piece of genuinely modular information, the way $\chi^{\perp}$ breaks up. That is the general shape of the problem.

Brauer's program provides information of exactly this kind, and it does not solve the problem. The relation $C = D^{\mathsf{T}}D$ determines C from D, and the counting theorem fixes the number of columns of D, but nothing here computes the entries of D itself. For the symmetric groups those entries are unknown in general.

The final obstruction is of a different kind, and it explains why the subject computes invariants and does not attempt a classification of modules.

Theorem 53.5.7: Higman's Theorem on Finite Representation Type

Let p be a prime, let k be a field of characteristic p, and let G be a finite group. Then $k[G]$ has only finitely many isomorphism classes of indecomposable modules if and only if the Sylow p-subgroups of G are cyclic.

The proof reduces to the case of a p-group and then to the two extremes, and it is given in [100, Theorem 11.4.3]. The negative half is the striking one. As soon as a Sylow p-subgroup fails to be cyclic it has $\mathbb{Z}/p\mathbb{Z} \times \mathbb{Z}/p\mathbb{Z}$ as a quotient, and $k[\mathbb{Z}/p\mathbb{Z} \times \mathbb{Z}/p\mathbb{Z}]$ already has infinitely many indecomposable modules, of unbounded dimension. For such a group the phrase "classify the modules" has no reasonable answer, and the invariants of this section are what one computes instead. Contrast this with chapter 52, where Krull-Schmidt guaranteed a unique decomposition into indecomposables: the guarantee is real, and it does not imply that the list of indecomposables is finite or knowable.

What survives is a body of conjectures relating the invariants of a block to the structure of an associated p-subgroup, its *defect group*. Two of them are among the central open problems of the subject.

Conjecture 53.5.8: Alperin's Weight Conjecture

Let k be an algebraically closed field of characteristic p and G a finite group. A *weight* is a pair (Q, S) with Q a p-subgroup of G and S a simple projective $k[N_G(Q)/Q]$-module. Then the number of simple modules in a p-block of $k[G]$ equals the number of G-conjugacy classes of weights belonging to that block.

Conjecture 53.5.9: Broué's Abelian Defect Group Conjecture

Let k be an algebraically closed field of characteristic p, and let B be a block of $k[G]$ whose defect group P is abelian. Let B' be the Brauer correspondent of B, a block of $k[N_G(P)]$. Then the bounded derived categories of B and B' are equivalent as triangulated categories.

Neither statement is self-contained here: the *defect group* of a block and the *Brauer correspondent* are the central constructions of the local theory, and defining them is where [36] does its work. Both conjectures remain open as of writing, and both have been verified in many cases. Broué's conjecture is known for blocks with cyclic defect groups, and Alperin's has been reduced to a statement about finite simple groups. The subject is not static: Brauer's height zero conjecture, open since 1955, was proved in 2024, and the McKay conjecture has also been settled. Alperin's book *Local Representation Theory* [2] is the standard introduction to the local theory these conjectures live in, and Curtis and Reiner [46] remains the comprehensive reference for the subject as a whole.

A last connection. *Algebraic Groups and Representations* [41] also meets a failure of complete reducibility in characteristic p, for reductive algebraic groups, where the simple objects again carry

known labels and unknown characters. One warning about the vocabulary. That book has its own *decomposition matrix*, which records how a Weyl module $V(\lambda)$ breaks into simple modules in a single characteristic. It is a different matrix from the D of definition 53.5.4, which compares characteristic 0 with characteristic p for a finite group. The two subjects are relatives, and each owns its own side of the difficulty.

Exercise 53.5.1

1. Let P be a finite p-group and let $\mathrm{char}(k) = p$. Show that $k[P]$ has exactly one simple module, the trivial one, and exactly one block. Deduce that the Cartan matrix of $k[P]$ is the 1×1 matrix $(|P|)$.

2. Show that if $\mathrm{char}(k) \nmid |G|$ then the Cartan matrix of $k[G]$ is the identity matrix, and that the blocks of $k[G]$ are exactly the Artin-Wedderburn factors of theorem 51.2.16. Which step fails when $\mathrm{char}(k)$ divides $|G|$?

3. Repeat example 53.5.6 for S_3 at $p = 2$. Show that there are two simple $k[S_3]$-modules, of dimensions 1 and 2, compute the decomposition matrix, and deduce the Cartan matrix. Check that $\det C$ is again the order of a Sylow 2-subgroup.

4. Using theorem 53.5.7, determine for which primes p the group algebra $k[A_5]$ has finite representation type, where $\mathrm{char}(k) = p$ and $|A_5| = 60$.

54

Quiver Representations and Path Algebras

A quiver is a directed graph, and a representation of a quiver assigns a vector space to each vertex and a linear map to each arrow. A single vertex carrying a single loop gives a vector space with one endomorphism, and two vertices joined by two parallel arrows give a pair of linear maps between the same two spaces. Every finite-dimensional representation is a finite direct sum of indecomposable ones, so the indecomposable representations are the objects to classify. For the loop they include a nilpotent Jordan block of every size, and their list is infinite over every field. Chapter 53 ended with the same phenomenon for group algebras: in characteristic p, the algebra $k[G]$ has only finitely many indecomposable modules exactly when the Sylow p-subgroups of G are cyclic (theorem 53.5.7).

Gabriel proved in 1972 that a connected quiver has only finitely many indecomposable representations exactly when the graph obtained by forgetting the orientation of its arrows is one of the Dynkin diagrams A_n, D_n, E_6, E_7, E_8. The dimension vectors of the indecomposable representations are then exactly the positive roots of an integral quadratic form attached to the graph, its Tits form. At a dimension vector, the Tits form is the dimension of the group of base changes acting on the representations with that dimension vector, minus the dimension of the space of these representations, and over an infinite field a quiver with finitely many indecomposables has a Tits form that is positive at every nonzero dimension vector. The proof given here that a positive definite Tits form gives finitely many indecomposables is due to Bernstein, Gelfand and Ponomarev (1973). It uses reflection functors, which carry the indecomposable representations of one orientation of a graph, other than one simple representation, to those of another, and act on dimension vectors by the reflections that permute the roots.[1] Quivers also describe algebras: the path algebra kQ has the representations of Q as its modules, and by a second theorem of Gabriel every finite-dimensional algebra over an

[1] The diagrams A_n, D_n, E_6, E_7, E_8, together with B_n, C_n, F_4 and G_2, also classify the finite-dimensional simple Lie algebras over $\mathbb{C}$ [64, §§11.4, 14.2, 18.4]. The diagrams of type A, D, E are those whose roots all have one length, the only case that quivers produce (box 54.1.44).

algebraically closed field is Morita equivalent to a quotient of a path algebra by an admissible ideal (theorem 54.2.10).

54.1 Quivers and Their Decomposition

Definition 54.1.1: Quiver

A *quiver* is a quadruple $Q = (I, E, s, t)$ consisting of a set I of *vertices*, a set E of *arrows* (also called *edges*) and two maps $s, t \colon E \to I$. An arrow e with $s(e) = i$ and $t(e) = j$ is drawn as

$$\overset{i}{\bullet} \xrightarrow{e} \overset{j}{\bullet}$$

and written $e \colon i \to j$, and the vertices $s(e)$ and $t(e)$ are its *source* and its *target*. The quiver Q is *finite* if I and E are finite sets.

A quiver is usually specified by a drawing, which leaves the maps s and t implicit. An arrow may have the same source and target, and several arrows may join the same two vertices.

Example 54.1.2: Quivers

1. The quiver with $I = \{1\}$, $E = \{e\}$ and $s(e) = t(e) = 1$ is drawn as

$$\overset{1}{\circlearrowleft}$$

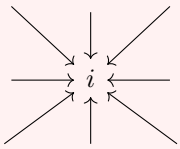
2. The quiver with $I = \{1, 2\}$, $E = \{e\}$, $s(e) = 1$ and $t(e) = 2$ is drawn as

$$1 \xrightarrow{e} 2$$

3. The quiver with $I = \{1, 2\}$, $E = \{e, f\}$, $s(e) = t(f) = 1$ and $t(e) = s(f) = 2$ is drawn as

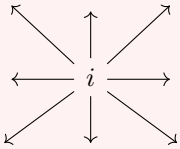
$$1 \underset{f}{\overset{e}{\rightleftarrows}} 2$$

Definition 54.1.3: Path and Oriented Cycle



Let $Q = (I, E, s, t)$ be a quiver.

1. A *path* of *length* $k \geq 1$ in Q is a sequence of k arrows, written from right to left as
$$\gamma = a_k a_{k-1} \cdots a_1$$
with $t(a_l) = s(a_{l+1})$ for $1 \leq l \leq k-1$, so that a_1 is traversed first. Its *source* is $s(\gamma) = s(a_1)$, its *target* is $t(\gamma) = t(a_k)$, and γ is a path *from* $s(\gamma)$ *to* $t(\gamma)$.
2. The *trivial path* at a vertex i is the path e_i of length 0, which contains no arrows and has $s(e_i) = t(e_i) = i$.
3. An *oriented cycle* is a path γ of positive length with $s(\gamma) = t(\gamma)$. An oriented cycle of length 1, that is, an arrow a with $s(a) = t(a)$, is a *loop*.



Definition 54.1.4: Sink And Source

Let $Q = (I, E, s, t)$ be a quiver, $e \in E$ and $i \in I$.

1. The arrow e is *incoming at* i if $t(e) = i$, *outgoing at* i if $s(e) = i$, and an *arrow at* i if it is incoming or outgoing at i.
2. The vertex i is a *sink* if no arrow is outgoing at i, as in

3. The vertex i is a *source* if no arrow is incoming at i, as in

4. If i is a sink or a source, then iQ denotes the quiver obtained from Q by reversing every arrow at i, that is, by exchanging the source and the target of each arrow at i.

54.1.1 Quiver Representation and Varieties

Definition 54.1.5: Quiver Representation

Let $Q = (I, E, s, t)$ be a quiver and $\mathbb{F}$ a field. A *representation* V *of* Q over $\mathbb{F}$ consists of

1. an $\mathbb{F}$-vector space $V(i)$ for each vertex $i \in I$, and
2. an $\mathbb{F}$-linear map $T_e \colon V(i) \to V(j)$ for each arrow $e \colon i \to j$.

The collection of all representations of Q over $\mathbb{F}$ is denoted $\mathrm{Rep}_{\mathbb{F}}(Q)$, or $\mathrm{Rep}(Q)$.

Example 54.1.6: Quiver Representations

1. A representation of the quiver
$$1 \xrightarrow{e} 2$$
is a pair of vector spaces $V(1)$, $V(2)$ with a linear map $T_e \colon V(1) \to V(2)$, so every linear map between two vector spaces is a representation of this quiver.

2. A representation of the quiver
$$\begin{array}{ccc} & \overset{f}{\circlearrowright} & \\ 1 & \xrightarrow{e} & 2 \end{array}$$
is a linear map $T_e \colon V(1) \to V(2)$ together with a linear map $T_f \colon V(2) \to V(2)$, which may be the identity or any other endomorphism of $V(2)$.

3. A representation of the quiver
$$1 \xrightarrow{e} 2 \xrightarrow{f} 3$$
is a pair of linear maps $V(1) \xrightarrow{T_e} V(2) \xrightarrow{T_f} V(3)$. Among them are the pairs exact at $V(2)$, those with $\mathrm{im}(T_e) = \ker(T_f)$. If $V(1) = V(2) = V(3)$, the two maps may be scalar multiplications. The representation $\mathbb{F} \to \mathbb{F}^2 \to \mathbb{F}$ with $T_e(x) = (x, 0)$ and $T_f(x, y) = x$ has $T_f \circ T_e = \mathrm{id}_{\mathbb{F}}$, although neither map is invertible.

Definition 54.1.7: Quiver Dimension

Let $Q = (I, E, s, t)$ be a quiver and V a representation of Q. The *dimension vector*, or *quiver dimension*, of V is the tuple
$$\dim_Q V = (\dim V(i))_{i \in I}$$
When every $V(i)$ is finite-dimensional and $I = \{1, \ldots, n\}$, it is the vector $\dim_Q V = (\dim V(1), \ldots, \dim V(n)) \in \mathbb{N}^n$.

Definition 54.1.8: Quiver Subrepresentation

Let $Q = (I, E, s, t)$ be a quiver and V a representation of Q. A *subrepresentation* W of V, written $W \subseteq V$, consists of a subspace $W(i) \subseteq V(i)$ for each vertex $i \in I$ such that $T_e(W(i)) \subseteq W(j)$ for every arrow $e\colon i \to j$. With the restricted maps $S_e = T_e|_{W(i)}\colon W(i) \to W(j)$ it is a representation of Q.

Definition 54.1.9: Quiver Morphisms

Let $Q = (I, E, s, t)$ be a quiver and let V and W be representations of Q, with maps T_e and S_e respectively. A *quiver morphism* $\varphi\colon V \to W$ is a family $\varphi = (\varphi(i))_{i \in I}$ of linear maps $\varphi(i)\colon V(i) \to W(i)$ such that for every arrow $e\colon i \to j$ the square

$$\begin{array}{ccc} V(i) & \xrightarrow{T_e} & V(j) \\ \downarrow{\scriptstyle \varphi(i)} & & \downarrow{\scriptstyle \varphi(j)} \\ W(i) & \xrightarrow{S_e} & W(j) \end{array}$$

commutes, that is, $S_e \circ \varphi(i) = \varphi(j) \circ T_e$. The set of quiver morphisms from V to W is denoted $\mathrm{Hom}_Q(V, W)$, or $\mathrm{Hom}(V, W)$ when Q is clear from the context. The composite of quiver morphisms $\varphi\colon V \to W$ and $\psi\colon W \to U$ is the family $\psi \circ \varphi = (\psi(i) \circ \varphi(i))_{i \in I}$, and the identity of V is the family $\mathrm{id}_V = (\mathrm{id}_{V(i)})_{i \in I}$.

Proposition 54.1.10: Structure Of $\mathrm{Hom}(V, W)$

Let $V, W \in \mathrm{Rep}(Q)$. Then $\mathrm{Hom}_Q(V, W)$ is a vector space over $\mathbb{F}$, with addition and scalar multiplication defined vertex by vertex.

***Proof*:**

A quiver morphism $\varphi\colon V \to W$ is the data of a linear map $\varphi(i)\colon V(i) \to W(i)$ for each vertex i, subject to the condition $S_e \circ \varphi(i) = \varphi(j) \circ T_e$ for every edge e from i to j. The collection of all vertex-indexed families of linear maps, $\prod_i \mathrm{Hom}_{\mathbb{F}}(V(i), W(i))$, is a vector space under vertexwise addition and scalar multiplication, so it suffices to show that $\mathrm{Hom}(V, W)$ is a subspace.

The zero family satisfies $S_e \circ 0 = 0 = 0 \circ T_e$, so it is a quiver morphism. If $\varphi, \psi \in \mathrm{Hom}(V, W)$ and $c \in \mathbb{F}$, then for every edge e from i to j, linearity of S_e gives

$$S_e \circ (\varphi(i) + c\psi(i)) = S_e \circ \varphi(i) + c\,(S_e \circ \psi(i)) = \varphi(j) \circ T_e + c\,(\psi(j) \circ T_e) = (\varphi(j) + c\psi(j)) \circ T_e$$

so the family $(\varphi(i) + c\psi(i))_i$ is again a quiver morphism. Hence $\mathrm{Hom}(V, W)$ contains 0 and is closed under addition and scalar multiplication, making it a subspace of $\prod_i \mathrm{Hom}_{\mathbb{F}}(V(i), W(i))$ and in particular a vector space over $\mathbb{F}$.

Example 54.1.11: Quiver Morphism

1. Let $V = \overset{\mathbb{F}}{\bullet} \xrightarrow{1} \overset{\mathbb{F}}{\bullet}$ and $W = \overset{\mathbb{F}}{\bullet} \xrightarrow{0} \overset{0}{\bullet}$ be representations of $1 \xrightarrow{e} 2$. The maps $\varphi(1) = 1$ and $\varphi(2) = 0$ form a quiver morphism $\varphi\colon V \to W$,

$$\begin{array}{ccc} V & & \mathbb{F} & \xrightarrow{1} & \mathbb{F} \\ \downarrow{\scriptstyle \varphi} & & \downarrow{\scriptstyle 1} & & \downarrow{\scriptstyle 0} \\ W & & \mathbb{F} & \xrightarrow{0} & 0 \end{array}$$

   since both composites $\mathbb{F} \to 0$ are zero. Every quiver morphism $\psi\colon W \to V$ is zero: its square at e reads $1 \circ \psi(1) = \psi(2) \circ 0 = 0$, so $\psi(1) = 0$, and $\psi(2)$ is defined on the zero space.

2. Let $V = \overset{\mathbb{R}}{\bullet} \xrightarrow{1} \overset{\mathbb{R}}{\bullet} \xrightarrow{1} \overset{\mathbb{R}}{\bullet}$ and $W = \overset{\mathbb{R}^2}{\bullet} \xrightarrow{A} \overset{\mathbb{R}^2}{\bullet} \xrightarrow{B} \overset{\mathbb{R}}{\bullet}$ be representations of $1 \to 2 \to 3$, with

$$A = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \qquad B = \begin{pmatrix} 1 & 1 \end{pmatrix}$$

   The matrices $\varphi(1) = \varphi(2) = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$ and $\varphi(3) = 2$ form a quiver morphism $\varphi\colon V \to W$, because $A\varphi(1) = \varphi(2) \cdot 1$ and $B\varphi(2) = 2 = \varphi(3) \cdot 1$. The matrices $\psi(1) = \psi(2) = \begin{pmatrix} 1 & 1 \end{pmatrix}$ and $\psi(3) = 1$ form a nonzero quiver morphism $\psi\colon W \to V$, because $1 \cdot \psi(1) = \psi(2)A$ and $1 \cdot \psi(2) = \psi(3)B$.

With the composites and identities of definition 54.1.9, the representations of Q form a category $\mathrm{Rep}(Q)$. For quiver morphisms $\varphi\colon V \to W$ and $\psi\colon W \to U$, where U has maps R_e, and an arrow $e\colon i \to j$, the squares of φ and ψ give

$$R_e \circ \psi(i) \circ \varphi(i) = \psi(j) \circ S_e \circ \varphi(i) = \psi(j) \circ \varphi(j) \circ T_e$$

so $\psi \circ \varphi$ is a quiver morphism. The family id_V is a quiver morphism because $T_e \circ \mathrm{id}_{V(i)} = \mathrm{id}_{V(j)} \circ T_e$, and composition is associative with the identities id_V as units because these laws hold for linear maps at each vertex. A quiver morphism is a morphism between representations of one quiver Q. A map from a quiver $Q = (I, E, s, t)$ to a quiver $Q' = (I', E', s', t')$ is a different notion, a pair of maps $m_I\colon I \to I'$ and $m_E\colon E \to E'$ with $m_I \circ s = s' \circ m_E$ and $m_I \circ t = t' \circ m_E$, and maps of quivers are not used in this chapter.

The *zero representation* 0 has the zero space at every vertex. Kernels and images of quiver morphisms are formed vertex by vertex.

Definition 54.1.12: Kernels And Images

Let $\varphi\colon V \to W$ be a quiver morphism. The *kernel* $\ker(\varphi)$ is the subrepresentation of V with $\ker(\varphi)(i) = \ker(\varphi(i))$, and the *image* $\mathrm{im}(\varphi)$ is the subrepresentation of W with $\mathrm{im}(\varphi)(i) = \mathrm{im}(\varphi(i))$, for every vertex i.

Both are subrepresentations in the sense of definition 54.1.8. Let $e\colon i \to j$ be an arrow. If $v \in \ker(\varphi(i))$, then $\varphi(j)(T_e v) = S_e(\varphi(i)v) = 0$, so T_e carries $\ker(\varphi(i))$ into $\ker(\varphi(j))$. For every $v \in V(i)$ the same square gives $S_e(\varphi(i)v) = \varphi(j)(T_e v)$, so S_e carries $\mathrm{im}(\varphi(i))$ into $\mathrm{im}(\varphi(j))$.

Definition 54.1.13: Quiver Isomorphisms

Let $V, W \in \mathrm{Rep}(Q)$. A quiver morphism $\varphi\colon V \to W$ is an *isomorphism* if there is a quiver morphism $\psi\colon W \to V$ with $\psi \circ \varphi = \mathrm{id}_V$ and $\varphi \circ \psi = \mathrm{id}_W$. The representations V and W are *isomorphic*, written $V \cong W$, if there is an isomorphism $V \to W$.

The components $\varphi(i)$ of an isomorphism are bijective, with inverses $\psi(i)$. Conversely, a quiver morphism φ whose components are all bijective is an isomorphism: composing $S_e \circ \varphi(i) = \varphi(j) \circ T_e$ with $\varphi(j)^{-1}$ on the left and with $\varphi(i)^{-1}$ on the right gives $\varphi(j)^{-1} \circ S_e = T_e \circ \varphi(i)^{-1}$, so the family $(\varphi(i)^{-1})_{i \in I}$ is a quiver morphism inverse to φ. In particular isomorphic representations have the same dimension vector.

Example 54.1.14: Quiver Isomorphism

Let Q be $1 \xrightarrow{e} 2$. Finite-dimensional representations V and W of Q, with maps T_e and S_e, are isomorphic if and only if $\dim V(1) = \dim W(1)$, $\dim V(2) = \dim W(2)$ and $\mathrm{rank}(T_e) = \mathrm{rank}(S_e)$.

If $\varphi\colon V \to W$ is an isomorphism, then $\varphi(1)$ and $\varphi(2)$ are linear isomorphisms, which gives the equalities of dimensions, and $S_e = \varphi(2) \circ T_e \circ \varphi(1)^{-1}$ has the same rank as T_e. Conversely, let $n_1 = \dim V(1)$, $n_2 = \dim V(2)$ and $r = \mathrm{rank}(T_e)$. By rank-nullity $\ker(T_e)$ has dimension $n_1 - r$, so $V(1)$ has a basis $u_1, \dots, u_{n_1}$ whose last $n_1 - r$ vectors form a basis of $\ker(T_e)$. The vectors $T_e u_1, \dots, T_e u_r$ span $\mathrm{im}(T_e)$, which has dimension r, so they are linearly independent, and they extend to a basis $T_e u_1, \dots, T_e u_r, w_{r+1}, \dots, w_{n_2}$ of $V(2)$. In these bases T_e has the matrix

$$\begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}$$

of size $n_2 \times n_1$, where I_r is the $r \times r$ identity matrix. The same construction for W gives bases in which S_e has the same matrix. The linear isomorphisms $\varphi(1)\colon V(1) \to W(1)$ and $\varphi(2)\colon V(2) \to W(2)$ that send each chosen basis vector for V to the chosen basis vector for W in the same position satisfy $S_e \circ \varphi(1) = \varphi(2) \circ T_e$, since in the chosen bases both sides have the matrix above. So φ is a quiver morphism with bijective components, hence an isomorphism. The isomorphism classes of finite-dimensional representations of Q are therefore in bijection with the triples (n_1, n_2, r) of nonnegative integers with $r \le \min(n_1, n_2)$, the triple being realized by the matrix above.

A subrepresentation has a quotient, formed vertex by vertex.

Definition 54.1.15: Quotient Representation

Let $V \in \mathrm{Rep}(Q)$ and let $W \subseteq V$ be a subrepresentation. The *quotient representation* V/W has the space $V(i)/W(i)$ at each vertex i, and along each arrow $e\colon i \to j$ the map $V(i)/W(i) \to V(j)/W(j)$, $x + W(i) \mapsto T_e(x) + W(j)$. This map is well defined because T_e carries $W(i)$ into $W(j)$, W being a subrepresentation.

Proposition 54.1.16: 1st Isomorphism for Quivers

Let $V, W \in \mathrm{Rep}(Q)$ and $\varphi\colon V \to W$ be a quiver morphism. Then:

$$\mathrm{im}(\varphi) \cong V/\ker(\varphi)$$

***Proof*:**
Write $K = \ker(\varphi)$, a subrepresentation of V (definition 54.1.12). First, the quotient V/K of definition 54.1.15 carries the edge maps induced by those of V: for an edge e from i to j, set $\overline{T}_e(v + K(i)) = T_e v + K(j)$. This is well defined, since $v \in K(i) = \ker(\varphi(i))$ gives $\varphi(j)(T_e v) = S_e(\varphi(i)v) = 0$, so $T_e v \in K(j)$. Second, S_e maps $\mathrm{im}(\varphi(i))$ into $\mathrm{im}(\varphi(j))$, since $S_e(\varphi(i)v) = \varphi(j)(T_e v)$, so the edge maps of the subrepresentation $\mathrm{im}(\varphi) \subseteq W$ are the restrictions of the S_e.

For each vertex i, define

$$\overline{\varphi}(i)\colon V(i)/K(i) \to \mathrm{im}(\varphi(i)) \qquad v + K(i) \mapsto \varphi(i)v$$

This is well defined and injective because $\varphi(i)v = \varphi(i)v'$ holds exactly when $v - v' \in \ker(\varphi(i)) = K(i)$, it is linear, and it is surjective onto $\mathrm{im}(\varphi(i))$ by construction. So each $\overline{\varphi}(i)$ is a linear isomorphism.

The family $\overline{\varphi} = (\overline{\varphi}(i))_i$ is a quiver morphism $V/K \to \mathrm{im}(\varphi)$: for every edge e from i to j and every $v \in V(i)$,

$$\overline{\varphi}(j)\left(\overline{T}_e(v + K(i))\right) = \varphi(j)(T_e v) = S_e(\varphi(i)v) = S_e\left(\overline{\varphi}(i)(v + K(i))\right)$$

where the middle equality is the commuting square for φ. Composing this identity with $\overline{\varphi}(j)^{-1}$ on the left and with $\overline{\varphi}(i)^{-1}$ on the right yields $\overline{T}_e \circ \overline{\varphi}(i)^{-1} = \overline{\varphi}(j)^{-1} \circ S_e$, so the vertexwise inverses also form a quiver morphism $\mathrm{im}(\varphi) \to V/K$. The two morphisms are mutually inverse at every vertex, so $\mathrm{im}(\varphi) \cong V/\ker(\varphi)$ (definition 54.1.13).

Definition 54.1.17: Direct Sum Of Representations

Let $V, W \in \mathrm{Rep}(Q)$, with maps T_e and S_e. The *direct sum* $V \oplus W \in \mathrm{Rep}(Q)$ has

1. the space $(V \oplus W)(i) = V(i) \oplus W(i)$ at each vertex i, and
2. the map $T_e \oplus S_e\colon V(i) \oplus W(i) \to V(j) \oplus W(j)$, $(v, w) \mapsto (T_e v, S_e w)$, along each arrow $e\colon i \to j$.

If $U_1, \ldots, U_n$ are subrepresentations of V with $V(i) = U_1(i) \oplus \cdots \oplus U_n(i)$ at every vertex i, then V is the *internal direct sum* of $U_1, \ldots, U_n$, written $V = U_1 \oplus \cdots \oplus U_n$.

An internal direct sum is isomorphic to the direct sum of its summands. For $V = U_1 \oplus U_2$, the maps $U_1(i) \oplus U_2(i) \to V(i)$, $(u_1, u_2) \mapsto u_1 + u_2$, are bijective, and they form a quiver morphism $U_1 \oplus U_2 \to V$ because $T_e(u_1 + u_2) = T_e u_1 + T_e u_2$ with $T_e u_1 \in U_1(j)$ and $T_e u_2 \in U_2(j)$. A quiver morphism with bijective components is an isomorphism, as noted after definition 54.1.13. For $n \geq 3$ summands, the vertexwise sums $U'(i) = U_1(i) \oplus \cdots \oplus U_{n-1}(i)$ form a subrepresentation U' with $V = U' \oplus U_n$, so induction on n gives $V \cong U_1 \oplus \cdots \oplus U_n$.

Definition 54.1.18: Representation Space

Let $Q = (I, E, s, t)$ be a finite quiver with $I = \{1, \dots, n\}$, and let $\underline{d} = (d_1, \dots, d_n) \in \mathbb{N}^n$. The *representation space* of dimension vector $\underline{d}$ is

$$\mathrm{Rep}(Q, \underline{d}) := \prod_{e \in E} M_{d_{t(e)} \times d_{s(e)}}(\mathbb{F})$$

A point $A = (A_e)_{e \in E}$ of $\mathrm{Rep}(Q, \underline{d})$ is the representation of Q with $\mathbb{F}^{d_i}$ at the vertex i and the matrix A_e along the arrow e, so every point is a representation with dimension vector $\underline{d}$. As a vector space, $\mathrm{Rep}(Q, \underline{d})$ has dimension $\sum_{e \in E} d_{s(e)} d_{t(e)}$.

Choosing a basis of every vertex space turns a representation with dimension vector $\underline{d}$ into a point of $\mathrm{Rep}(Q, \underline{d})$, and different choices of bases change the point by the following action.

Proposition 54.1.19: Action On The Representation Space

Let $Q = (I, E, s, t)$ be a finite quiver with $I = \{1, \dots, n\}$, let $\underline{d} \in \mathbb{N}^n$, and let $G(\underline{d}) = \prod_{i \in I} \mathrm{GL}_{d_i}(\mathbb{F})$. For $g = (g_1, \dots, g_n) \in G(\underline{d})$ and $A \in \mathrm{Rep}(Q, \underline{d})$ set

$$(g \cdot A)_e = g_{t(e)} A_e g_{s(e)}^{-1} \qquad e \in E$$

This defines an action of $G(\underline{d})$ on $\mathrm{Rep}(Q, \underline{d})$.

***Proof*:**

Each $g_{t(e)} A_e g_{s(e)}^{-1}$ is a $d_{t(e)} \times d_{s(e)}$ matrix, so $g \cdot A \in \mathrm{Rep}(Q, \underline{d})$, and the identity element $(I_{d_1}, \dots, I_{d_n})$ fixes every A. For $g, h \in G(\underline{d})$, whose product is computed vertex by vertex, and every arrow e,

$$(g \cdot (h \cdot A))_e = g_{t(e)} h_{t(e)} A_e h_{s(e)}^{-1} g_{s(e)}^{-1} = (gh)_{t(e)} A_e (gh)_{s(e)}^{-1} = ((gh) \cdot A)_e$$

because $(g_{s(e)} h_{s(e)})^{-1} = h_{s(e)}^{-1} g_{s(e)}^{-1}$. Hence $g \cdot (h \cdot A) = (gh) \cdot A$, and the formula is an action, as claimed.

Theorem 54.1.20: Isomorphism Equivalence

Let Q be a finite quiver with vertex set $I = \{1, \dots, n\}$, let $\underline{d} \in \mathbb{N}^n$, and let $G(\underline{d})$ act on $\mathrm{Rep}(Q, \underline{d})$ as in proposition 54.1.19. Two points $A, B \in \mathrm{Rep}(Q, \underline{d})$ are isomorphic representations if and only if $B = g \cdot A$ for some $g \in G(\underline{d})$. Consequently, sending the orbit of A to the isomorphism class of A is a bijection from the set of $G(\underline{d})$-orbits in $\mathrm{Rep}(Q, \underline{d})$ onto the set of isomorphism classes of representations of Q with dimension vector $\underline{d}$.

***Proof*:**

A morphism φ from the representation A to the representation B is a family of matrices $\varphi(i) \in M_{d_i}(\mathbb{F})$ with $\varphi(t(e)) A_e = B_e \varphi(s(e))$ for every arrow e (definition 54.1.9). If φ is an isomorphism with inverse ψ (definition 54.1.13), then $\psi(i)\varphi(i) = \varphi(i)\psi(i) = I_{d_i}$, so $g = (\varphi(1), \dots, \varphi(n))$ lies

in $G(\underline{d})$, and the condition reads $B_e = g_{t(e)} A_e g_{s(e)}^{-1}$, that is, $B = g \cdot A$. Conversely, if $B = g \cdot A$, then $\varphi(i) = g_i$ satisfies $\varphi(t(e))A_e = B_e\varphi(s(e))$ and $\psi(i) = g_i^{-1}$ satisfies $\psi(t(e))B_e = A_e\psi(s(e))$, so φ and ψ are mutually inverse morphisms and the two representations are isomorphic.

The map from orbits to isomorphism classes is therefore well defined and injective. For surjectivity, let V be a representation with dimension vector $\underline{d}$, choose a basis of each $V(i)$, and let A_e be the matrix of T_e in the chosen bases. The coordinate isomorphisms $V(i) \to \mathbb{F}^{d_i}$ carry each T_e to A_e, so they form an isomorphism from V to the representation A, and the isomorphism class of V is the image of the orbit of A, completing the proof.

54.1.2 Decomposing Quivers

Definition 54.1.21: Simple Representation

Let Q be a quiver. A representation $V \in \mathrm{Rep}(Q)$ is *simple*, or *irreducible*, if $V \neq 0$ and the only subrepresentations of V are 0 and V.

A finite-dimensional vector space, which is a representation of the quiver with one vertex and no arrows, is a direct sum of one-dimensional subspaces, and these are simple. For quivers with arrows this fails: example 54.1.23 below exhibits a representation that is not a direct sum of simple subrepresentations. The summands that cannot be split further are the indecomposable representations.

Definition 54.1.22: Indecomposable Representation

Let Q be a quiver. A representation $V \in \mathrm{Rep}(Q)$ is *decomposable* if there exist nonzero subrepresentations $V_1, V_2 \subseteq V$ such that

$$V \cong V_1 \oplus V_2$$

and *indecomposable* otherwise. In particular the zero representation is indecomposable.

Example 54.1.23: Simple And Indecomposable Representations

Let Q be $1 \xrightarrow{e} 2$. The representations

$$0 \xrightarrow{0} \mathbb{F} \qquad \mathbb{F} \xrightarrow{0} 0$$

have total dimension 1, so each is simple, its only subrepresentations being 0 and itself, and indecomposable, since a direct sum of two nonzero representations has total dimension at least 2. The representation $V = \mathbb{F} \xrightarrow{1} \mathbb{F}$ is not simple. Its subrepresentations are exactly 0, $0 \xrightarrow{0} \mathbb{F}$ and V, because a subrepresentation W with $W(1) = \mathbb{F}$ has $W(2) \supseteq T_e(\mathbb{F}) = \mathbb{F}$.

However, V is indecomposable. If $V \cong V_1 \oplus V_2$ with V_1 and V_2 nonzero subrepresentations, then $\dim_Q V_1 + \dim_Q V_2 = \dim_Q V = (1,1)$ with both summands nonzero, so one of V_1 and V_2 has dimension vector $(1,0)$, and the list of subrepresentations of V contains none with this dimension vector.

So a representation need not be a direct sum of simple subrepresentations: the only simple subrep-

resentation of $\mathbb{F} \xrightarrow{1} \mathbb{F}$ is $0 \xrightarrow{0} \mathbb{F}$, and no subrepresentation complements it. Every representation of finite total dimension is nevertheless a direct sum of indecomposable ones.

Theorem 54.1.24: Quiver Representation Decomposition

Let Q be a quiver and V a representation of Q with $\sum_i \dim V(i) < \infty$. Then there are finitely many indecomposable subrepresentations $U_1, \dots, U_n$ of V such that

$$V = U_1 \oplus U_2 \oplus \cdots \oplus U_n$$

***Proof*:**
Write $\mathrm{Tdim}(V) = \sum_i \dim V(i)$ for the *total dimension*, and argue by strong induction on $\mathrm{Tdim}(V)$. If V is indecomposable, then $V = V$ is the required decomposition, with a single summand. This covers every V with $\mathrm{Tdim}(V) \leq 1$, because an isomorphism $V \cong V_1 \oplus V_2$ with V_1 and V_2 nonzero would give $\mathrm{Tdim}(V) = \mathrm{Tdim}(V_1) + \mathrm{Tdim}(V_2) \geq 2$.

Suppose V is decomposable, and let $\theta\colon V_1 \oplus V_2 \to V$ be an isomorphism with V_1 and V_2 nonzero (definition 54.1.22). An isomorphism carries subrepresentations to subrepresentations, so $V_1' = \theta(V_1 \oplus 0)$ and $V_2' = \theta(0 \oplus V_2)$ are nonzero subrepresentations of V with $V(i) = V_1'(i) \oplus V_2'(i)$ at every vertex, each $\theta(i)$ being a linear isomorphism. Both total dimensions are positive and they add up to $\mathrm{Tdim}(V)$, so each is smaller than $\mathrm{Tdim}(V)$, and by the inductive hypothesis V_1' and V_2' are finite direct sums of indecomposable subrepresentations. Together these summands decompose V, completing the proof.

The indecomposable representations of $1 \to 2 \to \cdots \to n$, and with them the decompositions of all its finite-dimensional representations, are determined in example 54.1.54 below.

54.1.3 The Tits Form and Its Roots

Let $Q = (I, E, s, t)$ be a finite quiver, meaning that I and E are finite sets, with $I = \{1, \dots, n\}$, and let $\underline{d} \in \mathbb{N}^n$. By theorem 54.1.20, the isomorphism classes of representations with dimension vector $\underline{d}$ are the orbits of $G(\underline{d})$ on $\mathrm{Rep}(Q, \underline{d})$. The space $\mathrm{Rep}(Q, \underline{d})$ has dimension $\sum_{e \in E} d_{s(e)} d_{t(e)}$, the group $G(\underline{d})$ consists of invertible matrices inside a space of dimension $\sum_{i \in I} d_i^2$, and the scalar tuples $(\lambda I_{d_1}, \dots, \lambda I_{d_n})$ act trivially. A dimension count therefore suggests that, for nonzero $\underline{d}$ and over an infinite field, finitely many orbits can cover $\mathrm{Rep}(Q, \underline{d})$ only if

$$\sum_{i \in I} d_i^2 - \sum_{e \in E} d_{s(e)} d_{t(e)} \geq 1$$

and the proof of theorem 54.1.46 makes this precise with transcendence degrees. The left side is the Tits form of Q at $\underline{d}$.

Definition 54.1.25: Graph

A *graph* Γ consists of a finite set I of *vertices* and, for every pair of vertices i, j, a number $n_{ij} = n_{ji} \in \mathbb{N}$ of *edges* joining i and j. An edge joining a vertex to itself is a *loop*, two distinct vertices i, j with $n_{ij} \geq 2$ are joined by a *multiple edge*, and two distinct vertices are *adjacent* if $n_{ij} \geq 1$.

1. The *underlying graph* of a finite quiver $Q = (I, E, s, t)$ has vertex set I, with n_{ij} the number of arrows e with $\{s(e), t(e)\} = \{i, j\}$ for $i \neq j$, and n_{ii} the number of arrows with $s(e) = t(e) = i$.
2. A graph Γ' with vertex set I' and edge numbers n'_{ij} is a *subgraph* of Γ if $I' \subseteq I$ and $n'_{ij} \leq n_{ij}$ for all $i, j \in I'$. It is the *full subgraph* on I' if $n'_{ij} = n_{ij}$ for all $i, j \in I'$.
3. A *path* in Γ is a sequence $(v_1, \ldots, v_m)$ of distinct vertices, $m \geq 1$, with v_k adjacent to v_{k+1} for $1 \leq k < m$, and it *joins* v_1 and v_m. A *cycle* is a path $(v_1, \ldots, v_m)$ with $m \geq 3$ and v_m adjacent to v_1.
4. Γ is *connected* if any two vertices are joined by a path, and the *degree* of a vertex is the number of vertices adjacent to it.

Two graphs are identified when they differ only by a renaming of their vertices. Paths and cycles in a graph ignore orientation, and they are distinct from the paths and oriented cycles of a quiver (definition 54.1.3).

Definition 54.1.26: Euler And Tits Form

Let $Q = (I, E, s, t)$ be a finite quiver, and for $i \in I$ let $\alpha_i \in \mathbb{Z}^I$ be the vector with i-th coordinate 1 and all other coordinates 0, so that $x = \sum_i x_i \alpha_i$. The *Euler form* of Q is the bilinear form on $\mathbb{R}^I$ given by

$$\langle x, y \rangle = \sum_{i \in I} x_i y_i - \sum_{e \in E} x_{s(e)} y_{t(e)}$$

its *symmetrization* is $(x, y) = \langle x, y \rangle + \langle y, x \rangle$, and the *Tits form* of Q is the quadratic form $q(x) = \langle x, x \rangle = \frac{1}{2}(x, x)$. For $x \in \mathbb{Z}^I$, write $x \geq 0$ if $x_i \geq 0$ for every i, and $x \not\geq 0$ otherwise. The dimension vector $\dim_Q V$ of a finite-dimensional representation (definition 54.1.7) is a vector $\dim_Q V \geq 0$ in $\mathbb{Z}^I$.

The Euler form depends on the orientation of the arrows, but its symmetrization does not.

Proposition 54.1.27: The Tits Form Depends Only On The Underlying Graph

Let Q be a finite quiver whose underlying graph Γ has edge numbers n_{ij}. For every $x \in \mathbb{R}^I$,

$$q(x) = \sum_{i \in I} (1 - n_{ii}) x_i^2 - \sum_{\{i,j\}} n_{ij} x_i x_j$$

where the second sum runs over the unordered pairs of distinct vertices, and

$$(\alpha_i, \alpha_i) = 2 - 2n_{ii} \qquad (\alpha_i, \alpha_j) = -n_{ij} \text{ for } i \neq j$$

In particular q and $(\ ,\ )$ depend only on Γ. The same formulas define the *Tits form* q_Γ and the symmetric form $(\ ,\ )_\Gamma$ of an arbitrary graph Γ.

***Proof*:**
In $\sum_e x_{s(e)} x_{t(e)}$, each of the n_{ii} loops at i contributes x_i^2, and each of the n_{ij} arrows between distinct vertices i and j contributes $x_i x_j$, whichever its direction. This gives the formula for $q(x) = \langle x, x \rangle$. For the symmetric form, $\langle \alpha_i, \alpha_j \rangle = \delta_{ij} - a_{ij}$, where a_{ij} is the number of arrows from i to j, so $(\alpha_i, \alpha_j) = 2\delta_{ij} - a_{ij} - a_{ji}$. For $i = j$ this is $2 - 2n_{ii}$, and for $i \neq j$ it is $-n_{ij}$. Neither formula involves the direction of an arrow, completing the proof.

Example 54.1.28: Euler And Tits Forms

1. Let Q be $1 \xrightarrow{e} 2 \xrightarrow{f} 3$ and Q' be $1 \xleftarrow{e} 2 \xrightarrow{f} 3$. Their Euler forms

$$\langle x, y \rangle_Q = \sum_{i=1}^{3} x_i y_i - x_1 y_2 - x_2 y_3 \qquad \langle x, y \rangle_{Q'} = \sum_{i=1}^{3} x_i y_i - x_2 y_1 - x_2 y_3$$

   differ, since $\langle \alpha_1, \alpha_2 \rangle_Q = -1$ while $\langle \alpha_1, \alpha_2 \rangle_{Q'} = 0$, but both Tits forms equal $x_1^2 + x_2^2 + x_3^2 - x_1 x_2 - x_2 x_3$, as proposition 54.1.27 predicts. Completing squares,

$$q(x) = \left(x_1 - \tfrac{1}{2} x_2\right)^2 + \left(x_3 - \tfrac{1}{2} x_2\right)^2 + \tfrac{1}{2} x_2^2$$

   so $q(x) > 0$ for every nonzero $x \in \mathbb{R}^3$: the right side vanishes only if $x_2 = 0$, and then $x_1 = x_3 = 0$.

2. Let K be the *Kronecker quiver*, with two arrows a, b from 1 to 2. Its underlying graph has $n_{12} = 2$, and $q(x) = x_1^2 + x_2^2 - 2x_1 x_2 = (x_1 - x_2)^2$ vanishes at $x = \alpha_1 + \alpha_2$. For this dimension vector, $\mathrm{Rep}(K, (1,1)) = \mathbb{F}^2$, and $(g_1, g_2) \in \mathbb{F}^\times \times \mathbb{F}^\times$ sends (A_a, A_b) to $(g_2 g_1^{-1} A_a, g_2 g_1^{-1} A_b)$. The orbit of a nonzero point is the set of nonzero points of the line through it, so over an infinite field there are infinitely many orbits.

Gabriel's theorem singles out the first family of graphs below. The second family carries vectors at which the Tits form vanishes.

Definition 54.1.29: Dynkin and Extended Dynkin Diagrams

For integers $a, b, c \geq 1$, the *star* $T(a, b, c)$ is the graph consisting of a central vertex and three paths of a, b and c vertices, its *arms*, with the first vertex of each arm adjacent to the central vertex, consecutive vertices of each arm adjacent, and no other edges. The graphs below have no loops and no multiple edges, except $\tilde{A}_0$ and $\tilde{A}_1$.

1. The *Dynkin diagrams of type A, D, E* are the path A_n on n vertices ($n \geq 1$), $D_n = T(1, 1, n-3)$ ($n \geq 4$), $E_6 = T(1, 2, 2)$, $E_7 = T(1, 2, 3)$ and $E_8 = T(1, 2, 4)$, drawn in fig. 54.1. The subscript is the number of vertices.

2. The *extended Dynkin diagrams* are the following graphs. The graph $\tilde{A}_0$ is one vertex with one loop, $\tilde{A}_1$ is two vertices joined by two edges, and $\tilde{A}_n$ ($n \geq 2$) is the cycle on $n+1$ vertices. The graph $\tilde{D}_4$ is a central vertex adjacent to four further vertices, and for $n \geq 5$ the graph $\tilde{D}_n$ is a path $(v_1, \ldots, v_{n-3})$ together with two further vertices adjacent to v_1 and two further vertices adjacent to v_{n-3}. Finally, $\tilde{E}_6 = T(2, 2, 2)$, $\tilde{E}_7 = T(1, 3, 3)$ and $\tilde{E}_8 = T(1, 2, 5)$. The subscript is one less than the number of vertices.

Each extended Dynkin diagram $\hat{\Gamma}$ carries the vector $\delta_{\hat{\Gamma}}$, with one positive integer for each vertex, recorded in fig. 54.2. Every entry of $\delta_{\tilde{A}_n}$ is 1. The four vertices of $\tilde{D}_n$ of degree one carry 1, and the others carry 2. In $\tilde{E}_6$, $\tilde{E}_7$ and $\tilde{E}_8$ the central vertex carries 3, 4 and 6 respectively. Read away from the central vertex, each arm of $\tilde{E}_6$ carries $2, 1$. The arm of $\tilde{E}_7$ with one vertex carries 2, and its two arms with three vertices carry $3, 2, 1$. The arms of $\tilde{E}_8$ with one, two and five vertices carry 3, then $4, 2$, then $5, 4, 3, 2, 1$.

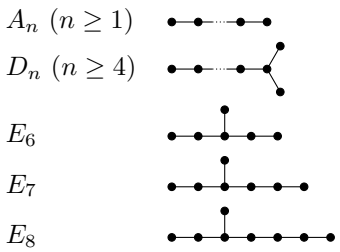


Figure 54.1: The Dynkin diagrams of type A, D, E

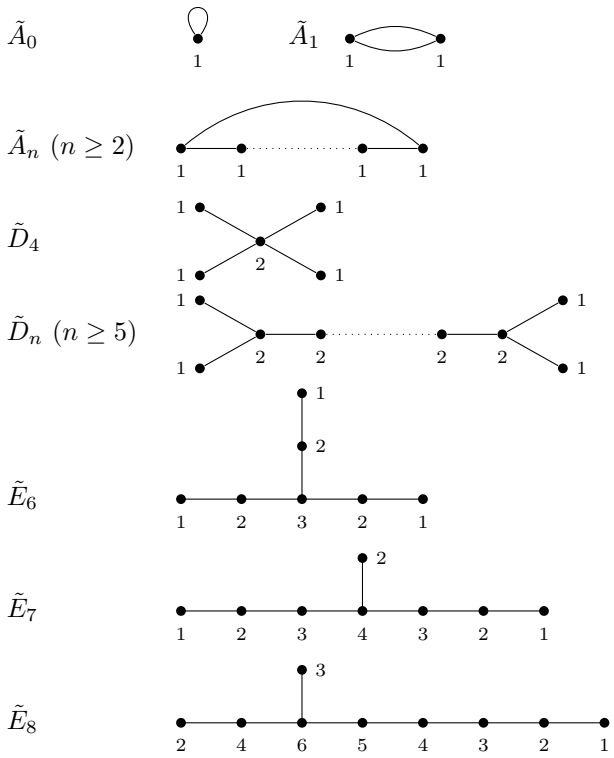

Figure 54.2: The extended Dynkin diagrams, each vertex labelled by its entry of δ

Each Dynkin diagram of type A, D, E is an extended Dynkin diagram with one vertex removed, and the vector δ of the larger graph writes the Tits form of the larger graph as a sum of squares.

Lemma 54.1.30: Null Vectors Of The Extended Dynkin Diagrams

Let $\hat{\Gamma}$ be an extended Dynkin diagram with vertex set $\hat{I}$, edge numbers n_{ij} and vector $\delta = \delta_{\hat{\Gamma}}$ (definition 54.1.29).

1. $(\delta, \alpha_i) = 0$ for every $i \in \hat{I}$, and $q(\delta) = 0$.
2. If $\hat{\Gamma} \neq \tilde{A}_0$, then for every $x \in \mathbb{R}^{\hat{I}}$

$$q(x) = \frac{1}{2} \sum_{\{i,j\}} n_{ij} \delta_i \delta_j \left(\frac{x_i}{\delta_i} - \frac{x_j}{\delta_j} \right)^2$$

the sum running over the unordered pairs of distinct vertices. Hence $q(x) \geq 0$, with equality if and only if x is a real multiple of δ.

***Proof*:**

1. For $\tilde{A}_0$, the single vertex has $(\alpha_1, \alpha_1) = 2 - 2 = 0$ by proposition 54.1.27, so $(\delta, \alpha_1) = 0$. Every other extended Dynkin diagram is loopless, and proposition 54.1.27 gives $(\delta, \alpha_i) = 2\delta_i - \sum_{j \neq i} n_{ij}\delta_j$, so the claim is that twice each entry of δ equals the sum of the entries at the adjacent vertices, each counted n_{ij} times. For $\tilde{A}_1$ this reads $2 \cdot 1 = 2 \cdot 1$, and for $\tilde{A}_n$ with $n \geq 2$ every vertex has two adjacent vertices and $2 \cdot 1 = 1 + 1$. In $\tilde{D}_n$, a vertex of degree one is adjacent only to a vertex carrying 2, and $2 \cdot 1 = 2$. For $n = 4$ the central vertex gives $2 \cdot 2 = 1 + 1 + 1 + 1$. For $n \geq 5$ the vertices v_1 and v_{n-3} are distinct, each is adjacent to two vertices carrying 1 and to one v_k, and $2 \cdot 2 = 1 + 1 + 2$, while each v_k with $1 < k < n - 3$ gives $2 \cdot 2 = 2 + 2$. In $\tilde{E}_6$, $\tilde{E}_7$ and $\tilde{E}_8$, the entries along each arm, preceded by the central entry and followed by 0, form an arithmetic progression, namely $3, 2, 1, 0$, then $4, 2, 0$ and $4, 3, 2, 1, 0$, then $6, 3, 0$ and $6, 4, 2, 0$ and $6, 5, 4, 3, 2, 1, 0$. Each arm vertex is adjacent exactly to its two neighbours in this progression (the 0 standing for no vertex), so twice its entry is the sum of theirs. At the central vertex, $2 \cdot 3 = 2 + 2 + 2$, $2 \cdot 4 = 2 + 3 + 3$ and $2 \cdot 6 = 3 + 4 + 5$. Finally, $q(\delta) = \frac{1}{2}(\delta, \delta) = \frac{1}{2}\sum_i \delta_i(\delta, \alpha_i) = 0$.

2. Now $\hat{\Gamma}$ has no loops, so $(x, x) = 2\sum_i x_i^2 - 2\sum_{\{i,j\}} n_{ij}x_i x_j$ by proposition 54.1.27. Part (1) gives $2\delta_i = \sum_{j \neq i} n_{ij}\delta_j$ for every i, and every δ_i is positive, so

$$2\sum_i x_i^2 = \sum_i \frac{x_i^2}{\delta_i} \sum_{j \neq i} n_{ij}\delta_j = \sum_{\{i,j\}} n_{ij} \left(\frac{\delta_j}{\delta_i} x_i^2 + \frac{\delta_i}{\delta_j} x_j^2 \right)$$

Therefore

$$(x, x) = \sum_{\{i,j\}} n_{ij} \left(\frac{\delta_j}{\delta_i} x_i^2 - 2x_i x_j + \frac{\delta_i}{\delta_j} x_j^2 \right) = \sum_{\{i,j\}} n_{ij}\delta_i\delta_j \left(\frac{x_i}{\delta_i} - \frac{x_j}{\delta_j} \right)^2$$

and halving gives the formula for $q(x)$. Every term is nonnegative, so $q(x) \geq 0$. If $q(x) = 0$, then $x_i/\delta_i = x_j/\delta_j$ for all adjacent i and j. The graph $\hat{\Gamma}$ is connected, so following a path from a fixed vertex shows that x_i/δ_i takes a single value t at every vertex, and $x = t\delta$. Conversely $q(t\delta) = t^2 q(\delta) = 0$ by part (1), completing the proof.

Lemma 54.1.31: Graphs Without Extended Dynkin Subgraphs

Let Γ be a connected graph, loops and multiple edges allowed, that contains none of the extended Dynkin diagrams as a subgraph. Then Γ is one of A_n $(n \geq 1)$, D_n $(n \geq 4)$, E_6, E_7, E_8.

***Proof*:**

Step 1: no loops, multiple edges or cycles. A loop at a vertex i, with the vertex i, is a subgraph $\tilde{A}_0$, and two of the edges of a multiple edge, with their two vertices, form a subgraph $\tilde{A}_1$. If $(v_1, \ldots, v_m)$ is a cycle, then these vertices, with the edges joining v_k to v_{k+1} and v_m to v_1, form a subgraph $\tilde{A}_{m-1}$. So Γ has no loops, no multiple edges and no cycles, and it is determined by its adjacency relation.

Step 2: every degree is at most 3. A vertex adjacent to four distinct vertices forms, with them

and the four edges, a subgraph $\tilde{D}_4$.

Step 3: at most one vertex has degree 3. Suppose $u \neq w$ both have degree 3, and choose a path $(u = v_1, \ldots, v_r = w)$, with $r \geq 2$, by connectedness. Choose two vertices $a \neq b$ adjacent to u and different from v_2, and two vertices $c \neq d$ adjacent to w and different from v_{r-1}. The vertex a is not on the path: $a \neq v_1$ because there are no loops, $a \neq v_2$ by choice, and $a = v_k$ with $k \geq 3$ would make $(v_1, \ldots, v_k)$ a cycle. The same holds for b, c and d. If $a = c$, then $(v_1, \ldots, v_r, a)$ is a cycle, since a is adjacent to v_r and to v_1, and similarly $a \neq d$, $b \neq c$, $b \neq d$. So the $r + 4$ vertices $v_1, \ldots, v_r, a, b, c, d$ are distinct, and with the edges of the path and the edges ua, ub, wc, wd they form a subgraph $\tilde{D}_{r+3}$, which is excluded.

Step 4: if no vertex has degree 3*, then* $\Gamma = A_n$. Choose a path $(v_1, \ldots, v_m)$ in Γ with m as large as possible. Suppose a vertex y is not among $v_1, \ldots, v_m$, choose a path $(y = w_1, \ldots, w_p = v_1)$, and let w_q be the first of its vertices among $v_1, \ldots, v_m$. Then $q \geq 2$, and $x = w_{q-1}$ is not among $v_1, \ldots, v_m$ and is adjacent to $w_q = v_k$ for some k. If $k = 1$ or $k = m$, adding x at that end gives a longer path, and if $1 < k < m$, then v_k is adjacent to v_{k-1}, v_{k+1} and x. Both are impossible, so the path contains every vertex. An edge joining v_i to v_j with $j \geq i+2$ would make $(v_i, \ldots, v_j)$ a cycle, so the edges are exactly those joining v_k to v_{k+1}, and $\Gamma = A_m$.

Step 5: if exactly one vertex z *has degree* 3*, then* Γ *is a star.* Let x_1, x_2, x_3 be the vertices adjacent to z, and let Γ' be the full subgraph on the vertices other than z. Every vertex $y \neq z$ is joined to some x_l by a path in Γ': in a path from y to z in Γ, the vertex before z is some x_l, and the part from y to x_l avoids z. No path in Γ' joins x_l to $x_{l'}$ with $l \neq l'$, since such a path followed by z would be a cycle in Γ. For $l = 1, 2, 3$, let C_l be the set of vertices joined to x_l by a path in Γ'. If $y \in C_l \cap C_{l'}$ with $l \neq l'$, take paths from x_l to y and from y to $x_{l'}$ in Γ', and let y' be the first vertex of the first path lying on the second. The first path up to y', followed by the second path from y', is a path in Γ' joining x_l to $x_{l'}$, which is excluded. So the sets C_1, C_2, C_3 are disjoint and cover the vertices other than z. No edge joins two of them: if $y \in C_l$ is adjacent to y', then a path from x_l to y, extended by y' or cut at y' if it already passes through y', joins x_l to y', so $y' \in C_l$. The full subgraph on each C_l is connected, has no cycle, and has every degree at most 2, so by the argument of Step 4 it is a path. In it, x_l has degree at most 1, because x_l has degree at most 2 in Γ and one of its edges goes to z, so x_l is an end of that path. Writing a_l for the number of vertices of C_l, $\Gamma = T(a_1, a_2, a_3)$.

Step 6: the arms. Order the arms so that $a_1 \leq a_2 \leq a_3$. If $a_1 \geq 2$, the central vertex and the first two vertices of each arm form a subgraph $T(2, 2, 2) = \tilde{E}_6$. If $a_1 = 1$ and $a_2 \geq 3$, the central vertex, the arm with one vertex and the first three vertices of the other arms form $T(1, 3, 3) = \tilde{E}_7$. If $a_1 = 1$, $a_2 = 2$ and $a_3 \geq 5$, the first five vertices of the longest arm give $T(1, 2, 5) = \tilde{E}_8$. The remaining possibilities are $T(1, 1, a_3) = D_{a_3+3}$, $T(1, 2, 2) = E_6$, $T(1, 2, 3) = E_7$ and $T(1, 2, 4) = E_8$. With Steps 2 to 5, every case has been treated, completing the proof.

Theorem 54.1.32: Positive Definite Forms And Dynkin Diagrams

Let Γ be a connected graph with vertex set I, loops and multiple edges allowed, and Tits form q. The following are equivalent.

1. Γ is one of the Dynkin diagrams A_n $(n \geq 1)$, D_n $(n \geq 4)$, E_6, E_7, E_8.
2. q is positive definite, that is, $q(x) > 0$ for every nonzero $x \in \mathbb{R}^I$.
3. $q(x) > 0$ for every nonzero $x \in \mathbb{Z}^I$ with $x \geq 0$.

***Proof*:**

1. *(1) implies (2).* Each graph in (1) is the full subgraph of an extended Dynkin diagram $\hat{\Gamma} \neq \tilde{A}_0$ on all its vertices but one, i_0. Removing a vertex of $\tilde{A}_n$ leaves the path A_n. Removing a vertex of degree one from $\tilde{D}_4$ leaves $T(1,1,1) = D_4$, and removing one of the two vertices of degree one adjacent to v_1 from $\tilde{D}_n$, $n \geq 5$, leaves the star with central vertex v_{n-3}, two arms with one vertex, and the arm $v_{n-4}, \dots, v_1$ followed by the other vertex of degree one adjacent to v_1, with $n-3$ vertices, which is $T(1,1,n-3) = D_n$. Removing the last vertex of an arm with two vertices of $\tilde{E}_6 = T(2,2,2)$, of an arm with three vertices of $\tilde{E}_7 = T(1,3,3)$, or of the arm with five vertices of $\tilde{E}_8 = T(1,2,5)$ leaves E_6, E_7 or E_8. For $x \in \mathbb{R}^I$ let $\hat{x} \in \mathbb{R}^{\hat{I}}$ agree with x on I and vanish at i_0. As Γ is the full subgraph on $I = \hat{I} \setminus \{i_0\}$, the formula of proposition 54.1.27 gives $q_\Gamma(x) = q_{\hat{\Gamma}}(\hat{x})$, every term involving i_0 being 0. By lemma 54.1.30(2), $q_\Gamma(x) \geq 0$, with equality only if $\hat{x} = t\delta$ for some $t \in \mathbb{R}$. In that case $0 = \hat{x}_{i_0} = t\delta_{i_0}$ with $\delta_{i_0} > 0$, so $t = 0$ and $x = 0$. Hence q_Γ is positive definite.
2. *(2) implies (3).* Every nonzero $x \in \mathbb{Z}^I$ is a nonzero vector of $\mathbb{R}^I$.
3. *(3) implies (1).* Suppose Γ is not one of the graphs in (1). By lemma 54.1.31, Γ has a subgraph Γ' that is an extended Dynkin diagram, with vertex set $I' \subseteq I$ and edge numbers $n'_{ij} \leq n_{ij}$. Let $\delta = \delta_{\Gamma'}$, and let $x \in \mathbb{Z}^I$ agree with δ on I' and vanish elsewhere, so $x \geq 0$ and $x \neq 0$. Only the vertices of I' contribute to the formula of proposition 54.1.27, and every product $\delta_i \delta_j$ is positive, so

$$q_\Gamma(x) = \sum_{i \in I'} (1 - n_{ii})\delta_i^2 - \sum_{\{i,j\} \subseteq I'} n_{ij}\delta_i\delta_j \leq \sum_{i \in I'} (1 - n'_{ii})\delta_i^2 - \sum_{\{i,j\} \subseteq I'} n'_{ij}\delta_i\delta_j = q_{\Gamma'}(\delta)$$

and $q_{\Gamma'}(\delta) = 0$ by lemma 54.1.30(1). So (3) fails.

The three implications prove the equivalence.

In particular, a connected graph with positive definite Tits form has no loops, no multiple edges and no cycles. The integer vectors at which a Tits form takes the value 1 are its roots.

Definition 54.1.33: Roots, Simple Reflections And The Weyl Group Of A Graph

Let Γ be a graph with vertex set I, Tits form q and symmetric form $(\ ,\ )$.

1. A *root* of Γ is a vector $x \in \mathbb{Z}^I$ with $q(x) = 1$, and Φ_Γ is the set of roots. A root x is *positive* if $x \geq 0$ and *negative* if $-x \geq 0$, and Φ_Γ^+ is the set of positive roots.
2. For a vertex i at which Γ has no loop, the *simple reflection* at i is the linear map $s_i \colon \mathbb{R}^I \to \mathbb{R}^I$, $s_i(x) = x - (x, \alpha_i)\alpha_i$. Since $(\alpha_i, \alpha_i) = 2$ by proposition 54.1.27, $(s_i(x), \alpha_i) = (x, \alpha_i) - 2(x, \alpha_i) = -(x, \alpha_i)$, so $s_i(s_i(x)) = x$ and s_i is invertible.
3. If Γ has no loops, its *Weyl group* W_Γ is the group of linear automorphisms of $\mathbb{R}^I$ generated by the simple reflections, and for an ordering $i_1, \ldots, i_n$ of the n vertices, each listed once, the product $c = s_{i_n} s_{i_{n-1}} \cdots s_{i_1} \in W_\Gamma$ is a *Coxeter element*.

Lemma 54.1.34: Simple Reflections Preserve The Tits Form

Let Γ be a graph and i a vertex at which Γ has no loop.

1. For every $x \in \mathbb{R}^I$, the vector $s_i(x)$ differs from x only in its i-th coordinate. Moreover $s_i(\alpha_i) = -\alpha_i$ and $s_i(\mathbb{Z}^I) = \mathbb{Z}^I$.
2. For all $x, y \in \mathbb{R}^I$, $(s_i(x), s_i(y)) = (x, y)$ and $q(s_i(x)) = q(x)$.
3. $s_i(\Phi_\Gamma) = \Phi_\Gamma$.

***Proof*:**

1. The difference $s_i(x) - x = -(x, \alpha_i)\alpha_i$ is a multiple of α_i, and $s_i(\alpha_i) = \alpha_i - 2\alpha_i = -\alpha_i$ because $(\alpha_i, \alpha_i) = 2$. For $x \in \mathbb{Z}^I$, $(x, \alpha_i) = \sum_j x_j(\alpha_j, \alpha_i)$ is an integer by proposition 54.1.27, so $s_i(\mathbb{Z}^I) \subseteq \mathbb{Z}^I$, and $s_i(s_i(x)) = x$ (definition 54.1.33) gives equality.
2. By bilinearity and $(\alpha_i, \alpha_i) = 2$,
$$(s_i(x), s_i(y)) = (x, y) - 2(x, \alpha_i)(y, \alpha_i) + (x, \alpha_i)(y, \alpha_i)(\alpha_i, \alpha_i) = (x, y)$$
and taking $y = x$ gives $q(s_i(x)) = \frac{1}{2}(s_i(x), s_i(x)) = q(x)$.
3. By (1) and (2), s_i maps Φ_Γ into Φ_Γ, and since $s_i(s_i(x)) = x$, every root x is the image $s_i(s_i(x))$ of the root $s_i(x)$, completing the proof.

Proposition 54.1.35: Roots Of A Positive Definite Tits Form

Let Γ be a graph with vertex set $I = \{1, \dots, n\}$ whose Tits form q is positive definite.

1. Γ has no loops, and $\alpha_1, \dots, \alpha_n$ are roots.
2. Every root is positive or negative, so Φ_Γ is the disjoint union of Φ_Γ^+ and $-\Phi_\Gamma^+$.
3. If x is a root and $i \in I$ with $x \neq \pm\alpha_i$, then $(x, \alpha_i) \in \{-1, 0, 1\}$. The set Φ_Γ is finite.
4. Every element of W_Γ permutes Φ_Γ, and W_Γ is finite.

***Proof*:**

The formula of proposition 54.1.27 shows that q takes integer values on $\mathbb{Z}^I$, and q is positive on nonzero vectors, so $q(y) \geq 1$ for every nonzero $y \in \mathbb{Z}^I$. Bilinearity gives $q(x + y) = q(x) + q(y) + (x, y)$ for all $x, y \in \mathbb{R}^I$.

1. By proposition 54.1.27, $q(\alpha_i) = 1 - n_{ii}$, which is positive only if $n_{ii} = 0$. Hence there are no loops and $q(\alpha_i) = 1$.
2. Let x be a root, and write $x = x^+ - x^-$, where $x_i^+ = \max(x_i, 0)$ and $x_i^- = \max(-x_i, 0)$, so that $x^+, x^- \geq 0$ and no coordinate is nonzero in both. In $(x^+, x^-) = \sum_{i,j} x_i^+ x_j^- (\alpha_i, \alpha_j)$, every nonzero term has $i \neq j$, so $(\alpha_i, \alpha_j) = -n_{ij} \leq 0$ and $(x^+, x^-) \leq 0$. Then
$$1 = q(x) = q(x^+) + q(x^-) - (x^+, x^-) \geq q(x^+) + q(x^-)$$
If x^+ and x^- were both nonzero, the right side would be at least 2. So $x = x^+ \geq 0$ or $x = -x^-$ with $x^- \geq 0$. The two cases exclude each other, since $q(0) = 0$ makes 0 a non-root.
3. Let x be a root and $i \in I$. If $x = \pm\alpha_i$, then $(x, \alpha_i) = \pm 2$. Otherwise $x - \alpha_i$ and $x + \alpha_i$ are nonzero vectors of $\mathbb{Z}^I$, and $q(x \mp \alpha_i) = q(x) + q(\alpha_i) \mp (x, \alpha_i) = 2 \mp (x, \alpha_i)$ is positive, so $(x, \alpha_i) \in \{-1, 0, 1\}$. In every case $(x, \alpha_i) \in \{-2, \dots, 2\}$. The map $\rho\colon \mathbb{Z}^I \to \mathbb{Z}^n$, $\rho(x) = ((x, \alpha_1), \dots, (x, \alpha_n))$, is injective: if $\rho(x) = \rho(y)$, then $(x - y, \alpha_i) = 0$ for all i, so $(x - y, x - y) = \sum_i (x_i - y_i)(x - y, \alpha_i) = 0$ and $x = y$ by positive definiteness. Since ρ maps Φ_Γ into $\{-2, \dots, 2\}^n$, the set Φ_Γ has at most 5^n elements.
4. By lemma 54.1.34(3), each s_i permutes Φ_Γ, and $s_i^{-1} = s_i$, so every element of W_Γ permutes Φ_Γ. Restriction to Φ_Γ is therefore a group homomorphism from W_Γ to the group of permutations of Φ_Γ. An element of its kernel fixes every root, in particular every α_i by (1), and the α_i form a basis of $\mathbb{R}^I$, so it is the identity. Hence W_Γ embeds in the permutation group of the finite set Φ_Γ and is finite, completing the proof.

Example 54.1.36: The Roots Of A_n

Number the vertices of the path A_n as $1, \dots, n$ in order, and for $x \in \mathbb{R}^n$ set $x_0 = x_{n+1} = 0$. Then
$$q(x) = \sum_{i=1}^{n} x_i^2 - \sum_{i=1}^{n-1} x_i x_{i+1} = \frac{1}{2} \sum_{i=0}^{n} (x_{i+1} - x_i)^2$$

because expanding the right side gives $\frac{1}{2}\big(\sum_{i=1}^{n} x_i^2 + \sum_{i=1}^{n} x_i^2 - 2\sum_{i=1}^{n-1} x_i x_{i+1}\big)$, the terms involving x_0 and x_{n+1} being 0. For $x \in \mathbb{Z}^n$, the condition $q(x) = 1$ says that the integer sequence $0 = x_0, x_1, \ldots, x_n, x_{n+1} = 0$ has exactly two steps $x_{i+1} - x_i$ equal to ± 1 and all other steps equal to 0. The sequence starts and ends at 0, so the two nonzero steps have opposite signs, and the sequence is constant equal to 1 or to -1 on an interval $\{i, i+1, \ldots, j\}$ and 0 outside it. Hence

$$\Phi^+_{A_n} = \{\alpha_i + \alpha_{i+1} + \cdots + \alpha_j \mid 1 \le i \le j \le n\}$$

a set of $\frac{n(n+1)}{2}$ positive roots, and Φ_{A_n} consists of these and their negatives.

The finiteness of W_Γ has a consequence for Coxeter elements, which the proof of theorem 54.1.46 uses to locate the indecomposable representations.

Lemma 54.1.37: Coxeter Element Lemma

Let Γ be a graph with vertex set I whose Tits form is positive definite, and let $c = s_{i_n} \cdots s_{i_1}$ be a Coxeter element of W_Γ (definition 54.1.33). For every nonzero $v \in \mathbb{Z}^I$ there is an integer $m \ge 0$ with $c^m(v) \not\ge 0$.

***Proof*:**

By proposition 54.1.35(4), W_Γ is finite, so c has finite order $h \ge 1$. Suppose, toward a contradiction, that $c^m(v) \ge 0$ for every $m \ge 0$, and set $u = \sum_{m=0}^{h-1} c^m(v) \in \mathbb{Z}^I$. Then $c(u) = \sum_{m=1}^{h} c^m(v) = u$, because $c^h(v) = v$.

Step 1: $u = 0$. Put $u_0 = u$ and $u_k = s_{i_k}(u_{k-1})$ for $1 \le k \le n$, so that $u_n = c(u) = u$. By definition 54.1.33, $u_k - u_{k-1} = -(u_{k-1}, \alpha_{i_k})\alpha_{i_k}$, and summing over k,

$$0 = u_n - u_0 = -\sum_{k=1}^{n} (u_{k-1}, \alpha_{i_k})\alpha_{i_k}$$

The vertices $i_1, \ldots, i_n$ are distinct, so the vectors α_{i_k} are linearly independent, and every coefficient (u_{k-1}, α_{i_k}) vanishes. Then $u_k = u_{k-1}$ for every k, so $u_{k-1} = u$ and $(u, \alpha_{i_k}) = 0$ for every k. Every vertex occurs as some i_k, so $(u, \alpha_i) = 0$ for all $i \in I$, and $(u, u) = \sum_i u_i(u, \alpha_i) = 0$. Positive definiteness gives $u = 0$.

Step 2: the contradiction. The vector $u = 0$ is the sum of the vectors $c^m(v) \ge 0$, $0 \le m \le h-1$, so every coordinate of every $c^m(v)$ is 0. In particular $v = c^0(v) = 0$, against the hypothesis. Hence $c^m(v) \not\ge 0$ for some $m \ge 0$, as claimed.

The roots of a positive definite Tits form are an instance of a structure that first appeared in the classification of the simple Lie algebras over $\mathbb{C}$. Its definition records the properties of Φ_Γ that do not refer to the lattice $\mathbb{Z}^I$.

Definition 54.1.38: Root System

Let E be a finite-dimensional real vector space with an inner product $(\ ,\ )$. For a nonzero $\alpha \in E$, the *reflection* in the hyperplane orthogonal to α is $s_\alpha(v) = v - \frac{2(v,\alpha)}{(\alpha,\alpha)}\alpha$. A *(reduced) root system* in E is a finite set $R \subseteq E$ of nonzero vectors, its *roots*, such that

1. R spans E,
2. $s_\alpha(R) = R$ for every $\alpha \in R$,
3. $\frac{2(\beta,\alpha)}{(\alpha,\alpha)} \in \mathbb{Z}$ for all $\alpha, \beta \in R$,
4. if $\alpha \in R$ and $c\alpha \in R$ for a real number c, then $c = \pm 1$.

A root system is *irreducible* if it is not the union of two nonempty subsets with every root of the first orthogonal to every root of the second, and *simply laced* if all its roots have the same length. Root systems $R \subseteq E$ and $R' \subseteq E'$ are *isomorphic* if a linear isomorphism $\varphi\colon E \to E'$ carries R onto R' and satisfies $\frac{2(\varphi(\beta),\varphi(\alpha))}{(\varphi(\alpha),\varphi(\alpha))} = \frac{2(\beta,\alpha)}{(\alpha,\alpha)}$ for all $\alpha, \beta \in R$.

Definition 54.1.39: Weyl Group And Base Of A Root System

Let R be a root system in E. Since $(s_\alpha(v), \alpha) = -(v, \alpha)$, applying s_α twice returns v, and the *Weyl group* $W(R)$ is the group generated by the reflections s_α, $\alpha \in R$. A *base* of R is a subset $\Pi \subseteq R$ that is a basis of E such that every root is an integer combination of Π whose coefficients are all ≥ 0 or all ≤ 0. The elements of a base are the *simple roots*, and the roots whose coefficients are all ≥ 0 are the *positive roots* relative to Π.

Example 54.1.40: The Root System A_2

Let $E = \left\{v \in \mathbb{R}^3 \;\middle|\; v_1 + v_2 + v_3 = 0\right\}$ with the dot product, let $\varepsilon_1, \varepsilon_2, \varepsilon_3$ be the standard basis of $\mathbb{R}^3$, and let

$$R = \{\pm(\varepsilon_1 - \varepsilon_2), \pm(\varepsilon_2 - \varepsilon_3), \pm(\varepsilon_1 - \varepsilon_3)\}$$

The vectors $\varepsilon_1 - \varepsilon_2$ and $\varepsilon_2 - \varepsilon_3$ are linearly independent and lie in the two-dimensional space E, so R spans E. Every root has $(\alpha, \alpha) = 2$, so $s_\alpha(v) = v - (v, \alpha)\alpha$, and for $\alpha = \pm(\varepsilon_i - \varepsilon_j)$ this exchanges the i-th and j-th coordinates of v. Exchanging two coordinates permutes R, and $W(R)$ is generated by the three transpositions of coordinates. The inner product of two roots lies in $\{\pm 1, \pm 2\}$, so $\frac{2(\beta,\alpha)}{(\alpha,\alpha)} = (\beta, \alpha) \in \mathbb{Z}$, and the only multiples of a root lying in R are the root and its negative. So R is a root system, and $\{\varepsilon_1 - \varepsilon_2, \varepsilon_2 - \varepsilon_3\}$ is a base, the third positive root $\varepsilon_1 - \varepsilon_3$ being their sum.

The linear isomorphism $\mathbb{R}^2 \to E$ sending α_1 to $\varepsilon_1 - \varepsilon_2$ and α_2 to $\varepsilon_2 - \varepsilon_3$ carries the symmetric form of A_2 to the dot product, since $(\alpha_1, \alpha_1) = (\alpha_2, \alpha_2) = 2$ and $(\alpha_1, \alpha_2) = -1$ (proposition 54.1.27) agree with the dot products of the images. By example 54.1.36 it carries $\Phi_{A_2} = \{\pm\alpha_1, \pm\alpha_2, \pm(\alpha_1 + \alpha_2)\}$ onto R.

Definition 54.1.41: Cartan Matrix And Dynkin Diagram

Let R be a root system with base $\Pi = \{\alpha_1, \dots, \alpha_r\}$. The *Cartan matrix* of R relative to Π is the $r \times r$ matrix with entries

$$A_{ij} = \frac{2(\alpha_i, \alpha_j)}{(\alpha_i, \alpha_i)}$$

The *Dynkin diagram* of R has vertex set $\{1, \dots, r\}$, two distinct vertices i, j being joined by $A_{ij}A_{ji}$ edges, and each multiple edge carrying an arrowhead pointing toward the shorter of α_i and α_j.

The integers A_{ij} and A_{ji} are positive multiples of (α_i, α_j), so $A_{ij}A_{ji} \geq 0$. The non-simply-laced case already occurs in rank two.

Example 54.1.42: Cartan Matrix

For each of the four sets R below, the two vectors α_1, α_2 chosen are linearly independent, so R spans the plane containing it. The reflections in the roots act as permutations of the coordinates, possibly combined with changes of sign, and these permute R. The integrality axiom follows from the inner products listed, and no two roots are proportional except a root and its negative, so each R is a root system. To see that $\{\alpha_1, \alpha_2\}$ is a base, it suffices to write each positive root as a nonnegative integer combination of α_1 and α_2, the other roots being their negatives. The diagonal entries of every Cartan matrix are 2.

1. $(A_1 \times A_1)$ In $\mathbb{R}^2$, $R = \{\pm\varepsilon_1, \pm\varepsilon_2\}$, with $\alpha_1 = \varepsilon_1$ and $\alpha_2 = \varepsilon_2$. The reflection s_{α_i} changes the sign of the i-th coordinate, every root has length 1, and inner products of roots lie in $\{0, \pm 1\}$. Since $(\alpha_1, \alpha_2) = 0$,
$$A = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$$
and the Dynkin diagram is two vertices with no edge.

2. (A_2) For R as in example 54.1.40, with $\alpha_1 = \varepsilon_1 - \varepsilon_2$ and $\alpha_2 = \varepsilon_2 - \varepsilon_3$, the third positive root is $\alpha_1 + \alpha_2$. Here $(\alpha_1, \alpha_1) = (\alpha_2, \alpha_2) = 2$ and $(\alpha_1, \alpha_2) = -1$, so
$$A = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}$$
and the Dynkin diagram is a single edge.

3. (B_2) In $\mathbb{R}^2$, $R = \{\pm\varepsilon_1, \pm\varepsilon_2, \pm\varepsilon_1 \pm \varepsilon_2\}$, eight roots with independent signs. The reflection in ε_i changes the sign of the i-th coordinate, the reflection in $\varepsilon_1 - \varepsilon_2$ exchanges the coordinates, and the reflection in $\varepsilon_1 + \varepsilon_2$ exchanges them and changes both signs. The inner products of roots lie in $\{0, \pm 1, \pm 2\}$, and $(\alpha, \alpha) \in \{1, 2\}$. With $\alpha_1 = \varepsilon_1 - \varepsilon_2$ and $\alpha_2 = \varepsilon_2$, the positive roots are α_1, α_2, $\varepsilon_1 = \alpha_1 + \alpha_2$ and $\varepsilon_1 + \varepsilon_2 = \alpha_1 + 2\alpha_2$. Here $(\alpha_1, \alpha_1) = 2$, $(\alpha_2, \alpha_2) = 1$ and $(\alpha_1, \alpha_2) = -1$, so $A_{12} = 2(-1)/2 = -1$ and $A_{21} = 2(-1)/1 = -2$:
$$A = \begin{pmatrix} 2 & -1 \\ -2 & 2 \end{pmatrix}$$
The Dynkin diagram is a double edge with its arrowhead pointing toward α_2, the shorter root.

4. (G_2) In the plane E of example 54.1.40, let

$$R = \{\pm(\varepsilon_i - \varepsilon_j) \mid i < j\} \cup \{\pm(2\varepsilon_1 - \varepsilon_2 - \varepsilon_3), \pm(2\varepsilon_2 - \varepsilon_1 - \varepsilon_3), \pm(2\varepsilon_3 - \varepsilon_1 - \varepsilon_2)\}$$

twelve roots, six of squared length 2 and six of squared length 6. The reflection in $\varepsilon_i - \varepsilon_j$ exchanges two coordinates, and for $v \in E$ the reflection in $\gamma = 2\varepsilon_i - \varepsilon_j - \varepsilon_l$ is $v \mapsto v - v_i\gamma$, because $(v, \gamma) = 3v_i$. It exchanges the j-th and l-th coordinates and changes all three signs. The inner product of two roots lies in $\{0, \pm1, \pm2\}$ when both are short, in $\{0, \pm3\}$ when exactly one is long, and in $\{\pm3, \pm6\}$ when both are long, so the integrality axiom holds. With $\alpha_1 = \varepsilon_1 - \varepsilon_2$ and $\alpha_2 = -2\varepsilon_1 + \varepsilon_2 + \varepsilon_3$, the positive roots are

$$\alpha_1 \qquad \alpha_2 \qquad \alpha_1 + \alpha_2 \qquad 2\alpha_1 + \alpha_2 \qquad 3\alpha_1 + \alpha_2 \qquad 3\alpha_1 + 2\alpha_2$$

equal to $\varepsilon_1 - \varepsilon_2$, $-2\varepsilon_1 + \varepsilon_2 + \varepsilon_3$, $\varepsilon_3 - \varepsilon_1$, $\varepsilon_3 - \varepsilon_2$, $\varepsilon_1 - 2\varepsilon_2 + \varepsilon_3$ and $2\varepsilon_3 - \varepsilon_1 - \varepsilon_2$. Here $(\alpha_1, \alpha_1) = 2$, $(\alpha_2, \alpha_2) = 6$ and $(\alpha_1, \alpha_2) = -3$, so $A_{12} = 2(-3)/2 = -3$ and $A_{21} = 2(-3)/6 = -1$:

$$A = \begin{pmatrix} 2 & -3 \\ -1 & 2 \end{pmatrix}$$

The Dynkin diagram is a triple edge with its arrowhead pointing toward α_1, the shorter root.

Definition 54.1.41 normalizes by the row index, so the matrices for B_2 and G_2 are the transposes of those in sources that normalize by the column index, such as [64, §11.1]. In the four cases $A_{12}A_{21}$ takes the values 0, 1, 2, 3.

The two meanings of "Dynkin diagram" in this subsection agree.

Proposition 54.1.43: The Roots Of A Dynkin Diagram Form A Root System

Let Γ be one of the Dynkin diagrams A_n, D_n, E_6, E_7, E_8, with vertex set I, and give $\mathbb{R}^I$ the symmetric form $(\ ,\ )$ of Γ.

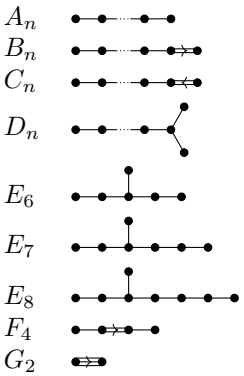
1. $(\ ,\ )$ is an inner product on $\mathbb{R}^I$, and Φ_Γ is a root system in $\mathbb{R}^I$.
2. $\{\alpha_i\}_{i \in I}$ is a base of Φ_Γ with positive roots Φ_Γ^+, and the Dynkin diagram of Φ_Γ relative to this base is Γ.
3. Φ_Γ is irreducible and simply laced.
4. Every root is $w(\alpha_i)$ for some $w \in W_\Gamma$ and $i \in I$, and $W(\Phi_\Gamma) = W_\Gamma$.

***Proof*:**
By theorem 54.1.32, the Tits form of Γ is positive definite, so proposition 54.1.35 applies, and Γ has no loops and no multiple edges.

1. The form $(\ ,\ )$ is symmetric and bilinear, and $(x, x) = 2q(x) > 0$ for $x \neq 0$, so it is an inner product. The set Φ_Γ is finite, does not contain 0, and contains every α_i, so it spans $\mathbb{R}^I$ (proposition 54.1.35). Every root has $(\alpha, \alpha) = 2q(\alpha) = 2$, so $s_\alpha(v) = v - (v, \alpha)\alpha$, and $\frac{2(\beta,\alpha)}{(\alpha,\alpha)} = (\beta, \alpha)$ is an integer for $\beta \in \mathbb{Z}^I$ by proposition 54.1.27. As in lemma 54.1.34, s_α maps $\mathbb{Z}^I$ to $\mathbb{Z}^I$, satisfies $(s_\alpha(x), s_\alpha(y)) = (x, y) - 2(x, \alpha)(y, \alpha) + (x, \alpha)(y, \alpha)(\alpha, \alpha) = (x, y)$,

and is its own inverse, so $s_\alpha(\Phi_\Gamma) = \Phi_\Gamma$. If α and $c\alpha$ are roots, then $1 = q(c\alpha) = c^2 q(\alpha) = c^2$ and $c = \pm 1$.

2. The α_i form a basis of $\mathbb{R}^I$, and by proposition 54.1.35(2) every root has coordinates all ≥ 0 or all ≤ 0. So $\{\alpha_i\}$ is a base, whose positive roots are Φ_Γ^+. Its Cartan matrix has $A_{ij} = (\alpha_i, \alpha_j)$, which by proposition 54.1.27 is -1 if i and j are adjacent and 0 if they are distinct and not adjacent. So $A_{ij}A_{ji}$ is 1 for adjacent vertices and 0 for other pairs, the Dynkin diagram has a single edge exactly between adjacent vertices and no arrowheads, and it is Γ.



3. Every root has $(\alpha, \alpha) = 2$, so Φ_Γ is simply laced. Suppose $\Phi_\Gamma = R_1 \cup R_2$ with R_1 and R_2 nonempty and orthogonal to each other. No root lies in both, as a root is not orthogonal to itself. If i and j are adjacent, then $(\alpha_i, \alpha_j) = -1 \neq 0$, so α_i and α_j lie in the same R_l, and as Γ is connected, all the α_i lie in one of them, say R_1. A root $\beta \in R_2$ is then orthogonal to every α_i, so $(\beta, \beta) = \sum_i \beta_i(\beta, \alpha_i) = 0$, which is impossible. Hence Φ_Γ is irreducible.

4. First let $x \in \Phi_\Gamma^+$, and argue by induction on $\mathrm{ht}(x) = \sum_i x_i \geq 1$. If $\mathrm{ht}(x) = 1$, then $x = \alpha_i$ for some i. If $\mathrm{ht}(x) \geq 2$, then $2 = (x, x) = \sum_i x_i(x, \alpha_i)$ with every $x_i \geq 0$, so some i has $x_i > 0$ and $(x, \alpha_i) > 0$. As $x \neq \pm\alpha_i$, proposition 54.1.35(3) gives $(x, \alpha_i) = 1$, so $s_i(x) = x - \alpha_i$ is a root (lemma 54.1.34) of height $\mathrm{ht}(x) - 1$. Some x_j with $j \neq i$ is positive, since otherwise $x = x_i\alpha_i$ and $q(x) = x_i^2 = 1$ would force $x = \alpha_i$, and $s_i(x)$ has the same j-th coordinate. So $s_i(x)$ is a positive root (proposition 54.1.35(2)), by induction $s_i(x) = w(\alpha_l)$ with $w \in W_\Gamma$, and $x = s_i w(\alpha_l)$. A negative root x has $-x = w(\alpha_l)$, and then $x = w(-\alpha_l) = ws_l(\alpha_l)$. Next, $s_i = s_{\alpha_i}$, so $W_\Gamma \subseteq W(\Phi_\Gamma)$. Conversely, write a root as $\alpha = w(\alpha_l)$ with $w \in W_\Gamma$. By lemma 54.1.34(2), w preserves $(\ ,\ )$, so $(v, w(\alpha_l)) = (w^{-1}(v), \alpha_l)$ and, for every $v \in \mathbb{R}^I$,

$$s_\alpha(v) = v - (w^{-1}(v), \alpha_l)w(\alpha_l) = w\big(w^{-1}(v) - (w^{-1}(v), \alpha_l)\alpha_l\big) = ws_lw^{-1}(v)$$

So every generator s_α of $W(\Phi_\Gamma)$ lies in W_Γ, and $W(\Phi_\Gamma) = W_\Gamma$, completing the proof.

54.1.44 Remark: The Classification Of Root Systems Every root system is the union of mutually orthogonal irreducible root systems, and an irreducible root system is determined up to isomorphism by its Dynkin diagram, which is one of the connected diagrams

with $n \geq 1$ for A_n, $n \geq 2$ for B_n, $n \geq 3$ for C_n and $n \geq 4$ for D_n, and every diagram on the list occurs [64, §§11.1, 11.3, 11.4, 12.1]. The proof is a case analysis of the possible Cartan matrices, and nothing in this book depends on it. The simply laced diagrams on the list are A_n, D_n, E_6, E_7 and E_8, and by proposition 54.1.43 their root systems are the sets Φ_Γ of the Tits forms. In B_n, C_n, F_4 and G_2 the roots have two different lengths, as in example 54.1.42 for B_2 and G_2. Every root of a graph has $(\alpha, \alpha) = 2$, so these four families never arise as Φ_Γ, and in particular never from the Tits form of a quiver.

54.1.4 Gabriel's Theorem

Theorem 54.1.32 singles out the Dynkin diagrams of type A, D, E among connected graphs by the positivity of their Tits forms, and proposition 54.1.35 attaches to each of them a finite set of positive roots. Gabriel's theorem identifies these positive roots with the indecomposable representations of every quiver whose underlying graph is one of these diagrams. Throughout, $\mathbb{F}$ is a field, representations are over $\mathbb{F}$, and quivers are finite.

Definition 54.1.45: Collection Of Indecomposables

Let Q be a finite quiver. Then $\mathrm{Ind}(Q)$ denotes the set of isomorphism classes of nonzero finite-dimensional indecomposable representations of Q over $\mathbb{F}$, and Q is of *finite type* over $\mathbb{F}$ if $\mathrm{Ind}(Q)$ is finite.

Theorem 54.1.46: Gabriel's Theorem

Let Q be a finite quiver whose underlying graph Γ is connected (definition 54.1.25), and let $\mathbb{F}$ be a field.

1. If Γ is one of the Dynkin diagrams A_n, D_n, E_6, E_7, E_8, then Q is of finite type over $\mathbb{F}$, and the dimension vector
$$\dim\colon \operatorname{Ind}(Q) \longrightarrow \Phi_\Gamma^+ \qquad [V] \longmapsto \dim_Q V$$
is a bijection onto the set of positive roots of Γ.
2. If $\mathbb{F}$ is infinite and Q is of finite type over $\mathbb{F}$, then Γ is one of the Dynkin diagrams A_n, D_n, E_6, E_7, E_8.

By part (1), the number of indecomposable representations of a quiver of type A, D, E depends only on its graph, not on the orientation of its arrows or on the field: a quiver whose underlying graph is A_n has $\frac{n(n+1)}{2}$ of them by example 54.1.36. The proof of part (2) below uses that $\mathbb{F}$ is infinite: over a finite field every representation space is a finite set, so the number of orbits of $G(\underline{d})$ carries no information.

By proposition 54.1.43(4), every positive root is obtained from some α_i by applying simple reflections. The reflection functors of Bernstein, Gelfand and Ponomarev are the corresponding operations on representations. A simple reflection s_i is defined at every vertex without a loop, hence at every vertex of an A, D, E graph, but a reflection functor at i is defined only when i is a sink or a source (definition 54.1.4), and it reverses the arrows at i. For a sink i write s_i^+Q, and for a source i write s_i^-Q, for the quiver iQ of definition 54.1.4, in which every arrow at i is reversed. The sink i of Q is a source of s_i^+Q, and $s_i^-(s_i^+Q) = Q$.

Let Q be $1 \xrightarrow{e} 2$, in which 2 is a sink, and let V be the representation $V(1) \xrightarrow{T_e} V(2)$. The reflection at the sink 2 keeps $V(1)$, replaces $V(2)$ by $\ker(T_e)$, and replaces the arrow by its reversal $2 \to 1$, carrying the inclusion of $\ker(T_e)$ into $V(1)$:

$$\left(V(1) \xrightarrow{T_e} V(2) \right) \longmapsto \left(V(1) \hookleftarrow \ker(T_e) \right)$$

If T_e is surjective, the dimension vector (d_1, d_2) becomes $(d_1, d_1 - d_2)$, and since $(d, \alpha_2) = 2d_2 - d_1$ by proposition 54.1.27, this is $s_2(d)$. The reflection at the source 1 replaces $V(1)$ by $\operatorname{coker}(T_e) = V(2)/\operatorname{im}(T_e)$ and the arrow by the quotient map $V(2) \to \operatorname{coker}(T_e)$, and if T_e is injective the dimension vector becomes $(d_2 - d_1, d_2) = s_1(d)$. At an arbitrary sink or source, all the arrows at the vertex are combined into one map. If i is a sink of Q and $V \in \operatorname{Rep}(Q)$, let

$$\Psi_i\colon \bigoplus_{e:j\to i} V(j) \to V(i)$$

be the map whose restriction to the summand indexed by an arrow $e\colon j \to i$ is T_e, the sum having one summand for each arrow into i. If i is a source, let

$$\Phi_i\colon V(i) \to \bigoplus_{e:i\to j} V(j)$$

be the map whose component in the summand indexed by an arrow $e\colon i \to j$ is T_e.

Definition 54.1.47: Reflection Functor

Let Q be a quiver.

1. For a sink i and $V \in \mathrm{Rep}(Q)$, define $S_i^+(V) \in \mathrm{Rep}(s_i^+ Q)$ by $S_i^+(V)(k) = V(k)$ for $k \neq i$ and $S_i^+(V)(i) = \ker(\Psi_i)$. The map along an arrow not at i is T_e, and the map along the reversal $i \to k$ of an arrow $e\colon k \to i$ is $\pi_k \circ \iota_i$, where $\iota_i\colon \ker(\Psi_i) \to \bigoplus_{e:j\to i} V(j)$ is the inclusion and π_k is the projection onto the summand $V(k)$ indexed by e (two arrows from k give two summands and two projections).

2. For a source i and $V \in \mathrm{Rep}(Q)$, define $S_i^-(V) \in \mathrm{Rep}(s_i^- Q)$ by $S_i^-(V)(k) = V(k)$ for $k \neq i$ and $S_i^-(V)(i) = \mathrm{coker}(\Phi_i)$. The map along an arrow not at i is T_e, and the map along the reversal $k \to i$ of an arrow $e\colon i \to k$ is $p \circ \iota_k$, where $\iota_k\colon V(k) \to \bigoplus_{e:i\to j} V(j)$ is the inclusion of the summand indexed by e and p is the quotient map onto $\mathrm{coker}(\Phi_i)$.

3. For a morphism $\varphi\colon V \to W$ and a sink i, the morphism $S_i^+(\varphi)$ is $\varphi(k)$ at $k \neq i$ and the restriction of $\bigoplus_{e:j\to i} \varphi(j)$ to $\ker(\Psi_i^V) \to \ker(\Psi_i^W)$ at i. For a source i, the morphism $S_i^-(\varphi)$ is $\varphi(k)$ at $k \neq i$ and the map induced by $\bigoplus_{e:i\to j} \varphi(j)$ on cokernels at i.

The functors $S_i^+\colon \mathrm{Rep}(Q) \to \mathrm{Rep}(s_i^+ Q)$ and $S_i^-\colon \mathrm{Rep}(Q) \to \mathrm{Rep}(s_i^- Q)$ are the *Bernstein-Gelfand-Ponomarev reflection functors*, or *reflection functors* for short. That (3) is well defined and gives functors is the first paragraph of the proof of proposition 54.1.49.

Example 54.1.48: Reflection Functor

Let Q be $1 \xrightarrow{e} 2$, so that $s_2^+ Q$ is $1 \leftarrow 2$. Three nonzero indecomposable representations of Q are $\mathbb{F} \xrightarrow{1} \mathbb{F}$, $\mathbb{F} \to 0$ and $0 \to \mathbb{F}$ (example 54.1.23), of dimension vectors $\alpha_1 + \alpha_2$, α_1 and α_2. Applying S_2^+:

1. For $\mathbb{F} \xrightarrow{1} \mathbb{F}$, the map Ψ_2 is the identity of $\mathbb{F}$, so $\ker(\Psi_2) = 0$ and S_2^+ gives $\mathbb{F} \leftarrow 0$, of dimension vector $\alpha_1 = s_2(\alpha_1 + \alpha_2)$.

2. For $\mathbb{F} \to 0$, the map Ψ_2 is zero on $\mathbb{F}$, so $\ker(\Psi_2) = \mathbb{F}$ and S_2^+ gives $\mathbb{F} \xleftarrow{1} \mathbb{F}$, of dimension vector $\alpha_1 + \alpha_2 = s_2(\alpha_1)$.

3. For $0 \to \mathbb{F}$, $\ker(\Psi_2) = 0$ and S_2^+ gives 0, while $s_2(\alpha_2) = -\alpha_2$ is negative.

So S_2^+ exchanges the representations of dimension vectors α_1 and $\alpha_1 + \alpha_2$, as s_2 exchanges these positive roots of A_2, and it sends the simple representation at the sink, whose dimension vector s_2 makes negative, to 0.

For a sink i, let $\mathrm{Rep}^{i,-}(Q)$ denote the full subcategory of representations of Q for which the map

$$\Psi_i\colon \bigoplus_{e:j\to i} V(j) \to V(i)$$

is surjective, and for a source i, let $\mathrm{Rep}^{i,+}(Q)$ denote the full subcategory of representations of Q for which the map

$$\Phi_i\colon V(i) \to \bigoplus_{e:i\to j} V(j)$$

is injective. For a vertex i, let $S(i) \in \mathrm{Rep}(Q)$ denote the representation with $S(i)(i) = \mathbb{F}$, with $S(i)(l) = 0$ for $l \neq i$, and with all edge maps zero. A representation is *simple at vertex i* if it is isomorphic to $S(i)$.

Proposition 54.1.49: Properties Of Reflection Functor

Let Q be a quiver. In items (4) to (7), the upper sign refers to a sink i and the lower sign to a source i. For items (6) and (7), assume in addition that Q is finite and that every representation named has finite total dimension $\sum_i \dim V(i)$, and let s_i be the simple reflection at i of the underlying graph of Q (definition 54.1.33), which is defined because a sink or a source carries no loop.

1. If i is a sink, then for any $V \in \mathrm{Rep}(Q)$, $S_i^+(V) \in \mathrm{Rep}^{i,+}(s_i^+(Q))$ (similarly for source)
2. If i is a sink, then for any $V \in \mathrm{Rep}(Q)$, $S_i^- S_i^+(V) \in \mathrm{Rep}^{i,-}(Q)$ (similarly for source)
3. The restrictions of the reflection functors are equivalences

$$S_i^+ : \mathrm{Rep}^{i,-}(Q) \to \mathrm{Rep}^{i,+}(s_i^+ Q) \qquad (i \text{ a sink of } Q)$$
$$S_i^- : \mathrm{Rep}^{i,+}(Q) \to \mathrm{Rep}^{i,-}(s_i^- Q) \qquad (i \text{ a source of } Q)$$

   where the inverse of each restriction is the restriction of the other functor, taken over the reflected quiver
4. If V is simple at vertex i, then $S_i^\pm(V) = 0$.
5. If V is a non-zero indecomposable representation of Q that is not simple at i, then $V \in \mathrm{Rep}^{i,\mp}(Q)$, the representation $S_i^\pm(V)$ of $s_i^\pm(Q)$ is nonzero and indecomposable, and $V \cong S_i^\mp S_i^\pm(V)$.
6. If V is a nonzero indecomposable representation of Q, then $S_i^\pm(V)$ is a nonzero indecomposable representation of $s_i^\pm(Q)$ if and only if $s_i(\dim_Q(V)) \geq 0$
7. If $V \in \mathrm{Rep}^{i,\mp}(Q)$ is a nonzero indecomposable representation, then $\dim_Q(S_i^\pm(V)) = s_i(\dim_Q(V))$

***Proof*:**

For a sink i of a quiver and a representation V, write $\Psi_i^V : \bigoplus_{e:j\to i} V(j) \to V(i)$ for the map whose component at an edge $e : j \to i$ is T_e, and for a source i write $\Phi_i^V : V(i) \to \bigoplus_{e:i\to j} V(j)$ for the map whose component at an edge $e : i \to j$ is T_e. These are the maps in the definition of the subcategories $\mathrm{Rep}^{i,\mp}$ above. On a quiver morphism $\varphi : V \to W$, the functor S_i^+ acts by $S_i^+(\varphi)(k) = \varphi(k)$ for $k \neq i$ and by taking $S_i^+(\varphi)(i)$ to be the restriction of $\bigoplus_{e:j\to i} \varphi(j)$ to a map $\ker(\Psi_i^V) \to \ker(\Psi_i^W)$, as in definition 54.1.47(3). The restriction lands in $\ker(\Psi_i^W)$ because summing the commuting squares of φ over the edges $e : j \to i$ (definition 54.1.9) gives $\Psi_i^W \circ \bigoplus_j \varphi(j) = \varphi(i) \circ \Psi_i^V$. The map $\bigoplus_j \varphi(j)$ acts summand by summand, so $\pi_k \circ \bigoplus_j \varphi(j) = \varphi(k) \circ \pi_k$ for the projection π_k onto the summand indexed by an edge $e\colon k \to i$, and this is the commuting square of $S_i^+(\varphi)$ at the reversal of e. At the edges not at i the squares are those of φ, so $S_i^+(\varphi)$ is a morphism. Dually, summing the squares of φ over the edges $e : i \to j$ gives $\Phi_i^W \circ \varphi(i) = \left(\bigoplus_j \varphi(j)\right) \circ \Phi_i^V$, so $\bigoplus_{e:i\to j} \varphi(j)$ carries $\mathrm{im}(\Phi_i^V)$ into $\mathrm{im}(\Phi_i^W)$ and induces the

map $S_i^-(\varphi)(i)$ on cokernels. It commutes with the inclusions of the summands and with the quotient maps, which gives the squares of $S_i^-(\varphi)$ at the reversed edges. Both constructions send identities to identities, and they respect composition because the restriction of a composite is the composite of the restrictions, and likewise for induced maps on quotients.

For representations V, W and a sink i, the canonical identification

$$\bigoplus_{e:j\to i}(V\oplus W)(j)=\Big(\bigoplus_{e:j\to i}V(j)\Big)\oplus\Big(\bigoplus_{e:j\to i}W(j)\Big)$$

carries $\Psi_i^{V\oplus W}$ to $\Psi_i^V\oplus\Psi_i^W$, and the kernel of a direct sum of linear maps is the direct sum of the kernels, so $S_i^+(V\oplus W)\cong S_i^+(V)\oplus S_i^+(W)$, the edge maps on both sides being assembled summand by summand from the same inclusions and projections. The same identification on cokernels gives $S_i^-(V\oplus W)\cong S_i^-(V)\oplus S_i^-(W)$ at a source.

Item (1). Let i be a sink of Q and $V\in\mathrm{Rep}(Q)$, and write $U=\bigoplus_{e:j\to i}V(j)$ and $K=\ker(\Psi_i^V)\subseteq U$. In $s_i^+(Q)$ the vertex i is a source, and its outgoing edges are exactly the reversals of the edges of Q into i. By definition 54.1.47, the map of $S_i^+(V)$ at the reversal of an edge $e:k\to i$ is $\pi_k\circ\iota_i$, where $\iota_i:K\to U$ is the inclusion and π_k is the projection of U onto the summand $V(k)$ indexed by e. The map $\Phi_i^{S_i^+(V)}$ therefore has components $\pi_k\circ\iota_i$ over all summands of U, and a vector of U is recovered from the family of all its components, so $\Phi_i^{S_i^+(V)}=\iota_i$. An inclusion is injective, so $S_i^+(V)\in\mathrm{Rep}^{i,+}(s_i^+(Q))$. For a source i, the edges of $s_i^-(Q)$ into i are the reversals of the edges of Q out of i, the map of $S_i^-(V)$ at such an edge is $p\circ\iota_k$ with $p:\bigoplus_{e:i\to j}V(j)\to\mathrm{coker}(\Phi_i^V)$ the quotient map, and assembling the components gives $\Psi_i^{S_i^-(V)}=p$. A quotient map is surjective, so $S_i^-(V)\in\mathrm{Rep}^{i,-}(s_i^-(Q))$.

Item (2). Let i be a sink of Q. Reversing the arrows at i twice returns the original quiver, so $s_i^-(s_i^+(Q))=Q$. The vertex i is a source of $s_i^+(Q)$, so the source half of item (1), applied to the quiver $s_i^+(Q)$ and the representation $S_i^+(V)$, gives $S_i^-S_i^+(V)\in\mathrm{Rep}^{i,-}(Q)$. If i is instead a source of Q, the sink half of item (1) applied to $s_i^-(Q)$ gives $S_i^+S_i^-(V)\in\mathrm{Rep}^{i,+}(Q)$.

Item (3). Let i be a sink of Q. By item (1), S_i^+ carries $\mathrm{Rep}^{i,-}(Q)$ into $\mathrm{Rep}^{i,+}(s_i^+(Q))$ and S_i^- carries $\mathrm{Rep}^{i,+}(s_i^+(Q))$ into $\mathrm{Rep}^{i,-}(Q)$, so both restrictions are defined.

Let $V\in\mathrm{Rep}^{i,-}(Q)$ and retain U, K, ι_i from item (1). By item (1), $\Phi_i^{S_i^+(V)}=\iota_i$, so $(S_i^-S_i^+(V))(i)=\mathrm{coker}(\iota_i)=U/K$, and the map of $S_i^-S_i^+(V)$ at an edge $e:j\to i$ of Q is $p\circ\iota_j:V(j)\to U/K$, with $p\colon U\to U/K$ the quotient map. At every other vertex and edge, $S_i^-S_i^+(V)$ agrees with V. Because $V\in\mathrm{Rep}^{i,-}(Q)$ the map Ψ_i^V is surjective, and $\Psi_i^V(u)=\Psi_i^V(u')$ holds exactly when $u-u'\in K$, so

$$\overline{\Psi_i}:U/K\to V(i)\qquad u+K\mapsto\Psi_i^V(u)$$

is a well-defined linear isomorphism. Define $\mu_V:S_i^-S_i^+(V)\to V$ by $\mu_V(i)=\overline{\Psi_i}$ and $\mu_V(k)=\mathrm{id}_{V(k)}$ for $k\neq i$. At an edge $e:j\to i$ the required square commutes because

$$\overline{\Psi_i}(p(\iota_j(x)))=\Psi_i^V(\iota_j(x))=T_e(x)$$

for $x\in V(j)$, and at every other edge both representations carry the same map with identities as the vertical maps. So μ_V is a quiver morphism that is a linear isomorphism at every vertex. Its vertexwise inverse is again a quiver morphism, because from $\mu_V(i')\circ S_e=T_e\circ\mu_V(j')$ at an edge $e:j'\to i'$ one gets $S_e\circ\mu_V(j')^{-1}=\mu_V(i')^{-1}\circ T_e$. Hence μ_V is an isomorphism $S_i^-S_i^+(V)\cong V$.

For naturality, let $\varphi : V \to V'$ be a morphism in $\mathrm{Rep}^{i,-}(Q)$. At a vertex $k \neq i$ both composites $\varphi \circ \mu_V$ and $\mu_{V'} \circ S_i^- S_i^+(\varphi)$ equal $\varphi(k)$. At i, the map $S_i^- S_i^+(\varphi)(i) : U/K \to U'/K'$ is induced by $\bigoplus_{e:j\to i} \varphi(j)$, so both composites send $u + K$ to

$$\varphi(i)(\Psi_i^V(u)) = \Psi_i^{V'}\Big(\bigoplus_j \varphi(j)(u)\Big)$$

the equality being the sum over the edges $e : j \to i$ of the commuting squares of φ.

Conversely, let $W \in \mathrm{Rep}^{i,+}(s_i^+(Q))$, write $U' = \bigoplus_{f:i\to k} W(k)$, summing over the edges of $s_i^+(Q)$ out of i, and write $\Phi = \Phi_i^W : W(i) \to U'$, an injective map because $W \in \mathrm{Rep}^{i,+}$. Then $(S_i^-(W))(i) = \mathrm{coker}(\Phi) = U'/\mathrm{im}(\Phi)$, and by the source half of item (1), $\Psi_i^{S_i^-(W)}$ is the quotient map $p' : U' \to U'/\mathrm{im}(\Phi)$, so

$$(S_i^+ S_i^-(W))(i) = \ker(p') = \mathrm{im}(\Phi)$$

Define $\nu_W : W \to S_i^+ S_i^-(W)$ by $\nu_W(k) = \mathrm{id}_{W(k)}$ for $k \neq i$ and $\nu_W(i) : W(i) \to \mathrm{im}(\Phi)$, $x \mapsto \Phi(x)$, a linear isomorphism because Φ is injective. At an edge $f : i \to k$ of $s_i^+(Q)$, the map of $S_i^+ S_i^-(W)$ is $\pi_k \circ \iota_i$ with $\iota_i : \ker(p') \to U'$ the inclusion, and

$$\pi_k(\iota_i(\Phi(x))) = \pi_k(\Phi(x)) = T_f(x)$$

because the f-component of Φ is T_f. At every edge not at i both representations carry the same map and the vertical maps are identities. As before, the vertexwise linear isomorphism ν_W is an isomorphism of representations. Naturality in W follows as for μ: for $\varphi : W \to W'$, the map $S_i^+ S_i^-(\varphi)(i)$ is the restriction of $\bigoplus_f \varphi(k)$ to the kernels, and $\Phi' \circ \varphi(i) = \big(\bigoplus_f \varphi(k)\big) \circ \Phi$ is the sum over the edges $f : i \to k$ of the commuting squares of φ.

The natural isomorphisms μ and ν exhibit $S_i^- S_i^+ \cong \mathrm{id}$ on $\mathrm{Rep}^{i,-}(Q)$ and $S_i^+ S_i^- \cong \mathrm{id}$ on $\mathrm{Rep}^{i,+}(s_i^+(Q))$, so the two restrictions are mutually inverse equivalences. This proves the first line of the display, together with the statement that its inverse is the restriction of S_i^-. The second line is the case just proved, applied to the quiver $s_i^-(Q)$: if i is a source of Q, then i is a sink of $s_i^-(Q)$ and $s_i^+(s_i^-(Q)) = Q$, so the restrictions

$$S_i^- : \mathrm{Rep}^{i,+}(Q) \to \mathrm{Rep}^{i,-}(s_i^-(Q)) \qquad S_i^+ : \mathrm{Rep}^{i,-}(s_i^-(Q)) \to \mathrm{Rep}^{i,+}(Q)$$

are mutually inverse equivalences.

The unrestricted functors are moreover adjoint. Fix a sink i of Q, and let $A \in \mathrm{Rep}(s_i^+(Q))$ and $B \in \mathrm{Rep}(Q)$. Away from i, the representations $S_i^-(A)$ and A carry the same spaces and maps, as do B and $S_i^+(B)$, so a family $(g(k))_{k\neq i}$ satisfies the square conditions away from i for a morphism $S_i^-(A) \to B$ exactly when it satisfies them for a morphism $A \to S_i^+(B)$. In a morphism $g : S_i^-(A) \to B$, the squares at the edges $e : k \to i$ of Q read $g(i) \circ p \circ \iota_k = T_e^B \circ g(k)$, with p the quotient map onto $\mathrm{coker}(\Phi_i^A)$, so $g(i)$ is the map that $\Psi_i^B \circ \bigoplus_k g(k)$ induces on $\mathrm{coker}(\Phi_i^A)$, and such a map exists, uniquely, exactly when this composite kills $\mathrm{im}(\Phi_i^A)$. In a morphism $h : A \to S_i^+(B)$ carrying the same family $g(k) = h(k)$ away from i, the squares at the edges $f : i \to k$ of $s_i^+(Q)$ read $\iota_i \circ h(i) = \big(\bigoplus_k g(k)\big) \circ \Phi_i^A$, so $h(i)$ exists, uniquely, exactly when the right-hand side lands in $\ker(\Psi_i^B)$. Both conditions state that $\Psi_i^B \circ \big(\bigoplus_k g(k)\big) \circ \Phi_i^A = 0$. Restricting to the components away from i is therefore a bijection

$$\mathrm{Hom}_Q(S_i^-(A), B) \cong \mathrm{Hom}_{s_i^+(Q)}(A, S_i^+(B))$$

natural in A and B, because composition with a morphism acts on the components away from i componentwise.

Item (4). Isomorphic representations have isomorphic images under the functors, so take $V = S(i)$. If i is a sink, every j with an edge $e : j \to i$ satisfies $V(j) = 0$, so $\bigoplus_{e:j\to i} V(j) = 0$ and $\ker(\Psi_i^V) = 0$. The representation $S_i^+(V)$ is then zero at i and equals $V(k) = 0$ at every $k \neq i$, so $S_i^+(V) = 0$. If i is a source, then $\bigoplus_{e:i\to j} V(j) = 0$, so $\operatorname{coker}(\Phi_i^V) = 0$ and $S_i^-(V) = 0$ for the same reason.

Item (5). First a dichotomy: if i is a sink and V is a nonzero indecomposable representation with $V \ncong S(i)$, then Ψ_i^V is surjective, that is, $V \in \operatorname{Rep}^{i,-}(Q)$. Suppose Ψ_i^V is not surjective and choose a subspace $C \subseteq V(i)$ with $V(i) = \operatorname{im}(\Psi_i^V) \oplus C$ and $C \neq 0$. Define $V', V'' \subseteq V$ by

$$V'(i) = \operatorname{im}(\Psi_i^V) \qquad V'(k) = V(k) \text{ for } k \neq i \qquad V''(i) = C \qquad V''(k) = 0 \text{ for } k \neq i$$

Both are subrepresentations (definition 54.1.8): every edge $e : j \to i$ satisfies $T_e(V(j)) \subseteq \operatorname{im}(\Psi_i^V) = V'(i)$ and $T_e(V''(j)) = T_e(0) = 0 \subseteq V''(i)$, the sink i has no outgoing edges, and edges away from i are unaffected. Every edge map is accordingly the direct sum of its restrictions to V' and V'', so $V = V' \oplus V''$ as in definition 54.1.17. Indecomposability of V with $V'' \neq 0$ forces $V' = 0$, so $V(k) = 0$ for all $k \neq i$ and $\operatorname{im}(\Psi_i^V) = 0$. All edge maps of V then vanish, so V is a direct sum of $\dim(C)$ copies of $S(i)$, and indecomposability forces $\dim(C) = 1$ and $V \cong S(i)$, against the hypothesis. The dichotomy follows. For a source the same construction splits off the kernel: if Φ_i^V is not injective, then V'' with $V''(i) = \ker(\Phi_i^V) \neq 0$ and $V''(k) = 0$ for $k \neq i$, together with V' given by a complement of $\ker(\Phi_i^V)$ at i and $V'(k) = V(k)$ for $k \neq i$, are subrepresentations with $V = V' \oplus V''$, and indecomposability forces, by the same argument, $V \cong S(i)$.

Now let V be nonzero indecomposable with $V \ncong S(i)$, and let i be a sink. By the dichotomy, $V \in \operatorname{Rep}^{i,-}(Q)$, which is the first claim of item (5), and item (3) gives $V \cong S_i^- S_i^+(V)$, which is the last. If $S_i^+(V) = 0$, then $V \cong S_i^-(0) = 0$, against $V \neq 0$. So $S_i^+(V) \neq 0$. Suppose $S_i^+(V) = W_1 \oplus W_2$ with both summands nonzero. Item (1) puts $S_i^+(V)$ in $\operatorname{Rep}^{i,+}(s_i^+(Q))$, and $\Phi_i^{W_1\oplus W_2} = \Phi_i^{W_1} \oplus \Phi_i^{W_2}$, so each $\Phi_i^{W_l}$ is injective and $W_l \in \operatorname{Rep}^{i,+}(s_i^+(Q))$. Item (3) gives $W_l \cong S_i^+ S_i^-(W_l)$, and $W_l \neq 0$ forces $S_i^-(W_l) \neq 0$. The additivity of S_i^- recorded at the start of the proof now gives

$$V \cong S_i^-(W_1 \oplus W_2) \cong S_i^-(W_1) \oplus S_i^-(W_2)$$

Let θ be the inverse of the displayed isomorphism, an isomorphism from $S_i^-(W_1) \oplus S_i^-(W_2)$ to V. An isomorphism carries subrepresentations to subrepresentations, so $V_1 = \theta(S_i^-(W_1) \oplus 0)$ and $V_2 = \theta(0 \oplus S_i^-(W_2))$ are nonzero subrepresentations of V with $V = V_1 \oplus V_2$, against definition 54.1.22. Hence $S_i^+(V)$ is indecomposable. For a source the argument runs with S_i^- and S_i^+ exchanged, using the source halves of items (1) and (3) and the additivity of S_i^+.

Item (7). Item (6) uses this item. Let i be a sink and $V \in \operatorname{Rep}^{i,-}(Q)$ of finite total dimension, and write $d = \dim_Q(V)$ (definition 54.1.7). Vertices $k \neq i$ contribute $\dim(S_i^+(V)(k)) = \dim V(k) = d_k$. At i, the map Ψ_i^V is surjective, so rank-nullity gives

$$\dim \ker(\Psi_i^V) = \sum_{e:j\to i} d_j - d_i$$

the sum running over the edges into i, each counted once. On the other side, by definition 54.1.26, $\langle d, \alpha_i\rangle = d_i - \sum_{e:j\to i} d_j$ and $\langle \alpha_i, d\rangle = d_i$, because no edge leaves the sink i. Hence $(d, \alpha_i) =$

$2d_i - \sum_{e:j\to i} d_j$, and $s_i(d) = d - (d,\alpha_i)\alpha_i$ agrees with d away from i and has i-th entry

$$d_i - \Big(2d_i - \sum_{e:j\to i} d_j\Big) = \sum_{e:j\to i} d_j - d_i$$

The two dimension vectors agree, so $\dim_Q(S_i^+(V)) = s_i(\dim_Q(V))$. For a source i and $V \in \mathrm{Rep}^{i,+}(Q)$, the map Φ_i^V is injective, so $\dim \operatorname{coker}(\Phi_i^V) = \sum_{e:i\to j} d_j - d_i$, while $\langle d,\alpha_i\rangle = d_i$ and $\langle \alpha_i, d\rangle = d_i - \sum_{e:i\to j} d_j$, and the same computation gives $\dim_Q(S_i^-(V)) = s_i(\dim_Q(V))$.

Item (6). Let V be nonzero indecomposable and let i be a sink. The source case replaces S_i^+ by S_i^- throughout, using the source halves of items (4), (5), and (7). If $V \cong S(i)$, then $S_i^+(V) = 0$ by item (4), and $\dim_Q(V) = \alpha_i$, so $s_i(\dim_Q(V)) = -\alpha_i$ (lemma 54.1.34), whose i-th entry is -1. Both sides of the equivalence fail. If $V \ncong S(i)$, then item (5) gives that $S_i^+(V)$ is nonzero indecomposable and that $V \in \mathrm{Rep}^{i,-}(Q)$, and item (7) gives $s_i(\dim_Q(V)) = \dim_Q(S_i^+(V))$, a vector of dimensions, hence ≥ 0. Both sides of the equivalence hold. In either case the equivalence is true.

Corollary 54.1.50: Reflection Functors Are Adjoint

Let i be a sink of Q. For $A \in \mathrm{Rep}(s_i^+(Q))$ and $B \in \mathrm{Rep}(Q)$ there is a bijection

$$\mathrm{Hom}_Q(S_i^-(A), B) \cong \mathrm{Hom}_{s_i^+(Q)}(A, S_i^+(B))$$

natural in both variables, so S_i^- is left adjoint to S_i^+.

***Proof*:**
This is the final paragraph of the proof of item (3) of proposition 54.1.49: both morphism spaces biject with the families $(g(k))_{k\neq i}$ satisfying the away-from-i squares together with the single condition $\Psi_i^B \circ \big(\bigoplus_k g(k)\big) \circ \Phi_i^A = 0$, and the bijection is natural in A and B by the uniqueness of the induced components at i.

A reflection functor at i requires i to be a sink or a source, so reflecting at every vertex in turn requires an ordering of the vertices adapted to the arrows.

Lemma 54.1.51: Sink Orderings

Let Q be a finite quiver with n vertices and without oriented cycles (definition 54.1.3). Then the vertices of Q can be listed as $i_1, \dots, i_n$ so that, with $Q_0 = Q$ and $Q_k = s_{i_k}^+ Q_{k-1}$, each i_k is a sink of Q_{k-1}, and then $Q_n = Q$. Moreover, a finite quiver whose underlying graph has no loops, no multiple edges and no cycles has no oriented cycles.

***Proof*:**
Step 1: an ordering in which every arrow points backward. The vertices can be listed so that $t(e)$ comes before $s(e)$ for every arrow e. Induct on n, the case $n = 0$ being empty. For $n \geq 1$, Q has a sink: otherwise, starting at any vertex and repeatedly following an arrow out of the current vertex produces vertices $w_0, w_1, \dots, w_n$ with an arrow from each w_{l-1} to w_l. Two of these $n+1$ vertices coincide, $w_a = w_b$ with $a < b$, and the arrows from w_a to w_b form an oriented cycle. Let

i_1 be a sink. The quiver obtained by deleting i_1 and its arrows has no oriented cycles, so by induction its vertices can be listed as $i_2, \dots, i_n$ with the required property. An arrow of Q at i_1 ends at i_1, which comes first, and every other arrow of Q is an arrow of the smaller quiver.

Step 2: each i_k is a sink of Q_{k-1}. List the vertices as in Step 1. Reflecting at a vertex reverses exactly the arrows at that vertex, and Q has no loops, since a loop is an oriented cycle. So an arrow e of Q appears in Q_{k-1} reversed once for each of its endpoints among $i_1, \dots, i_{k-1}$. Let e be an arrow at i_k. If $t(e) = i_k$, then $s(e)$ comes after i_k, so e has not been reversed and ends at i_k. If $s(e) = i_k$, then $t(e) = i_l$ with $l < k$, so e has been reversed once and, in Q_{k-1}, ends at i_k. Hence i_k is a sink of Q_{k-1}. After all n steps every arrow has been reversed once at each of its two endpoints, so $Q_n = Q$.

Step 3: underlying graphs without cycles. Suppose Q has an oriented cycle, and let $\gamma = e_m \cdots e_1$ be one of minimal length m, with $w_l = s(e_l)$. The vertices $w_1, \dots, w_m$ are distinct: if $w_a = w_b$ with $a < b$, then $e_{b-1} \cdots e_a$ is a shorter oriented cycle. If $m = 1$, then e_1 is a loop. If $m = 2$, then e_1 and e_2 are two arrows between w_1 and w_2, a multiple edge of the underlying graph. If $m \geq 3$, then $(w_1, \dots, w_m)$ is a cycle of the underlying graph, completing the proof.

Definition 54.1.52: Coxeter Functor

Let Q be a finite quiver without oriented cycles, and let $i_1, \dots, i_n$ be an ordering of its vertices as in lemma 54.1.51. The *Coxeter functor* is the composite

$$C^+ = S^+_{i_n} \circ \cdots \circ S^+_{i_1} \colon \mathrm{Rep}(Q) \to \mathrm{Rep}(Q)$$

in which $S^+_{i_k}$ is the reflection functor $\mathrm{Rep}(Q_{k-1}) \to \mathrm{Rep}(Q_k)$ at the sink i_k of Q_{k-1}. The corresponding Coxeter element of the underlying graph is $c = s_{i_n} \cdots s_{i_1}$ (definition 54.1.33).

When the underlying graph is of type A, D or E, proposition 54.1.49(5) and (7) show that, as long as no intermediate representation is simple at the vertex being reflected, C^+ carries a nonzero indecomposable representation to a nonzero indecomposable one and acts on its dimension vector by c. By lemma 54.1.37, the iterates of c eventually produce a vector that is not ≥ 0, so iterating C^+ must reach a representation that is simple at the vertex being reflected.

Lemma 54.1.53: Polynomials Over An Infinite Field

Let $\mathbb{F}$ be an infinite field and $N \geq 0$.

1. Every nonzero $f \in \mathbb{F}[x_1, \dots, x_N]$ satisfies $f(a) \neq 0$ for some $a \in \mathbb{F}^N$.
2. If $X_1, \dots, X_m \subseteq \mathbb{F}^N$ are subsets with $X_1 \cup \cdots \cup X_m = \mathbb{F}^N$, then for some j the only polynomial in $\mathbb{F}[x_1, \dots, x_N]$ vanishing at every point of X_j is 0.

***Proof*:**

1. Induct on N. For $N = 0$, f is a nonzero constant. For $N \geq 1$, write $f = \sum_{l=0}^{m} f_l x_N^l$ with $f_l \in \mathbb{F}[x_1, \dots, x_{N-1}]$ and $f_m \neq 0$. By induction $f_m(a') \neq 0$ for some $a' \in \mathbb{F}^{N-1}$, so $g(x_N) = f(a', x_N) = \sum_l f_l(a') x_N^l$ is a polynomial of degree m in one variable. It has at most m roots by corollary 11.3.2, and $\mathbb{F}$ is infinite, so $g(a_N) \neq 0$ for some $a_N \in \mathbb{F}$, and $a = (a', a_N)$ satisfies $f(a) \neq 0$.

2. Otherwise choose, for each j, a nonzero polynomial f_j vanishing on X_j. The ring $\mathbb{F}[x_1,\dots,x_N] = \mathbb{F}[x_1,\dots,x_{N-1}][x_N]$ is an integral domain, by proposition 9.2.3 applied once for each variable, so $f = f_1 \cdots f_m$ is nonzero. It vanishes on $X_1 \cup \cdots \cup X_m = \mathbb{F}^N$, against (1), completing the proof.

***Proof of theorem 54.1.46*:**
Let I be the vertex set of Q and $n = |I|$.

1. Let Γ be one of A_n, D_n, E_6, E_7, E_8. By theorem 54.1.32 its Tits form is positive definite, so proposition 54.1.35 and lemma 54.1.37 apply to Γ. The graph Γ is a path or a star, so it has no loops, no multiple edges and no cycles, and by lemma 54.1.51 the quiver Q has no oriented cycles and its vertices can be listed as $i_1,\dots,i_n$ with each i_k a sink of Q_{k-1} and $Q_n = Q$. Extend the list periodically: for $t \geq 1$ let $j_t = i_l$, where $1 \leq l \leq n$ and $t \equiv l \pmod n$. Put $Q^{(0)} = Q$ and $Q^{(t)} = s^+_{j_t} Q^{(t-1)}$. Since $Q_n = Q$, the quiver $Q^{(t)}$ is Q_l for $t \equiv l \pmod n$ (with $Q_0 = Q_n$), so j_{t+1} is a sink of $Q^{(t)}$ for every $t \geq 0$, and every $Q^{(t)}$ has underlying graph Γ. For $t = mn$, the product $s_{j_t} \cdots s_{j_1}$ is c^m, where $c = s_{i_n} \cdots s_{i_1}$. A representation U of some $Q^{(t)}$ with $\dim U = \alpha_j$ is isomorphic to $S(j)$: every arrow has a zero space at one of its ends, since Γ has no loops, so all maps of U are zero.

   Step 1: reflecting an indecomposable. Let V be a nonzero finite-dimensional indecomposable representation of Q, and $d = \dim_Q V$. Put $V^{(0)} = V$, and, as long as $V^{(t-1)}$ is not simple at j_t, put $V^{(t)} = S^+_{j_t}(V^{(t-1)})$, a representation of $Q^{(t)}$. Suppose that $V^{(t-1)}$ is not simple at j_t for $1 \leq t \leq N$. Then, for each such t, $V^{(t)}$ is nonzero, indecomposable and finite-dimensional, $V^{(t-1)} \cong S^-_{j_t}(V^{(t)})$, and $\dim V^{(t)} = s_{j_t} \cdots s_{j_1}(d)$. If this holds up to $t-1$, then proposition 54.1.49(5), at the sink j_t of $Q^{(t-1)}$, gives $V^{(t-1)} \in \mathrm{Rep}^{j_t,-}(Q^{(t-1)})$, shows that $V^{(t)}$ is nonzero and indecomposable, and gives $V^{(t-1)} \cong S^-_{j_t} S^+_{j_t}(V^{(t-1)}) = S^-_{j_t}(V^{(t)})$. The space $V^{(t)}(j_t)$ is the kernel of a map out of a finite-dimensional space, and proposition 54.1.49(7) gives $\dim V^{(t)} = s_{j_t}(\dim V^{(t-1)}) = s_{j_t} \cdots s_{j_1}(d)$. By lemma 54.1.37, choose $m \geq 0$ with $c^m(d) \not\geq 0$. The supposition fails for $N = mn$, since $\dim V^{(mn)} = c^m(d)$ would then be a dimension vector. Hence there is a least $T \geq 1$ such that $V^{(T-1)}$ is simple at j_T.

   Step 2: d is a positive root and determines V. By Step 1 with $N = T-1$, and since a functor carries isomorphic representations to isomorphic ones,

$$V \cong S^-_{j_1}(V^{(1)}) \cong S^-_{j_1} S^-_{j_2}(V^{(2)}) \cong \cdots \cong S^-_{j_1} \cdots S^-_{j_{T-1}}(V^{(T-1)}) \cong S^-_{j_1} \cdots S^-_{j_{T-1}}(S(j_T))$$

   where $S(j_T)$ is the simple representation of $Q^{(T-1)}$ at j_T. Also $\alpha_{j_T} = \dim V^{(T-1)} = s_{j_{T-1}} \cdots s_{j_1}(d)$, and each s_j is its own inverse, so $d = s_{j_1} \cdots s_{j_{T-1}}(\alpha_{j_T})$. By proposition 54.1.35(1) and (4), α_{j_T} is a root and W_Γ permutes the roots, so d is a root, and $d \geq 0$, so $d \in \Phi^+_\Gamma$. Thus $\dim\colon \mathrm{Ind}(Q) \to \Phi^+_\Gamma$ is well defined. Moreover T is the least $t \geq 1$ with $s_{j_{t-1}} \cdots s_{j_1}(d) = \alpha_{j_t}$: for $t < T$ this vector is the dimension vector of $V^{(t-1)}$, which is not simple at j_t, and is therefore different from α_{j_t}, while for $t = T$ the equality holds. So T, and with it the representation $S^-_{j_1} \cdots S^-_{j_{T-1}}(S(j_T))$, depends only on d. Two nonzero finite-dimensional indecomposable representations with the same dimension vector are therefore isomorphic, and $\dim$ is injective on $\mathrm{Ind}(Q)$.

   Step 3: every positive root occurs. Let $\alpha \in \Phi^+_\Gamma$. By lemma 54.1.37, $c^m(\alpha) \not\geq 0$ for some m, so there is a least $T \geq 1$ with $s_{j_T} \cdots s_{j_1}(\alpha) \not\geq 0$. The vector $\beta = s_{j_{T-1}} \cdots s_{j_1}(\alpha)$ is a

root (proposition 54.1.35(4)) and $\beta \geq 0$ by minimality. The root $s_{j_T}(\beta)$ is not ≥ 0, so it is negative (proposition 54.1.35(2)). It agrees with β away from j_T (lemma 54.1.34(1)), so β vanishes away from j_T, $\beta = b\alpha_{j_T}$ with $b \geq 0$, and $q(\beta) = b^2 = 1$ gives $\beta = \alpha_{j_T}$. Hence $\alpha = s_{j_1} \cdots s_{j_{T-1}}(\alpha_{j_T})$. For $1 \leq t \leq T$ put $\beta_t = s_{j_t} \cdots s_{j_{T-1}}(\alpha_{j_T})$, so that $\beta_T = \alpha_{j_T}$, $\beta_1 = \alpha$, and $\beta_t = s_{j_{t-1}} \cdots s_{j_1}(\alpha) \geq 0$ by minimality of T. Put $U_T = S(j_T) \in \operatorname{Rep}(Q^{(T-1)})$ and $U_t = S^-_{j_t}(U_{t+1})$ for $t = T-1, \ldots, 1$, which is defined because j_t is a source of $Q^{(t)} = s^+_{j_t} Q^{(t-1)}$ and $s^-_{j_t} Q^{(t)} = Q^{(t-1)}$. We show by downward induction that U_t is nonzero and indecomposable with $\dim U_t = \beta_t$. This holds for $t = T$. If it holds for $t+1 \leq T$, then U_{t+1} is not simple at j_t, since otherwise $\beta_{t+1} = \alpha_{j_t}$ and $\beta_t = s_{j_t}(\alpha_{j_t}) = -\alpha_{j_t}$ would not be ≥ 0. By proposition 54.1.49(5) at the source j_t of $Q^{(t)}$, $U_{t+1} \in \operatorname{Rep}^{j_t,+}(Q^{(t)})$ and U_t is nonzero and indecomposable, and by proposition 54.1.49(7), $\dim U_t = s_{j_t}(\beta_{t+1}) = \beta_t$. So U_1 is a nonzero finite-dimensional indecomposable representation of $Q^{(0)} = Q$ with dimension vector α, and dim is surjective.

Step 4: conclusion. The map $\dim\colon \operatorname{Ind}(Q) \to \Phi^+_\Gamma$ is a bijection, and Φ^+_Γ is finite by proposition 54.1.35(3), so Q is of finite type over $\mathbb{F}$. This proves (1).

2. Let $\mathbb{F}$ be infinite and Q of finite type over $\mathbb{F}$. Let $\underline{d} \in \mathbb{Z}^I$ with $\underline{d} \geq 0$ and $\underline{d} \neq 0$. By theorem 54.1.32, applied to the connected graph Γ, it suffices to show $q(\underline{d}) \geq 1$.

   Step 1: finitely many isomorphism classes of dimension vector $\underline{d}$. Let V be a representation with $\dim_Q V = \underline{d}$. By theorem 54.1.24, V is a direct sum of indecomposable subrepresentations, and discarding the zero summands, $V = V_1 \oplus \cdots \oplus V_r$ with every V_l nonzero, finite-dimensional and indecomposable, so $[V_l] \in \operatorname{Ind}(Q)$. Dimension vectors add, so $\sum_l \dim_Q V_l = \underline{d}$, and each V_l has total dimension at least 1, so $r \leq |\underline{d}| = \sum_i d_i$. A direct sum of isomorphisms is an isomorphism, so the isomorphism class of V is determined by the list $([V_1], \ldots, [V_r])$, and there are at most $\sum_{r=0}^{|\underline{d}|} |\operatorname{Ind}(Q)|^r$ such lists.

   Step 2: an orbit on which no nonzero polynomial vanishes. By theorem 54.1.20, the $G(\underline{d})$-orbits in $\operatorname{Rep}(Q, \underline{d})$ correspond bijectively to these isomorphism classes, so there are finitely many orbits $O_1, \ldots, O_m$, and they cover $\operatorname{Rep}(Q, \underline{d})$. Identify $\operatorname{Rep}(Q, \underline{d})$ with $\mathbb{F}^N$, where $N = \sum_e d_{s(e)} d_{t(e)}$, through the matrix entries, with coordinates $x_1, \ldots, x_N$. By lemma 54.1.53(2), some orbit $O = G(\underline{d}) \cdot A_0$ has the property that the only polynomial in $x_1, \ldots, x_N$ vanishing at every point of O is 0.

   Step 3: the orbit map. Let $M = \sum_i d_i^2$, let $\mathbb{F}[g]$ be the polynomial ring in M variables, one for each entry of each matrix g_i with $d_i \geq 1$, and identify a point of $\mathbb{F}^M$ with a tuple of matrices $a = (a_i)_i$. Let $D = \prod_i \det(g_i) \in \mathbb{F}[g]$, the product over the vertices with $d_i \geq 1$, which is a polynomial by the formula for the determinant (definition 13.4.5) and is nonzero because it takes the value 1 at the identity matrices. The group $G(\underline{d})$ is the set of points a with $D(a) \neq 0$. For such a, $a_i^{-1} = \det(a_i)^{-1} \operatorname{adj}(a_i)$ by proposition 13.4.12, and the entries of $\operatorname{adj}(a_i)$ are determinants of matrices whose entries are entries of a_i, 0 or 1 (definition 13.4.10), hence values of fixed polynomials at a. Multiplying numerator and denominator by $\prod_{i \neq s(e)} \det(a_i)$, each coordinate of $(a \cdot A_0)_e = a_{t(e)} (A_0)_e a_{s(e)}^{-1}$ is $P(a)/D(a)$ for a polynomial $P \in \mathbb{F}[g]$ that does not depend on a. Let $\varphi_1, \ldots, \varphi_N$ be the resulting fractions P/D in the field of fractions $\mathbb{F}(g)$ of $\mathbb{F}[g]$, and let $R = \left\{ P/D^l \;\middle|\; P \in \mathbb{F}[g],\ l \geq 0 \right\} \subseteq \mathbb{F}(g)$. For $a \in G(\underline{d})$, evaluation $P/D^l \mapsto P(a)/D(a)^l$ is a well-defined ring homomorphism $\operatorname{ev}_a\colon R \to \mathbb{F}$. It is well defined, since $P_1/D^{l_1} = P_2/D^{l_2}$ gives $P_1 D^{l_2} = P_2 D^{l_1}$, and evaluating at a gives equal values. It respects sums and products, since evaluation at a respects them on $\mathbb{F}[g]$ and $D(a) \neq 0$, and $\operatorname{ev}_a(\varphi_j) = x_j(a \cdot A_0)$. Substituting φ_j for x_j defines an $\mathbb{F}$-algebra homomorphism $\Lambda\colon \mathbb{F}[x_1, \ldots, x_N] \to R$ (theorem 9.2.4, applied once

for each variable). For $a \in G(\underline{d})$, the two $\mathbb{F}$-algebra homomorphisms $f \mapsto \mathrm{ev}_a(\Lambda(f))$ and $f \mapsto f(a \cdot A_0)$ agree on $x_1, \dots, x_N$, so by the uniqueness in the same universal property, $\mathrm{ev}_a(\Lambda(f)) = f(a \cdot A_0)$ for every polynomial f.

Step 4: one entry normalized. Choose a vertex i_0 with $d_{i_0} \geq 1$, let $z \in \mathbb{F}[g]$ be the variable for the $(1,1)$ entry of g_{i_0}, and let $\mathbb{F}[y]$ be the polynomial ring in the other $M-1$ variables. Substituting 1 for z is an $\mathbb{F}$-algebra homomorphism $\sigma\colon \mathbb{F}[g] \to \mathbb{F}[y]$, and $\sigma(D) \neq 0$ because $\sigma(D)$ takes the value 1 at the entries of the identity matrices. As in Step 3, σ extends to a ring homomorphism $R \to \mathbb{F}(y)$, $P/D^l \mapsto \sigma(P)/\sigma(D)^l$, and $\Theta = \sigma \circ \Lambda\colon \mathbb{F}[x_1, \dots, x_N] \to \mathbb{F}(y)$ is an $\mathbb{F}$-algebra homomorphism. We show that Θ is injective. Let $\Theta(f) = 0$ and write $\Lambda(f) = P/D^l$, so that $\sigma(P) = 0$. Let $a \in G(\underline{d})$ have $(1,1)$ entry $c = z(a) \neq 0$ in a_{i_0}. Then $c^{-1}a \in G(\underline{d})$ has $(1,1)$ entry 1 in its component at i_0, and $(c^{-1}a) \cdot A_0 = a \cdot A_0$ because the scalars cancel in $a_{t(e)}(A_0)_e a_{s(e)}^{-1}$. At a point where $z = 1$, the value of P is the value of $\sigma(P) = 0$, so

$$f(a \cdot A_0) = f((c^{-1}a) \cdot A_0) = \mathrm{ev}_{c^{-1}a}(\Lambda(f)) = \frac{P(c^{-1}a)}{D(c^{-1}a)^l} = 0$$

Hence $P(a) = D(a)^l \,\mathrm{ev}_a(\Lambda(f)) = D(a)^l f(a \cdot A_0) = 0$ for every $a \in \mathbb{F}^M$ with $D(a)z(a) \neq 0$, so the polynomial PDz vanishes at every point of $\mathbb{F}^M$. By lemma 54.1.53(1) it is 0, and since $\mathbb{F}[g]$ is an integral domain and D and z are nonzero, $P = 0$. Then $\Lambda(f) = 0$, so $f(a \cdot A_0) = \mathrm{ev}_a(\Lambda(f)) = 0$ for every $a \in G(\underline{d})$. Thus f vanishes on O, and $f = 0$ by Step 2.

Step 5: the count. By Step 4, a polynomial f with $f(\Theta(x_1), \dots, \Theta(x_N)) = \Theta(f) = 0$ is zero, so $\Theta(x_1), \dots, \Theta(x_N)$ are N distinct elements of $\mathbb{F}(y)$, algebraically independent over $\mathbb{F}$. By theorem 19.2.13, applied to the extension $\mathbb{F}(y)/\mathbb{F}$ with $S = \mathbb{F}(y)$ and $A = \{\Theta(x_1), \dots, \Theta(x_N)\}$, they lie in a transcendence basis B of $\mathbb{F}(y)/\mathbb{F}$. The $M-1$ variables y are algebraically independent and generate $\mathbb{F}(y)$, so they form a transcendence basis (definition 19.2.12), and $|B| = M-1$ by theorem 19.2.15. Hence $N \leq M-1$, that is,

$$q(\underline{d}) = \sum_{i \in I} d_i^2 - \sum_{e \in E} d_{s(e)} d_{t(e)} = M - N \geq 1$$

As $\underline{d}$ was an arbitrary nonzero vector with $\underline{d} \geq 0$, condition (3) of theorem 54.1.32 holds, and Γ is one of A_n, D_n, E_6, E_7, E_8, completing the proof.

Example 54.1.54: Indecomposable Representations Of A Linearly Oriented A_n

Let Q be $1 \to 2 \to \cdots \to n$. For $1 \leq i \leq j \leq n$, let $V_{[i,j]}$ be the representation with $V_{[i,j]}(l) = \mathbb{F}$ for $i \leq l \leq j$ and $V_{[i,j]}(l) = 0$ otherwise, the identity along each arrow $l \to l+1$ with $i \leq l < j$, and zero maps elsewhere. Its dimension vector is $\alpha_i + \cdots + \alpha_j$.

Each $V_{[i,j]}$ is indecomposable. Suppose $V_{[i,j]}(l) = U(l) \oplus U'(l)$ at every vertex, for subrepresentations U and U'. For $i \leq l \leq j$ the space $\mathbb{F}$ is one-dimensional, so exactly one of $U(l)$ and $U'(l)$ is $\mathbb{F}$. If $U(l) = \mathbb{F}$ and $l < j$, then $U(l+1)$ contains the image of $U(l)$ under the identity, so $U(l+1) = \mathbb{F}$. If $U(l) = \mathbb{F}$ and $l > i$, then $U'(l-1)$ maps injectively into $U'(l) = 0$, so $U'(l-1) = 0$ and $U(l-1) = \mathbb{F}$. Hence $U(l) = \mathbb{F}$ for all $i \leq l \leq j$ or for none of them, and one of U, U' is zero.

By theorem 54.1.46(1) and example 54.1.36, the dimension vectors of the nonzero finite-dimensional indecomposable representations of Q are exactly the vectors $\alpha_i + \cdots + \alpha_j$, each realized by a single isomorphism class. So the representations $V_{[i,j]}$, for $1 \leq i \leq j \leq n$, are up to isomorphism

all the nonzero finite-dimensional indecomposable representations of Q, over every field, and by theorem 54.1.24 every finite-dimensional representation of Q is isomorphic to a direct sum of them. For $n = 3$ these are the six representations, in which the unlabelled arrows are zero maps,

$$\begin{aligned} &\mathbb{F} \longrightarrow 0 \longrightarrow 0 && \mathbb{F} \xrightarrow{1} \mathbb{F} \longrightarrow 0 \\ &0 \longrightarrow \mathbb{F} \longrightarrow 0 && 0 \longrightarrow \mathbb{F} \xrightarrow{1} \mathbb{F} \\ &0 \longrightarrow 0 \longrightarrow \mathbb{F} && \mathbb{F} \xrightarrow{1} \mathbb{F} \xrightarrow{1} \mathbb{F} \end{aligned}$$

with dimension vectors the six positive roots of A_3.

54.1.5 Path Algebra of Quivers

A representation of a quiver assigns a linear map to each arrow, and composing these maps along a path gives a linear map from the space at its source to the space at its target. The path algebra has the paths of Q as a basis and concatenation of paths as multiplication, and theorem 54.1.58 below identifies the representations of Q with the left modules over it. Throughout, $\mathbb{F}$ is a field, arrows are denoted $a, b, \ldots$, and the letter e_i is reserved for the trivial path at the vertex i.

Two paths p and q with $t(q) = s(p)$ have a *concatenation* pq, the path from $s(q)$ to $t(p)$ that traverses the arrows of q and then those of p. If $p = a_k \cdots a_1$ and $q = b_m \cdots b_1$ have positive length, then $pq = a_k \cdots a_1 b_m \cdots b_1$, which is a path because $t(b_m) = t(q) = s(p) = s(a_1)$. A trivial path leaves the other factor unchanged, $pe_{s(p)} = p$ and $e_{t(q)}q = q$. The length of pq is the sum of the lengths of p and q, and concatenation is associative: if also $t(r) = s(q)$, then $(pq)r$ and $p(qr)$ are both the path from $s(r)$ that traverses the arrows of r, then those of q, then those of p.

Definition 54.1.55: Path Algebra

Let $Q = (I, E, s, t)$ be a quiver. The *path algebra* $\mathbb{F}Q$ of Q over $\mathbb{F}$ is the $\mathbb{F}$-vector space with basis the set of all paths in Q (definition 54.1.3), the trivial paths e_i for $i \in I$ included, with the $\mathbb{F}$-bilinear multiplication given on paths p and q by

$$p \cdot q = \begin{cases} pq & \text{if } t(q) = s(p) \\ 0 & \text{otherwise} \end{cases}$$

So $p \cdot q$ traverses q first and then p.

Proposition 54.1.56: Structure Of The Path Algebra

Let $Q = (I, E, s, t)$ be a quiver, and for $n \geq 0$ let $(\mathbb{F}Q)_n \subseteq \mathbb{F}Q$ be the span of the paths of length n.

1. The multiplication of $\mathbb{F}Q$ is associative.
2. The trivial paths are orthogonal idempotents, $e_i \cdot e_j = \delta_{ij} e_i$ for $i, j \in I$. For a path γ and a vertex j, $e_j \cdot \gamma$ is γ if $t(\gamma) = j$ and 0 otherwise, and $\gamma \cdot e_j$ is γ if $s(\gamma) = j$ and 0 otherwise. Consequently $(\mathbb{F}Q)e_i$ has basis the paths with source i, and $e_j(\mathbb{F}Q)e_i$ has basis the paths from i to j.
3. If I is finite, then $1 = \sum_{i \in I} e_i$ is an identity element of $\mathbb{F}Q$, so $\mathbb{F}Q$ is an associative $\mathbb{F}$-algebra with 1.
4. $\mathbb{F}Q = \bigoplus_{n \geq 0} (\mathbb{F}Q)_n$, the trivial paths form a basis of $(\mathbb{F}Q)_0$, and $(\mathbb{F}Q)_m \cdot (\mathbb{F}Q)_n \subseteq (\mathbb{F}Q)_{m+n}$ for all $m, n \geq 0$.
5. $\mathbb{F}Q$ is finite-dimensional if and only if Q is finite and has no oriented cycle.

***Proof*:**

1. Both $(x \cdot y) \cdot z$ and $x \cdot (y \cdot z)$ are trilinear in x, y, z, so it suffices to compare them on paths p, q, r. Recall that pq has source $s(q)$ and target $t(p)$. If $t(r) = s(q)$ and $t(q) = s(p)$, then $(p \cdot q) \cdot r = (pq)r$, because $t(r) = s(q) = s(pq)$, and $p \cdot (q \cdot r) = p(qr)$, because $t(qr) = t(q) = s(p)$, and these agree by the associativity of concatenation. If $t(q) \neq s(p)$, then $p \cdot q = 0$, and $q \cdot r$ is 0 or the path qr with target $t(q) \neq s(p)$, so both sides vanish. If $t(q) = s(p)$ and $t(r) \neq s(q)$, then $q \cdot r = 0$ and $(p \cdot q) \cdot r = (pq) \cdot r = 0$, because $s(pq) = s(q) \neq t(r)$.
2. The product $e_i \cdot e_j$ is nonzero only if $t(e_j) = s(e_i)$, that is, $j = i$, and $e_i e_i = e_i$. The product $e_j \cdot \gamma$ is nonzero only if $t(\gamma) = s(e_j) = j$, and then it is $e_j \gamma = \gamma$. The product $\gamma \cdot e_j$ is nonzero only if $s(\gamma) = t(e_j) = j$, and then it is $\gamma e_j = \gamma$. Hence for $x = \sum_\gamma c_\gamma \gamma \in \mathbb{F}Q$, the element $x \cdot e_i$ is the part of this sum over the paths with source i, and $e_j \cdot x \cdot e_i$ is the part over the paths from i to j. These paths are linearly independent, being part of a basis, which gives the two bases.
3. For a path γ, part (2) gives $(\sum_i e_i) \cdot \gamma = e_{t(\gamma)} \cdot \gamma = \gamma$ and $\gamma \cdot (\sum_i e_i) = \gamma \cdot e_{s(\gamma)} = \gamma$. By bilinearity $\sum_i e_i$ is a two-sided identity element.
4. Every path has exactly one length and the paths form a basis, so $\mathbb{F}Q = \bigoplus_n (\mathbb{F}Q)_n$, and the paths of length 0 are the trivial paths. The product of a path of length m and a path of length n is 0 or their concatenation, which has length $m + n$.
5. Suppose Q is finite with no oriented cycle, and let $\gamma = a_k \cdots a_1$ be a path of positive length. The vertices $v_0 = s(a_1)$ and $v_l = t(a_l)$ for $1 \leq l \leq k$ are pairwise distinct: if $v_p = v_q$ with $p < q$, then $a_q \cdots a_{p+1}$ is a path of positive length from v_p to $v_q = v_p$, an oriented cycle. So $k + 1 \leq |I|$. There are at most $|E|^k$ sequences of k arrows, so Q has at most $|I| + \sum_{k=1}^{|I|-1} |E|^k$ paths, and $\mathbb{F}Q$ is finite-dimensional. Conversely, if I is infinite then the trivial paths are infinitely many basis elements of $\mathbb{F}Q$, and if E is infinite then so are

the paths of length 1. If γ is an oriented cycle, of length $k \geq 1$, then $t(\gamma) = s(\gamma)$, so the products γ, $\gamma \cdot \gamma$, $\gamma \cdot \gamma \cdot \gamma, \ldots$ are paths of the distinct lengths $k, 2k, 3k, \ldots$, and again $\mathbb{F}Q$ is infinite-dimensional.

The five parts are proved, completing the proof.

Example 54.1.57: Path Algebras

1. Let Q be the quiver with one vertex 1 and one loop a. Its paths are e_1 and, for $n \geq 1$, the path a^n that traverses a n times. With $a^0 = e_1$, the product is $a^m \cdot a^n = a^{m+n}$ for all $m, n \geq 0$. The linear map $\mathbb{F}[x] \to \mathbb{F}Q$ with $x^n \mapsto a^n$ carries a basis to a basis and products of basis elements to products, so it is an isomorphism of algebras $\mathbb{F}[x] \cong \mathbb{F}Q$. The loop is an oriented cycle, and $\mathbb{F}Q$ is infinite-dimensional, in accordance with proposition 54.1.56(5).
2. With two loops a and b at one vertex, the paths are e_1 and the words in a and b, multiplied by juxtaposition. The products $a \cdot b = ab$ and $b \cdot a = ba$ are different paths, so $\mathbb{F}Q$ is not commutative.
3. Let K be the Kronecker quiver of example 54.1.28, with two arrows $a, b \colon 1 \to 2$. No arrow has source 2, so there is no path of length 2, and $\mathbb{F}K$ has basis e_1, e_2, a, b. The nonzero products of basis elements are $e_1 \cdot e_1 = e_1$, $e_2 \cdot e_2 = e_2$, $a \cdot e_1 = e_2 \cdot a = a$ and $b \cdot e_1 = e_2 \cdot b = b$.

For a representation V of Q and a path γ from i to j, let $T_\gamma \colon V(i) \to V(j)$ be $\mathrm{id}_{V(i)}$ if $\gamma = e_i$, and the composite $T_{a_k} \circ \cdots \circ T_{a_1}$ if $\gamma = a_k \cdots a_1$, writing T_γ^V when the representation must be named. If $t(q) = s(p)$, then $T_{pq} = T_p \circ T_q$, since both sides apply the maps of the arrows of q and then those of p. A quiver morphism $\varphi \colon V \to W$ satisfies

$$\varphi(j) \circ T_\gamma^V = T_\gamma^W \circ \varphi(i)$$

for every path γ from i to j, where T_a^W is the map written S_a in definition 54.1.9. For $\gamma = e_i$ both sides are $\varphi(i)$. For $\gamma = a_k \cdots a_1$ with $k \geq 1$, write $\gamma = a_k \gamma'$, where γ' is the path $a_{k-1} \cdots a_1$, or e_i if $k = 1$, from i to $l = s(a_k)$. The square of φ at a_k and induction on k give

$$\varphi(j) \circ T_{a_k}^V \circ T_{\gamma'}^V = T_{a_k}^W \circ \varphi(l) \circ T_{\gamma'}^V = T_{a_k}^W \circ T_{\gamma'}^W \circ \varphi(i)$$

and the outer terms are $\varphi(j) \circ T_\gamma^V$ and $T_\gamma^W \circ \varphi(i)$.

When Q has finitely many vertices, $\mathbb{F}Q$ has the identity element $1 = \sum_i e_i$ of proposition 54.1.56(3). Let $\mathbb{F}Q$**-Mod** denote the category of left $\mathbb{F}Q$-modules, on which 1 acts as the identity, with the $\mathbb{F}Q$-linear maps as morphisms. An $\mathbb{F}Q$-module is an $\mathbb{F}$-vector space through the action of the scalars $c = c \cdot 1 \in \mathbb{F}Q$.

Theorem 54.1.58: Representations Are Modules Over The Path Algebra

Let $Q = (I, E, s, t)$ be a quiver with finitely many vertices.

1. For a representation V of Q, let $\mathcal{M}(V) = \bigoplus_{i \in I} V(i)$, with $\iota_j \colon V(j) \to \mathcal{M}(V)$ the inclusion of the summand $V(j)$ and $\pi_j \colon \mathcal{M}(V) \to V(j)$ the projection onto it. Then $\mathcal{M}(V)$ is a left $\mathbb{F}Q$-module in which a path γ from i to j acts by $\iota_j \circ T_\gamma \circ \pi_i$. For a quiver morphism $\varphi \colon V \to W$, the map $\mathcal{M}(\varphi) = \bigoplus_i \varphi(i)$ is $\mathbb{F}Q$-linear, and $\mathcal{M}$ is a functor $\mathrm{Rep}(Q) \to \mathbb{F}Q$**-Mod**.

2. For a left $\mathbb{F}Q$-module M, let $\mathcal{R}(M)$ have the space $e_i M$ at each vertex i and the map $e_i M \to e_j M$, $m \mapsto a \cdot m$, along each arrow $a \colon i \to j$. For an $\mathbb{F}Q$-linear map $f \colon M \to N$, let $\mathcal{R}(f)(i) \colon e_i M \to e_i N$ be the restriction of f. Then $\mathcal{R}(M)$ is a representation of Q, $\mathcal{R}(f)$ is a quiver morphism, and $\mathcal{R}$ is a functor $\mathbb{F}Q$**-Mod** $\to \mathrm{Rep}(Q)$.

3. For every representation V, the maps $\eta_V(i) = \iota_i \colon V(i) \to e_i \mathcal{M}(V)$ form an isomorphism of representations $\eta_V \colon V \to \mathcal{R}(\mathcal{M}(V))$, natural in V.

4. For every left $\mathbb{F}Q$-module M, the map $\epsilon_M \colon \mathcal{M}(\mathcal{R}(M)) = \bigoplus_i e_i M \to M$, $(m_i)_{i \in I} \mapsto \sum_i m_i$, is an isomorphism of $\mathbb{F}Q$-modules, natural in M.

Consequently $\mathcal{M}$ and $\mathcal{R}$ are quasi-inverse equivalences of categories between $\mathrm{Rep}(Q)$ and $\mathbb{F}Q$**-Mod**.

***Proof*:**

1. For a path γ from i to j let $\rho(\gamma) = \iota_j \circ T_\gamma \circ \pi_i$, a linear map from $\mathcal{M}(V)$ to itself, and extend linearly to a linear map ρ from $\mathbb{F}Q$ to the algebra $\mathrm{End}_{\mathbb{F}}(\mathcal{M}(V))$ of linear maps from $\mathcal{M}(V)$ to itself. For paths p and q, the composite $\pi_{s(p)} \circ \iota_{t(q)}$ is the identity of $V(t(q))$ if $t(q) = s(p)$ and 0 otherwise. In the first case

$$\rho(p) \circ \rho(q) = \iota_{t(p)} \circ T_p \circ T_q \circ \pi_{s(q)} = \iota_{t(pq)} \circ T_{pq} \circ \pi_{s(pq)} = \rho(p \cdot q)$$

and in the second $\rho(p) \circ \rho(q) = 0 = \rho(p \cdot q)$. By bilinearity $\rho(x \cdot y) = \rho(x) \circ \rho(y)$ for all $x, y \in \mathbb{F}Q$, and $\rho(1) = \sum_i \iota_i \circ \pi_i$ is the identity. These identities, with the linearity of ρ and of each $\rho(x)$, are the axioms of a left module for $x \cdot v = \rho(x)(v)$, and a scalar $c = c \cdot 1$ acts as multiplication by c. For a quiver morphism $\varphi \colon V \to W$ and a path γ from i to j, the identity $\varphi(j) \circ T_\gamma^V = T_\gamma^W \circ \varphi(i)$ proved before the theorem gives

$$\mathcal{M}(\varphi) \circ \iota_j \circ T_\gamma^V \circ \pi_i = \iota_j \circ \varphi(j) \circ T_\gamma^V \circ \pi_i = \iota_j \circ T_\gamma^W \circ \varphi(i) \circ \pi_i = \iota_j \circ T_\gamma^W \circ \pi_i \circ \mathcal{M}(\varphi)$$

so $\mathcal{M}(\varphi)$ commutes with the action of every path, and by linearity with the action of every element of $\mathbb{F}Q$. The identities $\mathcal{M}(\psi \circ \varphi) = \mathcal{M}(\psi) \circ \mathcal{M}(\varphi)$ and $\mathcal{M}(\mathrm{id}_V) = \mathrm{id}_{\mathcal{M}(V)}$ hold summand by summand.

2. The subset $e_i M$ is an $\mathbb{F}$-subspace of M, since $c \cdot e_i m = e_i \cdot (c \cdot m)$ for $c \in \mathbb{F}$. An arrow $a \colon i \to j$ satisfies $a = e_j \cdot a$ by proposition 54.1.56(2), so $a \cdot m = e_j \cdot (a \cdot m)$ lies in $e_j M$ for every $m \in e_i M$, and $m \mapsto a \cdot m$ is a linear map $e_i M \to e_j M$. So $\mathcal{R}(M)$ is a representation. An $\mathbb{F}Q$-linear map f satisfies $f(e_i m) = e_i f(m)$, so it carries $e_i M$ into $e_i N$, and $f(a \cdot m) = a \cdot f(m)$ is the square of $\mathcal{R}(f)$ at a. Restriction preserves composites and identities.

3. The trivial path e_i acts on $\mathcal{M}(V)$ by $\iota_i \circ \pi_i$, so $e_i\mathcal{M}(V) = \iota_i(V(i))$, and $\iota_i \colon V(i) \to e_i\mathcal{M}(V)$ is a linear bijection. For an arrow $a \colon i \to j$ and $v \in V(i)$, $a \cdot \iota_i(v) = \iota_j(T_a v)$, so $\eta_V(j) \circ T_a$ is the map of $\mathcal{R}(\mathcal{M}(V))$ along a composed with $\eta_V(i)$. Hence η_V is a quiver morphism with bijective components, which is an isomorphism, as noted after definition 54.1.13. For a quiver morphism $\varphi \colon V \to W$, the morphism $\mathcal{R}(\mathcal{M}(\varphi))$ is the restriction of $\bigoplus_l \varphi(l)$, and $(\bigoplus_l \varphi(l)) \circ \iota_i = \iota_i \circ \varphi(i)$, that is, $\mathcal{R}(\mathcal{M}(\varphi)) \circ \eta_V = \eta_W \circ \varphi$, which is the naturality of η.

4. Every $m \in M$ satisfies $m = 1 \cdot m = \sum_i e_i m$, so ϵ_M is surjective. If $\sum_i m_i = 0$ with $m_i = e_i m_i'$, then multiplying by e_j and using $e_j e_i = \delta_{ij} e_i$ gives $0 = \sum_i e_j e_i m_i' = m_j$ for every j, so ϵ_M is injective. Let γ be a path from i to j. Its map in $\mathcal{R}(M)$ is $m \mapsto \gamma \cdot m$: for $\gamma = e_i$ it is the identity of $e_i M$, which is $m \mapsto e_i \cdot m$, and for $\gamma = a_k \cdots a_1$ it is $m \mapsto a_k \cdot (\cdots (a_1 \cdot m)) = \gamma \cdot m$, because the product $a_k \cdot \cdots \cdot a_1$ in $\mathbb{F}Q$ is the path γ. So γ sends $(m_l)_l \in \mathcal{M}(\mathcal{R}(M))$ to $\iota_j(\gamma \cdot m_i)$. Each $m_l \in e_l M$ satisfies $m_l = e_l \cdot m_l$, and $\gamma \cdot e_l = 0$ for $l \neq i$ by proposition 54.1.56(2), so

$$\epsilon_M\left(\gamma \cdot (m_l)_l\right) = \gamma \cdot m_i = \sum_l \gamma \cdot e_l \cdot m_l = \gamma \cdot \epsilon_M\left((m_l)_l\right)$$

   By linearity ϵ_M is $\mathbb{F}Q$-linear, and a bijective $\mathbb{F}Q$-linear map is an isomorphism of modules. For an $\mathbb{F}Q$-linear map $f \colon M \to N$, $\epsilon_N\left((f(m_l))_l\right) = \sum_l f(m_l) = f\left(\epsilon_M((m_l)_l)\right)$, which is the naturality of ϵ.

Items (3) and (4) give natural isomorphisms $\mathrm{id}_{\mathrm{Rep}(Q)} \cong \mathcal{R} \circ \mathcal{M}$ and $\mathcal{M} \circ \mathcal{R} \cong \mathrm{id}_{\mathbb{F}Q\textbf{-Mod}}$ (definition 18.2.1), which by definition 18.2.2 make $\mathcal{M}$ and $\mathcal{R}$ quasi-inverse equivalences, completing the proof.

Under this equivalence, the submodules of $\mathcal{M}(V)$ are the subspaces $\bigoplus_i \iota_i(W(i))$ for the subrepresentations $W \subseteq V$. Such a subspace is a submodule because T_γ carries $W(i)$ into $W(j)$ for every path γ from i to j: this holds for trivial paths and for arrows by definition 54.1.8, and for longer paths by induction on the length, as T_γ is the composite of the maps along the arrows of γ. Conversely, a submodule N contains $e_i n$ for each of its elements $n = \sum_i e_i n$, so $N = \bigoplus_i e_i N$ with $e_i N \subseteq \iota_i(V(i))$, and the subspaces $W(i) = \iota_i^{-1}(e_i N)$ form a subrepresentation, because $a \cdot e_i N \subseteq e_j N$ for every arrow $a \colon i \to j$. The two recipes are inverse to each other: starting from W, $e_i\big(\bigoplus_j \iota_j(W(j))\big) = \iota_i(W(i))$, so ι_i^{-1} of it is $W(i)$, and starting from N, $\bigoplus_i \iota_i\big(\iota_i^{-1}(e_i N)\big) = \bigoplus_i e_i N = N$. So V is simple exactly when $\mathcal{M}(V)$ is a simple module, and V is the internal direct sum of subrepresentations $U_1, \ldots, U_n$ exactly when $\mathcal{M}(V)$ is the internal direct sum of the corresponding submodules.

By proposition 54.1.56(2), the left ideal $\mathbb{F}Qe_i$ has basis the paths with source i. The representation with the paths from i to j as a basis at each vertex j is defined for every quiver, and when Q has finitely many vertices it corresponds to $\mathbb{F}Qe_i$ under theorem 54.1.58 (lemma 54.1.59(6) below).

Lemma 54.1.59: The Representation Of Paths From A Vertex

Let $Q = (I, E, s, t)$ be a quiver and $i \in I$. For each vertex j let $P_i(j) = e_j(\mathbb{F}Q)e_i$, the span of the paths from i to j, and for each arrow $a\colon j \to k$ let $P_i(j) \to P_i(k)$ be the map $x \mapsto a \cdot x$.

1. These spaces and maps form a representation P_i of Q, and its map along a path γ from j to k is $x \mapsto \gamma \cdot x$.
2. For every representation V of Q, the map $\mathrm{Hom}_Q(P_i, V) \to V(i)$, $\psi \mapsto \psi(i)(e_i)$, is an isomorphism of vector spaces, natural in V in the sense that $(\varphi \circ \psi)(i)(e_i) = \varphi(i)(\psi(i)(e_i))$ for every quiver morphism $\varphi\colon V \to W$. Its inverse sends $v \in V(i)$ to the quiver morphism ψ^v with $\psi^v(j)(\gamma) = T_\gamma(v)$ for every path γ from i to j.
3. P_i is projective: for every quiver morphism $\sigma\colon V \to W$ with every $\sigma(j)$ surjective and every quiver morphism $f\colon P_i \to W$, there is a quiver morphism $g\colon P_i \to V$ with $\sigma \circ g = f$.
4. The only elements $x \in e_i(\mathbb{F}Q)e_i$ with $x \cdot x = x$ are 0 and e_i, and P_i is nonzero and indecomposable.
5. P_i is simple if and only if i is a sink, and then $P_i \cong S(i)$.
6. If I is finite, then $P_i = \mathcal{R}(\mathbb{F}Qe_i)$ and $\mathcal{M}(P_i) \cong \mathbb{F}Qe_i$ as left $\mathbb{F}Q$-modules, for the functors of theorem 54.1.58.

***Proof*:**

1. For an arrow $a\colon j \to k$, proposition 54.1.56(2) gives $a = e_k \cdot a \cdot e_j$, so left multiplication by a carries $e_j(\mathbb{F}Q)e_i$ into $e_k(\mathbb{F}Q)e_i$, and it is linear. For a path $\gamma = a_l \cdots a_1$ from j to k, the map along γ is $x \mapsto a_l \cdot (\cdots (a_1 \cdot x)) = \gamma \cdot x$, since the product of the arrows $a_l, \ldots, a_1$ in $\mathbb{F}Q$ is γ. For $\gamma = e_j$ it is the identity, which is $x \mapsto e_j \cdot x$ on $e_j(\mathbb{F}Q)e_i$.
2. The map $\psi \mapsto \psi(i)(e_i)$ is linear for the vector space structure of proposition 54.1.10. Given $v \in V(i)$, define $\psi^v(j)\colon P_i(j) \to V(j)$ on the basis of paths from i to j by $\psi^v(j)(\gamma) = T_\gamma(v)$, extended linearly. For an arrow $a\colon j \to k$ and a path γ from i to j,
$$\psi^v(k)(a \cdot \gamma) = T_{a\gamma}(v) = T_a(T_\gamma(v)) = T_a\left(\psi^v(j)(\gamma)\right)$$
so ψ^v is a quiver morphism, and $\psi^v(i)(e_i) = T_{e_i}(v) = v$. Hence $\psi \mapsto \psi(i)(e_i)$ is surjective. Now let $\psi \in \mathrm{Hom}_Q(P_i, V)$ and $v = \psi(i)(e_i)$. By part (1), a path γ from i to j is the image $T_\gamma^{P_i}(e_i)$ of e_i under the map of P_i along γ, so the identity $\psi(j) \circ T_\gamma^{P_i} = T_\gamma^V \circ \psi(i)$ for quiver morphisms gives
$$\psi(j)(\gamma) = \psi(j)\left(T_\gamma^{P_i}(e_i)\right) = T_\gamma^V\left(\psi(i)(e_i)\right) = T_\gamma(v) = \psi^v(j)(\gamma)$$
So $\psi = \psi^v$ is determined by v, the map $\psi \mapsto \psi(i)(e_i)$ is injective, and $v \mapsto \psi^v$ is its inverse. The naturality identity is the definition of the composite, $(\varphi \circ \psi)(i) = \varphi(i) \circ \psi(i)$.
3. Let $w = f(i)(e_i)$, and choose $v \in V(i)$ with $\sigma(i)(v) = w$. Then $g = \psi^v$ satisfies $(\sigma \circ g)(i)(e_i) = \sigma(i)(v) = w = f(i)(e_i)$, and the injectivity in part (2), for the representation W, gives $\sigma \circ g = f$.

4. By proposition 54.1.56(2) and (4), an element $x \in e_i(\mathbb{F}Q)e_i$ is a finite sum $x = \sum_{n\geq 0} x_n$, with x_n in the span of the paths of length n from i to i, and $x_0 = ce_i$ for some $c \in \mathbb{F}$, since e_i is the only path of length 0 from i to i. Suppose $x \cdot x = x$. Every product $x_m \cdot x_n$ with $m+n > 0$ lies in $(\mathbb{F}Q)_{m+n}$, so the component of $x \cdot x$ in $(\mathbb{F}Q)_0$ is $x_0 \cdot x_0 = c^2 e_i$, and $c^2 = c$, that is, c is 0 or 1. If $c = 0$ and $x \neq 0$, let $m \geq 1$ be least with $x_m \neq 0$. Every product $x_p \cdot x_q$ with x_p and x_q nonzero lies in $(\mathbb{F}Q)_{p+q}$ with $p + q \geq 2m > m$, so the component of $x \cdot x$ in $(\mathbb{F}Q)_m$ is 0, while that of x is $x_m \neq 0$, which contradicts $x \cdot x = x$. So $c = 0$ forces $x = 0$. If $c = 1$, then $y = e_i - x$ lies in $e_i(\mathbb{F}Q)e_i$, on which e_i is an identity element by proposition 54.1.56(2), so $y \cdot y = e_i - 2x + x \cdot x = y$, and the component of y in $(\mathbb{F}Q)_0$ is 0. By the case $c = 0$, $y = 0$, that is, $x = e_i$.

   The space $P_i(i)$ contains $e_i \neq 0$, so $P_i \neq 0$. Suppose $\theta\colon V_1 \oplus V_2 \to P_i$ is an isomorphism with V_1 and V_2 nonzero (definition 54.1.22). The maps $(v_1, v_2) \mapsto (v_1, 0)$ at the vertices form a quiver morphism ϖ of $V_1 \oplus V_2$ to itself, and $\kappa = \theta \circ \varpi \circ \theta^{-1}\colon P_i \to P_i$ is a quiver morphism with $\kappa \circ \kappa = \kappa$. It is nonzero, because $V_1 \neq 0$, and it is not id_{P_i}, because it vanishes on the nonzero subrepresentation $\theta(0 \oplus V_2)$. Let $x = \kappa(i)(e_i) \in e_i(\mathbb{F}Q)e_i$. By part (2), $\kappa = \psi^x$, and $\psi^x(j)(\gamma) = T_\gamma^{P_i}(x) = \gamma \cdot x$ by part (1), so $\kappa(j)(y) = y \cdot x$ for every $y \in P_i(j)$. Then
   $$x \cdot x = \kappa(i)(x) = (\kappa \circ \kappa)(i)(e_i) = \kappa(i)(e_i) = x$$
   and x is neither 0 nor e_i, because $\psi^0 = 0$ and $\psi^{e_i} = \mathrm{id}_{P_i}$. This contradicts the first paragraph, so P_i is indecomposable.

5. If i is a sink, then no arrow has source i, so the only path from i is e_i, since a path $a_l \cdots a_1$ of positive length from i has $s(a_1) = i$. Then $P_i(i) = \mathbb{F}e_i$, $P_i(j) = 0$ for $j \neq i$, and every map of P_i is zero, so the maps $e_i \mapsto 1$ at i and 0 elsewhere form an isomorphism $P_i \to S(i)$. As P_i is nonzero and its only nonzero space $P_i(i)$ is one-dimensional, its only subrepresentations are 0 and P_i, so P_i is simple. If i is not a sink, choose an arrow $a\colon i \to k$, and let $U(j) \subseteq P_i(j)$ be the span of the paths of positive length from i to j. Left multiplication by an arrow carries such a path to a path of greater length, so U is a subrepresentation. It is nonzero, since $a \in U(k)$, and it is not P_i, since $e_i \notin U(i)$. So P_i is not simple.

6. The representation $\mathcal{R}(\mathbb{F}Qe_i)$ has the space $e_j(\mathbb{F}Qe_i) = P_i(j)$ at each vertex j, and its map along an arrow a is left multiplication by a, so it is P_i. By theorem 54.1.58(4), $\epsilon_{\mathbb{F}Qe_i}$ is an isomorphism from $\mathcal{M}(P_i) = \mathcal{M}(\mathcal{R}(\mathbb{F}Qe_i))$ onto $\mathbb{F}Qe_i$.

The six parts are proved, completing the proof.

Part (4) holds whether or not Q has oriented cycles, although P_i is infinite-dimensional when an oriented cycle passes through i. Part (3) corresponds to the projectivity of the module $\mathbb{F}Qe_i$: when I is finite, every $x \in \mathbb{F}Q$ is $x \cdot e_i + x \cdot (1 - e_i)$, and $e_i \cdot (1 - e_i) = 0$, so $\mathbb{F}Q = \mathbb{F}Qe_i \oplus \mathbb{F}Q(1 - e_i)$ exhibits $\mathbb{F}Qe_i$ as a direct summand of the free module $\mathbb{F}Q$, which makes it projective by theorem 17.2.4. If Q is finite without oriented cycles, then $\mathbb{F}Q$ is finite-dimensional by proposition 54.1.56(5), and by part (4) and theorem 52.3.2 each e_i is a primitive idempotent. So $1 = \sum_i e_i$ is a decomposition into primitive orthogonal idempotents, and the left ideals $\mathbb{F}Qe_i \cong \mathcal{M}(P_i)$ are the indecomposable projective modules Ae_i of definition 52.3.3 for $A = \mathbb{F}Q$.

Example 54.1.60: The Representations P_i

1. For $1 \xrightarrow{a} 2$, the paths from 1 are e_1 and a, so $P_1(1) = \mathbb{F}e_1$ and $P_1(2) = \mathbb{F}a$, with $e_1 \mapsto a$ along a, and $P_1 \cong (\mathbb{F} \xrightarrow{1} \mathbb{F})$. The vertex 2 is a sink, and $P_2 \cong S(2) = (0 \to \mathbb{F})$. So the indecomposable representation $\mathbb{F} \xrightarrow{1} \mathbb{F}$ of example 54.1.23 is projective, and it is not simple, as lemma 54.1.59(5) requires of P_1, the vertex 1 not being a sink.
2. For the loop quiver of example 54.1.57(1), $P_1(1) = \mathbb{F}Q \cong \mathbb{F}[x]$, on which the loop acts by multiplication by x. This representation is infinite-dimensional and indecomposable.
3. For the Kronecker quiver K, $P_1(1) = \mathbb{F}e_1$ and $P_1(2) = \mathbb{F}a \oplus \mathbb{F}b$, with $e_1 \mapsto a$ along a and $e_1 \mapsto b$ along b, and $P_2 \cong S(2)$. By lemma 54.1.59(2), $\mathrm{Hom}_K(P_2, P_1) \cong P_1(2)$ is two-dimensional.

Exercise 54.1.1

1. Let K be the Kronecker quiver of example 54.1.28, with arrows $a, b\colon 1 \to 2$. For $\lambda \in \mathbb{F}$ let V_λ be the representation with $V_\lambda(1) = V_\lambda(2) = \mathbb{F}$, $T_a = 1$ and $T_b = \lambda$. Show that every V_λ is indecomposable and that $V_\lambda \cong V_\mu$ only if $\lambda = \mu$. Conclude that K is not of finite type over an infinite field, as theorem 54.1.46 predicts.
2. Let L be the quiver with one vertex and one loop. For $m \geq 1$ let J_m be the representation $\mathbb{F}^m$ whose loop acts by the nilpotent Jordan block N_m, with $N_m\varepsilon_1 = 0$ and $N_m\varepsilon_l = \varepsilon_{l-1}$ for $l \geq 2$. Show that J_m is indecomposable, and deduce that L is not of finite type over any field, finite or infinite. Which extended Dynkin diagram is the underlying graph of L?
3. Let $\mathbb{F}$ be algebraically closed and let L and N_m be as in exercise 54.1.1 (2). For $\lambda \in \mathbb{F}$ and $m \geq 1$ let $J_m(\lambda)$ be the representation $\mathbb{F}^m$ of L on which the loop acts by $\lambda I_m + N_m$, so that $J_m(0) = J_m$. Show that the simple finite-dimensional representations of L are the representations $J_1(\lambda)$, $\lambda \in \mathbb{F}$, and that these are pairwise non-isomorphic. Using theorem 14.4.5, show that every finite-dimensional representation of L is an internal direct sum of subrepresentations each isomorphic to some $J_m(\lambda)$. Deduce from exercise 54.1.1 (2) that every $J_m(\lambda)$ is indecomposable, and show that $J_m(\lambda) \cong J_{m'}(\lambda')$ only if $m = m'$ and $\lambda = \lambda'$.
4. Show that D_4 has exactly 12 positive roots, and list them. (Write the Tits form as a sum of squares, one for each vertex of degree one and one for the central vertex.)
5. Let $\varepsilon_1, \ldots, \varepsilon_{n+1}$ be the standard basis of $\mathbb{R}^{n+1}$. Show that the linear map $\mathbb{R}^n \to \mathbb{R}^{n+1}$ sending α_i to $\varepsilon_i - \varepsilon_{i+1}$ carries the symmetric form of A_n to the dot product and Φ_{A_n} onto $\{\varepsilon_i - \varepsilon_j \mid i \neq j\}$. Show that, under this map, s_i becomes the exchange of the i-th and $(i+1)$-st coordinates, and deduce that W_{A_n} is isomorphic to the symmetric group on $n+1$ letters.
6. For A_2 and the Coxeter element $c = s_2 s_1$, compute the matrix of c in the basis α_1, α_2, show that $c^3 = \mathrm{id}$, and verify lemma 54.1.37 directly for $v = \alpha_1$ and for $v = \alpha_1 + \alpha_2$.
7. Let Q be $1 \to 2 \leftarrow 3$ and let V be the representation $\mathbb{F} \xrightarrow{1} \mathbb{F} \xleftarrow{1} \mathbb{F}$. Compute $S_2^+(V)$, show that it is indecomposable, and compare its dimension vector with $s_2(\dim_Q V)$.
8. Use theorem 54.1.46 to list, up to isomorphism, the nonzero finite-dimensional indecomposable representations of $1 \to 2 \leftarrow 3$.

9. For $a, b, c \geq 1$, show that the star $T(a, b, c)$ of definition 54.1.29 has positive definite Tits form if and only if
$$\frac{1}{a+1} + \frac{1}{b+1} + \frac{1}{c+1} > 1$$

10. Let Q be $1 \to 2 \to \cdots \to n$. Show that for $i \leq j$ there is exactly one path p_{ji} from i to j, and that there is no path from j to i when $i < j$. Show that the linear map sending p_{ji} to the matrix E_{ji}, whose entry in position (j, i) is 1 and whose other entries are 0, is an isomorphism of algebras from $\mathbb{F}Q$ onto the algebra of lower triangular $n \times n$ matrices over $\mathbb{F}$, and deduce that $\dim_{\mathbb{F}} \mathbb{F}Q = \frac{n(n+1)}{2}$.

11. Let Q be a finite quiver without oriented cycles and let V be a simple representation of Q. Show that $V \cong S(i)$ for some vertex i. (Choose a vertex i with $V(i) \neq 0$ such that no arrow with source i has a target j with $V(j) \neq 0$.) Show that for the loop quiver the representation $\mathbb{F}$ on which the loop acts by 1 is simple and not isomorphic to $S(1)$.

54.2 Bound Quiver Algebras

The path algebra of definition 54.1.55 turns a quiver into an associative algebra whose modules are the quiver representations of definition 54.1.5 (theorem 54.1.58). This passage runs in one direction: every quiver produces an algebra. The converse question is the one that completes the picture. Given an abstract finite-dimensional algebra A over a field k, is there a quiver Q whose path algebra is A, or close enough to A that the two have the same representation theory? A path algebra is rarely finite-dimensional (a quiver with an oriented cycle has arbitrarily long paths, proposition 54.1.56(5)), so one cannot hope for equality on the nose. The fix is to impose relations, cutting the path algebra down by an ideal, and the content of this section is that this always suffices: over an algebraically closed field, every finite-dimensional algebra is, up to the coarsening given by Morita equivalence, a path algebra modulo relations. This is the structure theorem of Gabriel, and it makes the theory of quivers the universal combinatorial model for finite-dimensional representation theory.

The route to this statement passes through three reductions. First we cut a path algebra by an *admissible* ideal, which is what makes it finite-dimensional while keeping its arrows intact. Then we isolate the class of algebras for which the reconstruction is cleanest, the *basic* algebras, and show via Morita theory that restricting to them loses nothing. Finally we read a quiver directly off an abstract algebra A (its *Gabriel quiver*) using the Jacobson radical of chapter 52, and prove that A is the path algebra of that quiver modulo an admissible ideal. Throughout, A denotes a finite-dimensional algebra over k, modules are left modules, and $\mathrm{Jac}(A)$ is the Jacobson radical. We write kQ for the path algebra of definition 54.1.55 over k, and recall its multiplication convention: for paths p and q the product $p \cdot q$ is the concatenation "q then p", nonzero exactly when $t(q) = s(p)$. In particular a path γ from i to j satisfies $e_j \gamma e_i = \gamma$, so it lives in $e_j(kQ)e_i$; this ordering of the idempotents matters when counting arrows.

The first task is to identify, inside kQ, the piece built from arrows of positive length. The constant paths e_i span a semisimple part, a product of copies of k, and everything else is generated by the arrows. Collecting the arrow-generated part into an ideal gives the object that measures "length at least one", and its powers measure length.

Definition 54.2.1: Arrow Ideal and Admissible Ideal

Let Q be a finite quiver and kQ its path algebra over k.

1. The *arrow ideal* $R_Q \subseteq kQ$ is the two-sided ideal generated by the arrows (the paths of length 1).
2. A two-sided ideal $I \subseteq kQ$ is *admissible* if there exists an integer $m \geq 2$ with
$$R_Q^m \subseteq I \subseteq R_Q^2$$

Two facts make this definition run, both consequences of the way paths concatenate. First, R_Q^ℓ is spanned by the paths of length at least ℓ: a product of ℓ arrows is a path of length ℓ (when the concatenation is legal) and zero otherwise, and every path of length ℓ factors as such a product. Consequently $kQ = kQ_0 \oplus R_Q$ as vector spaces, where $kQ_0 = \bigoplus_i ke_i$ is the span of the constant paths, and more generally the paths of a fixed length span a complement to $R_Q^{\ell+1}$ inside R_Q^ℓ. Second, the sandwiching $R_Q^m \subseteq I \subseteq R_Q^2$ has a concrete meaning at each end. The lower bound $R_Q^m \subseteq I$ forces I to contain all sufficiently long paths, which is exactly what truncates kQ/I to finite dimension. The upper bound $I \subseteq R_Q^2$ forbids relations of length 0 or 1: no relation may involve a constant path or set a single arrow equal to a combination of other arrows. This is the condition that keeps the arrows of Q visible in the quotient, so that Q can be recovered from the algebra kQ/I rather than being partly erased by the relations.

Definition 54.2.2: Bound Quiver Algebra

Let Q be a finite quiver and $I \subseteq kQ$ an admissible ideal. The quotient
$$kQ/I$$
is called the *bound quiver algebra* (or the path algebra of Q *bound by* the relations I). The pair (Q, I) is called a *bound quiver*.

Because $R_Q^m \subseteq I$, the quotient kQ/I is spanned by the images of the paths of length less than m, of which there are finitely many when Q is finite; so a bound quiver algebra is always finite-dimensional. The constant paths e_i descend to a complete set of orthogonal idempotents summing to 1, and R_Q/I is a nilpotent ideal with $(R_Q/I)^m = 0$. In fact R_Q/I is precisely the Jacobson radical of kQ/I. Being a nilpotent two-sided ideal, it lies in the radical by theorem 52.1.8, since kQ/I is finite-dimensional and hence left Artinian. Conversely, $kQ = kQ_0 \oplus R_Q$ and $I \subseteq R_Q$ give $(kQ/I)/(R_Q/I) \cong kQ_0 = \prod_i k$, and an element $\sum_i c_i e_i + r$ of kQ/I, with $r \in R_Q/I$, acts by c_i on the one-dimensional module on which e_i acts as 1 and every other e_j as 0. The radical annihilates each of these simple modules (theorem 52.1.4), so it lies in R_Q/I. This last observation is the seed of the reconstruction theorem: the arrows of Q will be recovered from $\mathrm{Jac}(kQ/I)/\mathrm{Jac}(kQ/I)^2$.

Example 54.2.3: Loops, Truncation, and the A_2 Quiver

We compute three bound quiver algebras from the ground up.

1. *The dual numbers as a bound one-loop quiver.* Let Q be the quiver with one vertex 1 and

one loop $\alpha\colon 1 \to 1$:

The paths in Q are $e_1, \alpha, \alpha^2, \alpha^3, \ldots$, so as a vector space $kQ = k[\alpha]$ is the polynomial ring in one variable (identifying e_1 with 1 and concatenation of the loop with multiplication). The arrow ideal is $R_Q = (\alpha)$, and $R_Q^m = (\alpha^m)$. Take $I = (\alpha^2) = R_Q^2$, which is admissible with $m = 2$ (indeed $R_Q^2 \subseteq I \subseteq R_Q^2$). Then

$$kQ/I = k[\alpha]/(\alpha^2)$$

is the algebra of *dual numbers*, two-dimensional over k with basis $\{e_1, \alpha\}$ and the single relation $\alpha^2 = 0$. Its radical is $R_Q/I = (\alpha)$, one-dimensional, with square zero, and kQ/I modulo its radical is k: there is exactly one simple module, and it is one-dimensional. This is the smallest example of a bound quiver algebra that is not itself a path algebra, the relation $\alpha^2 = 0$ being unavoidable if one wants a finite-dimensional quotient of $k[\alpha]$.

2. *Truncating a longer loop.* Keeping the same one-loop quiver but taking instead $I = (\alpha^3) = R_Q^3$ gives $kQ/I = k[\alpha]/(\alpha^3)$, three-dimensional with basis $\{e_1, \alpha, \alpha^2\}$. Here $m = 3$; the admissibility bound $I \subseteq R_Q^2$ holds because $\alpha^3 \in R_Q^3 \subseteq R_Q^2$, and the relation still involves no constant path and no bare arrow. More generally $k[\alpha]/(\alpha^n)$ is the one-loop quiver bound by (α^n) for each $n \geq 2$, and these exhaust the local algebras arising from a single loop.

3. *The A_2 quiver, hereditary case.* Let Q be the quiver

$$1 \xrightarrow{\alpha} 2$$

with two vertices and a single arrow $\alpha\colon 1 \to 2$. The only paths are e_1, e_2, and α, so kQ is already three-dimensional and $R_Q^2 = 0$ (there is no legal concatenation of two arrows). The only admissible ideal is therefore $I = 0$: admissibility requires $I \subseteq R_Q^2 = 0$, so nothing may be quotiented, and $R_Q^2 = 0 = I$ gives the lower bound with $m = 2$. Thus $kQ/I = kQ$, a path algebra with no relations. The path algebra of a finite connected quiver is *hereditary*, meaning that every submodule of a projective module is projective (theorem 54.1.58 and [68, Corollary 1.22]), so in particular kQ is hereditary.

   Concretely kQ is isomorphic to the lower-triangular matrix algebra

$$\begin{pmatrix} k & 0 \\ k & k \end{pmatrix}$$

via $e_1 \mapsto E_{11}$, $e_2 \mapsto E_{22}$, and $\alpha \mapsto E_{21}$, where E_{ij} is the elementary matrix with a 1 in position (i, j). Lower- rather than upper-triangular is forced by the multiplication convention: the arrow $\alpha\colon 1 \to 2$ satisfies $e_2 \alpha e_1 = \alpha$, so its image must land in position $(2, 1)$, the strictly lower-triangular slot. The check is direct on the multiplication table: $e_2 \cdot \alpha \cdot e_1 = \alpha$ matches $E_{22}E_{21}E_{11} = E_{21}$, and every other product of basis elements is forced to zero on both sides. (The upper-triangular algebra is the opposite algebra, the A_2 path algebra with the arrow reversed to $2 \to 1$; we recover it from the radical in example 54.2.9.) We return to this identification once we have located the indecomposable projectives.

The dual-numbers example already shows the shape of the reconstruction: a local algebra with

radical square zero came out as a single loop bound by α^2, and the loop is exactly a basis vector of $\mathrm{Jac}/\mathrm{Jac}^2$. Before making this into a theorem, one must decide which algebras to reconstruct. Not every finite-dimensional algebra is a bound quiver algebra on the nose. The matrix algebra $M_2(k)$, for instance, is simple, so its only simple module is two-dimensional, whereas a bound quiver algebra always has all its simples one-dimensional over k when k is algebraically closed (they are the vertex simples S_i). The class for which the reconstruction is exact is singled out by demanding that the semisimple quotient $A/\mathrm{Jac}(A)$ be as small as possible: a product of division rings, with no matrix blocks of size larger than one.

Definition 54.2.4: Basic Algebra

A finite-dimensional k-algebra A is *basic* if the quotient $A/\mathrm{Jac}(A)$ is a product of division rings,

$$A/\mathrm{Jac}(A) \cong D_1 \times \cdots \times D_n$$

with each D_i a division k-algebra. Equivalently, in the Artin–Wedderburn decomposition of $A/\mathrm{Jac}(A)$ (corollary 51.2.18) every matrix block $M_{n_i}(D_i)$ has $n_i = 1$.

When k is algebraically closed the finite-dimensional division k-algebras collapse to k itself (corollary 51.2.20), so a basic algebra over such a k has

$$A/\mathrm{Jac}(A) \cong k \times \cdots \times k$$

a product of n copies of k. Two consequences are worth stating plainly. First, the simple A-modules are the n simple modules of this product, each one-dimensional over k; a basic algebra over an algebraically closed field has *all simple modules one-dimensional*. Second, the number n of simple modules equals the number of factors, and it becomes the number of vertices of the reconstructed quiver. The condition "every matrix block has size one" is precisely the condition that the regular representation of $A/\mathrm{Jac}(A)$ contains each simple exactly once, so that A is, in the language of idempotents, a sum of pairwise non-isomorphic indecomposable projectives.

Example 54.2.5: Basic and Non-Basic Algebras

The bound quiver algebras of example 54.2.3 are all basic: for $k[\alpha]/(\alpha^2)$ the radical quotient is k, and for the A_2 path algebra it is $k \times k$, both products of copies of k. The upper-triangular algebra of 2×2 matrices is basic for the same reason. By contrast $M_2(k)$ is *not* basic: it is already semisimple, so $\mathrm{Jac}(M_2(k)) = 0$ and $M_2(k)/\mathrm{Jac}(M_2(k)) = M_2(k)$ is a single 2×2 block. The group algebra $k[S_3]$ over $k = \mathbb{C}$ is not basic either, since by Maschke's theorem it is semisimple and Artin–Wedderburn gives $\mathbb{C} \times \mathbb{C} \times M_2(\mathbb{C})$, a product with a 2×2 block coming from the two-dimensional irreducible representation of S_3. These non-basic examples are not pathological; they are the reason the theorem is stated up to Morita equivalence rather than isomorphism.

The point of Morita equivalence is that it does not see the difference between an algebra and its basic model. Two algebras are Morita equivalent when their module categories are equivalent, and Morita's theorem identifies exactly which algebras share a module category with a given one: they are the endomorphism algebras of progenerators. That theory, including generators, progenerators, and the classification of Morita equivalences by bimodules, is developed in *Core Algebra* chapter 18⋆. What is used here is the criterion for a corner ring, that Ae is a progenerator exactly when the idempotent e is full, in which case A and eAe are Morita equivalent. The block structure of the radical quotient is this book's own and is settled below.

Proposition 54.2.6: Reduction to the Basic Case

Let A be a finite-dimensional k-algebra. Then there is a basic finite-dimensional k-algebra A^b, the *basic algebra of* A, that is Morita equivalent to A: the categories of left modules A-**Mod** and A^b-**Mod** are equivalent. Up to isomorphism, A^b does not depend on the choices made in its construction, and A and A^b have the same number of simple modules and the same radical quotient block *data* in the sense that $A^b/\mathrm{Jac}(A^b) \cong D_1 \times \cdots \times D_n$ where $M_{n_i}(D_i)$ are the Artin–Wedderburn blocks of $A/\mathrm{Jac}(A)$.

***Proof*:**

Step 1: the idempotent. Write $1 = e_1 + \cdots + e_r$ as a sum of primitive orthogonal idempotents, following theorem 52.3.2, so that $A = \bigoplus_j Ae_j$ expresses the regular module as a direct sum of indecomposable projectives $P_j = Ae_j$. Two of these are isomorphic exactly when the corresponding simples $P_j/\mathrm{rad}(P_j)$ and $P_{j'}/\mathrm{rad}(P_{j'})$ agree, so grouping the e_j by the isomorphism class of P_j and choosing one representative from each class produces an idempotent

$$e = e_{i_1} + \cdots + e_{i_n}$$

with n the number of simple modules. It is idempotent because the e_{i_j} are orthogonal. Set $A^b := eAe$.

Step 2: e is full. Each e_{i_j} satisfies $e_{i_j}e = e_{i_j}$, again by orthogonality, so $Ae_{i_j}A = Ae_{i_j}eA \subseteq AeA$. For an arbitrary l the projective Ae_l is isomorphic to Ae_{i_j} for some j by the choice of representatives. If $\theta\colon Ae_l \to Ae_{i_j}$ is an isomorphism, then $u = \theta(e_l) \in Ae_{i_j}$ satisfies $u = ue_{i_j}$, and the A-linearity of θ^{-1} gives $e_l = \theta^{-1}(ue_{i_j}) = u\,\theta^{-1}(e_{i_j})$, so $e_l \in Ae_{i_j}A$ and $Ae_lA \subseteq Ae_{i_j}A \subseteq AeA$. Summing,

$$1 = \sum_{l=1}^{r} e_l \in \sum_{l=1}^{r} Ae_lA \subseteq AeA$$

so $AeA = A$ and e is full.

Step 3: the equivalence. By theorem 18.3.6, a full idempotent makes Ae a progenerator with $\mathrm{End}_A(Ae)^{\mathrm{op}} \cong eAe$, so A and $A^b = eAe$ are Morita equivalent. The equivalence is $\mathrm{Hom}_A(Ae, -)$, which sends an A-module M to eM.

Step 4: A^b is basic, with the stated radical quotient. The equivalence carries the indecomposable projectives of A to those of A^b and preserves isomorphism, and $Ae = \bigoplus_j Ae_{i_j}$ retains exactly one indecomposable projective from each isomorphism class. So the regular representation of A^b contains each simple exactly once, which is what it means for A^b to be basic, and its radical quotient has all blocks of size one. The division rings are unchanged: the equivalence induces a bijection on simple modules and a ring isomorphism on their endomorphism rings, so the blocks are over the same $D_i = \mathrm{End}_A(S_i)^{\mathrm{op}}$ furnished by Schur's lemma (lemma 51.1.5). Another decomposition of 1 and another choice of representatives give an idempotent e' with $Ae' \cong Ae$, since by theorem 52.2.4 the isomorphism classes of indecomposable summands of A do not depend on the decomposition, and Ae and Ae' are both direct sums of one module from each class. Steps 2 and 3 apply to e' as well, so $e'Ae' \cong \mathrm{End}_A(Ae')^{\mathrm{op}} \cong \mathrm{End}_A(Ae)^{\mathrm{op}} \cong eAe$, and A^b does not depend on the choices up to isomorphism, completing the proof.

The reduction lets us prove the structure theorem only for basic algebras and inherit it for all

finite-dimensional algebras through the equivalence of module categories: whatever we say about the representations of $A^b = kQ_A/I$ transfers verbatim to the representations of A. From now on A is basic, and for the reconstruction assume k is algebraically closed, so that all simple modules are one-dimensional and the radical quotient is a product of copies of k. This is the setting of Gabriel's theorem, and it is where the assumption $k = \overline{k}$ earns its place: over a non-closed field the division algebras D_i reappear and the vertices of the quiver would have to be weighted by them.

The quiver attached to an abstract algebra can now be defined. Its vertices are the simple modules; its arrows count how simples fail to split off one another, measured either homologically by Ext^1 or internally by the radical filtration. That these two counts agree is the bridge between the abstract and combinatorial descriptions.

Definition 54.2.7: Ext-Quiver (Gabriel Quiver)

Let A be a basic finite-dimensional algebra over an algebraically closed field k, with simple modules $S_1, \dots, S_n$ up to isomorphism and a complete set of primitive orthogonal idempotents $e_1, \dots, e_n$ with $S_i = Ae_i/\mathrm{rad}(Ae_i)$. The *Ext-quiver* (or *Gabriel quiver*) Q_A is the quiver with

1. vertex set $\{1, \dots, n\}$, one vertex for each simple module S_i, and
2. exactly
$$\dim_k \mathrm{Ext}^1_A(S_i, S_j) = \dim_k \, e_j\big(\mathrm{Jac}(A)/\mathrm{Jac}(A)^2\big)e_i$$
arrows from i to j.

The order of the idempotents in the formula is fixed by the multiplication convention of definition 54.1.55 and is worth pausing on, since it is easy to get backwards. In the path algebra a would-be arrow from i to j satisfies $e_j \alpha e_i = \alpha$, so it lives in $e_j(kQ)e_i$; matching this, the arrows from i to j in Q_A are counted by $e_j(\mathrm{Jac}/\mathrm{Jac}^2)e_i$, with e_j on the left and e_i on the right. A source using the opposite (left-to-right) convention for path multiplication would write $e_i(\mathrm{Jac}/\mathrm{Jac}^2)e_j$ instead; the two conventions transpose the quiver, so one must commit to one. Here the commitment is to the book's convention throughout. The equality of the two counts, homological and idempotent-theoretic, is the following lemma, proved here because it is what makes the definition well-posed: the arrow count must not depend on the choice of description.

Lemma 54.2.8: Arrows Count Radical Extensions

Let A be a finite-dimensional k-algebra with primitive orthogonal idempotents $e_1, \dots, e_n$ and simple modules $S_i = Ae_i/\mathrm{rad}(Ae_i)$, and assume k is algebraically closed. Then for all i, j,
$$\mathrm{Ext}^1_A(S_i, S_j) \cong e_j\big(\mathrm{Jac}(A)/\mathrm{Jac}(A)^2\big)e_i$$
as k-vector spaces. In particular the two are equidimensional.

***Proof*:**
Write $J = \mathrm{Jac}(A)$ and $P_i = Ae_i$, the indecomposable projective with top $S_i = P_i/\mathrm{rad}(P_i)$; recall from definition 52.3.3 that $\mathrm{rad}(P_i) = Je_i$, so that $S_i = Ae_i/Je_i$.

Step 1: A projective presentation of S_i. The surjection $P_i \twoheadrightarrow S_i$ has kernel $\mathrm{rad}(P_i) = Je_i$, giving

the short exact sequence

$$0 \to Je_i \to P_i \to S_i \to 0$$

Applying $\mathrm{Hom}_A(-, S_j)$ produces the exact sequence

$$0 \to \mathrm{Hom}_A(S_i, S_j) \to \mathrm{Hom}_A(P_i, S_j) \to \mathrm{Hom}_A(Je_i, S_j) \to \mathrm{Ext}^1_A(S_i, S_j) \to 0$$

where the last term is $\mathrm{Ext}^1_A(S_i, S_j)$ and not $\mathrm{Ext}^1(P_i, S_j)$ because P_i is projective, so $\mathrm{Ext}^1_A(P_i, S_j) = 0$ and the connecting map surjects onto $\mathrm{Ext}^1(S_i, S_j)$. The definition and basic properties of Ext^1 as the obstruction to lifting homomorphisms along a projective presentation are developed in the companion volume on homological algebra ([29, Computation Of Tor and Ext]). We use only that a projective resolution computes it and that projectives have no higher self-extensions.

Step 2: Evaluating the outer terms. For any simple S_j and any module M, a homomorphism $M \to S_j$ factors through $M/\mathrm{rad}(M)$ because $\mathrm{rad}(M)$ maps into $\mathrm{rad}(S_j) = 0$. Applying this to P_i gives $\mathrm{Hom}_A(P_i, S_j) = \mathrm{Hom}_A(S_i, S_j)$, so the first two terms of the sequence in Step 1 cancel and the map between them is an isomorphism. The sequence therefore collapses to

$$0 \to \mathrm{Hom}_A(Je_i, S_j)/\big(\text{image of } \mathrm{Hom}_A(P_i, S_j)\big) \to \mathrm{Ext}^1_A(S_i, S_j) \to 0$$

but the image of $\mathrm{Hom}_A(P_i, S_j)$ in $\mathrm{Hom}_A(Je_i, S_j)$ is zero: a homomorphism $P_i \to S_j$ vanishes on $\mathrm{rad}(P_i) = Je_i$ by the factoring just noted. Hence the connecting map is an isomorphism

$$\mathrm{Ext}^1_A(S_i, S_j) \cong \mathrm{Hom}_A(Je_i, S_j)$$

Step 3: The Hom into a simple is a radical layer. Again by the factoring through the top, any homomorphism $Je_i \to S_j$ kills $\mathrm{rad}(Je_i) = J^2 e_i$, so

$$\mathrm{Hom}_A(Je_i, S_j) = \mathrm{Hom}_A\big(Je_i/J^2e_i,\, S_j\big)$$

The module Je_i/J^2e_i is semisimple, being a module over the semisimple algebra A/J, and S_j is simple, so by Schur's lemma (lemma 51.1.5) and $\mathrm{End}_A(S_j) = k$ (from $k = \overline{k}$) the space $\mathrm{Hom}_A(Je_i/J^2e_i, S_j)$ has dimension equal to the multiplicity of S_j in Je_i/J^2e_i. That multiplicity is $\dim_k e_j(Je_i/J^2e_i)$. Indeed, for a semisimple module N the map $\varphi \mapsto \varphi(e_j)$ is a linear isomorphism $\mathrm{Hom}_A(Ae_j, N) \to e_jN$, with inverse $n \mapsto (ae_j \mapsto an)$. Every homomorphism $Ae_j \to N$ vanishes on Je_j, because $JN = 0$, so $\mathrm{Hom}_A(Ae_j, N) \cong \mathrm{Hom}_A(S_j, N)$, whose dimension is again the multiplicity of S_j in N by Schur's lemma and $\mathrm{End}_A(S_j) = k$. Therefore

$$\dim_k \mathrm{Ext}^1_A(S_i, S_j) = \dim_k e_j(Je_i/J^2e_i) = \dim_k e_j(J/J^2)e_i$$

the last equality because $e_j(J/J^2)e_i = e_j(Je_i)/e_j(J^2e_i)$ and right-multiplication by e_i identifies Je_i/J^2e_i with the e_i-column of J/J^2. Assembling the three isomorphisms gives $\mathrm{Ext}^1_A(S_i, S_j) \cong e_j(J/J^2)e_i$, as we sought to show.

The lemma says the arrows of Q_A have two readings. Homologically, an arrow $i \to j$ records a one-dimensional worth of non-split extension of S_i by S_j: a module of length two with S_j as a submodule and S_i on top that does not break as $S_i \oplus S_j$. Internally, the same arrow is a basis vector of the (j, i) block of the first radical layer $\mathrm{Jac}/\mathrm{Jac}^2$. The first reading is the reason the quiver is called the Ext-quiver and explains why it is an invariant of the module category, hence of the Morita equivalence class; the second reading is the one to compute with, because $\mathrm{Jac}/\mathrm{Jac}^2$ is a finite matrix of idempotent-sandwiched subspaces. The running examples compute it.

Example 54.2.9: Gabriel Quivers of the Running Algebras
Reading off Q_A for two algebras confirms it recovers the starting quiver.

1. *The dual numbers.* Let $A = k[\alpha]/(\alpha^2)$. This is local: its only maximal ideal is (α), so $\mathrm{Jac}(A) = (\alpha)$ and there is a single simple module $S_1 = A/(\alpha) = k$, giving one vertex. The first radical layer is $\mathrm{Jac}/\mathrm{Jac}^2 = (\alpha)/(\alpha^2)$, one-dimensional with basis the image of α, and with $e_1 = 1$ the block $e_1(\mathrm{Jac}/\mathrm{Jac}^2)e_1$ is all of it. So Q_A has one vertex and one arrow, a loop:

$$\overset{1}{\circlearrowleft}\ \alpha$$

   exactly the quiver we bound in example 54.2.3. The relation to be imposed will be $\alpha^2 = 0$, recovering A.

2. *The upper-triangular algebra.* Let $A = \begin{pmatrix} k & k \\ 0 & k \end{pmatrix}$, the 2×2 upper-triangular matrices. Its radical is the strictly upper-triangular part, $\mathrm{Jac}(A) = kE_{12}$, one-dimensional with square zero. The idempotents $e_1 = E_{11}$ and $e_2 = E_{22}$ are primitive orthogonal with $e_1 + e_2 = 1$, and $A/\mathrm{Jac}(A) \cong k \times k$, so there are two vertices with simples S_1, S_2. Since $\mathrm{Jac}^2 = 0$ we have $\mathrm{Jac}/\mathrm{Jac}^2 = kE_{12}$, and we locate E_{12} by its idempotent sandwich:

$$e_1 E_{12} e_2 = E_{11}E_{12}E_{22} = E_{12}, \qquad e_2 E_{12} e_1 = E_{22}E_{12}E_{11} = 0$$

   so the one basis vector of $\mathrm{Jac}/\mathrm{Jac}^2$ sits in the block $e_1(\mathrm{Jac}/\mathrm{Jac}^2)e_2$. By definition 54.2.7 the block $e_j(\cdots)e_i$ counts arrows $i \to j$, so with $j = 1$, $i = 2$ this is one arrow $2 \to 1$:

$$2 \xrightarrow{\ \alpha\ } 1$$

   Under the identification $\alpha \mapsto E_{12}$ this is the A_2 quiver of example 54.2.3, up to relabelling the vertices, and $\mathrm{Jac}^2 = 0$ forces the admissible ideal to be $I = 0$. The algebra is hereditary, and Q_A carries no relations: the upper-triangular algebra *is* its own path algebra kQ_A.

The two examples describe the same three-dimensional hereditary algebra, once as a bound quiver algebra and once reconstructed from its radical, and the indecomposable projectives match under the identification. Take the bound-quiver presentation of example 54.2.3, the A_2 path algebra with arrow $\alpha\colon 1 \to 2$ realized as the lower-triangular matrices via $e_1 \mapsto E_{11}$, $e_2 \mapsto E_{22}$, $\alpha \mapsto E_{21}$. The indecomposable projective $P_i = kQ \cdot e_i$ is spanned by the paths starting at i: P_1 has basis $\{e_1, \alpha\}$, the trivial path at 1 together with the arrow out of 1, and is two-dimensional with top S_1 and socle S_2, while P_2 has basis $\{e_2\}$ and is the simple S_2 itself. On the matrix side these are the column modules AE_{11} and AE_{22}: the first column of the lower-triangular algebra is two-dimensional, spanned by E_{11} and E_{21} (the entries in rows 1 and 2 of column 1), and the second column is one-dimensional, spanned by E_{22}. So the indecomposable projectives read off from the primitive idempotents of theorem 52.3.2 are exactly the projective quiver representations P_i of the path algebra. The Gabriel reconstruction of example 54.2.9 applied instead the upper-triangular representative, whose radical kE_{12} sits in the opposite corner and so produces the arrow $2 \to 1$; the two matrix algebras are opposite to one another (transpose exchanges upper and lower triangular), which is exactly the transposition of the quiver that the two multiplication conventions differ by. Either way the representation theory of A_2 is the same, and the two constructions coincide.

Everything is now in place for the structure theorem. It asserts that the passage from a basic algebra to its Gabriel quiver and back to a bound quiver algebra is a round trip: A is isomorphic to kQ_A modulo an admissible ideal. The proof builds a surjection $kQ_A \twoheadrightarrow A$ by sending vertices to the primitive idempotents and arrows to a lift of the radical layer, then shows the kernel is admissible using that $\mathrm{Jac}(A)$ is nilpotent.

Theorem 54.2.10: Structure of Basic Algebras (Gabriel)

Let A be a basic finite-dimensional algebra over an algebraically closed field k, with Gabriel quiver Q_A (definition 54.2.7). Then there is an admissible ideal $I \subseteq kQ_A$ and an isomorphism of k-algebras

$$A \cong kQ_A/I$$

Consequently, by the reduction to the basic case (proposition 54.2.6), every finite-dimensional k-algebra over an algebraically closed field is Morita equivalent to a bound quiver algebra kQ/I.

The quiver Q_A is determined by A, but the ideal I is not: different admissible ideals can present isomorphic algebras, so the theorem produces *some* admissible presentation rather than a canonical one. This is the one point where the correspondence between algebras and bound quivers fails to be a clean bijection, and it is the reason bound quiver algebras are studied through their quiver plus a choice of relations rather than through the quiver alone.

***Proof*:**

Write $J = \mathrm{Jac}(A)$, and recall J is nilpotent, say $J^m = 0$ for some $m \geq 2$, because A is finite-dimensional (a nilpotent radical is the Artinian case established in theorem 52.1.8). Let $e_1, \ldots, e_n$ be the complete set of primitive orthogonal idempotents underlying Q_A, with $1 = e_1 + \cdots + e_n$ and $S_i = Ae_i/Je_i$.

Step 1: Send vertices to idempotents and arrows to a radical lift. For each vertex i of Q_A set the constant path $\varepsilon_i \in kQ_A$ to map to $e_i \in A$. For the arrows, fix for each pair (i, j) a k-basis of the block $e_j(J/J^2)e_i$; by definition 54.2.7 and lemma 54.2.8 the arrows of Q_A from i to j are in bijection with this basis. For each arrow $\alpha\colon i \to j$ choose a lift $x_\alpha \in e_jJe_i \subseteq A$ of the corresponding basis vector of $e_j(J/J^2)e_i$; such a lift exists because $e_j(J/J^2)e_i$ is a quotient of e_jJe_i. Note $x_\alpha \in e_jJe_i$ means $e_jx_\alpha e_i = x_\alpha$, which is the algebra image of the path relation $e_j\alpha e_i = \alpha$, so the assignment respects the idempotent bookkeeping.

Step 2: Extend to an algebra homomorphism. Because kQ_A is free on paths, an algebra homomorphism out of it is determined by the images of the vertices and arrows, subject only to the relations $\varepsilon_i\varepsilon_{i'} = \delta_{ii'}\varepsilon_i$, $\sum_i \varepsilon_i = 1$, and the source-target matching for arrows. The chosen images e_i and x_α satisfy all of these: the e_i are orthogonal idempotents summing to 1, and $x_\alpha \in e_jAe_i$ matches the source i and target j of α. Extend multiplicatively, sending a path $\alpha_r \cdots \alpha_1$ to the product $x_{\alpha_r} \cdots x_{\alpha_1} \in A$ (in the algebra's own multiplication, so a path from i to j lands in e_jAe_i). This defines a k-algebra homomorphism

$$\varphi\colon kQ_A \to A$$

Step 3: φ is surjective. The image contains every e_i and every x_α, and the x_α lift a basis of J/J^2. We show $\mathrm{im}\varphi = A$ by descending the filtration $A \supseteq J \supseteq J^2 \supseteq \cdots \supseteq J^m = 0$ layer by layer. The images $\varphi(\varepsilon_i) = e_i$ generate $A/J = \prod_i ke_i$ over k, so $\mathrm{im}\varphi + J = A$. Next, the products of

length one, $x_\alpha = \varphi(\alpha)$, form lifts of a basis of J/J^2, so $\operatorname{im}\varphi + J^2 \supseteq J$, hence $\operatorname{im}\varphi + J^2 = A$. Inductively suppose $\operatorname{im}\varphi + J^\ell = A$; then J^ℓ is spanned modulo $J^{\ell+1}$ by products of ℓ elements of J, each of which may be taken from the spanning set $\{x_\alpha\}$ of J modulo J^2, so products $\varphi(\alpha_\ell \cdots \alpha_1)$ of ℓ arrows span J^ℓ modulo $J^{\ell+1}$. Thus $\operatorname{im}\varphi + J^{\ell+1} = A$. Since $J^m = 0$, after m steps $\operatorname{im}\varphi = \operatorname{im}\varphi + J^m = A$, so φ is surjective.

Step 4: The kernel is admissible. Let $I = \ker\varphi$, so $A \cong kQ_A/I$. It remains to check $R_Q^{m'} \subseteq I \subseteq R_Q^2$ for some m', where R_Q is the arrow ideal of kQ_A.

For the lower bound, $\varphi(R_Q^m) \subseteq J^m = 0$: a path of length at least m is a product of at least m arrows, and each arrow maps into J, so a length-$\geq m$ path maps into $J^m = 0$. Hence $R_Q^m \subseteq \ker\varphi = I$, giving the lower bound with $m' = m$.

For the upper bound $I \subseteq R_Q^2$, suppose $u \in I$ and write $u = u_0 + u_1 + u_2$ where $u_0 \in kQ_{A,0}$ is the constant-path part, u_1 is the arrow part (length exactly one), and $u_2 \in R_Q^2$ collects the length-≥ 2 paths. We must show $u_0 = 0$ and $u_1 = 0$. Applying φ and reducing modulo J: $\varphi(u_1) \in J$ and $\varphi(u_2) \in J^2 \subseteq J$, so $0 = \varphi(u) \equiv \varphi(u_0) \pmod J$. But φ restricted to constant paths is the isomorphism $kQ_{A,0} = \prod_i k\varepsilon_i \xrightarrow{\sim} \prod_i ke_i = A/J$ (the e_i are linearly independent modulo J because they are orthogonal idempotents with distinct simple tops), so $\varphi(u_0) \equiv 0 \pmod J$ forces $u_0 = 0$. Now reduce modulo J^2: with $u_0 = 0$ we have $0 = \varphi(u) = \varphi(u_1) + \varphi(u_2)$, and $\varphi(u_2) \in J^2$, so $\varphi(u_1) \equiv 0 \pmod{J^2}$. But $\varphi(u_1)$ is the image in J/J^2 of a linear combination of arrows, and the arrows were chosen to map to a *basis* of J/J^2; a linear combination of basis vectors that is zero in J/J^2 has all coefficients zero, so $u_1 = 0$. Therefore $u = u_2 \in R_Q^2$, proving $I \subseteq R_Q^2$.

Combining the two bounds, $R_Q^m \subseteq I \subseteq R_Q^2$, so I is admissible and $A \cong kQ_A/I$ is a bound quiver algebra. The final clause on general algebras follows by composing with the Morita reduction of proposition 54.2.6: an arbitrary finite-dimensional A is Morita equivalent to its basic algebra A^b, and $A^b \cong kQ_{A^b}/I$ by what was just proved, completing the proof.

Three features of the argument deserve a closing word. The surjectivity in Step 3 is a radical-filtration induction: because $\operatorname{Jac}(A)$ is nilpotent, generating $A/\operatorname{Jac}(A)$ by the idempotents and the first radical layer $\operatorname{Jac}/\operatorname{Jac}^2$ by the arrows suffices to generate all of A, since higher layers are spanned by products. The admissibility of the kernel in Step 4 is the exact counterpart of the two bounds in definition 54.2.1: the lower bound $R_Q^m \subseteq I$ is nilpotence of the radical, and the upper bound $I \subseteq R_Q^2$ is the choice of arrows as a basis of $\operatorname{Jac}/\operatorname{Jac}^2$, which is precisely why an admissible ideal is forbidden to contain constant paths or bare arrows. And the theorem is the structure theorem of Gabriel, to be kept distinct from Gabriel's other theorem in this chapter (theorem 54.1.46), which says that a finite quiver with connected underlying graph is of finite type exactly when its graph is a simply-laced Dynkin diagram A, D, E (the converse direction proved there over an infinite field). The two results are complementary: the present one says every finite-dimensional algebra is a bound quiver algebra, and the Dynkin classification says which of the unbound path algebras have only finitely many indecomposable modules.

Part XI

Homological Algebra

Throughout this book, the reader has encountered many functors, some notable examples being $\mathrm{Hom}_R(-,N)$, $\mathrm{Hom}_R(M,-)$ and $M\otimes_R -$ among many others. Each of these functors give some information about the objects and the morphisms passing through the functor. As we saw for the Hom and $M\otimes_R -$ functors, certain appropriate objects preserve exactness, while most preserve it only partially. Perhaps a crowning achievement of mid 20th century mathematics is to be able to quantify this lack of exactness, and rather spectacularly use the information given by this quantification to extract a (sometimes copious) amount of information about the objects of study. The great effectiveness with which homological algebra can produce interesting information may seem surprising at first, for example, using homological algebra the notion of *dimension* as it is understood in geometry is readily translatable to algebra, or that we may measure how far away a module is from being a vector-space (details are in K-theory)[2] How this is the case is perhaps best motivated by going through learning the subject to see for oneself, but it may be helpful for some readers to have some of my (the authors) intuition presented to stand on some ground before proceeding.

If we have two objects M_1 and M_2, we may wish to consider a way of constructing a new object M given M_1 and M_2. Ideally, we may form a short exact sequence like so:

$$0\to M_1\to M\to M_2\to 0$$

More generally, we may have a collection of objects $\{M_i\}_{i\in I}$ which we use to construct an object via a long exact sequence. However, it is often not the case that such an exact sequence is too strong, that is, it is not the case that $\mathrm{im}(\varphi_i)=\ker(\varphi_{i+1})$. Even if such a construction exists, we often then want to "transform" this information via a functor which shall then lose us exactness (one can think of a functor as asking some sort of "question" whose output is the answer). In this case, it has been eerily common that the image of φ_i is contained in the kernel of φ_{i+1}:

$$\mathrm{im}(\varphi_i)\subseteq\ker(\varphi_{i+1}) \tag{54.1}$$

Conceptually, this can be thought as the object "being obstructed" from fully being an extension. This new type of sequence is called a *cochain complex*. The reader with a good memory may recall definition 12.2.11 where it was given that another name for a long exact sequence is an exact cochain complex. In this way, the condition given by equation 54.1 is a generalization of the exact condition. The theoretical heart of homological algebra can be thought of how to extract "quantitatively" how a cochain complex *fails* to be an exact cochain complex. For example, in chapter 17⋆ it was have eluded that through the use of homology theory, the Ext functor gives us all the ways two modules M_1, M_2 may be extended. In this case, the failure of $\mathrm{Hom}(M,-)$ or $\mathrm{Hom}(-,N)$ preserving injectivity or surjectivity (equivalently, the "obstruction" to these functors being exact) gave rise to the Ext functor and the study of its homology.

The term "algebraic object" has been is a bit ambiguous. What type of algebraic objects can be used to in the theory of homological algebra? As it turns out, not all algebraic objects satisfy the right conditions for the theory of homological algebra (for example, **Grp** and **Fld** will be shown to be inappropriate for a theory of homology). However, there are non-algebraic objects for which a homological theory can be induced (famously, topological spaces and smooth manifolds admit a theory of homological algebra). This spurred the need to generalize the theory of homological algebra to the categorical level, where homological theory is well-defined on *abelian categories*. We thus shall start homological algebra with an overview of abelian categories. For those who are already familiar with some homological algebra, they may have studied homological algebra within the category of

[2]This is overviewed in chapter 58

R-**Mod**, which is a concrete abelian category. Doing so will in fact not loose any generality due to Freyd-Mitchell Theorem (theorem 55.1.15) which states that any [small] abelian category A admits a fully faithful exact functor to a category R-**Mod** for a suitable ring R. Working with the concrete category R-**Mod** brings it benefits as it may be easier to conceptualize the manipulation of elements, and so the reader may ask for the benefit in sticking to working with general abelian categories. As the author, I believe the benefits comes in being comfortable with more advanced category theory. Future algebraists are going to encounter more complicated problems involving category theory (higher order categories, topoi's, and stacks, are all examples the reader may see in the not too distant future). Hence, introducing a categorical perspective will familiarize the reader for more complicated categorical notions in their not too distant future[3].

The reader may wonder why a cochain complex is not called a chain complex. This is because we can work in the dual category, where all arrows are flipped. In the dual category, we shall get chain complexes. Homological algebra in the dual category is theoretically the same, however we shall see that cohomology is often computationally easier to work in, permitting more useful algebraic structures we can use to study. It is for this reason that most mathematicians work with cohomology rather than homology, even though every theorem we shall show for homology translates directly to cohomology[4]. In this book, we shall start with homology, and switch to cohomology when starting to work with more computational parts of the theory to get the reader accustomed to both modes of thinking.

Goal

Chapter 55 shall introduce the theory of abelian categories which shall be the types of categories in which homological algebra is well-defined.

The main result Chapter 56 of the book is trying to convey is what information from R-modules give rise to certain properties in its respective chain complex(es), and conversely what information from it's chain complex(es) gives us information about modules. A (co)chain complex need not be exact, and (co)homology shall be the algebraic object quantifying this failure of exactness. We shall see that given an object M within an abelian category, there are in general an infinite number of ways we may associate a [co]chain complex to it. Thus, there will have to be a way to either associate a canonical [co]chain complex (in a natural functorial manner), or we assign [co]chain complexes to an object up to appropriate notion of isomorphism. The latter shall be the approach in this book, where we shall see that we will want to consider [co]chain complexes up to something called *quasi-isomorphism* of [co]chain complexes. We shall then see what cohomological information we may deduce given different choices of functors and how they transform [co]chain complexes.

After having developed the ground work for extracting cohomological information, in Chapter 58 we shall put this knowledge to good use and apply cohomology theory to G-invariant functors and see what this this can tell us about groups. This shall also finally address what was foreshadowed in box 20.4.5 where it was said the units of a Galois field form a trivial 1st homology group. We shall define the notion of homological dimension which shall line up with the results presented in the section on commutative algebra. Finally, we present an interesting technical result to check flatness of a module over a local ring that builds on the same intuitions the Nakayama lemma (lemma 52.1.7)

[3] assuming, naturally, that the reader holds great interest in algebra and shall keep pursuing branches within the field

[4] there is even an equivalent algebraic structure for the additional algebraic structure that is induced in cohomology, however it is less useful

presented.

Finally, this Part concludes with the introduction to spectral sequences in chapter 60, which are the quintessential tool for many concrete computations in homological algebra and any serious work in many disciplines of algebra and geometry. The main idea is that most object of study can be broken down into a filtration of simpler objects whose cohomology is more computed. The spectral sequence will put piece together this cohomological information.

Connection to Singular Homology/Cohomology

For readers familiar with algebraic topology and the theory of (co)homology, the connection between the above abstraction and the homology theory of topological spaces comes from noticing that singular (co)homology on a manifold can be interpreted as taking the projective resolution $C_n(X) = \mathrm{Hom}_{\mathbf{Top}}(\Delta^n, X)$. In particular, given M, we can apply $C_*(-)$ to it and get a projective (even free) resolution from which we extract homological information. This should also motivate the use of $\mathrm{Hom}_R(M, -)$ and $\mathrm{Hom}_R(-, N)$ as the "right" functors to be considering when generalizing classical algebraic topology to the algebraic setting. As the tensor product it adjoint (theorem 15.3.9) it is another natural candidate.

54.2.11 Foreshadowing: Yoneda's Lemma The Hom is very useful as it is "represented" by an element (either in the domain or codomain). Even more is true: it can be used to represent other functors. In theorem 62.2.1 this is studied *representable functors* which are functors where $F(-) \Rightarrow \mathrm{Hom}_C(A, -)$ for natural transformation $\Rightarrow$, category C, object $A \in C$, and $F : C \to \mathbf{Set}$. The Yoneda lemma will give a way of representing objects using Hom.

Historical Origins

While modern homological algebra is phrased in the language of categories, its machinery evolved from two distinct 19th-century sources which converged in the mid-20th century.

The algebraic lineage begins around 1890 with David Hilbert's Invariant Theory. To prove the Basis Theorem, Hilbert studied the relations ("syzygies") between generators of an ideal. He constructed a chain of free modules to resolve these relations:

$$0 \to F_n \to \cdots \to F_1 \to F_0 \to M \to 0$$

Hilbert proved the *Syzygy Theorem*, showing that for polynomial rings, this chain of relations eventually terminates in an exact sequence of free modules. However, this theory encountered a significant obstruction when applied to rings with singularities (such as coordinate rings of singular curves). In these non-regular settings, Hilbert's resolutions do not terminate but continue infinitely. This failure shifted the mathematical focus from simply computing invariants to essentially classifying the severity of a singularity by the infinite length of its resolution.

Parallel to this, in the 1930s, number theorists like Emmy Noether, Richard Brauer, and Helmut Hasse were attempting to classify division algebras (generalizations of the quaternions) over number fields. They classified these algebras using "Crossed Products," which relied on complex systems of functions called "Factor Sets" ($c : G \times G \to K^\times$). While they successfully defined the *Brauer Group*

of a field to organize these algebras, the calculations were notoriously opaque. The "Factor Sets" satisfied a messy algebraic identity that seemed arbitrary, acting as a computational blocker that obscured the underlying structure of the fields they were studying.

Simultaneously, from 1895 onwards, the topological roots of the subject were forming as Henri Poincaré classified manifolds. He decomposed spaces into simplices and represented their boundaries using incidence matrices. He defined Betti numbers as the ranks of these matrices. However, Poincaré's numerical approach had a blind spot: rank obliterates "torsion." A twisted shape like the projective plane appeared numerically identical to a trivial one (both have rank 0 in dimension 1).

In 1925, Emmy Noether revolutionized this view. She realized that the matrices topologists were diagonalizing were actually presentations of abelian groups. By shifting focus from the numerical rank to the *Homology Group* itself ($\ker \partial / \operatorname{im} \partial$), she captured the torsion information, effectively "algebraizing" the topology. She showed that the matrix was not just a calculator for a number, but a presentation of a structure.

The convergence of these fields occurred in the 1940s when algebraists attempted to classify *Group Extensions*. Saunders Mac Lane and Samuel Eilenberg attempted to classify these extensions and rediscovered the same "Factor Sets" used by Brauer and Hasse. They discovered that the algebraic identity these functions satisfied was *identical* to the boundary formula for a 2-simplex in topology; essentially they realized they were calculating $H^2(G, N)$ (see [26] for this computation in the EYNTKA series). This was the turning point: it proved that "cohomology" was not just a property of geometric shapes, but a fundamental algebraic structure that arose whenever one tried to "extend" one object by another, whether in topology, group theory, or number theory.

The grand unification came in 1956 when Cartan and Eilenberg realized that the topological concept of "boundaries" and the algebraic concept of "extensions" were instances of the same phenomenon: the *failure of exactness*. They observed that while Hilbert's resolution is exact, applying a functor (like the tensor product or Hom) usually destroys that exactness. They realized that the "homology" groups were simply the mathematical terms required to repair this broken exactness. This birth of the *Derived Functor* (Tor and Ext) transformed the field from the study of static objects to the study of how functors distort structure. To build this machinery, they faced a technical blocker: Hilbert's reliance on "Free Modules." While free modules worked for Homology (Tor), they failed for the dual theory of Cohomology (Ext), as the dual of a free module is rarely free. To achieve the necessary symmetry, they replaced the specific condition of "Freeness" with the categorical properties of *Projectivity* and *Injectivity*. This allowed them to define derived functors for any ring, regardless of whether a basis existed.

With this machinery established, the period from 1955 to 1980 saw these newly developed tools being used to solving the original obstructions in geometry and number theory. In geometry, Jean-Pierre Serre proved that a local ring is regular (non-singular) if and only if it has finite global homological dimension (theorem 58.2.9). This transformed the "problem" of infinite resolutions into a precise detection tool: the non-terminating resolution was effectively the algebraic signature of a geometric singularity. Alexander Grothendieck later introduced *Local Cohomology* ($H^i_{\mathfrak{m}}$) to quantify the depth and severity of these singularities, eventually leading to Intersection Homology which restored Poincaré Duality to singular spaces.

In number theory, the mysterious "Factor Sets" of the 1930s were identified as elements of the second Galois Cohomology group, $H^2(\mathrm{Gal}(L/K), L^\times)$. This realization allowed Emil Artin and John Tate to rewrite Class Field Theory entirely in the language of cohomology. The obscure identities of the past were revealed to be standard cohomological relations, and the *Tate Cohomology* groups ($\hat{H}^i$) were developed specifically to handle the arithmetic of finite groups, solving the classification problems

that had stalled the previous generation (see [77] for the EYNTKA series exposition of modern class field theory).

55

Abelian Categories

This chapter focuses on the category in which we may define "cohomological theories" as not all categories are well-suited for this endeavor

55.1 Definitions and Properties

We have extensively worked with categories which have a multitudes of different properties. Some important terms to recall are the following:

- *zero-object*: an object 0 in a category C $0 \in \text{Obj}(C)$ that is both the initial and final object. Such an object is also called a terminal object. Similarly, a zero morphism is a morphism $f : X \to Y$ such that for any other morphisms $g, h : X \to Y$, $fg = fh$ and $hf = gf$.
- *Products* and *Coproducts*: Given two objects $a, b \in \text{Obj}(C)$, if there exists an object $c \in \text{Obj}(C)$ that is the limit (resp. colimit) of the diagram:

  $$\overset{A}{\bullet} \qquad \overset{B}{\bullet}$$

  then c is the product (resp. coproduct) of a and b, and is usually written as $a \times b$ (resp. $a \amalg b$)
- *kernels* and *cokernels*: Given a morphism $f : a \to b$, the kernel (resp. cokernel) of f is an object k and a morphism $\iota : k \to a$ such that k is the limit (resp. colimit) of the diagarm:

  $$\overset{a}{\bullet} \xrightarrow{f} \overset{b}{\bullet}$$

  with the added restriction that the map $\varphi : k \to y$ must be the zero morphism (namely, by commutativity, $f\iota = 0_{kb}$ must be the zero morphism). In terms of diagrams, we get that that

for any $\iota' : K \to A$ such that $f\pi\iota' = 0$, that there exists a morphism φ such that the following diagram commutes:

and simmilarly for cokernels:

Kernels and cokernels do not necessarily exist in a category, or not all morphisms have kernels (ex. the category of finitely generated R-modules for any ring R need has morphisms without kernels). Furthermore, monomorphism need not be kernels (not all subgroups are normal) and epimorphisms need not be cokernels (recall $\mathbb{Z} \to \mathbb{Q}$ is an epimorphism in **Ring**)

Not all categories we have worked with have these properties. For example, **Fld** does not have products (what would be the characteristic of the product of $\mathbb{F}_p$ and $\mathbb{F}_q$ for $p \neq q$?), some categories do not have zero morphisms (set being an example), some have monomorphisms/epimorphisms that do not correspond to kernels (as showed above). We first limit our attention to categories which have these nice properties:

Definition 55.1.1: Additive Category

Let **A** be a category. Then **A** is said to be *additive* if it has a zero-object, has both finite products and coproducts, and each $\mathrm{Hom}_A(X, Y)$ can be given an abelian group structure such that the composition of maps:

$$\mathrm{Hom}_A(X, Y) \times \mathrm{Hom}_A(Y, Z) \to \mathrm{Hom}_A(X, Z)$$

is bilinear. A functor between additive categories is *additive* if it is a group homomorphism on hom-sets.

A functor between two additive categories is called an *additive functor* if the maps between the hom-sets is a homomorphism.

The term "additive" comes froms the fact that we may interpret the additive category as a monoidal category (a category which we may add a functor $\otimes : C \times C \to C$ that is given the property of a monoid operation, for an additive category this would be the direct product), where the hom-sets are "enriched" to also be abelian groups. Another way of looking at additive categories is in which the algebra of matrices is well-defined.

Example 55.1.2: Additive Categories

1. The category of R-modules is an example of an additive category.

2. **Grp** is not additive, for $\mathrm{Hom}_{\mathbf{Grp}}(A, B)$ does not have an abelian group strucuture satisfying the above condition.
3. The category of matrices over a ring is an additive category.
4. The category of finitely generated R-modules is an additive category

A key realisation is that in the absence of kernels and cokernels as objects monomorphisms and epimorphisms take their place:

Lemma 55.1.3: Additive Categories: Monomorphisms and Kernels I

Let A be an additive category. Then kernels are monomorphisms and cokernels are epimorphisms

***Proof*:**
Let $k\colon K \to A$ be a kernel of $\varphi\colon A \to B$, and let $f, g\colon X \to K$ satisfy $k \circ f = k \circ g$. Because the hom-sets of an additive category are abelian groups and composition is bilinear, this says $k \circ (f - g) = 0$.

Now apply the universal property of the kernel to the zero morphism $0\colon X \to A$. It satisfies $\varphi \circ 0 = 0$, so there is a *unique* morphism $u\colon X \to K$ with $k \circ u = 0$. Both $f - g$ and the zero morphism $X \to K$ have this property, so uniqueness forces $f - g = 0$, that is $f = g$. Hence k is a monomorphism.

The statement for cokernels is the same argument in the opposite category: a cokernel of φ in A is a kernel of φ in A^{op}, an additive category, and a monomorphism there is an epimorphism in A, completing the proof.

Note that kernels and cokernels need not exist in an additive category, hence the converse of each accession need not be the case (in a vacuous way). If a morphism φ has a kernel then we may identify exactly what this kernel is:

Lemma 55.1.4: Additive Categories: Monomorphisms and Kernels II

Let A be an additive category and $\varphi : X \to Y$ a morphism. Then:

1. If φ has a kernel, then φ is a monomorphism if and only if $0 \to X$ is its kernel
2. If φ has a cokernel, then φ is an epimorphism if and only if $Y \to 0$ is its cokernel

***Proof*:**

1. Suppose first that the zero morphism $0 \to X$ is a kernel of φ, and let $f, g\colon Z \to X$ satisfy $\varphi \circ f = \varphi \circ g$. Then $\varphi \circ (f - g) = 0$, so $f - g$ factors through the kernel: there is $u\colon Z \to 0$ with $f - g = 0 \circ u = 0$. Hence $f = g$ and φ is a monomorphism.

   Conversely suppose φ is a monomorphism and let $k\colon K \to X$ be a kernel of φ. From

$\varphi \circ k = 0 = \varphi \circ 0$ and φ monic it follows that $k = 0$. But k is itself a monomorphism by lemma 55.1.3, and $k \circ \mathrm{id}_K = 0 = k \circ 0$, so $\mathrm{id}_K = 0$. An object whose identity is the zero morphism is a zero object, so $K \cong 0$ and the kernel is $0 \to X$.

2. This is the statement of (1) in the opposite category, where kernels and monomorphisms become cokernels and epimorphisms.

This completes the proof.

As mentioned, it is not guaranteed that kernels and cokernels exist. We shall shortly axiomatically add them to our category by adding them into the definition of a new category that supersedes additive categories, but first we show a few more important results about abelian categories. Namely, in an additive category, products and coproducts are equivalent:

Lemma 55.1.5: Additive Categories: Products and Coproducts

Let A be an additive category and $X, Y \in \mathrm{Obj}(A)$. Then if $X \times Y$ exists, so does $X \amalg Y$, and if $X \amalg Y$ exists, so does $X \times Y$. Furthermore,

$$X \times Y \cong X \amalg Y$$

***Proof*:**
Suppose $P = X \times Y$ exists, with projections $p_X \colon P \to X$ and $p_Y \colon P \to Y$. Let $i_X \colon X \to P$ be the unique morphism with $p_X i_X = \mathrm{id}_X$ and $p_Y i_X = 0$, and let $i_Y \colon Y \to P$ be defined symmetrically; both exist by the universal property of the product.

Step 1: The key identity $i_X p_X + i_Y p_Y = \mathrm{id}_P$. Two morphisms out of P into P agree as soon as their composites with p_X and with p_Y agree, again by the universal property of the product. Compute

$$p_X(i_X p_X + i_Y p_Y) = (p_X i_X)p_X + (p_X i_Y)p_Y = \mathrm{id}_X \circ p_X + 0 \circ p_Y = p_X$$

using bilinearity of composition, and symmetrically $p_Y(i_X p_X + i_Y p_Y) = p_Y$. Since id_P has the same two composites, the identity holds.

Step 2: (P, i_X, i_Y) is a coproduct. Let $f \colon X \to Z$ and $g \colon Y \to Z$ be given and set $h = f p_X + g p_Y \colon P \to Z$. Then

$$h i_X = f(p_X i_X) + g(p_Y i_X) = f, \qquad h i_Y = f(p_X i_Y) + g(p_Y i_Y) = g$$

so h is a morphism with the required restrictions. For uniqueness, suppose h' also satisfies $h' i_X = f$ and $h' i_Y = g$. Then by Step 1,

$$h' = h' \mathrm{id}_P = h'(i_X p_X + i_Y p_Y) = (h' i_X)p_X + (h' i_Y)p_Y = f p_X + g p_Y = h$$

Hence P with i_X, i_Y satisfies the universal property of $X \amalg Y$, and in particular $X \times Y \cong X \amalg Y$.

If instead $X \amalg Y$ is assumed to exist, the same argument in the opposite category produces the product, completing the proof.

Hence, additive categories behave very much like abelian groups, however as we pointed out kernels and cokernels need not exist. We thus define a new category that forces these conditions:

Definition 55.1.6: Abelian Category

[Abelian Category] Let A be an additive category. Then A is an *abelian* category if

1. kernels and cokernels exist in A;
2. every monomorphism is the kernel of some morphism, and every epimorphism is the cokernel of some morphism.

The second condition is not a consequence of the first, and it is the one that does the work. An additive category satisfying only (1) is called *pre-abelian*, and there the canonical map from the coimage to the image of a morphism (theorem 55.1.9) need not be an isomorphism; the category of torsion-free abelian groups is pre-abelian but not abelian, since $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ is there both a monomorphism and an epimorphism without being an isomorphism. Condition (2) rules this out, and is what makes lemma 55.1.8 true.

Note that lemma 55.1.4 is a weaker statement, not this one: it characterizes a monomorphism by having *zero* kernel, which says nothing about whether the monomorphism is itself a kernel.

Since each kernel is associated to a monomorphism, we may intuitively think of the association:

$$\text{kernel} \iff \text{submodule}$$

and similarly:

$$\text{cokernel} \iff \text{quotient module}$$

In many ways, an abelian category should be thought of as the minimum number of conditions necessary to define exact sequence[1]. To see this, we require the following:

Lemma 55.1.7: Abelian Category: Kernels And Cokernels

Let A be an abelian category. Then every kernel is the kernel of its cokernel, and every cokernel is the cokernel of its kernel.

***Proof*:**
Let $k\colon K \to A$ be a kernel, say of $\varphi\colon A \to B$, and let $c\colon A \to C$ be a cokernel of k. The claim is that k is a kernel of c.

First, $c \circ k = 0$ holds by the definition of a cokernel. Now let $t\colon T \to A$ satisfy $c \circ t = 0$; a unique factorization of t through k is needed. Since $\varphi \circ k = 0$ and c is the cokernel of k, the morphism φ factors as $\varphi = \bar{\varphi} \circ c$ for some $\bar{\varphi}\colon C \to B$. Therefore

$$\varphi \circ t = \bar{\varphi} \circ c \circ t = 0$$

and since k is the kernel of φ, there is a unique $u\colon T \to K$ with $k \circ u = t$. Uniqueness is automatic because k is a monomorphism by lemma 55.1.3. So k satisfies the universal property of $\ker c$.

[1]Those familiar with some algebraic topology may find it insightful that an abelian category is the the category with ninimum number of condition so that the snake lemma (theorem 56.1.18) holds

The dual statement, that every cokernel is the cokernel of its kernel, is this argument in the opposite category, completing the proof.

Lemma 55.1.8: Abelian Categories: Isomorphisms

[Abelian Categories, Isomorphisms] Let A be an abelian category and $\varphi : A \to B$ a morphism in A. Then if φ is a monomorphism and an epimorphism, it is an isomorphism

Note that this does not hold in additive categories, nor even in pre-abelian ones: condition (2) of definition 55.1.6 is exactly what the proof below uses.

***Proof*:**
Since φ is an epimorphism, condition (2) of definition 55.1.6 makes it the cokernel of some morphism $\psi\colon C \to A$. By the definition of a cokernel $\varphi \circ \psi = 0$, so ψ factors through $\ker\varphi$ by the universal property of the kernel.

Now φ is also a monomorphism, so $\ker\varphi = 0$ by lemma 55.1.4. The factorization of the previous paragraph then runs through the zero object, so $\psi = 0$ outright and φ is a cokernel of the zero morphism $0 \to A$. But the identity $\mathrm{id}_A\colon A \to A$ is also a cokernel of $0 \to A$: any $f\colon A \to X$ with $f \circ 0 = 0$, which is every f, factors uniquely through id_A. Cokernels are unique up to unique isomorphism, so there is an isomorphism $A \to B$ commuting with φ and id_A, which forces φ to be that isomorphism, as we sought to show.

Theorem 55.1.9: Abelian Category: Canonical Decomposition

[Abelian Category, Canonical Decomposition] Let A be an abelian category and $\varphi : A \to B$ a morphism. Write $C = \mathrm{coker}(\ker\varphi)$ and $K = \ker(\mathrm{coker}\varphi)$. Then φ decomposes in the following cannonical way:

$$A \twoheadrightarrow C \xrightarrow[\tilde{\varphi}]{} K \rightarrowtail B, \qquad A \xrightarrow{\varphi} B$$

where the first morphism is an epimorphism, the last a monomorphism, and the middle morphism $\tilde{\varphi}$ is an *isomorphism*.

***Proof*:**
Write $k\colon N \to A$ for $\ker\varphi$ and $p\colon A \to C$ for its cokernel, and $q\colon B \to Q$ for $\mathrm{coker}\varphi$ and $\iota\colon K \to B$ for its kernel. By lemma 55.1.3 the morphism p is an epimorphism and ι is a monomorphism.

Step 1: φ factors through ι. Since q is the cokernel of φ, $q \circ \varphi = 0$, and since ι is the kernel of q there is a unique $\varphi'\colon A \to K$ with $\varphi = \iota \circ \varphi'$.

Step 2: φ' factors through p. From $\iota \circ \varphi' \circ k = \varphi \circ k = 0$ and ι monic it follows that $\varphi' \circ k = 0$. As p is the cokernel of k, there is a unique $\tilde{\varphi}\colon C \to K$ with $\varphi' = \tilde{\varphi} \circ p$. Combining, $\varphi = \iota \circ \tilde{\varphi} \circ p$, which is the displayed factorization.

Step 3: ι is the smallest subobject through which φ factors. Let $m\colon V \to B$ be any monomorphism with $\varphi = m \circ \psi$ for some ψ. By condition (2) of definition 55.1.6 the monomorphism m is a kernel, so by lemma 55.1.7 it is the kernel of its own cokernel; write $d\colon B \to D$ for $\operatorname{coker} m$, so that $m = \ker d$. Then

$$d \circ \varphi = d \circ m \circ \psi = 0$$

so d factors through the cokernel of φ, say $d = \bar{d} \circ q$. Since $\iota = \ker q$ gives $q \circ \iota = 0$, it follows that $d \circ \iota = \bar{d} \circ q \circ \iota = 0$, and therefore ι factors through $\ker d = m$.

Step 4: φ' is an epimorphism. Let $c\colon K \to W$ be the cokernel of φ' and $n\colon V \to K$ its kernel. From $c \circ \varphi' = 0$ the morphism φ' factors as $\varphi' = n \circ \psi$, whence $\varphi = \iota \circ n \circ \psi$. The composite $\iota \circ n$ is a monomorphism, being a composite of two (each is a kernel, so lemma 55.1.3 applies), so Step 3 gives a t with $\iota = \iota \circ n \circ t$. As ι is monic this yields $n \circ t = \mathrm{id}_K$, so n is a split epimorphism as well as a monomorphism, hence an isomorphism by lemma 55.1.8. Then $c \circ n = 0$ with n invertible forces $c = 0$; but c is a cokernel, hence an epimorphism by lemma 55.1.3, and $\mathrm{id}_W \circ c = 0 = 0 \circ c$ then gives $\mathrm{id}_W = 0$, so $W \cong 0$. A morphism with zero cokernel is an epimorphism, so φ' is one.

Step 5: $\tilde{\varphi}$ is an isomorphism. By Step 4 the composite $\tilde{\varphi} \circ p = \varphi'$ is an epimorphism, and if $u \circ \tilde{\varphi} = 0$ then $u \circ \tilde{\varphi} \circ p = 0$ and hence $u = 0$; so $\tilde{\varphi}$ is an epimorphism. Dually, running Steps 1 to 4 in the opposite category shows that the induced morphism $C \to B$, which is $\iota \circ \tilde{\varphi}$, is a monomorphism; and a composite $g \circ h$ can be a monomorphism only if h is, so $\tilde{\varphi}$ is a monomorphism. Being both, it is an isomorphism by lemma 55.1.8, completing the proof.

From the above, we may think of $\ker(\operatorname{coker}) : K \to B$ as representing the "image" of φ:

Lemma 55.1.10: Abelian Category: Images

Let $\varphi : A \to B$ be a morphism in an abelian category, and let $\iota : K \to B$ be the kernel of the cokernel of φ. Then:

1. ι is a monomorphism
2. φ factors through ι
3. ι is initial with these properties

***Proof*:**
Part (1) is lemma 55.1.3, since ι is a kernel. Part (2) is Step 1 of the proof of theorem 55.1.9: writing $q = \operatorname{coker}\varphi$, the identity $q \circ \varphi = 0$ makes φ factor uniquely through $\iota = \ker q$.

Part (3) is the minimality established in Step 3 of that proof: if $m\colon V \to B$ is any monomorphism through which φ factors, then ι factors through m. Concretely, m is a kernel by condition (2) of definition 55.1.6, hence the kernel of its own cokernel d by lemma 55.1.7; then $d \circ \varphi = 0$ makes d factor through q, so $d \circ \iota = 0$ and ι factors through $\ker d = m$, as we sought to show.

Definition 55.1.11: Abelian Category: Image

Let $\varphi : A \to B$ be a morphism in an abelian category. Then the *iamge* of φ is $\ker(\text{coker}(\varphi))$ and is denoted $\text{im}(\varphi)$. Similarly, its co-image is $\text{coker}(\ker(\varphi))$ and is dentoed $\text{coim}(\varphi)$.

With our intuition from working with R-modules, given a morphism $\varphi : A \to B$ with image $\iota : K \to B$, we may imagine there is an induced epimorphism $\overline{\varphi} : A \to K$. This is indeed the case:

Proposition 55.1.12: Abelian Category: sub object and quotient objects

Let $\varphi : A \to B$ be a morphism in an abelian category with image $\text{im}\varphi\colon K \to B$ and coimage $\text{coim}\,\varphi\colon A \to C$. Then the induced morphism $A \to K$ is an epimorphism and the induced morphism $C \to B$ is a monomorphism.

***Proof*:**
The induced morphism $A \to K$ is the morphism φ' of theorem 55.1.9, shown to be an epimorphism in Step 4 of that proof. The induced morphism $C \to B$ is the composite $\iota \circ \tilde{\varphi}$, a composite of a monomorphism with an isomorphism, hence a monomorphism, completing the proof.

From the cannonical decomposition, we may say that the image and coimage are "isomorphic" (which is not strictly true since these are morphisms, however by the Freyd-Mitchell Theorem this is a safe way of looking at it).

Definition 55.1.13: Abelian Category: Exactness

Consider a sequence of objects in an abelian category

$$\cdots \to A \xrightarrow{\varphi} B \xrightarrow{\psi} C \to \cdots$$

This sequence is *exact at* B if:

1. $\psi \circ \varphi = 0$
2. $\text{coker}\varphi \circ \ker \psi = 0$

and it is *exact* if it is exact at each of its interior objects.

Example 55.1.14: Categorical Exactness

1. In R-Mod, $\ker \psi$ is the inclusion of $\{b \in B \mid \psi(b) = 0\}$ and $\text{coker}\varphi$ is the projection $B \to B/\text{im}\varphi$. So condition (2) says that every b with $\psi(b) = 0$ lies in $\text{im}\varphi$, condition (1) says $\text{im}\varphi \subseteq \ker \psi$, and together they are the usual condition $\text{im}\varphi = \ker \psi$.
2. The sequence $0 \to A \xrightarrow{\varphi} B \to 0$ is exact if and only if φ is an isomorphism. The cokernel of $0 \to A$ is id_A, so exactness at A says that $\ker \varphi$ is the zero morphism. A kernel is a monomorphism (lemma 55.1.3), so its object is then a zero object, which means that φ is a monomorphism (lemma 55.1.4). In the same way, the kernel of $B \to 0$ is id_B, so exactness at B says that the epimorphism $\text{coker}\varphi$ is zero, which means that φ is an epimorphism. A

morphism that is both is an isomorphism (lemma 55.1.8), and an isomorphism is both.

3. For objects A and B, let $P = A \times B$ with projections p_A, p_B, and let i_A, i_B be as in the proof of lemma 55.1.5, so that $p_A i_A = \mathrm{id}_A$, $p_B i_A = 0$, $p_B i_B = \mathrm{id}_B$ and $i_A p_A + i_B p_B = \mathrm{id}_P$. Then $0 \to A \xrightarrow{i_A} P \xrightarrow{p_B} B \to 0$ is exact. As in (2), exactness at A and at B means that i_A is a monomorphism and p_B an epimorphism, which hold because $p_A i_A = \mathrm{id}_A$ and $p_B i_B = \mathrm{id}_B$. At P, $p_B i_A = 0$, and every t with $p_B t = 0$ satisfies $t = (i_A p_A + i_B p_B)t = i_A(p_A t)$, the factorization being unique as i_A is monic. So i_A is a kernel of p_B, and $\mathrm{coker} i_A \circ \ker p_B = \mathrm{coker} i_A \circ i_A = 0$.

Freyd-Mitchell Theorem

As mentioned, R-mod is an abelian category, and as we shall develop a bit later it the categories R-mod "represent" all abelian categories.

Theorem 55.1.15: Freyd-Mitchell Theorem

Let A be a small abelian category. Then there is a fully faithful exact functor $A \to R\text{-Mod}$ for a suitable ring R. Such a functor reflects exactness: a sequence in A is exact if and only if its image in R-Mod is.

***Proof Key ideas*:**
The proof constructs R as the endomorphism ring of a suitable injective cogenerator in the category of left exact functors $A^{\mathrm{op}} \to \mathbf{Ab}$, and occupies a chapter's worth of category theory that this book does not otherwise need; it is given in full in *An Introduction to Homological Algebra* [101], §1.6. The idea is that A embeds into its category of left exact presheaves by Yoneda, that this larger category is a Grothendieck category with enough injectives, and that a single injective cogenerator there converts the whole category into modules over its endomorphism ring.

The clause about reflecting exactness is immediate from the rest and is what the theorem is used for: a fully faithful exact functor reflects kernels and cokernels, so a diagram chase valid in R-Mod transfers back to A. This is what permits the element-based arguments in lemma 56.1.20 and throughout chapter 60.

55.2 Localization of Categories

The constructions of this book repeatedly produce morphisms that ought to be invertible but are not. The model for what to do about it is already familiar from commutative algebra: a ring R and a multiplicative set S of elements one wishes to invert are replaced by $S^{-1}R$, together with a map $R \to S^{-1}R$ that is universal among ring maps sending S into the units. Nothing in that description mentions elements of a ring rather than morphisms of a category, and the same universal property can be imposed one level up.

The payoff comes in chapter 56, where the class to be inverted is the class of quasi-isomorphisms and

the resulting category is the derived category. The construction is recorded here, before it is needed, because it is a statement about categories and not about complexes.

Definition 55.2.1: Localization of a Category

Let $\mathcal{C}$ be a category and W a class of morphisms of $\mathcal{C}$. A *localization* of $\mathcal{C}$ at W is a category $\mathcal{C}[W^{-1}]$ together with a functor $Q\colon \mathcal{C} \to \mathcal{C}[W^{-1}]$ such that

1. $Q(w)$ is an isomorphism for every $w \in W$;
2. for every category $\mathcal{D}$ and every functor $F\colon \mathcal{C} \to \mathcal{D}$ carrying each element of W to an isomorphism, there is a functor $\overline{F}\colon \mathcal{C}[W^{-1}] \to \mathcal{D}$ with $\overline{F} \circ Q = F$, and $\overline{F}$ is unique with this property.

As with every universal property, the definition determines the answer up to canonical isomorphism as soon as an answer exists: two localizations receive unique comparison functors from one another whose composites must be the identity, by the uniqueness clause applied to Q itself. Existence is the substantive point, and it is settled by a construction that simply writes down the morphisms that formal inversion forces to exist.

Theorem 55.2.2: Existence of the Localization

Let $\mathcal{C}$ be a category and W a class of morphisms. Then a localization $Q\colon \mathcal{C} \to \mathcal{C}[W^{-1}]$ exists.

***Proof*:**

Step 1: The construction. Let $\mathcal{C}[W^{-1}]$ have the same objects as $\mathcal{C}$. For objects X and Y, consider finite *zigzags* from X to Y: alternating strings of morphisms of $\mathcal{C}$

$$X = X_0 \;\; \text{⊢} X_1 \;\; \text{⊢} \;\; \cdots \;\; \text{⊢} X_n = Y$$

in which each link $X_i \text{⊢} X_{i+1}$ is either a morphism $X_i \to X_{i+1}$ of $\mathcal{C}$, called a forward link, or a morphism $X_{i+1} \to X_i$ that belongs to W, called a backward link. Enlarging W to contain all identities and to be closed under composition changes neither the class of functors inverting it nor, therefore, the localization, so assume this without loss of generality; it is what makes the second move below well formed. Impose on the collection of zigzags the smallest equivalence relation generated by: replacing two consecutive forward links by their composite; replacing two consecutive backward links by their composite; deleting a forward or backward link that is an identity; and deleting a pair of adjacent links w forward followed by w backward, or w backward followed by w forward, for $w \in W$. Let $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(X, Y)$ be the collection of equivalence classes, with composition given by concatenation, which is well defined because the generating relations are local to the links they touch. Concatenation is associative and the empty zigzag is an identity, so this is a category. Let Q send an object to itself and a morphism to the one-link forward zigzag.

Step 2: Q inverts W. For $w \in W$ the backward one-link zigzag on w is a morphism in the opposite direction, and concatenating it with the forward one-link zigzag on w in either order produces a pair of adjacent links which the last generating relation deletes, leaving the empty zigzag. So $Q(w)$ is an isomorphism.

Step 3: The universal property. Let $F\colon \mathcal{C} \to \mathcal{D}$ carry W into isomorphisms. Define $\overline{F}$ to be F on objects, and on a zigzag to be the composite in $\mathcal{D}$ obtained by applying F to each forward link and $F(-)^{-1}$ to each backward link. Each generating relation is respected: composites go to composites by functoriality, identities to identities, and an adjacent pair w, w of opposite orientation goes to $F(w)F(w)^{-1}$ or $F(w)^{-1}F(w)$, both identities. So $\overline{F}$ is well defined on equivalence classes, and it is a functor because concatenation goes to composition. By construction $\overline{F} \circ Q = F$.

For uniqueness, suppose $G \circ Q = F$ for a functor G. Every morphism of $\mathcal{C}[W^{-1}]$ is a concatenation of one-link zigzags, each of which is $Q(f)$ or $Q(w)^{-1}$; a functor is determined by its values on these, and $G(Q(f)) = F(f)$ forces $G(Q(w)^{-1}) = G(Q(w))^{-1} = F(w)^{-1}$. So G agrees with $\overline{F}$ on every morphism, completing the proof.

55.2.3 Warning: Localization and Set Theory The construction above builds each $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(X, Y)$ out of *all* zigzags, and for a category $\mathcal{C}$ that is not small there is no guarantee that the result is a set rather than a proper class. The property at risk is *local smallness*: the localization of a locally small category need not be locally small.

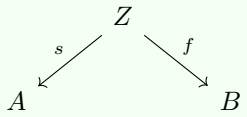
Two remedies are standard. The first is to assume $\mathcal{C}$ small, which is of no use here since $\mathrm{Ch}(\mathbf{A})$ never is. The second is to exhibit a calculus of fractions as in theorem 55.2.5, which replaces arbitrary zigzags by roofs; note that this alone does not bound anything, since the roofs over a fixed object are indexed by a proper class. What is needed in addition is that the W-morphisms into each object admit a *set* that is cofinal among them, and a multiplicative system with that property is what makes the localization locally small.

Neither remedy applies to $\mathrm{Ch}(\mathbf{A})$ localized at quasi-isomorphisms, because the quasi-isomorphisms there are *not* a multiplicative system. Both conditions (2) and (3) of definition 55.2.4 fail: taking $C^\bullet = (\mathbb{Z} \xrightarrow{\mathrm{id}} \mathbb{Z})$ in degrees $-1, 0$, which is acyclic, and $h\colon \mathbb{Z}[0] \to C^\bullet$ the chain map that is the identity in degree 0, every chain map $t\colon X^\bullet \to \mathbb{Z}[0]$ has only a degree-zero component, so $h \circ t = 0$ forces $t = 0$, which is not a quasi-isomorphism. The standard route is instead to pass to the homotopy category first: quasi-isomorphisms *are* a multiplicative system in $K(\mathbf{A})$, and $D(\mathbf{A}) = K(\mathbf{A})[\mathrm{qis}^{-1}]$, which is how section 57.2 presents it.

The zigzag description settles existence and is useless for computation: a morphism is an equivalence class of arbitrarily long strings, and deciding when two strings agree is not something one does by hand. Under a mild hypothesis on W every zigzag collapses to a single roof, and then morphisms become genuinely manipulable.

Definition 55.2.4: Multiplicative System

A class W of morphisms in a category $\mathcal{C}$ is a *multiplicative system* if



1. W contains every identity and is closed under composition;
2. (Ore condition) for every $f\colon Z \to B$ in $\mathcal{C}$ and every $t\colon V \to B$ in W there are $t'\colon Z' \to Z$ in W and $f'\colon Z' \to V$ in $\mathcal{C}$ with $f \circ t' = t \circ f'$;
3. for every pair $f, g\colon X \to Y$ and every $s\colon Y \to Y'$ in W with $s \circ f = s \circ g$, there is $t\colon X' \to X$ in W with $f \circ t = g \circ t$.

Condition (2) is what lets two roofs be composed, and condition (3) is what makes the resulting notion of equality between roofs transitive. Both are visible in the ring case: for a commutative ring every S is a multiplicative system, and the conditions are the familiar manipulations that put two fractions over a common denominator.

Theorem 55.2.5: Calculus of Fractions

Let W be a multiplicative system in $\mathcal{C}$. Then:

1. every morphism $A \to B$ in $\mathcal{C}[W^{-1}]$ is represented by a *roof*

   with $s \in W$, standing for $Q(f) \circ Q(s)^{-1}$;
2. if two roofs (s, f) and (s', f') are *commonly dominated*, meaning there are $u\colon Z'' \to Z$ and $u'\colon Z'' \to Z'$ with $su = s'u' \in W$ and $fu = f'u'$, then they represent the same morphism;
3. conversely, two roofs representing the same morphism are commonly dominated, so that roofs modulo common domination compute $\mathrm{Hom}_{\mathcal{C}[W^{-1}]}(A, B)$.

***Proof*:**

Step 1: Roofs compose. Given roofs $A \xleftarrow{s} Z \xrightarrow{f} B$ and $B \xleftarrow{t} V \xrightarrow{g} C$, apply the Ore condition to $f\colon Z \to B$ and $t \in W$ to obtain $t'\colon Z' \to Z$ in W and $f'\colon Z' \to V$ with $ft' = tf'$. Then $A \xleftarrow{st'} Z' \xrightarrow{gf'} C$ is a roof, since $st' \in W$ by closure under composition, and in $\mathcal{C}[W^{-1}]$ it represents

$$Q(g)Q(f')Q(t')^{-1}Q(s)^{-1} = Q(g)Q(t)^{-1}Q(f)Q(s)^{-1}$$

the identity following by rearranging $Q(f)Q(t') = Q(t)Q(f')$, both $Q(t)$ and $Q(t')$ being invertible. This is the composite of the two given morphisms.

Step 2: Part (2). Suppose (s, f) and (s', f') are commonly dominated by u, u'. Since $su = s'u'$

lies in W and $Q(s)$ is invertible, $Q(u)$ is invertible too, and then

$$Q(f)Q(s)^{-1} = Q(fu)Q(su)^{-1} = Q(f'u')Q(s'u')^{-1} = Q(f')Q(s')^{-1}$$

so the two roofs represent the same morphism.

Step 3: Common domination is an equivalence relation. Reflexivity and symmetry are immediate. For transitivity, suppose Z_1 dominates (s, f) and (s', f') through u_1, v_1 with $\sigma_1 := su_1 = s'v_1 \in W$, and Z_2 dominates (s', f') and (s'', f'') through u_2, v_2 with $\sigma_2 := s'u_2 = s''v_2 \in W$. Apply the Ore condition to $\sigma_1 \colon Z_1 \to A$ and $\sigma_2 \in W$ to get $t' \colon Z_3 \to Z_1$ in W and $w \colon Z_3 \to Z_2$ with $\sigma_1 t' = \sigma_2 w$. Then

$$s'(v_1 t') = \sigma_1 t' = \sigma_2 w = s'(u_2 w)$$

so condition (3) of definition 55.2.4, applied to the parallel pair v_1t', $u_2w \colon Z_3 \rightrightarrows Z'$ and to $s' \in W$, yields $t \colon Z_4 \to Z_3$ in W with $v_1t't = u_2wt$. The roof with middle leg $\sigma_1 t't \in W$ and legs $u_1t't$ and v_2wt then dominates both (s, f) and (s'', f''): the middle leg lies in W by closure, and the two outer compatibilities follow because $fu_1 = f'v_1$ and $f''v_2 = f'u_2$ both factor through f'.

Step 4: Part (1). Every morphism of $\mathcal{C}[W^{-1}]$ is a zigzag, and it suffices to show every zigzag is equivalent to one of the form backward-then-forward. Assign to a zigzag the number of pairs $i < j$ with link i forward and link j backward. Composing two adjacent links of the same orientation strictly decreases the length and does not increase this number; and given an adjacent pair $Z \xrightarrow{f} B \xleftarrow{t} V$ with $t \in W$, the Ore condition gives $Z \xleftarrow{t'} Z' \xrightarrow{f'} V$ with $t' \in W$ and $ft' = tf'$, which represents the same morphism because $Q(t)^{-1}Q(f) = Q(f')Q(t')^{-1}$, and which strictly decreases the count. The count cannot decrease forever, so the process terminates at a zigzag with no forward link preceding a backward one; composing along each run leaves a single roof.

Step 5: Part (3). What remains is the converse of Step 2. The standard route builds the category whose morphisms are roofs modulo common domination, with composition as in Step 1, and checks that this is well defined on classes, associative and unital, and that it satisfies the universal property of definition 55.2.1; comparing with $\mathcal{C}[W^{-1}]$ through that universal property then forces the two to agree, which is exactly the converse. Those verifications are bookkeeping of the same kind as Steps 1 and 3, carrying no further idea, and they are carried out in full in *An Introduction to Homological Algebra* [101]. This completes the proof.

The construction now applies verbatim to the situation this book treats, and it is recorded as a corollary so that later chapters may cite existence rather than assume it.

Corollary 55.2.6: Existence of the Derived Category

Let $\mathbf{A}$ be an abelian category and let qis denote the class of quasi-isomorphisms in $\mathrm{Ch}(\mathbf{A})$. Then the localization

$$D(\mathbf{A}) := \mathrm{Ch}(\mathbf{A})[\mathrm{qis}^{-1}]$$

exists, and the canonical functor $Q \colon \mathrm{Ch}(\mathbf{A}) \to D(\mathbf{A})$ is universal among functors carrying quasi-isomorphisms to isomorphisms.

***Proof*:**
Apply theorem 55.2.2 with $\mathcal{C} = \mathrm{Ch}(\mathbf{A})$ and $W = \mathrm{qis}$; no hypothesis on W is needed for existence. The universal property is clause (2) of definition 55.2.1.

The construction says nothing about local smallness, and by box 55.2.3 neither remedy applies here, so $D(\mathbf{A})$ is produced only as a possibly non-locally-small category. The route that repairs this, and the one section 57.2 follows, is to localize $K(\mathbf{A})$ in place of $\mathrm{Ch}(\mathbf{A})$, where the quasi-isomorphisms do form a multiplicative system (theorem 57.2.3) and theorem 55.2.5 applies, as we sought to show.

55.2.1 Serre Subcategories and the Quotient

Localizing a category at a class of morphisms is one way to force objects to become isomorphic. There is a second, available when the ambient category is abelian: kill a class of *objects* and keep track of what survives. The result is again abelian, which is what makes it useful, and it is the construction under the localization sequence in K-theory.

Definition 55.2.7: Serre Subcategory

Let $\mathcal{A}$ be an abelian category. A non-empty full subcategory $\mathcal{B} \subseteq \mathcal{A}$ is a *Serre subcategory* if it is closed under subobjects, quotient objects, and extensions: for every short exact sequence

$$0 \to A' \to A \to A'' \to 0$$

in $\mathcal{A}$, the object A lies in $\mathcal{B}$ if and only if both A' and A'' do.

The single biconditional packages all three closure conditions. It is strictly stronger than a two-out-of-three rule: from $A \in \mathcal{B}$ alone it concludes that *both* A' and A'' lie in $\mathcal{B}$, and that direction, which is what gives closure under subobjects and quotients, is the one the proof below leans on most.

Example 55.2.8: Torsion Modules
Let R be a commutative domain. The torsion modules form a Serre subcategory of R-**Mod**: a submodule of a torsion module is torsion, a quotient of one is torsion, and if A' and A'' are torsion in $0 \to A' \to A \to A'' \to 0$ then every $a \in A$ has $ra \in A'$ for some $r \neq 0$ and then $sra = 0$ for some $s \neq 0$, so A is torsion.

By contrast the free R-modules are *not* a Serre subcategory: they are closed under neither quotients (over $R = \mathbb{Z}$, $\mathbb{Z} \twoheadrightarrow \mathbb{Z}/2$) nor subobjects in general.

Theorem 55.2.9: The Quotient Abelian Category

Let $\mathcal{A}$ be a small abelian category and $\mathcal{B} \subseteq \mathcal{A}$ a Serre subcategory. Then there is an abelian category $\mathcal{A}/\mathcal{B}$ and an exact functor $\pi\colon \mathcal{A} \to \mathcal{A}/\mathcal{B}$ with the following properties.

1. $\pi(B) = 0$ for every $B \in \mathcal{B}$, and an object A of $\mathcal{A}$ has $\pi(A) = 0$ if and only if $A \in \mathcal{B}$.
2. π is universal: any exact functor $F\colon \mathcal{A} \to \mathcal{D}$ into an abelian category with $F(B) = 0$ for all $B \in \mathcal{B}$ factors as $F = \bar{F} \circ \pi$ for an exact $\bar{F}\colon \mathcal{A}/\mathcal{B} \to \mathcal{D}$, unique up to natural isomorphism.

The category $\mathcal{A}/\mathcal{B}$ is the *Gabriel quotient* of $\mathcal{A}$ by $\mathcal{B}$.

***Proof*:**
The construction is a localization in the sense of definition 55.2.1, taken at the class

$$W = \{\, f \in \mathcal{A} \;:\; \ker f \in \mathcal{B} \text{ and } \operatorname{coker} f \in \mathcal{B} \,\}$$

of morphisms whose kernel and cokernel are both killed, and $\mathcal{A}/\mathcal{B} := \mathcal{A}[W^{-1}]$ with π the canonical functor. Existence is theorem 55.2.2, which needs no hypothesis on W; smallness of $\mathcal{A}$ is what keeps the result locally small, by box 55.2.3.

That W is a multiplicative system is where the Serre condition is consumed, and each clause of definition 55.2.4 uses it differently, so all three are worth doing.

Identities and composition. Every identity has zero kernel and cokernel, and $0 \in \mathcal{B}$ since $\mathcal{B}$ is non-empty and closed under subobjects. For composition, take $f\colon A \to A'$ and $g\colon A' \to A''$ in W. Two elementary exact fragments suffice, and neither needs the full six-term Ker-Coker sequence, which this book does not have at this point. First, $\ker f \subseteq \ker(gf)$ and f carries $\ker(gf)$ into $\ker g$, giving

$$0 \to \ker f \to \ker(gf) \to \ker g$$

so $\ker(gf)$ is an extension of a subobject of $\ker g$ by $\ker f$. Dually,

$$\operatorname{coker} f \to \operatorname{coker}(gf) \to \operatorname{coker} g \to 0$$

exhibits $\operatorname{coker}(gf)$ as an extension of $\operatorname{coker} g$ by a quotient of $\operatorname{coker} f$. Closure under subobjects, quotients and extensions puts both in $\mathcal{B}$, so $gf \in W$.

The Ore condition. Given $t\colon B \to B'$ in W and $f\colon Z \to B'$, form the pullback of t along f. Its projection $t'\colon B \times_{B'} Z \to Z$ has $\ker t' \cong \ker t$ and $\operatorname{coker} t' \hookrightarrow \operatorname{coker} t$. The first is formal; the second holds because $\operatorname{im} t' = f^{-1}(\operatorname{im} t)$, so $Z/f^{-1}(\operatorname{im} t) \hookrightarrow B'/\operatorname{im} t$, an element argument legitimate here because $\mathcal{A}$ is small and theorem 55.1.15 embeds it exactly-and-fully faithfully in a module category. Hence $\ker t' \in \mathcal{B}$ and, by closure under *subobjects*, $\operatorname{coker} t' \in \mathcal{B}$, so $t' \in W$.

The cancellation condition. Suppose $sf = sg$ for $f, g\colon A \to B$ and $s \in W$. Here it is the additive structure of $\mathcal{A}$ that does the work, and no pullback helps. Set $h = f - g$, so $sh = 0$ and hence $\operatorname{im} h \subseteq \ker s$. Since $\ker s \in \mathcal{B}$, closure under subobjects gives $\operatorname{im} h \in \mathcal{B}$. Let $t\colon K \rightarrowtail A$ be the kernel of $A \twoheadrightarrow \operatorname{im} h$. Then $\ker t = 0$ and $\operatorname{coker} t \cong \operatorname{im} h \in \mathcal{B}$, so $t \in W$, and $ht = 0$ gives $ft = gt$.

For (1), $\pi(B) = 0$ because $B \to 0$ lies in W when $B \in \mathcal{B}$. The converse needs an argument, and it is worth giving the right one, since the tempting route is circular: from $\pi(A) = 0$ one would like to say $A \to 0$ is inverted, hence lies in W, hence has kernel A in $\mathcal{B}$. But "inverted $\Rightarrow$ in

> W" is the statement that W is *saturated*, and definition 55.2.1 gives only the inclusion, not the converse.
>
> Argue from clause (3) of theorem 55.2.5 instead. If $\pi(A) = 0$ then $\mathrm{id}_{\pi(A)} = 0$, so the roofs $(\mathrm{id}_A, \mathrm{id}_A)$ and $(\mathrm{id}_A, 0)$ from A to A represent the same morphism, and clause (3) makes them commonly dominated: there is $t\colon Z \to A$ with $t \in W$ and $\mathrm{id}_A \circ t = 0 \circ t$, that is $t = 0$. A zero map has $\operatorname{coker} t = A$, and $t \in W$ puts that cokernel in $\mathcal{B}$. Hence $A \in \mathcal{B}$. Exactness of π and the abelian structure on $\mathcal{A}/\mathcal{B}$ are transported along the calculus of fractions, kernels and cokernels being computed by representative fractions. Clause (2) is clause (2) of definition 55.2.1 together with the observation that an exact F killing $\mathcal{B}$ inverts every element of W: exactness gives $\ker F(f) = F(\ker f) = 0$ and $\operatorname{coker} F(f) = F(\operatorname{coker} f) = 0$, and a map both monic and epic in an abelian category is an isomorphism. That produces a functor $\bar{F}$ with $\bar{F}\pi = F$. That $\bar{F}$ is moreover *exact* then follows in two lines, granting that kernels and cokernels in $\mathcal{A}/\mathcal{B}$ are computed as π-images of those in $\mathcal{A}$: every morphism of $\mathcal{A}/\mathcal{B}$ is $\pi(f)$ composed with an isomorphism, so it is enough to check on π-images, where $\bar{F}(\ker \pi f) = \bar{F}\pi(\ker f) = F(\ker f) = \ker F(f)$. That the transported kernels and cokernels are indeed computed this way is part of the verification recorded as omitted below.
>
> What is omitted is the routine verification that the transported kernels and cokernels satisfy the abelian axioms, which is a diagram chase on representative fractions with no new idea in it. The construction is Gabriel's, as we sought to show.

The quotient is the categorical analogue of localizing a ring: for R commutative and $S \subseteq R$ multiplicative, $S^{-1}R$**-mod** is the quotient of R**-mod** by the S-torsion modules. That example is the one to keep in mind, and it is the case that appears in the localization sequence of algebraic K-theory.

56

Complexes and (co)Homology

Let **A** be a fixed abelian category, which by theorem 55.1.15 may without loss of generality it can be considered ${}_R\text{Mod}$. In this chapter, we shall focus on studying (co)chains of such modules, that is sequence of modules that respect equation (54.1):

$$\text{im}(d^n) \subseteq \ker(d^{n+1})$$

The collection of all chains shall be denoted $\text{Ch}(\mathbf{A})$. We shall see that $\text{Ch}(\mathbf{A})$ is an abelian category, the notion of extensions (and snakes lemma) is well defined, which will be explored. In the right categories, it is relatively easy to construct a concrete complex given the category has enough objects, for example $M \in \text{Obj}(R\text{-}\mathbf{Mod})$ always has a complex known as a *free resolution* (see definition 12.3.27). There will be many different ways of creating complexes given an object, giving us different types of resolutions. We shall see that when a category has enough projective objects (resp. Injective objects), then "up to homotopy equivalence", projective resolutions shall be *initial* (resp. final) in the category of complexes $\text{Ch}(A)$. Thus, we shall take the time to develop the homology theory in categories with enough projective or injective objects. We shall see that under appropriate circumstances, taking (co)homology of a projective resolution of an object can give us some important information about said object.

Homology and cohomology are duals of each other, which means on the theoretical level they are the same. As cohomology is the more computationally useful tool, we shall be focusing on cohomology on this chapter, with the idea that the reader shall be comfortable being able to switch indices when necessary. Taking the cohomology of a complex shall be shown to be an additive functorial process, meaning for a given morphism of complexes $\alpha^\bullet : A^\bullet \to B^\bullet$, we shall get a morphism each cohomology $H^i(\alpha) : H^i(A^\bullet) \to H^i(B^\bullet)$ which will be shown can be to form a new complex $H^\bullet(\alpha) : H^\bullet(A^\bullet) \to H^\bullet(B^\bullet)$.

The goal of this chapter is to show how to extract information given a complexes (co)homology. Given this, it is important to know what information a morphism of complexes preserves in cohomology, that is given a morphism of complexes, $\alpha^\bullet : A^\bullet \to B^\bullet$, when is $H^\bullet(\alpha) : H^\bullet(A^\bullet) \to H^\bullet(B^\bullet)$ an

isomorphism? This shall lead us to the notion of *quasi-isomorphisms*, and their "representation" through mapping cones. As it turns out, quasi-isomorphisms do not behave nicely in general. What we shall then seek out is a stricter concept known as a *homotopy equivalence* that will still be a quasi-isomorphism, but will be invertible in the appropriate category.

56.1 Basic Definition and Properties

Starting with defining the generalization of an exact sequence:

Definition 56.1.1: Chain Complex

A *chain complex* $(C_\bullet, d_\bullet)$ is a sequence of objects and morphisms:

$$\cdots \xleftarrow{d_i} M_i \xleftarrow{d_{i+1}} M_{i+1} \xleftarrow{d_{i+2}} \cdots$$

with the indices running through $\mathbb{Z}$, such that

$$d_i \circ d_{i+1} = 0$$

and each d_i is called a *boundary map*. Similarly, a *cochain complex* $(C^\bullet, d^\bullet)$ is a sequence of objects

$$\cdots \xrightarrow{d^{i-1}} M^i \xrightarrow{d^i} M^{i+1} \xrightarrow{d^{i+1}} \cdots$$

with the indices running through $\mathbb{Z}$, such that

$$d^i \circ d^{i-1} = 0$$

where $d^\bullet$ is called the *differential*[a].

[a] Due to it's origin's in differential geometry and algebraic topology

Chains and cochains can be interchanged by taking

$$M_i = M^{-i}$$

Working with one or the other makes essentially no difference for homological algebra. In certain cases, some structures present themselves more in the cohomological case (ex. a natural ring structure called the *cohomology ring* shall become important to us), and so we opt to work with the cohomology, even though at this stage this can be considered to be an arbitrary choice. The condition that $d^i \circ d^{i-1} = 0$ is the same as $\mathrm{im} d^{i-1} \subseteq \ker d^i$. If the complex is exact, then $\mathrm{im} d^{i-1} = \ker d^i$ for all i. We also often write $C^\bullet$ instead of $(C^\bullet, d^\bullet)$ if the mappings $d^\bullet$ are clear from context or implied. In some textbooks, even the bullet is dropped and M represents the complex. Sometime, for homology, the notation $\partial_\bullet$ shall be used instead of $d_\bullet$ due to it's connection to being the boundary map for topological spaces when creating complexes out of topological spaces[1].The condition that $d^i \circ d^{i-1} = 0$ (resp. $d_i \circ d_{i+1} = 0$) is often abbreviated to $d \circ d = 0$.

Due to historical origins in algebraic topology, the kernel and image of the differential

[1] Similarly, $d^\bullet$ stands for the *differential* due to it's link to the derivative, which would be explored in a class in algebraic topology, or see EYNTKA Algebraic Topology

Definition 56.1.2: Cycles and Boundaries

Let $C_\bullet$ (resp. $C^\bullet$) be a chain complex (resp. cochain complex). Then:

1. $\ker(d_n)$ is called the *n-cycles* of $C_\bullet$ and $\operatorname{im}(d_{n+1})$ is called the n-boundary of $C_\bullet$. The n-cycle is represented as $Z_n = Z_n(C_\bullet)$ and the *n-boundary* is represented as $B_n = B_n(C_\bullet)$
2. $\ker(d^n)$ is called the *n-cocycles* of $C^\bullet$ and $\operatorname{im}(d^{n-1})$ is called the *n-coboundary* of $C^\bullet$. The n-cocycle is represented as $Z^n = Z^n(C^\bullet)$ and the n-coboundary is represented as $B^n = B^n(C^\bullet)$

The name cycles and boundaries has its origin in algebraic topology:

Example 56.1.3: Cycles and Boundaries

Let T be the boundary of a triangle, with vertices v_0, v_1, v_2 and oriented edges $e_{01} = [v_0, v_1]$, $e_{12} = [v_1, v_2]$ and $e_{20} = [v_2, v_0]$. Its simplicial chain complex has $C_1 = \mathbb{Z}e_{01} \oplus \mathbb{Z}e_{12} \oplus \mathbb{Z}e_{20}$, $C_0 = \mathbb{Z}v_0 \oplus \mathbb{Z}v_1 \oplus \mathbb{Z}v_2$ and $C_n = 0$ otherwise, with $d_1[v_i, v_j] = v_j - v_i$. Since $d_1(ae_{01} + be_{12} + ce_{20}) = (c-a)v_0 + (a-b)v_1 + (b-c)v_2$, the 1-cycles are the multiples of $z = e_{01} + e_{12} + e_{20}$, the chain that runs once around the triangle. As $C_2 = 0$, the only 1-boundary is 0, so z is a cycle that is not a boundary, and $Z_1/B_1 \cong \mathbb{Z}$ detects the hole enclosed by T.

The collection of all complexes forms a Category:

Definition 56.1.4: Category Of Complexes

Let $\mathbf{A}$ be an abelian category. Then $\mathrm{Ch}^\bullet(\mathbf{A})$ is a new category called the *category of complexes of A* where

1. $\mathrm{Obj}(\mathrm{Ch}^\bullet(\mathbf{A})) = \{\text{cochain complexes in } \mathbf{A}\}$
2. For two complexes $C^\bullet$ and $N^\bullet$, a morphism $\alpha^\bullet \in \mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(C^\bullet, N^\bullet)$ consists of morphisms such that the following diagram commute:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & M^{i-1} & \xrightarrow{d^{i-1}_{C^\bullet}} & M^i & \xrightarrow{d^i_{C^\bullet}} & M^{i+1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle \alpha^{i-1}} & & \downarrow{\scriptstyle \alpha^{i-1}} & & \downarrow{\scriptstyle \alpha^{i-1}} & & \\
\cdots & \longrightarrow & N^{i-1} & \xrightarrow{d^{i-1}_{N^\bullet}} & N^i & \xrightarrow{d^i_{N^\bullet}} & N^{i+1} & \longrightarrow & \cdots
\end{array}$$

Similarly for $\mathrm{Ch}_\bullet(\mathbf{A})$ with chain complexes.

If unambiguous, the bullet is dropped giving $\mathrm{Ch}(\mathbf{A})$. It should be checked that $\mathrm{Ch}(A)$ is indeed a category. There are many variations of $\mathrm{Ch}(A)$ which will be important:

1. $C^+(A)$ is the full subcategory of $\mathrm{Ch}(A)$ of complexes which are bounded from bellow, so that $L^i = 0$ for $i \ll 0$
2. $C^-(A)$ is the full subcategory of $\mathrm{Ch}(A)$ of complexes which are bounded from above, so that $L^i = 0$ for $i \gg 0$
3. $C^{\geq 0}(A)$ (resp. $C^{\leq 0}$) for which $L^i = 0$ for $i \leq 0$ (resp. $i \geq 0$)

4. P, I are full subcategories of A consisting of projective and injective objects in A respectively, and hence we have $\mathrm{Ch}(P)$, $\mathrm{Ch}(I)$, and all its variants

There are also a few simple functors we may immediately define:

1. Take $\iota_r : \mathbf{A} \to \mathrm{Ch}(\mathbf{A})$ that sends an object A form $\mathbf{A}$ to a complex that is zero every and A in the rth degree. We shall commonly identify A with the complex given by ι_0.
2. Take $s_r : \mathrm{Ch}(\mathbf{A}) \to \mathrm{Ch}(\mathbf{A})$ which shifts over the complex, namely
$$C^\bullet \mapsto M[r]^\bullet$$
where $M[r]^i = M^{i+r}$ and $d^i_{M[r]^\bullet} = (-1)^r d^{i+r}_{C^\bullet}$ (the $(-1)^r$ shall be explained shortly).
3. the canonical truncations $\tau^{\leq n}$ and $\tau^{\geq n}$, defined in definition 56.1.12 once cohomology is available.

More importantly, $\mathrm{Ch}(A)$ is an abelian category, allowing the notion of exactness between complexes to be well-defined:

Lemma 56.1.5: Complex Category Is Abelian

Let A be an abelian category and $\mathrm{Ch}(A)$ the category of complexes of A. Then $\mathrm{Ch}(A)$ is an abelian category, in which kernels and cokernels are computed degreewise. In particular, a sequence of complexes is exact if and only if it is exact in each degree.

***Proof*:**
Write $d^n_C \colon C^n \to C^{n+1}$ for the differentials of a complex $C^\bullet$. Every condition below is checked in each degree n.

Step 1: $\mathrm{Ch}(A)$ *is additive (definition 55.1.1).* For chain maps $\alpha, \beta \colon C^\bullet \to D^\bullet$ put $(\alpha+\beta)^n = \alpha^n + \beta^n$. By bilinearity of composition in A,
$$d^n_D(\alpha^n + \beta^n) = \alpha^{n+1} d^n_C + \beta^{n+1} d^n_C = (\alpha^{n+1} + \beta^{n+1}) d^n_C$$
so $\alpha+\beta$ is a chain map, and the same computation shows that $-\alpha$ and the zero family are chain maps. The group axioms hold in each degree, so $\mathrm{Hom}_{\mathrm{Ch}(A)}(C^\bullet, D^\bullet)$ is an abelian group, and composition, which is computed degreewise, is bilinear because composition in A is. The complex $0^\bullet$ with a zero object in every degree is a zero object of $\mathrm{Ch}(A)$, since the unique morphisms $0 \to C^n$ and $C^n \to 0$ commute with all differentials (every composite through 0 is zero).

For complexes $C^\bullet$ and $D^\bullet$, let $P^n = C^n \times D^n$ with projections p_C, p_D, and let i_C, i_D be the morphisms into P^n with $p_C i_C = \mathrm{id}$, $p_D i_C = 0$, $p_C i_D = 0$ and $p_D i_D = \mathrm{id}$ (the degree is dropped from this notation). Then $i_C p_C + i_D p_D = \mathrm{id}_{P^n}$, since both sides have the same composites with p_C and with p_D. Put $d^n_P = i_C d^n_C p_C + i_D d^n_D p_D$. These identities give
$$d^{n+1}_P d^n_P = i_C d^{n+1}_C d^n_C p_C + i_D d^{n+1}_D d^n_D p_D = 0 \qquad p_C d^n_P = d^n_C p_C \qquad d^n_P i_C = i_C d^n_C$$
and the same identities with D in place of C, so $P^\bullet$ is a complex and p_C, p_D, i_C, i_D are chain maps satisfying the same identities in $\mathrm{Ch}(A)$. If $\alpha \colon T^\bullet \to C^\bullet$ and $\beta \colon T^\bullet \to D^\bullet$ are chain

maps, then $\gamma = i_C\alpha + i_D\beta$ is a chain map with $p_C\gamma = \alpha$ and $p_D\gamma = \beta$, and any γ' with these two properties equals $(i_Cp_C + i_Dp_D)\gamma' = i_C\alpha + i_D\beta$. So $P^\bullet$ is a product of $C^\bullet$ and $D^\bullet$. If $\alpha\colon C^\bullet \to T^\bullet$ and $\beta\colon D^\bullet \to T^\bullet$ are chain maps, then $h = \alpha p_C + \beta p_D$ satisfies $hi_C = \alpha$ and $hi_D = \beta$, and any h' with these two properties equals $h'(i_Cp_C + i_Dp_D) = \alpha p_C + \beta p_D$. So $P^\bullet$ is also a coproduct. Iterating gives all finite products and coproducts, the empty ones being $0^\bullet$, so $\mathrm{Ch}(A)$ is additive.

Step 2: kernels and cokernels, degreewise. Let $f\colon C^\bullet \to D^\bullet$ be a chain map, and suppose $j\colon J^\bullet \to C^\bullet$ is a chain map such that each j^n is a kernel of f^n. Then $fj = 0$. If $g\colon T^\bullet \to C^\bullet$ is a chain map with $fg = 0$, then each $g^n = j^nu^n$ for a unique u^n, and

$$j^{n+1}d_J^nu^n = d_C^nj^nu^n = d_C^ng^n = g^{n+1}d_T^n = j^{n+1}u^{n+1}d_T^n$$

so $d_J^nu^n = u^{n+1}d_T^n$, because j^{n+1} is a monomorphism (lemma 55.1.3). Thus u is the unique chain map with $ju = g$, and j is a kernel of f in $\mathrm{Ch}(A)$. Such a j exists: choose kernels $j^n\colon J^n \to C^n$ of the f^n in A (definition 55.1.6). As $f^{n+1}d_C^nj^n = d_D^nf^nj^n = 0$, there is a unique d_J^n with $j^{n+1}d_J^n = d_C^nj^n$, and $j^{n+2}d_J^{n+1}d_J^n = d_C^{n+1}d_C^nj^n = 0$ gives $d_J^{n+1}d_J^n = 0$, again because j^{n+2} is monic. Kernels are unique up to isomorphism, so every kernel of f in $\mathrm{Ch}(A)$ is a kernel of f^n in each degree.

If $q\colon D^\bullet \to Q^\bullet$ is a chain map such that each q^n is a cokernel of f^n, and $g\colon D^\bullet \to T^\bullet$ is a chain map with $gf = 0$, then each $g^n = v^nq^n$ for a unique v^n, and

$$d_T^nv^nq^n = d_T^ng^n = g^{n+1}d_D^n = v^{n+1}q^{n+1}d_D^n = v^{n+1}d_Q^nq^n$$

gives $d_T^nv^n = v^{n+1}d_Q^n$, because q^n is an epimorphism (lemma 55.1.3). So q is a cokernel of f in $\mathrm{Ch}(A)$. Such a q exists: choose cokernels q^n of the f^n. As $q^{n+1}d_D^nf^n = q^{n+1}f^{n+1}d_C^n = 0$, there is a unique d_Q^n with $d_Q^nq^n = q^{n+1}d_D^n$, and $d_Q^{n+1}d_Q^nq^n = q^{n+2}d_D^{n+1}d_D^n = 0$ gives $d_Q^{n+1}d_Q^n = 0$. As for kernels, every cokernel of f in $\mathrm{Ch}(A)$ is a cokernel of f^n in each degree.

Step 3: monomorphisms and epimorphisms are degreewise. If each f^n is a monomorphism, so is f: from $fg = fh$ we get $f^ng^n = f^nh^n$, hence $g^n = h^n$, for every n. Conversely, let f be a monomorphism of $\mathrm{Ch}(A)$ with kernel j as in Step 2. From $fj = 0 = f \circ 0$ we get $j = 0$, so each $j^n = 0$, and since j^n is a monomorphism, $j^n \circ \mathrm{id}_{J^n} = 0 = j^n \circ 0$ gives $\mathrm{id}_{J^n} = 0$. So J^n is a zero object, $0 \to C^n$ is a kernel of f^n, and f^n is a monomorphism by lemma 55.1.4(1). If each f^n is an epimorphism, then $gf = hf$ gives $g^n = h^n$ for every n, so f is an epimorphism. Conversely, if f is an epimorphism of $\mathrm{Ch}(A)$ with cokernel q as in Step 2, then $qf = 0 = 0 \circ f$ gives $q = 0$, and $\mathrm{id}_{Q^n} \circ q^n = 0 = 0 \circ q^n$ with q^n an epimorphism gives $\mathrm{id}_{Q^n} = 0$. So $D^n \to 0$ is a cokernel of f^n, and f^n is an epimorphism by lemma 55.1.4(2).

Step 4: condition (2) of definition 55.1.6. Let $f\colon C^\bullet \to D^\bullet$ be a monomorphism of $\mathrm{Ch}(A)$ and q a cokernel of f as in Step 2. By Step 3 each f^n is a monomorphism, hence the kernel of some morphism by condition (2) of definition 55.1.6 in A, hence a kernel of its own cokernel q^n by lemma 55.1.7. As f is a chain map, Step 2 applied to q shows that f is a kernel of q in $\mathrm{Ch}(A)$. If instead f is an epimorphism of $\mathrm{Ch}(A)$ and j is a kernel of f as in Step 2, then each f^n is an epimorphism by Step 3, hence a cokernel of its own kernel j^n by condition (2) of definition 55.1.6 and lemma 55.1.7, and Step 2 applied to j shows that f is a cokernel of j. Together with Steps 1 and 2, this verifies definition 55.1.6 for $\mathrm{Ch}(A)$.

Step 5: exactness. By definition 55.1.13, a sequence $C^\bullet \xrightarrow{\varphi} D^\bullet \xrightarrow{\psi} E^\bullet$ is exact at $D^\bullet$ when $\psi\varphi = 0$ and $\operatorname{coker}\varphi \circ \ker\psi = 0$. By Step 2, $\ker\psi$ and $\operatorname{coker}\varphi$ may be taken with components $\ker\psi^n$ and $\operatorname{coker}\varphi^n$, and a chain map is zero exactly when all its components are, so both conditions hold in $\mathrm{Ch}(A)$ exactly when they hold for $C^n \to D^n \to E^n$ for every n. Hence a sequence of complexes is exact if and only if it is exact in each degree, completing the proof.

Since it is an abelian category, we shall be able to consider sequences of complexes, and in particular exact sequences of complexes:

$$\cdots \to L^\bullet \to C^\bullet \to N^\bullet \to \cdots$$

which give a commutative diagram like so:

$$\begin{array}{ccccccccc}
 & & 0 & & 0 & & 0 & & 0 & & \\
 & & \downarrow & & \downarrow & & \downarrow & & \downarrow & & \\
\cdots & \longrightarrow & A_{n+2} & \longrightarrow & A_{n+1} & \longrightarrow & A_n & \longrightarrow & A_{n-1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle \iota} & & \downarrow{\scriptstyle \iota} & & \downarrow{\scriptstyle \iota} & & \downarrow{\scriptstyle \iota} & & \\
\cdots & \longrightarrow & B_{n+2} & \longrightarrow & B_{n+1} & \longrightarrow & B_n & \longrightarrow & B_{n-1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle \pi} & & \downarrow{\scriptstyle \pi} & & \downarrow{\scriptstyle \pi} & & \downarrow{\scriptstyle \pi} & & \\
\cdots & \longrightarrow & C_{n+2} & \longrightarrow & C_{n+1} & \longrightarrow & C_n & \longrightarrow & C_{n-1} & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow & & \downarrow & & \\
 & & 0 & & 0 & & 0 & & 0 & &
\end{array} \tag{56.1}$$

Example 56.1.6: Complexes

1. Given any object M, we may always create the trivial complex
$$\cdots 0 \to 0 \to M \to 0 \to 0 \to \cdots$$
Verify that this is indeed a complex.
2. As mentioned, In R-**Mod**, the free resolution is an example of a complex.
3. Any short exact sequence can be thought of an (exact) complex if we add 0's that extend arbitrarily to the left and right.
4. Let $C^n = \mathbb{Z}/8\mathbb{Z}$ for $n \geq 0$ and $C^n = 0$ for $n < 0$. Let each d^n be defined as:
$$\overline{x} \mapsto \overline{4x}$$
Show that this is a cochain complex.
5. Let $\{V_i, W_i\}_{i\in\mathbb{Z}}$ be a collection of vector spaces. Define:
$$A_n = V_n \oplus W_n \oplus V_{n-1}$$
Combining the projection and inclusion maps $A_n \to V_{n-1} \to A_{n-1}$, show that $A_\bullet$ forms a chain complex.
6. Let $C^\bullet$ be a cochain complex, choose an object $A \in \mathbf{A}$, and apply $\mathrm{Hom}_A(-, A)$ to each object. Show that this is a cochain complex.

Since Ch($\mathbf{A}$) is an abelian category, kernels and cokernels exist and match with monomorphisms/epimorphisms, hence giving us the following:

Definition 56.1.7: Sub-complexes And Quotient Complexes

Let $C^\bullet$ be a (co)chain complex. Then a (co)chain complex $N^\bullet$ is called a *subcomplex* if each N_n is a sub-object of C_n and the differential on B_n is the restriction of the differential in C_n (categorically, the inclusion map $\iota : N^\bullet \to C^\bullet$ is a morphism of complexes).

Furthermore, C^n/B^n is a *quotient-complex*. Furthermore, by the canonical decomposition of morphisms in abelian categories, for any complex-morphism $\alpha^\bullet$, $\{\ker(\alpha^\bullet)\}$ and $\{\text{coker}(\alpha^\bullet)\}$ is a sub-complex and quotient complex respectively.

56.1.1 Homology and Cohomology

Chain complexes need not be exact. The cohomology of a complex measures how far away a complex is from being exact, that is how far away a complex is form representing a sequence of extensions

Definition 56.1.8: Homology and Cohomology Of A Complex

Let $(C^\bullet, d^\bullet)$ be a complex. Then the ith homology and cohomology of the complex at M^i is, respectively:

$$H_i(C^\bullet) = \frac{\ker d_i}{\text{im} d_{i+1}} \qquad H^i(C^\bullet) := \frac{\ker d^i}{\text{im} d^{i-1}}$$

Though homology and cohomology are similar, it is not necessarily the case that $H^i(C^\bullet) = H_{n-i}(C^\bullet)$ for some appropriate n around which the chain can "pivot". We shall see such examples soon, and later also show under what conditions we may compare homology and cohomology[2]

Example 56.1.9: Cohomology Of Complex

Let's compute the cohomology of sequences in example 56.1.6.

1. The homology and cohomology at the 0th entry is:
$$\frac{\ker(d_0)}{\text{im}(d_1)} = \frac{\ker(d^0)}{\text{im}(d^{-1})} = M$$
which shows that at this position, the chain is "off" by M in being exact.
2. A free resolution $\cdots \to F_1 \to F_0 \to M \to 0$, with M kept as the last term, is exact, meaning $\text{im}(d^{i-1}) = \ker(d^i)$ in every degree, so its homology and cohomology vanish. With M removed the complex $\cdots \to F_1 \to F_0 \to 0$ has homology M in degree 0 and 0 elsewhere.
3. Any exact sequence has trivial homology and cohomology
4. This complex is not exact. Since d^n is multiplication by 4 on $\mathbb{Z}/8\mathbb{Z}$, its kernel is $\{\overline{0}, \overline{2}, \overline{4}, \overline{6}\}$ and its image is $\{\overline{0}, \overline{4}\}$. So $H^0 = \ker d^0 \cong \mathbb{Z}/4\mathbb{Z}$, and $H^n \cong \mathbb{Z}/2\mathbb{Z}$ for every $n \geq 1$.

[2]The universal coefficient theorem and Poincaré duality being two famous examples the reader may have heard of if they took algebraic topology

5. The reader should calculate this cohomology as an exercise
6. This cohomology shall be calculated later in this chapter.

Lemma 56.1.10: Cohomology Functor

For every $i \in \mathbb{Z}$, there exists a functor:

$$H^i : \mathrm{Ch}(A) \to A \qquad C^\bullet \mapsto H^i(C^\bullet)$$

which is additive and covariant.

This shows that taking cohomology is indeed a way of analyzing resolutions, for it preserves enough of the structures of modules and complexes. Notice it is not necessarily an exact functor, hence it will not in general preserve extensions.

***Proof*:**
We compute with elements, as theorem 55.1.15 permits when applied to a small abelian subcategory containing the objects involved. Let $\alpha\colon C^\bullet \to N^\bullet$ be a chain map, so that $d^i_N\alpha^i = \alpha^{i+1}d^i_C$ for every i. If $z \in \ker d^i_C$, then $d^i_N(\alpha^i(z)) = \alpha^{i+1}(d^i_C(z)) = 0$, so α^i maps $\ker d^i_C$ into $\ker d^i_N$. If $z = d^{i-1}_C(w)$, then $\alpha^i(z) = d^{i-1}_N(\alpha^{i-1}(w))$, so α^i maps $\mathrm{im}d^{i-1}_C$ into $\mathrm{im}d^{i-1}_N$. Hence

$$H^i(\alpha)\colon H^i(C^\bullet) \to H^i(N^\bullet) \qquad z + \mathrm{im}d^{i-1}_C \mapsto \alpha^i(z) + \mathrm{im}d^{i-1}_N$$

is a well-defined homomorphism of the quotients of definition 56.1.8. The formula gives $H^i(\mathrm{id}_{C^\bullet}) = \mathrm{id}$ and, since $(\beta\circ\alpha)^i = \beta^i\circ\alpha^i$, also $H^i(\beta\circ\alpha) = H^i(\beta)\circ H^i(\alpha)$, so H^i is a covariant functor. It is additive because $(\alpha+\alpha')^i(z) = \alpha^i(z) + \alpha'^i(z)$ gives $H^i(\alpha+\alpha') = H^i(\alpha) + H^i(\alpha')$, as claimed.

Notice that each H^i takes d^i to the zero map. Hence, we may consider the following functor:

$$H^\bullet : \mathrm{Ch}(\mathbf{A}) \to \mathrm{Ch}(\mathbf{A})$$

by taking $H^i(C^\bullet)$ for each i and connecting them by the zero-morphism. This is the cohomology of this complex then equals that of $C^\bullet$, namely:

$$H^\bullet(H^\bullet(C^\bullet)) = H^\bullet(C^\bullet)$$

Lemma 56.1.11: Cohomology And Products

Let $\{A^\bullet_\alpha\}$ be a collection of complexes in $\mathbf{A}$, and suppose the coproduct (respectively the product) indexed by α exists and is an exact functor. Then

$$H^n\Big(\bigoplus_\alpha A^\bullet_\alpha\Big) = \bigoplus_\alpha H^n(A^\bullet_\alpha) \qquad H^n\Big(\prod_\alpha A^\bullet_\alpha\Big) = \prod_\alpha H^n(A^\bullet_\alpha)$$

The exactness hypothesis is automatic for *finite* index sets, where the two agree by lemma 55.1.5, and it holds for arbitrary index sets in R-Mod.

***Proof*:**
Treat the coproduct; the product is the same argument in the opposite category. The complex $\bigoplus_\alpha A_\alpha^\bullet$ has n-th term $\bigoplus_\alpha A_\alpha^n$ and differential $\bigoplus_\alpha d_\alpha^n$.

An exact functor preserves kernels and images, so

$$\ker\Big(\bigoplus_\alpha d_\alpha^n\Big) = \bigoplus_\alpha \ker d_\alpha^n, \qquad \operatorname{im}\Big(\bigoplus_\alpha d_\alpha^{n-1}\Big) = \bigoplus_\alpha \operatorname{im} d_\alpha^{n-1}$$

and it preserves the quotient of the second by the first, being exact. Hence

$$H^n\Big(\bigoplus_\alpha A_\alpha^\bullet\Big) = \frac{\bigoplus_\alpha \ker d_\alpha^n}{\bigoplus_\alpha \operatorname{im} d_\alpha^{n-1}} = \bigoplus_\alpha \frac{\ker d_\alpha^n}{\operatorname{im} d_\alpha^{n-1}} = \bigoplus_\alpha H^n(A_\alpha^\bullet)$$

For a finite index set the coproduct is a finite biproduct, which every additive functor preserves, so no hypothesis is needed; in R-Mod both $\bigoplus$ and $\prod$ are exact and kernels and images are computed componentwise, giving the statement for arbitrary index sets. This completes the proof.

A complex can be cut off at a degree n so as to keep exactly its cohomology in degrees at most n, or exactly its cohomology in degrees at least n.

Definition 56.1.12: Canonical Truncation

Let $X \in \mathrm{Ch}(\mathbf{A})$ and $n \in \mathbb{Z}$, and write $Z^n = \ker d^n$ and $B^n = \operatorname{im} d^{n-1}$ as in definition 56.1.2. The *canonical truncations* of X at n are the complexes

$$\begin{aligned} \tau^{\le n}X: &\quad \cdots \to X^{n-2} \to X^{n-1} \to Z^n \to 0 \to \cdots \\ \tau^{\ge n}X: &\quad \cdots \to 0 \to X^n/B^n \to X^{n+1} \to X^{n+2} \to \cdots \end{aligned}$$

with Z^n and X^n/B^n in degree n. The map $X^{n-1} \to Z^n$ is d^{n-1}, which lands in Z^n because $d^n d^{n-1} = 0$, and $X^n/B^n \to X^{n+1}$ is induced by d^n, which vanishes on B^n. All other differentials are those of X. The inclusion $Z^n \to X^n$ together with identities in degrees below n is a chain map $i_n : \tau^{\le n}X \to X$, and the quotient $X^n \to X^n/B^n$ together with identities in degrees above n is a chain map $p_n : X \to \tau^{\ge n}X$.

Both squares at degree n commute: d^n vanishes on Z^n, and the quotient map kills $\operatorname{im} d^{n-1} = B^n$. A chain map $f : X \to Y$ carries $Z^n(X)$ into $Z^n(Y)$ and $B^n(X)$ into $B^n(Y)$, so it induces chain maps $\tau^{\le n}f$ and $\tau^{\ge n}f$. This makes $\tau^{\le n}$ and $\tau^{\ge n}$ functors $\mathrm{Ch}(\mathbf{A}) \to \mathrm{Ch}(\mathbf{A})$, with i_n and p_n natural.

Example 56.1.13: Truncating a Resolution of $\mathbb{Z}/2$

Let X be the complex $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ in degrees -1 and 0. Then $Z^{-1} = \ker(2) = 0$, so $\tau^{\le -1}X = 0$. Also $B^0 = 2\mathbb{Z}$, so $\tau^{\ge 0}X$ is $\mathbb{Z}/2\mathbb{Z}$ in degree 0, and $p_0 : X \to \tau^{\ge 0}X$ is the reduction map $\mathbb{Z} \to \mathbb{Z}/2\mathbb{Z}$ in degree 0. Since $B^{-1} = 0$ and $Z^0 = X^0$, both $\tau^{\ge -1}X$ and $\tau^{\le 0}X$ equal X.

Proposition 56.1.14: Cohomology of the Canonical Truncations

Let $X \in \mathrm{Ch}(\mathbf{A})$ and $n \in \mathbb{Z}$. Then $H^i(i_n)\colon H^i(\tau^{\leq n}X) \to H^i(X)$ is an isomorphism for $i \leq n$, and $H^i(\tau^{\leq n}X) = 0$ for $i > n$. Likewise $H^i(p_n)\colon H^i(X) \to H^i(\tau^{\geq n}X)$ is an isomorphism for $i \geq n$, and $H^i(\tau^{\geq n}X) = 0$ for $i < n$. In particular i_n induces an isomorphism on every H^i when $H^i(X) = 0$ for all $i > n$, and p_n does when $H^i(X) = 0$ for all $i < n$.

***Proof*:**
We compute with elements, as theorem 55.1.15 permits.

Step 1: $\tau^{\leq n}X$. For $i \leq n-2$ the complexes $\tau^{\leq n}X$ and X agree in degrees $i-1$, i and $i+1$, and i_n is the identity there. For $i = n-1$ the kernel of $X^{n-1} \to Z^n$ equals the kernel of d^{n-1}, because $Z^n \to X^n$ is a monomorphism, and the image from degree $n-2$ is unchanged, so $H^{n-1}(i_n)$ is the identity of $H^{n-1}(X)$. In degree n the kernel of $Z^n \to 0$ is Z^n and the image of $X^{n-1} \to Z^n$ is B^n, so $H^n(\tau^{\leq n}X) = Z^n/B^n = H^n(X)$, and $H^n(i_n)$, induced by the inclusion $Z^n \to X^n$, is the identity of Z^n/B^n. Above degree n the complex $\tau^{\leq n}X$ is zero.

Step 2: $\tau^{\geq n}X$. For $i \geq n+2$ the two complexes agree in degrees $i-1$, i, $i+1$. For $i = n+1$ the kernel of d^{n+1} is unchanged, and the image of $X^n/B^n \to X^{n+1}$ equals the image of d^n, because $X^n \to X^n/B^n$ is an epimorphism. In degree n the induced map sends $x + B^n$ to $d^n x$, so its kernel is Z^n/B^n, and nothing maps into degree n. So $H^n(\tau^{\geq n}X) = Z^n/B^n = H^n(X)$, and $H^n(p_n)$ is the identity of Z^n/B^n. Below degree n the complex $\tau^{\geq n}X$ is zero. The last sentence of the statement follows from the two descriptions, completing the proof.

Now, given a morphism of complexes $\alpha^\bullet : C^\bullet \to N^\bullet$, we may ask what (co)homological information such a morphism preserves. In other words, given a morphism $\alpha^\bullet$, when is $H^\bullet(\alpha^\bullet)$ an isomorphism? We give such morphisms a name:

Definition 56.1.15: Quasi-Isomorphism

Let $\alpha^\bullet : C^\bullet \to N^\bullet$ be a morphism of complexes. Then if $H^\bullet(\alpha^\bullet) : H^\bullet(C^\bullet) \to H^\bullet(N^\bullet)$ is an isomorphism, $\alpha^\bullet$ is called a *quasi-isomorphism*

One may wonder if the fact that the (co)homology is isomorphism is strong enough of a condition for the chains to be isomorphic. This turns out to be rather far from the case:

Example 56.1.16: Quasi-Isomorphism

1. The following counter example shall come up with many different minor variations, and so the reader should keep this in mind. Take the following morphism of complexes:

$$\begin{array}{ccccccccccc}
\cdots & \longrightarrow & 0 & \longrightarrow & \mathbb{Z} & \xrightarrow{\cdot 2} & \mathbb{Z} & \longrightarrow & 0 & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow{\scriptstyle \pi} & & \downarrow & & \\
\cdots & \longrightarrow & 0 & \longrightarrow & 0 & \longrightarrow & \mathbb{Z}/2\mathbb{Z} & \longrightarrow & 0 & \longrightarrow & \cdots
\end{array}$$

   This is a quasi-isomorphism, as the reader should check, however it does not have an inverse.

More generally, it is not even an equivalence relation, failing to be symmetric (show there is no morphism the other way around that is a quasi-isomorphism).

2. A quasi-isomorphism between $C^\bullet$ and the complex $H^\bullet(C^\bullet)$ need not exist in a given direction. For $C^\bullet$ as in (1), every chain map $\mathbb{Z}/2 \to C^\bullet$ is zero, since $\mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}) = 0$, so no quasi-isomorphism $H^\bullet(C^\bullet) \to C^\bullet$ exists. What does hold is the case of cohomology in a single degree n: then $i_n : \tau^{\leq n} C^\bullet \to C^\bullet$ and $\tau^{\leq n} C^\bullet \to \tau^{\geq n}\tau^{\leq n} C^\bullet = H^n(C^\bullet)[-n]$ are quasi-isomorphisms, by proposition 56.1.14.

3. Let $\iota(A) \in \mathrm{Obj}(\mathrm{Ch}(\mathbf{A}))$ be the complex with A at the 0th position and zero's everywhere else. Say that $C^\bullet$ is a resolution such that $C^\bullet \to \iota(A)$ is a quasi-isomorphism. Show that this implies $C^\bullet$ is exact everywhere except possibly at $H^0(M^0)$

The lack of symmetry means that quasi-isomorphisms do not form an equivalence relation, but a *weak equivalence relation* (a relation that is reflective and transitive, but not symmetric). This is rather a pity, since if it did form an equivalence relation, then the equivalence class of morphisms up to weak isomorphism would hold all the necessary (co)homological information. Alas, this was not mean to be. Thus, in the pursuit of finding (co)homological invariants, it productive to ask how (co)homological information can be detected between (co)chain complexes. One idea is to map $\mathrm{Ch}(\mathbf{A})$ into another category $D(\mathbf{A})$ in which quasi-isomorphisms become isomorphisms. If quasi-isomorphisms formed equivalence relationships, we could have formed a congruence category which would satisfy this condition, however as just mentioned this cannot be the case.

Such a functor has already been encountered: the (co)homology functor is already one such example. It is more fruitful to as if this can be done in a *univerasl* way, that is if there is a category $D(\mathbf{A})$ where for any category D for which there exists an additive functor $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to D$ where every quasi-isomorphism in $\mathrm{Ch}(\mathbf{A})$ becomes an isomorphism in D, there exists a unique functor such that the following diagram commutes:

$$\begin{array}{ccc} \mathrm{Ch}(\mathbf{A}) & \xrightarrow{\mathscr{F}} & D \\ \downarrow & \nearrow_{\exists!} & \\ D(\mathbf{A}) & & \end{array} \tag{56.2}$$

This category does indeed exist, by corollary 55.2.6, and is called the *derived category* (hence the $D(-)$ notation). This category shall further be explored in the coming sections. In some nice categories $\mathbf{A}$, quasi-isomorphisms will line up with the nicer notion of *homotopy-equivalence*, in which case the derived category will be eminently understandable. We shall explore these all in greater detail section 56.2.

Though quasi-isomorphisms may not be ideal in computing (co)homological invariants, they are still important as the defining concept for (co)homological information. For example, the following shows the relationship between quasi-isomorphism and exactness:

Lemma 56.1.17: Quasi-isomorphisms And Exactness

Let $C^\bullet$ be a cochain complex. Then the following are equivalent:

1. $C^\bullet$ is exact
2. $C^\bullet$ is acyclic, that is $H^\bullet(C^\bullet) = 0$
3. The morphism of complexes $0 \to C^\bullet$ is a quasi-isomorphism

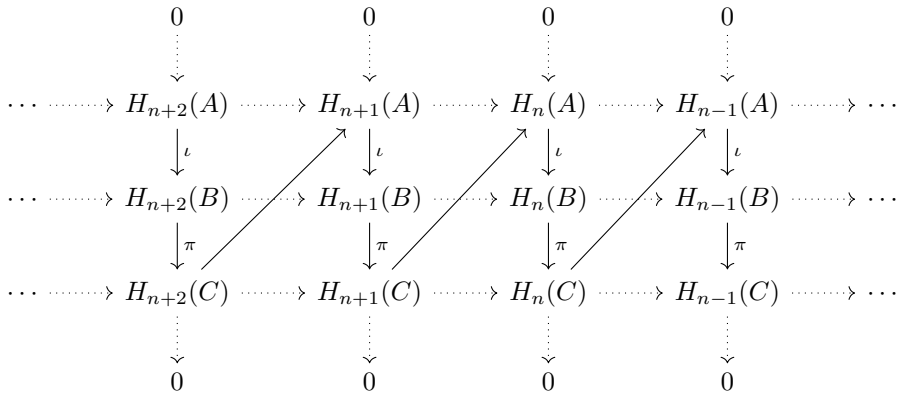
***Proof*:**
(1) $\Leftrightarrow$ (2): exactness of $C^\bullet$ at degree n means $\ker d^n = \text{im} d^{n-1}$, and $H^n(C^\bullet) = \ker d^n / \text{im} d^{n-1}$ by definition 56.1.8. A quotient object is zero exactly when the two are equal, so $C^\bullet$ is exact at every degree if and only if $H^n(C^\bullet) = 0$ for every n.

(2) $\Leftrightarrow$ (3): the zero complex has $H^n(0) = 0$ for every n, and the unique morphism $0 \to C^\bullet$ induces the unique morphism $0 \to H^n(C^\bullet)$ in each degree. That morphism is an isomorphism precisely when $H^n(C^\bullet) = 0$. So $0 \to C^\bullet$ is a quasi-isomorphism, meaning it induces isomorphisms in every degree, if and only if $H^\bullet(C^\bullet) = 0$, completing the proof.

56.1.2 Snake Lemma

We often have multiple ways of constructions a resolution for an object M. We shall often extend resolutions using smaller resolutions. We then get cohomology of this new extended resolution by simply applying the cohomology functor. However, is is this functor exact? More generally, let's say we have a short exact sequence of complexes, then after applying cohomology do we get a short exact sequence of homology complexes? The answer is no: if

$$0 \to L^\bullet \to C^\bullet \to N^\bullet \to 0$$



is a short exact sequence, then we get the (not necessarily exact) sequence:

$$H^i(L^\bullet) \to H^i(C^\bullet) \to H^i(N^\bullet)$$

In terms of morphisms, if we have:

$$\alpha^\bullet : C^\bullet \to N^\bullet$$

Then the morphism after applying the cohomology functor $H^\bullet(\alpha^\bullet) : H^\bullet(C^\bullet) \to H^\bullet(N^\bullet)$ need not be exact, i.e. it does not preserve kernels and cokernels. Can we "fix" this in some way by recovering some exact sequence from this and thus allowing our analysis of building more complicated resolutions for M to be independent of cohomology. The answer is yes, Namely, if we take the cohomology of complexes, we may "snake" like in the following diagram:

Theorem 56.1.18: Snake Lemma

Given a short exact sequence of complexes $0 \to A \xrightarrow{i} B \xrightarrow{j} C \to 0$, we may form a long exact sequence of modules using cohomology:

$$\cdots \to H^n(A) \xrightarrow{i^*} H^n(B) \xrightarrow{j^*} H^n(C) \xrightarrow{\partial} H^{n+1}(A) \xrightarrow{i^*} H^{n+1}(B) \xrightarrow{j^*} H^{n+1}(C) \to \cdots$$

Equivalently, in homological indexing, where the differential lowers degree and H_n is written for the homology in degree n, the same statement reads

$$\cdots \to H_n(A) \xrightarrow{i_*} H_n(B) \xrightarrow{j_*} H_n(C) \xrightarrow{\partial} H_{n-1}(A) \xrightarrow{i_*} H_{n-1}(B) \to \cdots$$

and it is this form that the proof below constructs. The two are the same statement under $H_n = H^{-n}$, and both are used in this book.

The sequence is natural in the short exact sequence of complexes. Given a commutative diagram of complexes with exact rows

$$\begin{array}{ccccccccc} 0 & \longrightarrow & A & \xrightarrow{i} & B & \xrightarrow{j} & C & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle f} & & \downarrow{\scriptstyle g} & & \downarrow{\scriptstyle h} & & \\ 0 & \longrightarrow & A' & \xrightarrow[i']{} & B' & \xrightarrow[j']{} & C' & \longrightarrow & 0 \end{array}$$

the two long exact sequences form a commutative ladder whose vertical morphisms are $H_n(f)$, $H_n(g)$ and $H_n(h)$. Writing ∂' for the connecting morphism of the second row, the square carrying the two connecting morphisms reads $\partial' \circ H_n(h) = H_{n-1}(f) \circ \partial$.

The homological variant of the following proof also appears in [76].

***Proof*:**
We first define the map $\partial : H_n(C) \to H_{n-1}(A)$. We should keep in mind the following diagram:

$$\begin{array}{ccc} & & A_{n-1} \\ & & \downarrow{\scriptstyle i} \\ B_n & \xrightarrow{\partial} & B_{n-1} \\ \downarrow{\scriptstyle j} & & \\ C_n & & \end{array}$$

Let $c \in C_n$ be a cycle so that $c \in \ker \partial_n$. Since j is surjective, $c = j(b)$ for some $b \in B_n$. Then by definition $\partial : B_n \to B_{n-1}$ so $\partial(b) \in B_{n-1}$. Then by commutativity $j(\partial(b)) = \partial(j(b)) = \partial(c) = 0$ (since c is a cycle), thus $\partial b \in \ker(j)$. Since $\ker j = \mathrm{im} i$, $\partial b = i(a)$ for some $a \in A_{n-1}$. Since $i(\partial a) = \partial i(a) = \partial\partial b = 0$ and i is injective, $\partial a = 0$. Thus, define $\partial : H_n(C) \to H_{n-1}(A)$ by $[c] \mapsto [a]$. This is well defined since:

1. The element a is uniquely determined by ∂b since i is injective.
2. For a different choice b' of b, we get $j(b') = j(b)$, so $b' - b \in \ker(j)$, which is equal to $\mathrm{im}(i)$. Thus $b' - b = i(a')$ for some a', hence $b' = b + i(a')$. This replaces a by the homologous element $a + \partial a'$, since
$$i(a + \partial a') = i(a) + i(\partial a') = \partial b + \partial i(a') = \partial(b + i(a')) = \partial b'$$
3. A different choice of c within its homology class has the form $c + \partial c'$. Since $c' = j(b')$ for some b',
$$c + \partial c' = c + \partial j(b') = c + j(\partial b') = j(b + \partial b')$$
so b is replaced by $b + \partial b'$, which has the same boundary ∂b, and thus a is unchanged.

Finally, $\partial : H_n(C) \to H_{n-1}(A)$ is a homomorphism, for if $\partial[c_1] = [a_1]$ and $\partial[c_2] = [a_2]$ via elements b_1, b_2, then
$$j(b_1 + b_2) = j(b_1) + j(b_2) = c_1 + c_2$$
and
$$i(a_1 + a_2) = i(a_1) + i(a_2) = \partial b_1 + \partial b_2 = \partial(b_1 + b_2)$$
hence
$$\partial([c_1] + [c_2]) = [a_1] + [a_2]$$
so ∂ is a homomorphism. It remains to show the following inclusions.

1. $\mathrm{im} i_* \subseteq \ker j_*$. Since $ji = 0$, $j_* i_* = 0$.
2. $\mathrm{im} j_* \subseteq \ker \partial$. For a cycle $b \in B_n$, the class $[j(b)]$ may be lifted to b itself, and $\partial b = 0 = i(0)$, so $\partial j_* = 0$.
3. $\mathrm{im}\partial \subseteq \ker i_*$. If $\partial[c] = [a]$ through the choice $b \in B_n$, then $i(a) = \partial b$ is a boundary, so $i_*[a] = [\partial b] = 0$.

4. $\ker j_* \subseteq \mathrm{im} i_*$. Let a cycle $b \in B_n$ represent a homology class in $\ker j_*$, so $j(b) = \partial c'$ for some $c' \in C_{n+1}$. Since j is surjective, $c' = j(b')$ for some $b' \in B_{n+1}$. Then since $\partial j(b') = \partial c' = j(b)$,

$$j(b - \partial b') = j(b) - j(\partial b') = j(b) - \partial j(b') = 0$$

Thus, $b - \partial b' = i(a)$ for some $a \in A_n$. Since $i(\partial a) = \partial i(a) = \partial(b - \partial b') = \partial b = 0$ and i is injective, a is a cycle. Thus:

$$i_*[a] = [b - \partial b'] = [b]$$

showing that i_* maps onto $\ker j_*$.

5. $\ker \partial \subseteq \mathrm{im} j_*$. By definition of ∂, if c represents a homology class in $\ker \partial$, then $a = \partial a'$ for some $a' \in A_n$. The element $b - i(a')$ is a cycle since $\partial(b - i(a')) = \partial b - \partial i(a') = \partial b - i(\partial a') = \partial b - i(a) = 0$. Since

$$j(b - i(a')) = j(b) - ji(a') = j(b) = c$$

we get that $j_*[b - i(a')] = [c]$.

6. $\ker i_* \subseteq \mathrm{im} \partial$. Given a cycle $a \in A_{n-1}$ such that $i(a) = \partial b$ for some $b \in B_n$, then $j(b)$ is a cycle since $\partial j(b) = j(\partial b) = ji(a) = 0$, hence $\partial[j(b)] = [a]$.

It remains to prove naturality. Let a commutative diagram as in the statement be given and let $[c] \in H_n(C)$. Running the construction above, $\partial[c] = [a]$, where $b \in B_n$ satisfies $j(b) = c$ and $i(a) = \partial b$. The element $h(c)$ is a cycle, since $\partial h(c) = h(\partial c) = 0$, and it represents $H_n(h)[c]$. Commutativity of the right-hand square gives $j'(g(b)) = h(j(b)) = h(c)$, so $g(b)$ is an admissible choice of preimage for $h(c)$, and commutativity of the left-hand square gives

$$i'(f(a)) = g(i(a)) = g(\partial b) = \partial(g(b))$$

So $f(a)$ is the element of A'_{n-1} that the construction attaches to $h(c)$ through the choice $g(b)$, and since ∂' does not depend on that choice, $\partial'(H_n(h)[c]) = [f(a)] = H_{n-1}(f)(\partial[c])$. The remaining squares of the ladder commute because H_n is a functor and the given diagram commutes, completing the proof.

Example 56.1.19: Uses Of Snake Lemma

1. *The six-term kernel-cokernel sequence.* The classical statement that carries the name "snake" is a special case of theorem 56.1.18. Suppose given a commutative diagram with exact rows

$$\begin{array}{ccccccccc} 0 & \longrightarrow & A^0 & \longrightarrow & B^0 & \longrightarrow & C^0 & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle f} & & \downarrow{\scriptstyle g} & & \downarrow{\scriptstyle h} & & \\ 0 & \longrightarrow & A^1 & \longrightarrow & B^1 & \longrightarrow & C^1 & \longrightarrow & 0 \end{array}$$

Read each column as a complex concentrated in degrees 0 and 1, so that $A^\bullet = (A^0 \xrightarrow{f} A^1)$ and likewise for $B^\bullet$ and $C^\bullet$. Exactness of the two rows says precisely that $0 \to A^\bullet \to B^\bullet \to C^\bullet \to 0$ is a short exact sequence of complexes, and for a two-term complex $H^0 = \ker$

and $H^1 = \operatorname{coker}$. Since H^n vanishes outside degrees 0 and 1, the long exact sequence of theorem 56.1.18 has only six nonzero terms:

$$0 \to \ker f \to \ker g \to \ker h \xrightarrow{\partial} \operatorname{coker} f \to \operatorname{coker} g \to \operatorname{coker} h \to 0$$

The connecting morphism ∂ is the "snake" that crosses from the kernel row to the cokernel row.

2. *A computation.* Apply the six-term sequence to multiplication by a fixed integer $n \geq 1$ on the short exact sequence $0 \to \mathbb{Z} \to \mathbb{Q} \to \mathbb{Q}/\mathbb{Z} \to 0$. Multiplication by n is injective on $\mathbb{Z}$ and bijective on $\mathbb{Q}$, and $\mathbb{Q}/\mathbb{Z}$ is divisible, so

$$\ker f = 0, \quad \ker g = 0, \quad \ker h = \tfrac{1}{n}\mathbb{Z}/\mathbb{Z} \cong \mathbb{Z}/n\mathbb{Z}$$

$$\operatorname{coker} f = \mathbb{Z}/n\mathbb{Z}, \quad \operatorname{coker} g = 0, \quad \operatorname{coker} h = 0$$

The six-term sequence collapses to $0 \to \mathbb{Z}/n\mathbb{Z} \xrightarrow{\partial} \mathbb{Z}/n\mathbb{Z} \to 0$, forcing ∂ to be an isomorphism. The explicit description confirms it: an element of $\ker h$ is the class of some $q \in \mathbb{Q}$ with $nq \in \mathbb{Z}$, and ∂ sends it to the class of nq in $\mathbb{Z}/n\mathbb{Z}$; the generator $1/n$ goes to the generator 1.

3. *Where the machine is used later.* Every long exact sequence in this book is an instance of theorem 56.1.18. The long exact sequence of derived functors (theorem 56.3.11) applies it to a short exact sequence of resolutions, the exact triangle of a mapping cone (proposition 56.1.22) applies it to the cone sequence, and the exact couple that generates a spectral sequence (theorem 60.2.2) is nothing but all the long exact sequences of a filtration assembled at once. The topological applications, the Mayer-Vietoris sequence and the long exact sequence of a pair, are developed where they are used, in *Algebraic Topology* [76].

The most-used consequence of the snake lemma is a criterion for recognizing an isomorphism in the middle of a diagram from isomorphisms on either side. It is stated here because it is needed whenever two exact sequences are compared, and in particular in the comparison theorem for spectral sequences (theorem 60.2.9).

Lemma 56.1.20: Five Lemma

Consider a commutative diagram in an abelian category with exact rows

$$\begin{array}{ccccccccc} A_1 & \longrightarrow & A_2 & \longrightarrow & A_3 & \longrightarrow & A_4 & \longrightarrow & A_5 \\ \downarrow{\scriptstyle f_1} & & \downarrow{\scriptstyle f_2} & & \downarrow{\scriptstyle f_3} & & \downarrow{\scriptstyle f_4} & & \downarrow{\scriptstyle f_5} \\ B_1 & \longrightarrow & B_2 & \longrightarrow & B_3 & \longrightarrow & B_4 & \longrightarrow & B_5 \end{array}$$

If f_2 and f_4 are isomorphisms, f_1 is an epimorphism, and f_5 is a monomorphism, then f_3 is an isomorphism.
More precisely, f_3 is a monomorphism as soon as f_2 and f_4 are monomorphisms and f_1 is an epimorphism, and f_3 is an epimorphism as soon as f_2 and f_4 are epimorphisms and f_5 is a monomorphism.

***Proof*:**
By theorem 55.1.15 the diagram may be chased with elements. Label the horizontal maps $\alpha_i \colon A_i \to A_{i+1}$ and $\beta_i \colon B_i \to B_{i+1}$.

Step 1: f_3 is a monomorphism. Assume f_2, f_4 monomorphisms and f_1 an epimorphism, and let $a \in A_3$ with $f_3(a) = 0$. Then $f_4(\alpha_3(a)) = \beta_3(f_3(a)) = 0$, and f_4 is a monomorphism, so $\alpha_3(a) = 0$. By exactness of the top row at A_3 there is $b \in A_2$ with $\alpha_2(b) = a$. Now $\beta_2(f_2(b)) = f_3(\alpha_2(b)) = f_3(a) = 0$, so by exactness of the bottom row at B_2 there is $c \in B_1$ with $\beta_1(c) = f_2(b)$. Since f_1 is an epimorphism, $c = f_1(e)$ for some $e \in A_1$. Then

$$f_2(\alpha_1(e)) = \beta_1(f_1(e)) = \beta_1(c) = f_2(b)$$

and f_2 is a monomorphism, so $\alpha_1(e) = b$. Therefore $a = \alpha_2(b) = \alpha_2(\alpha_1(e)) = 0$, the last equality by exactness of the top row at A_2.

Step 2: f_3 is an epimorphism. Assume f_2, f_4 epimorphisms and f_5 a monomorphism, and let $b \in B_3$. Since f_4 is an epimorphism, $\beta_3(b) = f_4(a)$ for some $a \in A_4$. Then

$$f_5(\alpha_4(a)) = \beta_4(f_4(a)) = \beta_4(\beta_3(b)) = 0$$

by exactness of the bottom row at B_4, and f_5 is a monomorphism, so $\alpha_4(a) = 0$. By exactness of the top row at A_4 there is $c \in A_3$ with $\alpha_3(c) = a$. The element $b - f_3(c)$ satisfies

$$\beta_3(b - f_3(c)) = \beta_3(b) - f_4(\alpha_3(c)) = f_4(a) - f_4(a) = 0$$

so by exactness of the bottom row at B_3 there is $e \in B_2$ with $\beta_2(e) = b - f_3(c)$. Since f_2 is an epimorphism, $e = f_2(g)$ for some $g \in A_2$, and then

$$f_3\big(\alpha_2(g) + c\big) = \beta_2(f_2(g)) + f_3(c) = \big(b - f_3(c)\big) + f_3(c) = b$$

so b lies in the image of f_3.

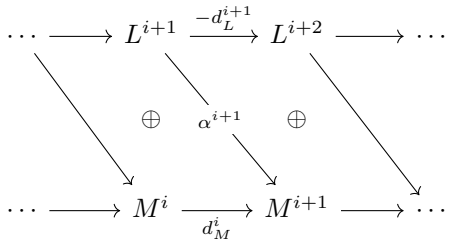
Under the hypotheses of the first statement both steps apply, so f_3 is both a monomorphism and an epimorphism, hence an isomorphism by lemma 55.1.8, completing the proof.

There is another way of looking at chain complexes which shall be important in elucidating triangle categories in section 57.1.

Mapping Cones

Using a particular total complex, we can detect when a quasi-isomorphism is an isomorphism. This result requires the snake lemma to prove, hence the need to put this section after the snake lemma.

Definition 56.1.21: Mapping Cone



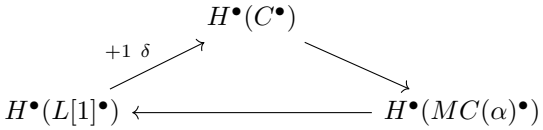
Let $\alpha^\bullet : L^\bullet \to M^\bullet$ be a morphism of complexes. Then the *mapping cone* is the complex denoted by $MC(\alpha^\bullet)$ defined by:

$$MC(\alpha)^i := L[1]^i \oplus M^i = L^{i+1} \oplus M^i$$

where the morphism $d^i_{MC(\alpha)} : MC(\alpha)^i \to MC(\alpha)^{i+1}$ are given by:

$$d^i_{MC(\alpha)}(l, m) := (-d^{i+1}_L(l), \alpha^{i+1}(l) + d^i_M(m))$$

The term mapping cone comes from the topological notion of a mapping cone of a function. Visually, the mapping cone can be seen as the following commutative diagram:



Given $MC(\alpha)^\bullet$, we may define two natural chain maps $C^\bullet \to MC(\alpha)^\bullet$ and $MC(\alpha)^\bullet \to L[1]^\bullet$ induced by the natural exact morphisms $M^i \to L^{i+1} \oplus M^i \to L^{i+1}$ which implies that:

$$0 \to C^\bullet \to MC(\alpha)^\bullet \to L[1]^\bullet \to 0$$

is exact.

Proposition 56.1.22: Mapping Cone And Exact Triangles

There is an exact triangle

where δ is the morphism induced by cohomology

***Proof*:**
The short exact sequence of complexes displayed above,

$$0 \to C^\bullet \to MC(\alpha)^\bullet \to L[1]^\bullet \to 0$$

is exact, so theorem 56.1.18 produces a long exact sequence in cohomology

$$\cdots \to H^n(C^\bullet) \to H^n(MC(\alpha)^\bullet) \to H^n(L[1]^\bullet) \xrightarrow{\delta} H^{n+1}(C^\bullet) \to \cdots$$

Exactness at each of the three kinds of term is precisely exactness of the displayed triangle at each of its three corners, the degree shift $H^n(L[1]^\bullet) = H^{n+1}(L^\bullet)$ being what the label $+1$ records.

The connecting morphism is the one induced by α, with no intervening sign; the projection $MC(\alpha)^\bullet \to L[1]^\bullet$ is a chain map precisely because the shift carries the differential $-d_L$, which is what cancels against the sign in the cone. To see this, unwind definition 56.1.21 on representatives: a class in $H^n(L[1]^\bullet)$ is represented by some $l \in L^{n+1}$ with $d_L l = 0$, and its preimage in $MC(\alpha)^n = L^{n+1} \oplus C^n$ may be taken to be $(l, 0)$. Applying the differential of the cone,

$$d_{MC(\alpha)}(l,0) = \big(-d_L l,\ \alpha^{n+1}(l)\big) = \big(0,\ \alpha^{n+1}(l)\big)$$

which is the image of $\alpha^{n+1}(l) \in C^{n+1}$ under the inclusion. Hence $\delta[l] = [\alpha^{n+1}(l)]$, that is $\delta = H^{n+1}(\alpha)$, completing the proof.

56.1.23 Remark Not all categories have this triangle property, categories which will have this will be called *triangulated categories*

Proposition 56.1.24: Quasi-isomorphism And Isomorphism

Let $\alpha^\bullet : C^\bullet \to N^\bullet$. Then $H^\bullet(\alpha^\bullet)$ is an isomorphism if and only if $MC(\alpha)^\bullet$ is an exact complex.

***Proof*:**
By proposition 56.1.22, applied with $\alpha\colon C^\bullet \to N^\bullet$, the cone sits in a long exact sequence

$$\cdots \to H^n\big(MC(\alpha)^\bullet\big) \to H^n\big(C[1]^\bullet\big) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet) \to H^{n+1}\big(MC(\alpha)^\bullet\big) \to \cdots$$

the connecting morphism having been identified there as the map induced by α, and $H^n(C[1]^\bullet) = H^{n+1}(C^\bullet)$.

Suppose $MC(\alpha)^\bullet$ is exact, so that $H^\bullet(MC(\alpha)^\bullet) = 0$ by lemma 56.1.17. Deleting the vanishing terms leaves

$$0 \to H^{n+1}(C^\bullet) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet) \to 0$$

exact for every n, so each $H^{n+1}(\alpha)$ is an isomorphism.

Conversely suppose every $H^n(\alpha)$ is an isomorphism. Fix n and read the sequence around $H^n(MC(\alpha)^\bullet)$:

$$H^{n-1}(C[1]^\bullet) \xrightarrow{H^n(\alpha)} H^n(N^\bullet) \to H^n\big(MC(\alpha)^\bullet\big) \to H^n(C[1]^\bullet) \xrightarrow{H^{n+1}(\alpha)} H^{n+1}(N^\bullet)$$

The left-hand map is surjective and the right-hand map is injective, both being isomorphisms. Exactness at $H^n(N^\bullet)$ then makes the morphism $H^n(N^\bullet) \to H^n(MC(\alpha)^\bullet)$ zero, and exactness at $H^n(C[1]^\bullet)$ makes the morphism $H^n(MC(\alpha)^\bullet) \to H^n(C[1]^\bullet)$ zero. Exactness at $H^n(MC(\alpha)^\bullet)$ therefore gives

$$H^n\big(MC(\alpha)^\bullet\big) = \ker\big(\text{zero morphism}\big) = \operatorname{im}\big(\text{zero morphism}\big) = 0$$

As n was arbitrary the cone is acyclic, hence exact by lemma 56.1.17, completing the proof.

56.1.3 Chain Homotopies and Homotopic Categories

The notion of homotopies originated in topology as a weaker alternative to continuous functions[3]. The topological notion of homotopy settled on the level of continuous functions, where $f, g : X \to Y$ are homotopic (denoted $f \simeq g$) if there exists a continuous function $F : X \times [0,1] \to Y$ where $F(\cdot, t) = f_t$ is continuous, $f_0 = f$ and $f_1 = g$. If we represent X, Y as one dimensional lines, then we may visualize a homotopy as:

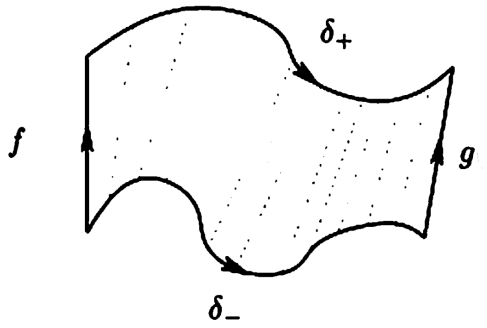


Figure 56.1: homotopy

In the development of homotopy theory, it was found that the (co)homology and homotopy of topological spaces (or their representations as chain complexes) is homology-invariant, hence homotopies are examples of quasi-isomorphisms. The proofs of these results turn out to be independent of the underlying topological structures and is purely algebraic, and hence the notion of homotopy has found a generalization as a purely algebraic notion between two (co)chain complexes.

Due to its origin in topology, the intuitions behind the following definitions will proceed more naturally with a more geometric build-up. Since homotopy may be interpreted purely algebraically, this geometrica build-up will be followed by a more algebraic interpretation. First, the reader may take for granted that given a topological space X, we may induce a chain $C_\bullet$, which is a topological object[4]. Given two continuous maps $f, g : X \to Y$, we may push forward the chain like so:

update image

[3] every homeomorphic is a homotopy equivalence, however not every homotopy equivalence is a homeomorphism, hence homotopy can be seen as weaker than continuity

[4] The construction of singular chains is in *Algebraic Topology* [76, Singular n-Simplex, Singular Homology Group]. [59] is the standard outside reference.

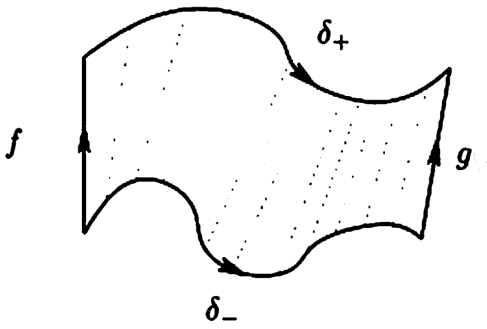

Figure 56.2: homotopy on chain

The space $h(C_\bullet)$ is a topological space, hence we may ask for it's border, $\partial h(C_\bullet)$. By inspecting the image, we see that:

$$\partial h(C_\bullet) = g(C_\bullet) - \delta_+ - f(C_\bullet) + \delta_- = g(C_\bullet) - f(C_\bullet) - h(\partial C_\bullet)$$

re-ordering, we get:

$$g(C_\bullet) - f(C_\bullet) = \partial h(C_\bullet) + h(\partial C_\bullet)$$

Abstracting notation, we get:

$$g - f = \partial h + h\partial \tag{56.3}$$

Now, recall that in a chain complex, the image of the function ∂ is called the boundary, and that by definition of homology the boundary becomes trivial. In a topological setting, this vocabulary reflects the concrete of the boundary map ∂: it maps a chain to it's boundary. What this means for us is that when taking homology on both sides, we get:

$$H^k(g|_{C_\bullet} - f|_{C_\bullet}) = \overline{0}$$

meaning the two maps are equivalent up to homology! In other words, this "geometric intuition" shows that a homotopy is an example of a quasi-isomorphism. Even better, homotopies shall form an equivalence relation, hence they are an example of a quasi-isomorphism that shall capture some (co)homological information (and in the case where all quasi-isomorphisms are homotopies, they could fully capture the (co)homological information!)

Though this is the origins of chain homotopies being (co)homology-invariant, since they may be interpreted in pure algebraic terms, it is worthwhile taking a moment to have an algebraic build-up as well. Algebraically, homotopies can be seen as forming equivalence classes of (co)chain complexes up to *obstruction from being split-exact*. Recall that a split exact sequence is a short exact sequence that is also split at each map, that is there exists a section morphism $s^n : C^n \to C^{n-1}$ such that $d^{n-1} \circ s^n \circ d^{n-1} = d$, or if we drop the indices and collect all the section maps:

$$d = dsd$$

In other words, it is possible to "inverse" the map d via the map s in such a way that it "cancels" the effect of d (for we may re-apply the map d after sd and get the same result). The simplest source of split-exact (co)chains are exact (co)chains of vector-spaces, for any vector-space maps split[5]. Given a

[5]More generally, any maps of projective modules split

cochain, we may write:

$$C^n = Z^n \oplus B' \qquad (B^n)' \cong C^n/Z^n = d(C^n) = B^{n+1}$$

$$Z^n = B^n \oplus (H^n)' \qquad (H^n)' = Z^n/B^n = H^n(C)$$

Hence, $C^n \cong Z^n \oplus B^{n+1}$. This allows for the definition of the section map via the composition:

$$C^n \hookrightarrow Z^n \hookrightarrow B^n \cong d(C^n) \cong B^{n+1} \subseteq C^{n+1}$$

We may thus define the maps $d \circ s$ and $s \circ d$ where $d \circ s(C^n) = B^n$ and $s \circ d(C^n)(B^n)' \cong B^{n+1}$. Adding these maps together, we get a map $ds + sd : C^n \to C^n$ whose kernel is the homology:

$$\ker(ds + sd)_n = H^n(C^\bullet)$$

The kernel (and cokernel) of the chain map $ds + sd$ is naturally $H^\bullet(C^\bullet)$. Working over more general R-modules (and more generally in an arbitrary abelian category), we loose the natural section maps, for example $0 \to \mathbb{Z} \twoheadrightarrow \mathbb{Z}/2\mathbb{Z} \to 0$ does note have a section map for each map. Instead, we may define arbitrary maps $s^n : C^n \to D^{n-1}$ where we may put them in the following (*not* necessarily commutative) diagram:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & C^{n-1} & \xrightarrow{d} & C^n & \xrightarrow{d} & C^{n+1} & \longrightarrow & \cdots \\
 & & \downarrow & \swarrow_{s^n} & \downarrow & \swarrow_{s^{n+1}} & \downarrow & & \\
\cdots & \longrightarrow & D^{n-1} & \xrightarrow{d} & D^n & \xrightarrow{d} & D^{n+1} & \longrightarrow & \cdots
\end{array}$$

Given any such collection of morphisms, we may define $f^n = s^{n+1} \circ d^n + d^{n-1} \circ s^n$ (or, if dropping indices and abbreviate, $f = sd + ds$). Notice that even though the maps $s^\bullet$ do not commute, $f^\bullet$ *will* create a commutative diagram, in particular it is a chain map. To see this, notice that (after dropping indices):

$$df = d(ds + sd) = dsd = (ds + sd)d = fd$$

showing it is indeed a chain map:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & C^{n-1} & \xrightarrow{d} & C^n & \xrightarrow{d} & C^{n+1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle f^{n-1}} & \swarrow_{s^n} & \downarrow{\scriptstyle f^n} & \swarrow_{s^{n+1}} & \downarrow{\scriptstyle f^{n+1}} & & \\
\cdots & \longrightarrow & D^{n-1} & \xrightarrow{d} & D^n & \xrightarrow{d} & D^{n+1} & \longrightarrow & \cdots
\end{array}$$

Thus, given any collection of morphisms $s^\bullet$, we may naturally define a chain map using the differentials. Conversely, is every morphism of complexes representable as $ds + sd$. This is not in general the case; maps being representable like so are given a name:

Definition 56.1.25: Null-homotopic Maps

Let $f^\bullet : C^\bullet \to D^\bullet$ be a morphism of complexes. Then f is called *null-homotopic* if there exists a collection $\{s^i\}_{i\in\mathbb{Z}}$ of morphisms $s^i : C^i \to D^{i-1}$ such that

$$f^\bullet = ds + sd$$

The maps $s^\bullet$ are called the *chain contraction* of $f^\bullet$

To show that not all maps are null-homotopic, consider the following lemma:

Lemma 56.1.26: Null-homotopic And Split Exact Complexes

Let $C^\bullet$ be a complex. Then $C^\bullet$ is split exact if and only if the identity map is null-homotopic.

***Proof*:**
Throughout, split exact means exact together with a family $s^n \colon C^n \to C^{n-1}$ satisfying $dsd = d$, and null-homotopic means $\mathrm{id} = ds + sd$ for some such family.

Step 1: Null-homotopic implies split exact. Suppose $\mathrm{id} = dt + td$. For exactness, let $c \in \ker d^n$; then

$$c = dt(c) + td(c) = dt(c)$$

so $c \in \mathrm{im} d^{n-1}$, and the reverse inclusion $\mathrm{im} d^{n-1} \subseteq \ker d^n$ holds because $d \circ d = 0$. For the splitting, compute

$$dtd = d(td) = d(\mathrm{id} - dt) = d - d^2 t = d$$

so t is a splitting family.

Step 2: Split exact implies null-homotopic. Suppose $C^\bullet$ is exact and $dsd = d$. Set

$$\varphi = ds + sd$$

Then $d\varphi = dsd = d$ and $\varphi d = dsd = d$, both using $d \circ d = 0$; in particular φ commutes with d.

Put $\psi = \mathrm{id} - \varphi$. From the two identities just proved, $d\psi = d - d = 0$ and $\psi d = d - d = 0$. The first says $\mathrm{im}\psi \subseteq \ker d$, and exactness gives $\ker d = \mathrm{im} d$, so $\mathrm{im}\psi \subseteq \mathrm{im} d$; the second says ψ vanishes on $\mathrm{im} d$. Composing, $\psi \circ \psi = 0$.

Therefore $\varphi = \mathrm{id} - \psi$ is invertible, with inverse $\mathrm{id} + \psi$, and φ^{-1} commutes with d because φ does. Set $t = \varphi^{-1} s$. Then

$$dt + td = d\varphi^{-1} s + \varphi^{-1} sd = \varphi^{-1}(ds + sd) = \varphi^{-1}\varphi = \mathrm{id}$$

so the identity is null-homotopic with contraction t, completing the proof.

The name "null-homotopic" comes from how the (co)homology of such maps are trivial:

Proposition 56.1.27: Null-homotopic And Cohomology

Let $f^\bullet : C^\bullet \to D^\bullet$ be null-homotopic. Then $H^\bullet(f)$ is the zero map

***Proof*:**
We compute with elements, applying theorem 55.1.15 to a small abelian subcategory containing the objects involved. Since f is null-homotopic, there are morphisms $s^i \colon C^i \to D^{i-1}$ with $f^n = d_D^{n-1} s^n + s^{n+1} d_C^n$ for every n (definition 56.1.25). Let $x \in C^n$ be a cocycle representing a

class $\overline{x} \in H^n(C^\bullet)$. Since $d_C^n(x) = 0$,

$$f^n(x) = d_D^{n-1}(s^n(x)) + s^{n+1}(d_C^n(x)) = d_D^{n-1}(s^n(x))$$

so $f^n(x)$ is a coboundary of $D^\bullet$. The map $H^n(f)$ of lemma 56.1.10 sends $\overline{x}$ to the class of $f^n(x)$, which is therefore $\overline{0}$ in $H^n(D^\bullet)$, as we sought to show.

Thus, maps that are null-homotopic induce zero (co)homology maps![6] Thus, we may think of maps that are null-homotopic as being the "zero" maps. This leads us to the following definition:

Definition 56.1.28: Chain-homotopy

Let $f^\bullet, g^\bullet : C^\bullet \to D^\bullet$ be two morphisms of complexes. Then we say that these two maps are *chain homotopic* or just *homotopic* if there exists maps $h^i : C^i \to D^{i-1}$ such that

$$g^i - f^i = d_{D^\bullet}^{i-1} \circ h^i + h^{i+1} \circ d_{C^\bullet}^i$$

or, dropping indices:

$$g^\bullet - f^\bullet = dh + hd$$

If $f^\bullet, g^\bullet$ are homotopic, we write $f^\bullet \sim g^\bullet$

The s notation has been replaced with h notation to emphasize now the "homotopy" aspect of it rather than the "section" property that was evident in the case of vector spaces. If we were working with chains, then we would have

$$g_\bullet - f_\bullet = \partial h + h\partial$$

which, the reader may recognize as equation (56.3). If we were working with chains, then $h_i : C_i \to D_{i+1}$ would shift up a degree, which would be interpreted in the geometrical setting as moving *up* a dimension, in the same way that homotopies are a "dimension more" than the original spaces X, Y. Furthermore, the reader should verify the "up to homotopy" *is* an equivalence relation, as the reader should verify!

Importantly, two chain-homotopic maps induce the same (co)homology:

Proposition 56.1.29: Chain-Homotopy and Cohomology

Let $f^\bullet, g^\bullet : C^\bullet \to D^\bullet$ be chain homotopic. Then

$$H^\bullet(f^\bullet) = H^\bullet(g^\bullet)$$

***Proof*:**
Since $f^\bullet$ and $g^\bullet$ are chain-homotopic, by proposition 56.1.27 for each element in $H^k(C^\bullet)$ (since it is an additive functor):

$$H^k(f^\bullet)(\overline{x}) - H^k(g^\bullet)(\overline{x}) = 0 \qquad \Rightarrow \qquad H^k(f^\bullet)(\overline{x}) = H^k(g^\bullet)(\overline{x})$$

as we sought to show.

[6] TBD How much can we say about the converse, if a map induces the zero morphism, then is it null-homotopic?

The above result shows promise in using chain-homotopies to hold (co)homological information. The following definition is the important connection idea:

Definition 56.1.30: Homotopy Equivalent Chains

Let $f^\bullet : C^\bullet \to D^\bullet$ be a morphism of complexes. Then $f^\bullet$ is a *homotopy equivalence* if there exists a morphisms of complexes $g^\bullet : D^\bullet \to C^\bullet$ such that

$$f^\bullet \circ g^\bullet \sim 1_{D^\bullet} \qquad \text{and} \qquad g^\bullet \circ f^\bullet \sim 1_{C^\bullet}$$

If $f^\bullet : C^\bullet \to D^\bullet$ is a homotopy equivalence, then $C^\bullet$ and $D^\bullet$ are said to be *homotopy equivalent*

Proposition 56.1.31: Homotopy Equivalence Ans Cohomology

Let $f^\bullet : C^\bullet \to D^\bullet$ be a homotopy equivalence. Then $f^\bullet$ is a quasi-isomorphism, that is $H^\bullet(f^\bullet)$ is an isomorphism

***Proof*:**
Since $f^\bullet$ is a homotopy equivalence, we have $g^\bullet$ that is it's homotopic inverse. Then the maps $f^\bullet \circ g^\bullet$ and $g^\bullet \circ f^\bullet$ induce inverse morphisms of cohomology by proposition 56.1.29, and hence give an isomorphism, as we sought to show.

As demonstrated in example 56.1.16 not all quasi-isomorphisms are invertible even up to homotopy equivalence, hence quasi-isomorphisms are more general. As mentioned earlier, in nice enough categories these two concepts shall coincide.

Now that homotopy equivalences is established, can be asked if given an (additive) functor $\mathscr{F} : \mathbf{A} \to \mathbf{B}$, if there are two homotopic complexes in $\mathrm{Ch}(\mathbf{A})$, will the (co)homology be isomorphic in $\mathbf{B}$? In other words, when trying to define the derived category that was mentioned earlier, can this category be defined at least up to homotopy? The answer is yes! The proof of this result essentially follows from the following lemma:

Lemma 56.1.32: Homotopy Equivalence And Additive Functors

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories, $C(\mathscr{F})$ the induced functor on chains. Then if $f^\bullet \sim g^\bullet$ in $\mathrm{Ch}(\mathbf{A})$, $C(\mathscr{F})(f^\bullet) \sim \mathrm{Ch}(\mathbf{B})(g^\bullet)$ in $\mathrm{Ch}(\mathbf{B})$. Furthermore, if $C^\bullet$ and $D^\bullet$ are homotopy equivalence, $C(\mathscr{F})(C^\bullet)$ and $C(\mathscr{F})(D^\bullet)$ are homotopy equivalent

***Proof*:**
Given the first assertion, the second is an immediate consequence, hence we prove the first. Let $f^\bullet \sim g^\bullet$ so that :

$$f^i - g^i = d^{i-1}_{D^\bullet} \circ h^i + h^{i+1} \circ d^i_{C^\bullet}$$

Since $\mathscr{F}$ is an additive functor:

$$\mathscr{F}(f^i) - \mathscr{F}(g^i) = \mathscr{F}\left(d^{i-1}_{D^\bullet}\right) \circ \mathscr{F}(h^i) + \mathscr{F}\left(h^{i+1}\right) \circ \mathscr{F}\left(d^i_{C^\bullet}\right)$$

hence, the morphisms $\mathscr{F}(h^i)$ gives a homotopy between $\mathscr{F}(f^\bullet)$ and $\mathscr{F}(g^\bullet)$, as we sought to show.

Note this does *not* hold for quasi-isomorphisms (exercise 4.15 in Aluffi), needing the stronger condition of exact functors.

Theorem 56.1.33: Derived Category And Homotopy Equivalence

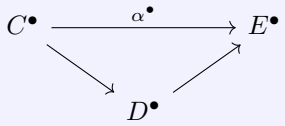
Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories. Then if $C^\bullet$ and $D^\bullet$ are homotopy-equivalent, then:

$$H^\bullet(\mathscr{F}(C^\bullet)) \cong H^\bullet(\mathscr{F}(D^\bullet))$$

that is, their cohomology is isomorphic.

***Proof*:**
By lemma 56.1.32, an additive functor carries homotopy-equivalent complexes to homotopy-equivalent complexes, so $\mathscr{F}(C^\bullet)$ and $\mathscr{F}(D^\bullet)$ are homotopy equivalent in $\mathrm{Ch}(\mathbf{B})$. By proposition 56.1.31 a homotopy equivalence is a quasi-isomorphism, so the induced map on cohomology is an isomorphism, giving $H^\bullet(\mathscr{F}(C^\bullet)) \cong H^\bullet(\mathscr{F}(D^\bullet))$, as we sought to show.

Hence, up to homotopy, the choice of cochain shall give the same cohomology information!



Homotopic Categories

With chain homotopies being a nicer sub-class of quasi-isomorphisms, their exploration is worth further pursuing. They are in fact almost the solution to the universal problem given in equation (56.2). Let us take for granted that a category $D(A)$ exists that satisfies the universal property. What necessary conditions can be deduced about $D(A)$?

Lemma 56.1.34: Derived Category And Additive Functors

Let $\mathbf{D}$ be an additive category, $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to \mathbf{D}$ be an additive functor that takes quasi-isomorphisms to isomorphisms.

1. Let $C^\bullet$ be an exact complex in $\mathrm{Ch}(\mathbf{A})$. Then $\mathscr{F}(C^\bullet) = 0$, that is $\mathscr{F}(C^\bullet)$ is the zero object in $\mathbf{D}$.
2. Let $\alpha^\bullet : C^\bullet \to E^\bullet$ be a morphism of complexes that factors through an exact complex:

   where $D^\bullet$ is exact. Then $\mathscr{F}(\alpha^\bullet)$ is the zero morphism.

***Proof*:**

1. Since $C^\bullet$ is exact, the zero morphism $0^\bullet : C^\bullet \to C^\bullet$ is a quasi-isomorphism, and so $\mathscr{F}(0^\bullet)$

maps to an isomorphism (i.e. an invertible morphism in $\mathbf{D}$). Thus:

$$\mathscr{F}(C^\bullet) \xrightarrow[\mathscr{F}(0^\bullet)]{} \mathscr{F}(C^\bullet) \xrightarrow[\mathscr{F}(0^\bullet)^{-1}]{} \mathscr{F}(C^\bullet), \qquad \mathrm{id}_{\mathscr{F}(C^\bullet)} : \mathscr{F}(C^\bullet) \to \mathscr{F}(C^\bullet)$$

Since $\mathscr{F}$ is additive functor, in particular a group homomorphism on hom-sets, $\mathscr{F}(0) = 0$. Thus:

$$\mathrm{id}_{\mathscr{F}(C^\bullet)} = 0$$

It follows that $\mathscr{F}(C^\bullet)$ must be the zero object: an object whose identity morphism is zero admits only the zero endomorphism, so it is isomorphic to 0

2. Applying $\mathscr{F}$ to the diagram in the question, we get the diagram:

$$\begin{array}{ccc} \mathscr{F}(C^\bullet) & \longrightarrow & \mathscr{F}(E^\bullet) \\ & \searrow \quad \nearrow & \\ & \mathscr{F}(D^\bullet) & \end{array}$$

Since $\mathscr{F}(D^\bullet) = 0$ by the above result, we see that $\mathscr{F}(\alpha^\bullet)$ must be the zero morphisms, completing the proof.

Lemma 56.1.35: Derived Categories And Homotopies

Let $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to \mathbf{D}$ be an additive functor that maps quasi-isomorphisms to isomorphisms. Let $f^\bullet, g^\bullet : C^\bullet \to D^\bullet$ be homotopic morphisms in $\mathrm{Ch}(\mathbf{A})$. Then

$$\mathscr{F}(f^\bullet) = \mathscr{F}(g^\bullet)$$

Note that this was shown explicitly when $\mathscr{F} = H^i(-)$.

***Proof*:**
Since $\mathscr{F}$ is additive, it suffices to show that if $f^\bullet \sim 0$, then $\mathscr{F}(f^\bullet) = 0$. By lemma 56.1.34, it suffices to show $f^\bullet$ factors through an exact complex. The exact complex that shall be used is the mapping cone $MC(\mathrm{id}_{C^\bullet})$ for the identity map $\mathrm{id}_{C^\bullet} : C^\bullet \to C^\bullet$, namely

$$MC(\mathrm{id}_{C^\bullet})^i = C^{i+1} \oplus C^i$$

$$d^i_{MC(\mathrm{id}_{C^\bullet})}(a, b) = (-d^{i+1}_{C^\bullet}(a), a + d^i_{C^\bullet}(b))$$

By proposition 56.1.24, since the identity map $\mathrm{id}_{C^\bullet}$ is (trivially) a quasi-isomorphism, $MC(\mathrm{id}_{C^\bullet})$ is an exact complex.

Now, the goal is to find morphism of complexes where:

$$C^\bullet \to MC(\mathrm{id}_{C^\bullet}) \to D^\bullet$$

the morphism of complexes $C^\bullet \to MC(\mathrm{id}_{C^\bullet})$ is readily available: for each i:

$$b \mapsto (0, b)$$

On the other hand, it is not immediately clear there is a morphism of complexes $MC(\mathrm{id}_{C^\bullet}) \to D^\bullet$. To find such a morphism, we take advantage of the homotopy $f^\bullet \sim 0$, that is there exists maps:

$$h^i : C^i \to D^{i-1}$$

such that $f^\bullet = fh + hd$. With these, define the maps:

$$\pi^i : MC(\mathrm{id}_{C^\bullet})i \to D^i \qquad (a, b) \mapsto h^{i+1}(a) + f^i(b)$$

If this is indeed a morphism of complexes, then the map $f : C^\bullet \to D^\bullet$ factored through an exact complex and hence must be trivial. What must be verified is that:

$$d^{i-1}_{D^\bullet} \circ \pi^{i+1} = \pi^i \circ d^{i-1}_{MC(\mathrm{id}_{C^\bullet})} \tag{56.4}$$

The left hand side of equation (56.4) gives:

$$(a, b) \mapsto h^i(a) + f^{i-1}(b) \mapsto d^{i-1}_{D^\bullet}(h^i(a) + f^{i-1}(b))$$

while the right hand side gives:

$$(a, b) \mapsto (-d^i_{C^\bullet}(a), a + d^{i-1}_{L^\bullet}(b)) \mapsto -h^{i+1}(d^i_{C^\bullet}(a) + f^i(a + d^{i-1}_{C^\bullet}(b))$$

These two sides must be equal. Simplifying the equality, we get:

$$(d^{i-1}_{D^\bullet} \circ h^i + h^{i+1} \circ d^i_{C^\bullet} - f^i)(a) = (f^i \circ d^{i-1}_{C^\bullet} - d^{i-1}_{D^\bullet} \circ f^{-1})(a)$$

for all $a \in C^{i+1}, b \in C^i$. But notice that both sides are zero: the right hand side b $f^\bullet$ is a morphism of complexes, while the left hand side because h is a homotopy and $f^\bullet \sim 0$. But then this gives us our desired result, completing the proof.

Thus, behave well for the desired universal property presented in equation 56.2. We formalize the category in question:

Definition 56.1.36: Homotopy Category

Let $\mathbf{A}$ be an abelian category. Then the *homotopy category* of $\mathbf{A}$, denoted $K(\mathbf{A})$ is the category whose objects ar ethe (co)chain complexes in $\mathbf{A}$ (i.e. $\mathrm{Ch}(\mathbf{A})$), and whose morphisms are:

$$\mathrm{Hom}_{K(\mathbf{A})}(C^\bullet, D^\bullet) = \mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(C^\bullet, D^\bullet)/\sim$$

where $\sim$ is the homotopy relation, that is, the morphisms are morphisms of complexes up to homotopy.

These are indeed morphisms, namely $\sim$ is transitive, it respects composition (exercise). Naturally, the equivalent bounded variations $K^-(\mathbf{A})$ and $K^+(\mathbf{A})$ are obtained from $\mathrm{Ch}^+(\mathbf{A})$ and $\mathrm{Ch}^-(\mathbf{A})$.

Lemma 56.1.37: Homotopy Category Is Additive

Let $\mathbf{A}$ be an abelian category. Then $K(\mathbf{A})$ is an *additive category*

***Proof*:**
Recall from definition 56.1.36 that $K(\mathbf{A})$ has the same objects as $\mathrm{Ch}(\mathbf{A})$ and $\mathrm{Hom}_{K(\mathbf{A})}(C^\bullet, D^\bullet) = \mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(C^\bullet, D^\bullet)/\sim$, the quotient by chain homotopy.

Step 1: The hom-sets are abelian groups. The null-homotopic morphisms form a subgroup of $\mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(C^\bullet, D^\bullet)$: if $f = ds + sd$ and $f' = ds' + s'd$ then $f - f' = d(s - s') + (s - s')d$ is null-homotopic. Being a quotient of an abelian group by a subgroup, each hom-set of $K(\mathbf{A})$ is an abelian group, and $f \sim g$ exactly when $f - g$ is null-homotopic.

Step 2: Composition is well defined and bilinear. Suppose $f \sim f'$, say $f - f' = ds + sd$, and let g be a chain map composable on the left. Since g commutes with the differentials,

$$gf - gf' = g(ds + sd) = d(gs) + (gs)d$$

so $gf \sim gf'$; composing on the right with a chain map h gives $fh - f'h = d(sh) + (sh)d$ likewise. Hence composition descends to the quotient, and it is bilinear because it is bilinear in $\mathrm{Ch}(\mathbf{A})$ and the quotient maps are group homomorphisms.

Step 3: Zero object and biproducts. The zero complex is a zero object in $\mathrm{Ch}(\mathbf{A})$ and remains one after the quotient, since its hom-sets are already zero. For two complexes $C^\bullet$ and $D^\bullet$, the degreewise direct sum $C^\bullet \oplus D^\bullet$ carries the four structure morphisms i_C, i_D, p_C, p_D, which are chain maps and satisfy the biproduct identities $p_C i_C = \mathrm{id}$, $p_D i_D = \mathrm{id}$, $p_C i_D = 0$, $p_D i_C = 0$ and $i_C p_C + i_D p_D = \mathrm{id}$ in $\mathrm{Ch}(\mathbf{A})$. Identities between morphisms are preserved by the quotient functor, so they continue to hold in $K(\mathbf{A})$, and an object with such data is a biproduct there as well.

Together these are the axioms of an additive category, completing the proof.

Note that in general homotopic categories are *not* abelian. Indeed, homotopic maps $f^\bullet \sim g^\bullet$ need not have the same kernel/cokernel, giving no natural definition of these concepts. The homotopic category is a type of category that is stronger than additive but weaker than abelian, known as a *triangulated category* (recall box 56.1.23).

In $K(\mathbf{A})$, homotopy equivalences become isomorphisms. This comes straight from the definition, for if $f^\bullet \circ g^\bullet \sim \mathrm{id}$ in $\mathrm{Ch}(\mathbf{A})$, then $f^\bullet \circ g^\bullet = \mathrm{id}$ in $K(\mathbf{A})$, which can be thought of as formally inverting homotopy equivalences. Using this, we have the following almost universal property, or factorization

It looks like a universal property because it is one, though not the one for quasi-isomorphisms. Comparing with definition 55.2.1, the homotopy category is precisely the localization

$$K(\mathbf{A}) \cong \mathrm{Ch}(\mathbf{A})\big[\{\text{homotopy equivalences}\}^{-1}\big]$$

The proposition below is stated with the hypothesis that $\mathscr{F}$ inverts *quasi-isomorphisms*, which is strictly stronger than it needs to be, and that mismatch is what makes it read as an "almost" universal property. Its proof uses only that $\mathscr{F}$ inverts homotopy equivalences. Inverting all quasi-isomorphisms is the stronger requirement that produces $D(\mathbf{A})$ instead (corollary 55.2.6), and the gap between the two is exactly example 56.1.16: a quasi-isomorphism need not be a homotopy equivalence.

Proposition 56.1.38: Homotopy Category Factorization

Let $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to D$ be a functor that maps quasi-isomorphisms to isomorphisms. Then $\mathscr{F}$ factors uniquely through $K(\mathbf{A})$:

$$\begin{array}{ccc} \mathrm{Ch}(\mathbf{A}) & \xrightarrow{\mathscr{F}} & D \\ \downarrow & \nearrow_{\exists!} & \\ K(\mathbf{A}) & & \end{array}$$

***Proof*:**
Since every homotopy equivalence is a quasi-isomorphism (proposition 56.1.31), the hypothesis in particular sends homotopy equivalences to isomorphisms, and that is all the proof uses. Because $\mathscr{F}$ is defined on $\mathrm{Ch}(\mathbf{A})$ and $K(\mathbf{A})$ has the same objects, the only thing to establish is that $f \sim g$ implies $\mathscr{F}(f) = \mathscr{F}(g)$; the factorization and its uniqueness are then forced, since the quotient functor $\mathrm{Ch}(\mathbf{A}) \to K(\mathbf{A})$ is the identity on objects and surjective on morphisms.

Step 1: The cylinder of a complex. For a complex $C^\bullet$ define

$$\mathrm{Cyl}(C)^n = C^n \oplus C^{n+1} \oplus C^n, \qquad d(a,b,c) = (da - b,\ -db,\ dc + b)$$

This squares to zero, since $d^2(a,b,c) = (d(da-b)+db,\ d(db),\ d(dc+b)-db) = (0,0,0)$. Define chain maps

$$i_0(a) = (a,0,0), \qquad i_1(c) = (0,0,c), \qquad p(a,b,c) = a + c$$

Each is compatible with the differentials: $d\,i_0(a) = (da,0,0) = i_0(da)$, similarly for i_1, and $p(d(a,b,c)) = (da-b)+(dc+b) = d(a+c)$. Moreover $pi_0 = \mathrm{id}_C = pi_1$.

Step 2: p is a homotopy equivalence. The composite $i_0 p - \mathrm{id}$ sends (a,b,c) to $(c,-b,-c)$, and setting $s(a,b,c) = (0,-c,0)$ gives

$$ds(a,b,c) = (c,\ dc,\ -c), \qquad sd(a,b,c) = (0,\ -(dc+b),\ 0)$$

whose sum is $(c,-b,-c)$. So $i_0 p \sim \mathrm{id}_{\mathrm{Cyl}(C)}$ while $pi_0 = \mathrm{id}_C$, making i_0 and p mutually inverse homotopy equivalences. The symmetric computation applies to i_1, with the contracting homotopy $s'(a,b,c) = (0,a,0)$ in place of s, since $i_1 p - \mathrm{id}$ sends (a,b,c) to $(-a,-b,a)$.

Step 3: Homotopies are morphisms out of the cylinder. Let $f, g \colon C^\bullet \to D^\bullet$ with $g - f = ds + sd$. Define $H \colon \mathrm{Cyl}(C) \to D^\bullet$ by $H(a,b,c) = f(a) + s(b) + g(c)$. It is a chain map: expanding both sides, $H(d(a,b,c)) - dH(a,b,c) = (g - f - ds - sd)(b) = 0$. By construction $Hi_0 = f$ and $Hi_1 = g$.

Step 4: Conclusion. Apply $\mathscr{F}$. By Step 2 the morphisms i_0 and i_1 are homotopy equivalences, hence quasi-isomorphisms, so $\mathscr{F}(i_0)$ and $\mathscr{F}(i_1)$ are isomorphisms by hypothesis. From $pi_0 = \mathrm{id} = pi_1$ and functoriality, $\mathscr{F}(p)\mathscr{F}(i_0) = \mathrm{id} = \mathscr{F}(p)\mathscr{F}(i_1)$, and since $\mathscr{F}(i_0)$ is invertible so is $\mathscr{F}(p)$; cancelling it gives $\mathscr{F}(i_0) = \mathscr{F}(p)^{-1} = \mathscr{F}(i_1)$. Therefore

$$\mathscr{F}(f) = \mathscr{F}(Hi_0) = \mathscr{F}(H)\mathscr{F}(i_0) = \mathscr{F}(H)\mathscr{F}(i_1) = \mathscr{F}(Hi_1) = \mathscr{F}(g)$$

so $\mathscr{F}$ identifies homotopic morphisms and factors uniquely through $K(\mathbf{A})$. Note that $\mathscr{F}$ was used only through functoriality and the hypothesis that it inverts quasi-isomorphisms. The direct sums and sums of morphisms above all live in $\mathrm{Ch}(\mathbf{A})$, so no additivity of $\mathscr{F}$ itself is required. This matters in section 57.2, where the functor to be factored is the localization onto $D(\mathbf{A})$, whose additive structure is not available until later. This completes the proof.

Hence, in the case where $K(\mathbf{A})$ is *not* the universal object satisfying equation (56.2), there must be a unique functor from $K(\mathbf{A})$ to $D(\mathbf{A})$.

56.2 Projective and Injective Resolutions

It has been alluded to a few times that for special categories, homotopy equivalence and quasi-isomorphism coincide. This shall now be covered in this section. In particular, this shall linked to the idea of an abelian category $\mathbf{A}$ being bounded from above or bellow, and having *enough projective objects* or *enough injective objects*. These categories shall furthermore be shown to be universal in some appropriate way, making their choice not arbitrary. Recall that in $\mathbf{A} = R\text{-}\mathbf{Mod}$, an R-module M Is called projective if $\mathrm{Hom}_R(M, -)$ is exact, and injective if $\mathrm{Hom}_R(-, M)$ is exact. Recall that projective/injective modules nicely lend themselves to a splitting condition on short exact sequences for which they are one of the modules forming them (recall theorem 17.2.4 and theorem 17.3.4). This will be important, due to the link of chain homotopies with split exact sequences.

Definition 56.2.1: Projective And Injective Objects

Let $\mathbf{A}$ be an abelian category. Then

1. An object $P \in \mathbf{A}$ is said to be *projective* if the functor $\mathrm{Hom}_A(P, -)$ is exact.
2. An object $Q \in \mathbf{A}$ is said to be *injective* if the functor $\mathrm{Hom}_A(-, Q)$ is exact

theorem 17.2.4 and theorem 17.3.4 hold for abelian categories more generally (in particular the splitting remarks), as the reader may venture to check. Since the axioms for an abelian category are self-dual, so that $\mathbf{A}^{\mathrm{op}}$ is abelian whenever $\mathbf{A}$ is, the theory on projective objects is dual to that of injective object, and the functor $(-)^{\mathrm{op}}$ maps projective/injectives to injectives/projectives respectively. Thus, many proofs shall simply proof the result for projectives, the result for injectives coming automatically. Note that as we have seen in chapter 17$\star$ in a fixed [abelian] category $\mathbf{A}$, projective and injective may have very different features.

In what follows, let $\mathbf{P}$ denote the full subcategory of $\mathbf{A}$ determined by the projective objects, and let $\mathbf{I}$ denote the full subcategory of $\mathbf{A}$ determined by the injective objects. Let $K^-(\mathbf{P})$ denote the full subcategory of $K(\mathbf{A})$ consisting of bounded-above complexes of projective objects of $\mathbf{A}$, and $K^+(\mathbf{I})$ be the full subcategory of $K(\mathbf{A})$ consisting of bounded-below complexes of injective objects of $\mathbf{A}$. Note that these are generally not abelian categories, and furthermore projective and injective objects need not exist:

Example 56.2.2: Category With And Without Projective/Injective Resolutions

1. The category of finite abelian groups has no projective or injective, hence no projective/injective resolution.

2. The category of finitely generated abelian groups has projectives, but no injectives, namely since $\mathbb{Z}^n$ for every n are objects this category. Thus, it is possible to create a free, and hence projective, resolution.
3. the dual of the above category has enough injectives but not enough projectives.
4. The category of R-modules has both projective and injective resolutions (projective resolutions comes from free resolutions, while injective resolutions comes from repeated application of theorem 17.3.19)

It is thus helpful to add the following condition to an abelian category

Definition 56.2.3: Enough Projective And Enough Injectives

Let $\mathbf{A}$ be an abelian category. Then:

1. we say that $\mathbf{A}$ as *enough projectives* if for every object A of $\mathbf{A}$, there exists a projective object P of $\mathbf{A}$ and an epimorphism $P \twoheadrightarrow A$.
2. we say that $\mathbf{A}$ as *enough injectives* if for every object A of $\mathbf{A}$, there exists a injective object Q of $\mathbf{A}$ and a monomorphism $A \hookrightarrow Q$.

With the important definitions established, the main objective of this section may start going under way. The goal is to show that if we have a quasi-isomorphism between two bounded-above complexes of projectives $f^\bullet : P_0^\bullet \to P_1^\bullet$ (resp. quasi-isomorphism between two bounded-bellow complexes of injectives $f^\bullet : Q_0^\bullet \to Q_1^\bullet$), then $f^\bullet$ is in fact a homotopy-equivalence, from which it can be concluded that in $K^-(\mathbf{P})$ and $K^+(\mathbf{I})$ (homotopy-classes of) quasi-isomorphisms are isomorphisms, which shall give us the desired derived category $D^-(\mathbf{A})$ and $D^+(\mathbf{A})$ in the case where A has enough projectives (resp. enough injectives).

Let us now revisit this splitting condition. Recall that if $C^\bullet$ in $\mathrm{Ch}(\mathbf{A})$ is exact, then the identity map $\mathrm{id}_{C^\bullet}$ and the trivial map induce the same morphisms in (co)homology. However, there do exist exact complexes that are *not* homotopic to 0. As discussed earlier, this directly links to the splitting condition, namely the identity is homotopic to 0 if the sequence is split exact. Being projective is exactly the condition that causes splitting behavior. With this in mind, let us prove the first lemma:

Lemma 56.2.4: Zero-morphism In Cohomology And Homotopy

Let $\mathbf{A}$ be an abelian category, $P^\bullet \in \mathrm{Ch}^-(\mathbf{P})$ (i.e. $P^i = 0$ for $i > 0$), and let $C^\bullet$ be a complex in $\mathrm{Ch}(\mathbf{A})$ such that $H^i(C^\bullet) = 0$ for $i < 0$ (i.e. has trivial cohomology in negative coefficients). Let $f^\bullet : P^\bullet \to C^\bullet$ be a morphism of complexes that induces the zero-morphism in cohomology: $H^\bullet(f^\bullet) = 0$. Then

$$f^\bullet \sim 0$$

i.e., $f^\bullet$ is null-homotopic.

The injective version of this statement is comes from dualizing the appropriate terms.

***Proof*:**
To show $f^\bullet$ is null-homotopic, we must show there exists maps $h^i : P^i \to C^{i-1}$ such that

$$f^i = d^{i-1}_{C^\bullet} \circ h^i + h^{i+1} \circ d^i_{P^\bullet} \tag{56.5}$$

as a diagram:

$$\begin{array}{ccccccccccccc}
\cdots & \longrightarrow & P^{-2} & \longrightarrow & P^{-1} & \longrightarrow & P^0 & \longrightarrow & 0 & \longrightarrow & \cdots \\
 & \swarrow^{h^{-2}} & \downarrow{\scriptstyle f^{-2}} & \swarrow^{h^{-1}} & \downarrow{\scriptstyle f^{-1}} & \swarrow^{h^0} & \downarrow{\scriptstyle f^0} & \swarrow^{h^1=0} & \downarrow & & \\
\cdots & \longrightarrow & C^{-2} & \longrightarrow & C^{-1} & \longrightarrow & C^0 & \longrightarrow & C^1 & \longrightarrow & \cdots
\end{array}$$

Naturally, $h^i = 0$ for $i > 0$. For the rest, we shall use induction. The base case is $i = 0$. Since the cohomology induced by $f^\bullet$ is zero, f^0 factors through the image of $d^{-1}_{C^\bullet}$:

$$\begin{array}{ccccc}
 & & P^0 & & \\
 & & \downarrow{\scriptstyle f^0} & & \\
C^{-1} & \xrightarrow{d^{-1}_{C^\bullet}} & \mathrm{im} d^{-1}_{C^\bullet} & \longrightarrow & 0
\end{array}$$

Now, since P^0 is projective, there exists a morphism $h^0 : P^0 \to C^{-1}$ such that $f^0 = d^{-1}_{C^\bullet} \circ h^0$, as needed.

Next, assume h^i and h^{i+1} satisfies equation (56.5). The goal is to show h^{i-1} satisfies it too. By equation (56.5) and the fact that $P^\bullet$ is a complex:

$$d^{i-2}_{C^\bullet} \circ h^i \circ d^{i-1}_{P^\bullet} = (f^i - h^{i+1} \circ d^{i-1}_{P^\bullet}) = f^i \circ d^{i-1}_{P^\bullet} - h^{i+1} \circ 0 = f^i \circ d^{i-1}_{P^\bullet}$$

which can be seen by staring at the following diagram:

$$\begin{array}{ccccccccc}
\cdots & \cdots\cdots\to & P^{i-1} & \xrightarrow{d^{i-1}_{P^\bullet}} & P^i & \xrightarrow{d^i_{P^\bullet}} & P^{i+1} & \cdots\cdots\to & \\
 & & \vdots & \swarrow^{h^i} & \downarrow{\scriptstyle f^i} & \swarrow^{h^{i+1}} & \vdots & & \\
\cdots & \cdots\cdots\to & C^{i-1} & \xrightarrow[d^{i-1}_{C^\bullet}]{} & C^i & \cdots\cdots\to & C^{i+1} & \cdots\cdots\to &
\end{array}$$

Thus, since f^b is a morphism of cochain complexes:

$$d^{i-1}_{C^\bullet} \circ (f^{i-1} - h^i \circ d^{i-1}_{P^\bullet}) = d^{i-1}_{C^\bullet} \circ f^{i-1} - f^i \circ d^{i-1}_{P^\bullet} = 0$$

Importantly, $(f^{i-1} - h^i \circ d^{i-1}_{P^\bullet})$ factors through $\ker d^{i-1}_{C^\bullet}$. Since $C^\bullet$ is exact at C^{i-1} for $i \leq 0$, $\ker d_{C^\bullet} = \mathrm{im}^{i-2}_{C^\bullet}$. Thus, we get:

$$\begin{array}{ccccc}
 & & P^{i-1} & & \\
 & & \downarrow{\scriptstyle f^{i-1} - h^i \circ d^{i-1}_{P^\bullet}} & & \\
C^{i-2} & \xrightarrow{d^{i-2}_{C^\bullet}} & \mathrm{im}(d^{i-2}_{C^\bullet}) & \longrightarrow & 0
\end{array}$$

Now, since P^{i-1} is projective, there exists a lift $h^{i-1} : P^{i-1} \to C^{i-2}$ such that

$$f^{i-1} - h^i \circ d^{i-1}_{P^\bullet} = d^{i-2}_{C^\bullet} \circ h^{i-1}$$

which, shuffling around, gives us

$$f^{i-1} = d^{i-2}_{C^\bullet} \circ h^{i-1} + h^i \circ d^{i-1}_{P^\bullet}$$

as we sought to show.

Corollary 56.2.5: Exactness Cohomology And Homotopy

Let $\mathbf{A}$ be an abelian category, $P^\bullet \in \mathrm{Ch}^-(\mathbf{P})$ a bounded-above complex of projectives, and $C^\bullet \in \mathrm{Ch}(\mathbf{A})$ an exact complex. Then every morphism $P^\bullet \to C^\bullet$ is homotopic to 0.

***Proof*:**
Every morphism to an exact complex induces the zero morphism in cohomology. After a translation of degrees, which changes neither the hypotheses nor the conclusion, $P^i = 0$ for $i > 0$, and $H^i(C^\bullet) = 0$ for every i, so lemma 56.2.4 applies, completing the proof.

Note the importance of the bounding from above/bellow (depending on whether working with projectives or injective) in the inductive argument, without it there would not be an appropriate base case. Using the above results, the first quasi-isomorphism to homotopy equivalence can be established:

Corollary 56.2.6: Projectives With Quasi-isomorphism And Zero Morphisms

Let $P^\bullet$ (resp. $Q^\bullet$) be a bounded-above exact complex of projectives (resp. a bounded bellow exact complex of injectives). Then $P^\bullet$ (resp. $Q^b b$) is homotopy-equivalent to the zero-complex.

***Proof*:**
Treat the projective case; the injective one is the same argument in the opposite category. A complex is homotopy equivalent to the zero complex exactly when its identity morphism is null-homotopic, since a homotopy inverse to the zero complex forces $\mathrm{id} \sim 0$ and conversely. By lemma 56.1.26 it therefore suffices to show that $P^\bullet$ is split exact.

Write $Z^n = \ker d^n$ and $B^n = \mathrm{im} d^{n-1}$; exactness gives $Z^n = B^n$, so for every n there is a short exact sequence

$$0 \to B^n \to P^n \to B^{n+1} \to 0$$

Since $P^\bullet$ is bounded above there is an N with $P^n = 0$ for $n > N$, whence $B^n = 0$ for $n > N+1$.

Argue by descending induction that each B^n is projective. For $n > N+1$ it is zero. Suppose B^{n+1} is projective. Then the displayed short exact sequence splits, because a surjection onto a projective object admits a section, so $P^n \cong B^n \oplus B^{n+1}$ and B^n is a direct summand of the projective object P^n, hence projective itself.

Every one of the short exact sequences therefore splits. Choosing a section $\sigma^{n+1} \colon B^{n+1} \to P^n$ of d^n for each n and letting $s^{n+1} \colon P^{n+1} \to P^n$ be σ^{n+1} composed with the projection $P^{n+1} \twoheadrightarrow B^{n+1}$ gives $dsd = d$, since $d^n \sigma^{n+1}$ is the identity on B^{n+1} and d factors through B^{n+1}. So $P^\bullet$ is split exact, and lemma 56.1.26 makes $\mathrm{id}_{P^\bullet}$ null-homotopic, completing the proof.

Another important result that will be used in the next section is that quasi-isomorphisms are "non-zero-divisors" up to homotopy wrt morphisms from commplexes of projectives:

Lemma 56.2.7: Quasi-isomorphisms Of Projectives And Zero-divisor

Let $\mathbf{A}$ be an abelian category, $f^\bullet : C^\bullet \to D^\bullet$ be a quasi-isomorphism. Let $P^\bullet$ be a bounded-above complex of projectives, and let $\alpha^\bullet : P^\bullet \to C^\bullet$ be a morphism of cochain complexes such that the composition:

$$P^\bullet \xrightarrow{\alpha^\bullet} C^\bullet \xrightarrow{f^\bullet} D^\bullet$$

is homotopic to the zero-morphism. Then $\alpha^\bullet \sim 0$

***Proof*:**
Let $h^i : P^i \to D^{i-1}$ define the homotopy between $f^\bullet \circ \alpha^\bullet$ and 0, namely:

$$-f^i \circ \alpha^i = d^{i-1}_{C^\bullet} \circ h^i + h^{i+1} \circ d^i_{P^\bullet}$$

Take the mapping cone $MC(f)^\bullet$ of $f^\bullet$ and define the morphisms:

$$\beta^i = (\alpha^\cdot h^i) : P^i \to MC(f)^{i-1}$$

which may be visualized in the following diagram:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & P^{i-1} & \xrightarrow{d^{i-1}_{P^\bullet}} & P^i & \xrightarrow{d^i_{P^\bullet}} & P^{i+1} & \longrightarrow & \\
 & & \downarrow{\scriptstyle \beta^{i-1}} & & \downarrow{\scriptstyle \beta^i} & & \downarrow{\scriptstyle \beta^{i+1}} & & \\
\cdots & \longrightarrow & C^{i-1} \oplus D^{i-2} & \xrightarrow[d^{i-2}_{MC(f)^\bullet}]{} & C^i \oplus D^{i-1} & \xrightarrow[d^{i-1}_{MC(f)^\bullet}]{} & C^{i+1} \oplus D^i & \longrightarrow &
\end{array}$$

These give a morphism of cochain complexes $P^\bullet \to MC(f)[-1]^\bullet$. Indeed:

$$\begin{aligned}
\beta^{i+1} \circ d^i_{P^\bullet} &= (\alpha^{i+1} \circ d^i_{P^\bullet}, h^{i+1} \circ d^i_{P^\bullet}) \\
-d^{i-1}_{MC(f)} \circ \beta^i &= (d^i_{C^\bullet} \circ \alpha^i, -f^i \circ \alpha^i - d^{i-1}_{M^\bullet} \circ h^i)
\end{aligned}$$

Then by definition of h^i and by the morphism property of $\alpha^\bullet$, these are equal. Now, by hypothesis, $f^\bullet$ is a quasi-isomorphism. Then by proposition 56.1.24 $MC(f)^\bullet$ is an exact complex. Then by corollary 56.2.6 $\beta^\bullet$ is homotopic to 0. Since $\alpha^\bullet$ is the composition:

$$P^\bullet \xrightarrow{\beta^\bullet} MC(f)[-1]^\bullet = L^\bullet \oplus M[-1]^\bullet \to L^\bullet$$

it follows that $\beta^\bullet \sim 0$ implies $\alpha^\bullet \sim 0$, as we sought to show.

Though $\alpha^\bullet$ must be homotopic to 0, it need not be the case that $\alpha^\bullet = 0$. Take for example:

$$\begin{array}{ccccccccccc}
\cdots & \longrightarrow & 0 & \longrightarrow & \mathbb{Z} & \longrightarrow & \mathbb{Z} & \longrightarrow & 0 & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow{\scriptstyle \mathrm{id}} & & \downarrow{\scriptstyle \cdot 2} & & \downarrow & & \\
\cdots & \longrightarrow & 0 & \longrightarrow & \mathbb{Z} & \xrightarrow{\cdot 2} & \mathbb{Z} & \longrightarrow & 0 & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow{\scriptstyle \pi} & & \downarrow & & \\
\cdots & \longrightarrow & 0 & \longrightarrow & 0 & \longrightarrow & \mathbb{Z}/2\mathbb{Z} & \longrightarrow & 0 & \longrightarrow & \cdots
\end{array}$$

In this case, $f^\bullet$ is a quasi-isomorphism and $f^\bullet \circ \alpha^\bullet = 0$, and so $\alpha^\bullet \sim 0$, even though it is not equal to 0. With this, one more result is required before the desired goal:

Proposition 56.2.8: projectives, and one-sided inverses

Let $\mathbf{A}$ be an abelian category, $C^\bullet \in \mathrm{Ch}(\mathbf{A})$, $P^\bullet \in \mathrm{Ch}^-(\mathbf{P})$, and $f^\bullet : C^\bullet \to P^\bullet$ a quasi-isomorphism. Then there exists a morphism of complexes $g^\bullet : P^\bullet \to C^\bullet$ such that:

$$f^\bullet \circ g^\bullet \sim \mathrm{id}_{P^\bullet}$$

For injective, $Q^\bullet \in \mathrm{Ch}^+(\mathbf{I})$, $f^\bullet : Q^\bullet \to C^\bullet$ is a quasi-isomorphism, for which then there exists a morphism $g^\bullet : C^\bullet \to Q^\bullet$ such that $g^\bullet \circ f^\bullet \sim \mathrm{id}_{Q^\bullet}$. Notice that this is a one-sided inverse, hence is a slightly more general result than what is being built up to.

***Proof*:**
Since $f^\bullet : C^\bullet \to P^\bullet$ is a quasi-isomorphism, $MC(f)^\bullet = C[1]^\bullet \oplus P^\bullet$ is an exact complex. Define $\rho^\bullet = (0, \mathrm{id}_{P^\bullet})$ to be the morphism:

$$\rho^\bullet : P^\bullet \to MC(f)^\bullet$$

By corollary 56.2.5, since $MC(f)^\bullet$ is exact, $\rho^\bullet$ is homotopic to the zero morphism. Thus, there exists morphisms:

$$\widehat{h}^i : P^i \to MC(f)^{i-1} = C^i \oplus P^{i-1}$$

such that

$$\rho^i = d^{i-1}_{MC(f)^\bullet} \circ \widehat{h}^i + \widehat{h}^{i+1} \circ d^i_{P^\bullet}$$

Visually, we may see this as:

$$\begin{array}{ccccccccccc}
\cdots & \longrightarrow & P^{i-1} & \xrightarrow{d^{i-1}_{P^\bullet}} & P^i & \xrightarrow{d^i_{P^\bullet}} & P^{i+1} & \longrightarrow & \cdots \\
 & & \downarrow{\scriptstyle \rho^{i-1}} & \swarrow{\scriptstyle \widehat{h}^i} & \downarrow{\scriptstyle \rho^i} & \swarrow{\scriptstyle \widehat{h}^{i+1}} & \downarrow{\scriptstyle \rho^{i+1}} & & \\
\cdots & \longrightarrow & C^i \oplus P^{i-1} & \xrightarrow[d^{i-1}_{MC(f)^\bullet}]{} & C^{i+1} \oplus P^i & \xrightarrow[d^i_{MC(f)^\bullet}]{} & C^{i+2} \oplus P^{i+1} & \longrightarrow & \cdots
\end{array}$$

Now, write out $\widehat{h}^i$ out in components so that $\widehat{h}^i = (g^i, h^i)$ where $g^i : P^i \to C^i$ and $h^i : P^i \to P^{i-1}$. We will show that the collection $\{g^i\}_{i \in \mathbb{Z}}$ is a morphism of cochain complexes (i.e. they form commutative squares $g^{i+1} \circ d^i_{P^\bullet} = d^i_{C^\bullet} \circ g^i$) such that $f^\bullet \circ g^\bullet \sim \mathrm{id}_{P^\bullet}$. Indeed, since

$$\begin{aligned}
(0, \mathrm{id}_{P^i}) &= \rho^i \\
&= d^{i-1}_{MC(f)^\bullet} \circ \widehat{h}^i + \widehat{h}^{i+1} \circ d^i_{P^\bullet} \\
&= (d_{MC}(f)^\bullet)^{i-1} \circ (g^i, h^i) + (g^{i+1}, h^{i+1}) \circ d^i_{P^\bullet} \\
&= (-d^i_{C^\bullet} \circ g^i, f^i \circ g^i + d^{i-1}_{P^\bullet} \circ h^i) + (g^{i+1} \circ d^i_{P^\bullet}, h^{i+1} \circ d^i_{P^\bullet})
\end{aligned}$$

It follows that:

$$\begin{aligned}
g^{i+1} \circ d^i_{P^\bullet} - d^i_{C^\bullet} \circ g^i &= 0 \\
\mathrm{id}_{P^i} - f^i \circ g^i &= d^{i-1}_{P^\bullet} \circ h^i + h^{i+1} \circ d^i_{P^\bullet}
\end{aligned}$$

which is exactly what we need, hence the morphism of complexes $g^\bullet : P^\bullet - > C^\bullet$ is the needed homotopy right-inverse of $f^\bullet$, as we sought to show.

With this, we can finally prove the desired result:

Theorem 56.2.9: Projective, Quasi-isomorphism Becomes Homotopy

Let $\mathbf{A}$ be an abelian category, and let $\alpha^\bullet : P_0^\bullet - > P_1^\bullet$ be a quasi-isomorphism between bounded-above complexes of projectives (resp. quasi-isomorphism between two bounded-bellow complexes of injectives $f^\bullet : Q_0^\bullet \to Q_1^\bullet$). Then $\alpha^b b$ is a homotopy-equivalence.

***Proof*:**
The argument for projectives shall be given, the injective argument following by appropriate dualizing. By proposition 56.2.8, since $P_1^\bullet$ is in $C^-(\mathbf{P})$ and $\alpha^\bullet : P_0^\bullet \to P_1^\bullet$ is a quasi-isomorphism, there exists a morphism of complexes $\beta^\bullet : P_1^\bullet \to p_0^\bullet$ such that

$$\alpha^\bullet \circ \beta^\bullet \sim \mathrm{id}^\bullet_{P_1}$$

Then by proposition 56.1.29, $H^\bullet(\alpha^\bullet) \circ H^\bullet(\beta^\bullet) = \mathrm{id}$. Since $H^\bullet(\alpha^\bullet)$ is invertible, so is $H^\bullet(\beta^\bullet)$, and so $\beta^\bullet$ must be a quasi-isomorphism. Since $P_0^\bullet$ is also in $\mathrm{Ch}^-(\mathbf{P})$, we have that there exists a morphism $(\alpha^\bullet)' : P_0^\bullet \to P_1^\bullet$ such that $\beta^\bullet \circ (\alpha^\bullet)' \sim \mathrm{id}_{P_0^\bullet}$. Since:

$$(\alpha^\bullet)' \sim (\alpha^\bullet \circ \beta^\bullet) \circ (\alpha^\bullet)' = \alpha^\bullet(\beta^\bullet \circ (\alpha^\bullet)') \sim \alpha^\bullet$$

it follows that $\beta^\bullet \sim \alpha^\bullet \sim_{P_0^\bullet}$ (exercise 4.6 in Aluffi). Thus, $\alpha^\bullet$ is indeed a homotopy equivalence, as we sought to show.

Corollary 56.2.10: Projective In Homotopy Category

In $K^-(\mathbf{P})$ and $K^+(\mathbf{I})$, (homotopy classes of) quasi-isomorphissm are isomorphisms.

***Proof*:**
follows immediately form theorem 56.2.9.

56.2.1 Resolutions

With the important equivalence between quasi-isomorphisms and homotopy-equivalence established in the case of complexes of projective (resp. projective) objects, we turn back our attention to the question of finding (co)homological invariants, focusing on categories with enough projective s(resp. Injectives). In particular, given an object A in an abelian category $\mathbf{A}$, it wouldb e desirable to associate to it a (co)chain of projective (resp. injective) objects in some universal way (up to homotopy) from which information can be extracted.

Let us first refine the definition of projective/injective resolutions of an object. Recall that there i a copy of $\mathbf{A}$ in $\mathrm{Ch}(\mathbf{A})$ given by mapping $A \mapsto \iota(A)$.

Definition 56.2.11: Projective And Injective Resolution

Let $A \in \mathrm{Obj}(\mathbf{A})$ be an object in an abelian category A. Then:

1. A *resolution* of A is a quasi-isomorphism $C^\bullet \to \iota(A)$ for some complex $C^\bullet \in \mathrm{Obj}(\mathrm{Ch}(\mathbf{A}))$.
2. A *projective resolution* of A is a quasi-isomorphism $P^\bullet \to \iota(A)$ where $P^\bullet$ is a complex in $\mathrm{Ch}^{\leq 0}(\mathbf{P})$
3. An *injective resolution* of A is a quasi-isomorphism $\iota(A) \to Q^\bullet$ where $Q^\bullet$ is a complex in $\mathrm{Ch}^{\geq 0}(\mathbf{I})$

Often, $P^\bullet$ and $Q^\bullet$ shall be referred to as the projective resolution and injective resolution respectively, omitting the quasi-isomorphism.

56.2.12 Remark There is a point of confusion that may arise. It may seem that the resolutions *themselves* are projective/injective objects in the abelian category $\mathrm{Ch}(\mathbf{A})$. However, this is not the case: a projective object of $\mathrm{Ch}(\mathbf{A})$ must be a complex of projectives that is moreover split exact in the relevant range, which a resolution is not.

Recall further that any resolution $C^\bullet$ will be exact everywhere except possibly at C^0 (exercise, or double-check example 56.1.16). Hence, the non-trivial cohomological information lies in $H^0(C^\bullet)$. Let us now focus on resolutions for a particular object A: consider the category of homotopy classes of quasi-isomorphisms with *target* $\iota(A)$. Then we shall show that, if they exist, projective resolution are initial in this category.

$$\begin{array}{ccc} P^\bullet & & \\ \downarrow{\scriptstyle \exists!} & \searrow & \\ C^\bullet & \xrightarrow[\text{q-iso}]{} & \iota(A) \end{array}$$

Analogously, injective resolutions are final in homotopic category of quasi-isomorphisms with *source* $\iota(A)$. Given this universal property, this means that each projective resolution maps uniquely (in $K(\mathbf{A})$) to *every* resolution of A. The following lemma proves this:

Lemma 56.2.13: Projective Resolution As Initial Objects

Let $A \in \mathbf{A}$, let $C^\bullet$ be a resolution of A (so that $C^i = 0$ for $i > 0$, $H^i(C^\bullet) = 0$ for $i < 0$, and $H^0(C^\bullet) = A$), and let $P^\bullet \in \mathrm{Ch}^{\leq 0}(\mathbf{P})$ be a bounded-above complex of projectives. Then any morphism

$$\varphi : H^0(P^\bullet) \to H^0(C^\bullet) \; [= A]$$

is induced by a morphism of complexes $\varphi^\bullet : P^\bullet \to C^\bullet$, and any two such $\varphi^\bullet$ are homotopic.

***Proof*:**

Since both complexes vanish in positive degrees, $H^0(P^\bullet) = \mathrm{coker} d_P^{-1}$ and $H^0(C^\bullet) = \mathrm{coker} d_C^{-1}$; write $\pi_P \colon P^0 \twoheadrightarrow H^0(P^\bullet)$ and $\pi_C \colon C^0 \twoheadrightarrow A$ for the two quotient maps.

Step 1: Degree 0. The composite $\varphi \circ \pi_P \colon P^0 \to A$ is a morphism out of a projective object, and

π_C is an epimorphism, so by definition 56.2.1 it lifts: there is $\varphi^0 \colon P^0 \to C^0$ with $\pi_C \circ \varphi^0 = \varphi \circ \pi_P$.

Step 2: Degree -1. Compute

$$\pi_C \circ \varphi^0 \circ d_P^{-1} = \varphi \circ \pi_P \circ d_P^{-1} = 0$$

since $\pi_P \circ d_P^{-1} = 0$. Hence $\varphi^0 \circ d_P^{-1}$ factors through $\ker \pi_C = \mathrm{im} d_C^{-1}$. As P^{-1} is projective and d_C^{-1} is an epimorphism onto its image, the map $P^{-1} \to \mathrm{im} d_C^{-1}$ lifts to $\varphi^{-1} \colon P^{-1} \to C^{-1}$ with $d_C^{-1} \circ \varphi^{-1} = \varphi^0 \circ d_P^{-1}$.

Step 3: The induction. Suppose φ^{-i} has been constructed for $i < n$ with every square commuting. Then

$$d_C^{-n+1} \circ \left(\varphi^{-n+1} \circ d_P^{-n}\right) = \varphi^{-n+2} \circ d_P^{-n+1} \circ d_P^{-n} = 0$$

so $\varphi^{-n+1} \circ d_P^{-n}$ lands in $\ker d_C^{-n+1}$, which for $n \geq 2$ equals $\mathrm{im} d_C^{-n}$ because $C^\bullet$ is exact in degree $-n+1 < 0$; the case $n = 1$ is Step 2, where $\ker \pi_C$ plays that role. Projectivity of P^{-n} again lifts it along the epimorphism $C^{-n} \twoheadrightarrow \mathrm{im} d_C^{-n}$, producing φ^{-n} with $d_C^{-n} \circ \varphi^{-n} = \varphi^{-n+1} \circ d_P^{-n}$. This constructs $\varphi^\bullet$ in every degree, and Step 1 arranges that it induces φ on H^0.

Step 4: Uniqueness up to homotopy. Let $\varphi^\bullet$ and $\psi^\bullet$ both induce φ, and set $f^\bullet = \varphi^\bullet - \psi^\bullet$. On H^0 it induces $\varphi - \varphi = 0$, and in every negative degree $H^i(C^\bullet) = 0$, so $H^i(f^\bullet) = 0$ there as well; in positive degrees both complexes vanish. Hence $H^\bullet(f^\bullet) = 0$. The hypotheses of lemma 56.2.4 are met, $P^\bullet$ being a bounded-above complex of projectives and $C^\bullet$ having vanishing cohomology in negative degrees, so $f^\bullet \sim 0$, that is $\varphi^\bullet \sim \psi^\bullet$, completing the proof.

Since these are initial (resp. final) objects in the category, we have a unique isomorphism beetween any two solutions to the universal problem. In this case, this may be stated as followed:

Proposition 56.2.14: Unique Projection Resolution

Let $\mathbf{A}$ be an abelian category. Then any two projective (resp. injective) resolutions of an object A in $\mathbf{A}$ are homotopy equivalent

***Proof*:**
Let $P^\bullet$ and $Q^\bullet$ be two projective resolutions of A, so that each is a bounded-above complex of projectives with $H^0 = A$. Apply lemma 56.2.13 twice to the morphism id_A: once with source $P^\bullet$ and target $Q^\bullet$, giving $f^\bullet \colon P^\bullet \to Q^\bullet$, and once the other way, giving $g^\bullet \colon Q^\bullet \to P^\bullet$. Each is unique up to homotopy.

The composite $g^\bullet \circ f^\bullet \colon P^\bullet \to P^\bullet$ induces id_A on H^0, and so does $\mathrm{id}_{P^\bullet}$. Both are therefore lifts of the same morphism id_A, and the uniqueness clause of lemma 56.2.13 gives $g^\bullet \circ f^\bullet \sim \mathrm{id}_{P^\bullet}$. Symmetrically $f^\bullet \circ g^\bullet \sim \mathrm{id}_{Q^\bullet}$. Hence $f^\bullet$ is a homotopy equivalence with homotopy inverse $g^\bullet$, as we sought to show. The injective case is dual.

A final important observation is that this lift is functorial!

Proposition 56.2.15: Projective Resolution Functoriality

Let $\mathbf{A}$ be an abelian category, and let A_0, A_1 be objects of $\mathbf{A}$. Let $P_0^\bullet$ and $P_1^\bullet$ be projective resolutions for A_0 and A_1 respectively. Then every morphism $\varphi : A_0 \to A_1$ in $\mathbf{A}$ induces a morphism $\alpha^\bullet : P_0^\bullet \to P_1^\bullet$ that is unique up to homotopy

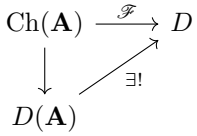
***Proof*:**
Notice that φ can be interpreted as a morphism $\varphi : H^0(P_0^\bullet) \to H^0(P_1^\bullet)$. The complex $P_0^\bullet$ consists of projectives, and $P1^\bullet$ is a resolution of A_1. Thus, by lemma 56.2.13, there exists a list α^b that is unique up to homotopy, as we sought to show.

Corollary 56.2.16: Full Subcategory Of Homotopic Category

Let $\mathbf{A}$ be an abelian category with enough projectives (resp. enough injectives). Then $\mathbf{A}$ is equivalent to a full subcategory of $K^-(\mathbf{P})$ (resp. $K^+(\mathbf{I})$).

***Proof*:**
Treat the projective case. Choose for each object A of $\mathbf{A}$ a projective resolution $P_A^\bullet$, possible because $\mathbf{A}$ has enough projectives, and send $A \mapsto P_A^\bullet$. By proposition 56.2.15 every $\varphi\colon A_0 \to A_1$ lifts to a morphism of resolutions, well defined up to homotopy, so this is a functor $R\colon \mathbf{A} \to K^-(\mathbf{P})$: composites and identities are preserved because a lift of a composite and the composite of lifts both lift the same morphism and so agree up to homotopy, which is equality in $K^-(\mathbf{P})$.

R is faithful. If $R(\varphi) = 0$ then a lift $\varphi^\bullet$ of φ is null-homotopic, so it induces the zero morphism on cohomology by proposition 56.1.27. Since $H^0(\varphi^\bullet) = \varphi$ under the identifications $H^0(P_{A_i}^\bullet) = A_i$, this gives $\varphi = 0$.



R is full. Let $f^\bullet\colon P_{A_0}^\bullet \to P_{A_1}^\bullet$ be any morphism in $K^-(\mathbf{P})$, represented by a chain map. It induces $\varphi := H^0(f^\bullet)\colon A_0 \to A_1$, and $f^\bullet$ is then a lift of φ. By the uniqueness clause of lemma 56.2.13 any two lifts of φ are homotopic, so $R(\varphi) = [f^\bullet] = f^\bullet$ in $K^-(\mathbf{P})$.

A fully faithful functor is an equivalence onto its essential image, which is a full subcategory of $K^-(\mathbf{P})$. Hence $\mathbf{A}$ is equivalent to a full subcategory of $K^-(\mathbf{P})$, and dually to one of $K^+(\mathbf{I})$ when $\mathbf{A}$ has enough injectives, completing the proof.

56.2.2 Derived Category with Enough Projectives

Let us finally confirm that the solution to the universal problem in equation 56.2. Recall that the derived category is a category $D(\mathbf{A})$ where for any category D for which there exists an additive functor $\mathscr{F} : \mathrm{Ch}(\mathbf{A}) \to D$ where every quasi-isomorphism in $\mathrm{Ch}(\mathbf{A})$ becomes an isomorphism in D,

there exists a unique functor such that the following diagram commutes:

In the case where $\mathbf{A}$ has enough projectives (resp. enough injectives) and is bounded from above (resp. from bellow), then $K^-(\mathbf{P})$ (resp. $K^+(\mathbf{I})$) is the solution to the above universal problem. In particular, there is an equivalence of categories between $K^-(\mathbf{P})$ and $D^-(\mathbf{A})$. The formal definition of the derived category shall be given in section 57.2, hence this equivalence shall not be proven, however the universal property is readily provable, and once the derived category is formally defined it will be the equivalence essentially come to proper manipulation of universal properties.

To start, a general procedure for finding projective/injective resolutions for any (co)chain must be explored. The discussion so far has been for projective/injective resolution, that is quasi-isomorphisms $P^\bullet \to \iota(A)$ or $\iota(A) \to Q^\bullet$. Is it possible to replace $\iota(A)$ with any bounded complex? The answer is yes, though rather technical. The importance of this will be the existence of a functor p that maps $\mathrm{Ch}^-(\mathbf{P})$ into $K^-(\mathbf{P})$, which shall be important for solving the universal problem above, as well as finding functors between derived categories. Such functors shall also be key in solving the "extension problem" that was mentioned all the way back in chapter 17⋆.

Theorem 56.2.17: Resolution And Complexes

Let $\mathbf{A}$ be an abelian category with enough projectives and $C^\bullet$ a complex in $C^-(\mathbf{A})$. Then there exists a bounded-above complex of projective $P^\bullet$ and a quasi-isomorphism $P^\bullet \to C^\bullet$, where $P^\bullet$ is uniquely defined up to homotopy equivalence. Furthermore, every morphism $\alpha^\bullet$ of complexes in $C^-(\mathbf{A})$ lifts to a morphism of the corresponding projective resolutions in $K^-(\mathbf{P})$, which is uniquely defined up to homotopy.

***Proof Key ideas*:**
The uniqueness and lifting halves are already available; only the existence half needs a construction, and that construction is a descending induction whose bookkeeping is long without being conceptually informative, so it is given in outline here and in full in *An Introduction to Homological Algebra* [101].

Existence. Let $C^\bullet$ be bounded above, say $C^n = 0$ for $n > N$. Build P^n by descending induction on n, starting with $P^n = 0$ for $n > N$. At each stage one has already constructed the terms above degree n together with the maps to $C^\bullet$, and one chooses a projective object surjecting onto the pullback of C^n against the cycles constructed one degree up. That single choice simultaneously arranges surjectivity on cohomology in degree n and injectivity in degree $n+1$, which is what makes the resulting map a quasi-isomorphism; enough projectives is exactly what gives the surjection at each stage.

Uniqueness up to homotopy equivalence. Two such projective complexes over $C^\bullet$ are homotopy equivalent by the argument of proposition 56.2.14, with its object-level input lemma 56.2.13 replaced by the lifting of morphisms in the next paragraph, whose existence comes from corollary 56.2.5 and whose uniqueness up to homotopy comes from lemma 56.2.7. Applied to

$\mathrm{id}_{C^\bullet}$, it gives a map each way over $C^\bullet$, and both composites lift the identity, hence are homotopic to it by that uniqueness.

Lifting of morphisms. Given $\alpha^\bullet : C^\bullet \to D^\bullet$ and projective complexes $P^\bullet \to C^\bullet$, $Q^\bullet \to D^\bullet$, the composite $P^\bullet \to C^\bullet \to D^\bullet$ is a morphism from a bounded-above complex of projectives into a complex quasi-isomorphic to $Q^\bullet$. Existence of a factorization through $Q^\bullet$ comes from corollary 56.2.5, applied to the cone of $Q^\bullet \to D^\bullet$, and its uniqueness up to homotopy from the cancellation property lemma 56.2.7. Together they give a well-defined morphism in $K^-(\mathbf{P})$.

Thus, given an abelian category $\mathbf{A}$ with enough projective, there is a functor

$$\mathscr{P} : C^-(\mathbf{A}) \to K^-(\mathbf{P})$$

associating each (bounded-above) complex $C^\bullet$ to a projective resolution $\mathscr{P}(C^\bullet)$ in a functorial manner (so that morphisms $f^\bullet$, $g^\bullet$ are lifted and $\mathscr{P}(g^\bullet \circ f^\bullet) = \mathscr{P}(g^\bullet) \circ \mathscr{P}(f^\bullet)$ since both sides are classes of homotopy lifts of $g^\bullet \circ f^\bullet$). The uniqueness of $\mathscr{P}$ is up to natural transformation, that is if another functor $\mathscr{P}'$ is chosen that assigns a different choice of projective resolution, then by theorem 56.2.17 there is a homotopy equivalence between $\mathscr{P}(C^\bullet)$ and $\mathscr{P}'(C^\bullet)$, hence an isomorphism $\varphi_{C^\bullet} : \mathscr{P}(C^\bullet) \to \mathscr{P}'(C^\bullet)$ in $K^-(\mathbf{P})$. Since the identity on $C^\bullet$ lifts to a unique map up to homotopy, the isomorphism $\varphi_{C^\bullet}$ is unique. Furthermore, given a morphism $f^\bullet : C^\bullet \to D^\bullet$, the diagram:

$$\begin{array}{ccc} \mathscr{P}(C^\bullet) & \xrightarrow{\mathscr{P}(f^\bullet)} & \mathscr{P}(D^\bullet) \\ {\scriptstyle \varphi_{C^\bullet}}\downarrow{\scriptstyle \sim} & & {\scriptstyle \sim}\downarrow{\scriptstyle \varphi_{D^\bullet}} \\ \mathscr{P}'(C^\bullet) & \xrightarrow[\mathscr{P}'(f^\bullet)]{} & \mathscr{P}'(D^\bullet) \end{array}$$

commutes (again by the uniqueness of lifts up to homotopy, can you see why)? Thus, we have the unique natural isomorphism for any two choices of functors giving a projective resolution.

Theorem 56.2.18: Universal Property Of Derived Category With Enough Projectives

Let $\mathbf{A}$ be an abelian category with enough projectives, and $\mathscr{P}$ a functor sending bounded-above cochains to projective resolutions. Then:

1. If $f^\bullet$ is a quasi-isomorphism in $C^-(\mathbf{A})$, then $\mathscr{P}(f^\bullet)$ is an isomorphism in $K^-(\mathbf{P})$
2. If $\mathscr{F} : C^-(\mathbf{A}) \to D$ is an additive functor that takes quasi-isomorphisms to isomorphisms, then there exists a unique functor $\widetilde{\mathscr{F}} : K^-(\mathbf{P}) \to D$ unique up to natural isomorphism such that the following diagram commutes up to natural isomorphism:

$$\begin{array}{ccc} C^-(\mathbf{A}) & \xrightarrow{\mathscr{F}} & D \\ {\scriptstyle \mathscr{P}}\downarrow & \nearrow_{\widetilde{\mathscr{F}}} & \\ K^-(\mathbf{P}) & & \end{array}$$

where commuting up to natural transformation means there exists a natural transformation $\nu : \widetilde{\mathscr{F}} \circ \mathscr{P} \rightsquigarrow \mathscr{F}$ such that:

$$\nu_{C^\bullet} : \widetilde{\mathscr{F}} \circ \mathscr{P}(C^\bullet) \xrightarrow{\sim} \mathscr{F}(C^\bullet)$$

is an isomorphism for every complex $C^\bullet$ in $C^-(\mathbf{A})$.

The fact that the commutative diagram commutes up to natural isomorphism reflects that the homotopic category is categorically equivalent to the derived category. If $\mathbf{A}$ has enough injective, then we may instead define the functor $\mathscr{I} : C^+(\mathbf{A}) \to K^+(\mathbf{I})$ that shall satisfy the dual universal property.

***Proof*:**

1. Let $f^\bullet : C^\bullet \to D^\bullet$ be any morphism in $C^-(\mathbf{A})$. By theorem 56.2.17, $f^\bullet$ lifts to a morphism of resolutions which commutes up to homotopy in the following diagram:

$$\begin{array}{ccc} \mathscr{P}(C^\bullet) & \xrightarrow{\mathscr{P}(f^\bullet)} & \mathscr{P}(C^\bullet) \\ {\scriptstyle \mu_{C^\bullet}}\downarrow & & \downarrow{\scriptstyle \mu_{D^\bullet}} \\ C^\bullet & \xrightarrow{f^\bullet} & D^\bullet \end{array}$$

where $\mu_{C^\bullet}, \mu_{D^\bullet}$ are the quasi-isomorphisms of the projective resolutions. Since the diagram commute up to homootpy, it commutes after taking cohomology, thus since $f^\bullet$ is a quasi-isomorphism, so is $\mathscr{P}(f^\bullet)$. Then by corollary 56.2.10, $\mathscr{P}(f^\bullet)$ is an isomorphism.

2. Define $\widetilde{\mathscr{F}} : K^-(\mathbf{P}) \to D$ via:

$$\widetilde{\mathscr{F}}(P^\bullet) := \mathscr{F}(P^\bullet) \qquad \widetilde{\mathscr{F}}(f^\bullet) := \mathscr{F}(f^\bullet)$$

where $\widetilde{\mathscr{F}}(f^\bullet)$ can be any representative of $f^\bullet$. This map is well-defined, since homotopic morphisms have the same image in D (lemma 56.1.35). Naturally, $\widetilde{\mathscr{F}}$ is a functor. We

need to check the commutativity up to morphism of the diagram and the uniqueness of $\widetilde{\mathscr{F}}$ up to natural isomorphism.

First, let $C^\bullet \in C^-(\mathbf{A})$. Then (by construction of $\mathscr{P}$, there exists a quasi-isomorphism

$$\mu_{C^\bullet} : \mathscr{P}(C^\bullet) \to C^\bullet$$

Since $\mathscr{F}$ maps quasi-isomorphisms to isomorphism, the induced morphism $\nu_{C^\bullet} := \mathscr{F}(\mu_{C^\bullet})$:

$$\nu_{C^\bullet} : \widetilde{\mathscr{F}}(\mathscr{P}(C^\bullet)) = \mathscr{F}(\mathscr{P}(C^\bullet)) \to \mathscr{F}(C^\bullet)$$

is an isomorphism. What's left to check is that $\nu_{C^\bullet}$ defines a natural transformation. Let $f^\bullet : C^\bullet \to D^\bullet$ in $C^-(\mathbf{A})$. We want to show the following diagram commutes:

$$\begin{array}{ccc} \widetilde{\mathscr{F}}(\mathscr{P}(C^\bullet)) & \xrightarrow{\widetilde{\mathscr{F}}(\mathscr{P}(f^\bullet))} & \widetilde{\mathscr{F}}(\mathscr{P}(D^\bullet)) \\ {\scriptstyle \nu_{C^\bullet}}\downarrow & & \downarrow{\scriptstyle \nu_{D^\bullet}} \\ \mathscr{F}(C^\bullet) & \xrightarrow{\mathscr{F}(f^\bullet)} & \mathscr{F}(D^\bullet) \end{array}$$

This diagram is obtained by applying $\mathscr{F}$ to the diagram discussed above the theorem:

$$\begin{array}{ccc} \mathscr{P}(C^\bullet) & \xrightarrow{\mathscr{P}(f^\bullet)} & \mathscr{P}(D^\bullet) \\ {\scriptstyle \varphi_{C^\bullet}}\downarrow{\scriptstyle \sim} & & {\scriptstyle \sim}\downarrow{\scriptstyle \varphi_{D^\bullet}} \\ \mathscr{P}'(C^\bullet) & \xrightarrow[\mathscr{P}'(f^\bullet)]{} & \mathscr{P}'(D^\bullet) \end{array}$$

This diagram commutes up to homotopy, hence the other diagram commutes directly (lemma 56.1.35).

For uniqueness up to isomorphism, say $\overline{\mathscr{F}} : K^-(\mathbf{P}) \to D$ is another functor satisfying the properties. Then there exists a natural isomorphism:

$$\overline{\nu} : \overline{\mathscr{F}} \circ \mathscr{P} \rightsquigarrow \mathscr{F}$$

Now, for any $P^\bullet \in K^-(\mathbf{P})$, take the composition:

$$\overline{\mathscr{F}}(P^\bullet) \xrightarrow[\sim]{\overline{\mathscr{F}}(\mu_{P^\bullet})^{-1}} \overline{\mathscr{F}}(\mathscr{P}((P^\bullet)) \xrightarrow[\sim]{\overline{\nu}_{P^\bullet}} = \widetilde{\mathscr{F}}(P^\bullet)$$

If φ is this composition, then it is easy to verify that $\varphi : \overline{\mathscr{F}} \to \widetilde{\mathscr{F}}$ is a natural isomorphism, completing the proof.

56.3 Derived Functors: Ext and Tor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor. Often, we study information about $\mathbf{A}$ by passing it through $\mathbf{B}$ (think of $- \otimes N$ or $\mathrm{Hom}_R(N, -)$). As alluded to in section 17.6, such information may be the number of extensions two objects may have, the amount of torsion an object may have. In section 17.6, it was claimed that this comes from "fixing" the lack of exactness of a left- or right-exact functor using

homological algebra. We are finally in a position to make this precise. In this section, we shall show how to take a (not-necessarily left/right exact) additive functor between two abelian categories with $\mathbf{A}$ having enough projectives (resp. injectives) $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ and get a *derived functor*:

$$D^-(\mathscr{F}) : D^-(\mathbf{A}) \to D^-(\mathbf{B}) \qquad (\text{resp. } D^-(\mathscr{F}) : D^-(\mathbf{A}) \to D^-(\mathbf{B}))$$

This functor shall be used to develop a long-exact sequence in $\mathbf{B}$, given a short exact sequence of objects in $\mathbf{A}$.

56.3.1 Derived Functor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories. Then $\mathscr{F}$ extends to a functor:

$$\mathrm{Ch}(\mathscr{F}) : \mathrm{Ch}(\mathbf{A}) \to \mathrm{Ch}(\mathbf{B})$$

namely, if $C^\bullet$ is a complex:

$$\mathscr{F}(d^{i+1}_{C^\bullet}) \circ \mathscr{F}(d^i_{C^\bullet}) = \mathscr{F}(d^{i+1}_{C^\bullet} \circ d^i_{C^\bullet}) = \mathscr{F}(0) = 0$$

hence, $\mathrm{Ch}(\mathscr{F})(C^\bullet)$ is indeed a complex. Then since homotopic morphisms are sent to homotopic morphisms (lemma 56.1.32), $\mathrm{Ch}(\mathscr{F})$ induces a morphism $K(\mathscr{F})$:

$$K(\mathscr{F}) : K(\mathbf{A}) \to K(\mathbf{B})$$

From the results we have proved, we have the following commutative diagram:

$$\begin{array}{ccc} \mathbf{A} & \xrightarrow{\mathscr{F}} & \mathbf{B} \\ {\scriptstyle\iota}\downarrow & & \downarrow{\scriptstyle\iota} \\ K(\mathbf{A}) & \xrightarrow{K(\mathscr{F})} & K(\mathbf{B}) \end{array}$$

Furthermore, if the complexes are bounded, then certainly $\mathrm{Ch}(\mathscr{F})$ sends bounded complexes to bounded complexes, and hence the same holds for $K(\mathscr{F})$. Now, if $\mathbf{A}$ has enough projectives so that we may consider $K^-(\mathbf{P})$, can we restrict $K(\mathbf{A})$ to $K(P(\mathbf{A}))$, and map to $K(P(\mathbf{B}))$ (where $P(\mathbf{A})$ and $P(\mathbf{B})$ are the projectives of $\mathbf{A}$ and $\mathbf{B}$ respectively)? This is not the case in general; for example we saw that $- \otimes N$ in R-**Mod** does not preserve projectives. If $\mathbf{B}$ has enough projectives, then we may choose a projective resolution functor $\mathscr{P}_B : \mathrm{Ch}^-(B) \to K^-(\mathbf{P}^{-1})$ mapping each complex to a projective resolution in a functorial manner. Since $\mathscr{P}_B$ sends homotopic morphisms to homotopic morphisms (lemma 56.2.7), $\mathscr{P}_B$ descends to a functor $K(\mathscr{P}_B)$. Combining these facts, we may define the following functor:

Definition 56.3.1: Left-Derived (right-Derived) Functor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor. Then the *left-derived functor* of $\mathscr{F}$ is the composition:

$$K^-(P(\mathbf{A})) \xrightarrow[\iota_A]{} K^-(\mathbf{A}) \xrightarrow[K(\mathscr{F})]{} K^-(\mathbf{B}) \xrightarrow[K(\mathscr{P}_B))]{} K^-(P(\mathbf{B})) \qquad \mathbf{L}\mathscr{F} : K^-(\mathbf{A}) \to K^-(P(\mathbf{B}))$$

where ι_A is the inclusion of $K^-(P(\mathbf{A}))$ as a full subcategory of $K^-(\mathbf{A})$. The resulting functor is denoted $\mathbf{L}\mathscr{F}$.

It may seem that the natural notation would be $D^-(\mathscr{F})$, however the $\mathbf{L}\mathscr{F}$ notation was established before the abstraction given above, and has stuck. Similarly, if $\mathbf{A}$, $\mathbf{B}$ has enough injectives, we may define the right-derived functor $\mathbf{R}\mathscr{F}$.

It is natural to want to characterize $\mathbf{L}\mathscr{F}$ and $\mathbf{R}\mathscr{F}$ in terms of some universal property. Naturally, this universal property would be defined up to natural isomorphism, for $\mathscr{P}_A$ and $\mathscr{P}_B$ are chosen up to natural isomorphism. This turns to be a bit subtle. For example, there is no natural functor which shall always make the following diagram commute:

$$\begin{array}{ccc} \hat{\mathbf{A}} & \dashrightarrow^{??} & \hat{\mathbf{B}} \\ \downarrow & & \downarrow \\ K^-(P(\mathbf{A})) & \xrightarrow{\mathbf{L}\mathscr{F}} & K^-(P(\mathbf{B})) \end{array}$$

The reason is, it is not necessarily the case that a complex whose cohomology is concentrated at 0 would map via $\mathbf{L}\mathscr{F}$ to a complex with the same property. In fact, the reader may expect this, for the image of a functor $\mathscr{F}$ may present some non-trivial cohomological information, (think of $\mathscr{F} := \mathrm{Hom}_R(N, -)$ where N is non-projective). If the functor $\mathscr{F}$ is *exact*, then then there is essentially no "change in cohomology". This is captured in the following proposition:

Proposition 56.3.2: Derived Functors And Exactness

Let $\mathscr{F}$ be an additive *exact* functor. Then $\hat{\mathbf{A}}$ is in fact sent to $\hat{\mathbf{B}}$ via $\mathbf{L}\mathscr{F}$

***Proof*:**

Let $P^\bullet \in \hat{\mathbf{A}}$ so that $H^i(P^\bullet) = 0$ for all $i \neq 0$. Then $\mathbf{L}\mathscr{F}(P^\bullet)$ is given by choosing a projective resolution $P^\bullet_{\mathscr{F}(P^\bullet)}$ of $\mathscr{F}(P^\bullet)$. Since quasi-isomorphissm preserve cohomology and (key!) exact functors *commute* with cohomology, an exact functor carrying kernels to kernels and images to images and hence subquotients to subquotients:

$$H^i(\mathbf{L}\mathscr{F}(P^\bullet)) = H^i(P^\bullet_{\mathscr{F}(P^\bullet)}) \cong H^i(\mathscr{F}(P^\bullet)) \cong \mathscr{F}(H^i(P^\bullet)) = \mathscr{F}(0) \overset{i\neq 0}{=} 0$$

Thus, $\mathbf{L}\mathscr{F}(P^\bullet)$ does indeed map to an object of $\hat{\mathbf{B}}$.

Even more is true if $\mathscr{F}$ is exact: $H^i(\mathbf{L}\mathscr{F}(P^\bullet)) \cong \mathscr{F}(H^0(P^\bullet))$, saying that the restriction of $\mathbf{L}\mathscr{F}$ agrees with $\mathscr{F}$ (modulo equivalence of categories). Hence, in general we shall be interested in non-exact functors, usually functors that are only left or right exact.

Returning to finding an appropriate universal property for derived functors, another natural candidate would be given by taking a "step back" from the above diagram and consider instead if the following diagram commutes (up to natural isomorphism)

$$\begin{array}{ccc} K^-(\mathbf{A}) & \xrightarrow{K(\mathscr{F})} & K^-(\mathbf{B}) \\ \downarrow{\scriptstyle \mathscr{P}_A} & & \downarrow{\scriptstyle \mathscr{P}_B} \\ K^-(P(\mathbf{A})) & \xrightarrow[\mathbf{L}\mathscr{F}]{} & K^-(P(\mathbf{B})) \end{array}$$

in particular, that there may be a natural isomorphism:

$$\mathbf{L}\mathscr{F} \circ \mathscr{P}_A \overset{\sim}{\rightsquigarrow} \mathscr{P}_B \circ K(\mathscr{F})$$

Unfortunately, this is not in general the case

Example 56.3.3: Lacking Natural Isomorphism
(exercise 7.3 in Aluffi, should I put solution here?)

The following is the best we can hope for:

Proposition 56.3.4: Universal Property of (left-)Derived Functor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between abelian categories. Then $\mathbf{L}\mathscr{F}$ satisfies the following universal property:

1. There is a natural transformation:
$$\mathbf{L}\mathscr{F} \circ \mathscr{P}_A \overset{\sim}{\rightsquigarrow} \mathscr{P}_B \circ K(\mathscr{F})$$
2. for every functor $\mathscr{G} : K^-(P(\mathbf{A})) \to K^-(P(\mathbf{B}))$ and every natural tarnsformation $\gamma : \mathscr{G} \circ \mathscr{P}_A \rightsquigarrow \mathscr{P}_B \circ K(\mathscr{F})$, there is a unique (up to natural isomorphism) natural transformation $\mathscr{G} \rightsquigarrow \mathbf{L}\mathscr{F}$ inducign a factorization:
$$\gamma : \mathscr{G} \circ \mathscr{P}_A \rightsquigarrow \mathbf{L}\mathscr{F} \circ \mathscr{P}_A \rightsquigarrow \mathscr{P}_B \circ K(\mathscr{F})$$

A similar result holds for right-derived functors.

***Proof Key ideas*:**
The argument is the usual one for a Kan-extension-style universal property, and it is stated here rather than carried out because the ambient apparatus is not yet in place: the definition of $D(\mathbf{A})$ used below rests on the localization machinery that section 55.2 defers. The full treatment is in *An Introduction to Homological Algebra* [101].

For (1), the natural transformation is the comparison map induced by functoriality of projective resolutions: $\mathscr{P}_A$ picks a resolution, $K(\mathscr{F})$ applies $\mathscr{F}$ termwise, and proposition 56.2.15 makes the resulting square commute up to homotopy, which is commutativity in K^-.

For (2), given $\mathscr{G}$ and γ, the factorization is forced on objects because a projective resolution is initial among complexes of projectives mapping to the object (lemma 56.2.13), so any transformation out of $\mathscr{G} \circ \mathscr{P}_A$ is determined by its value on resolutions; uniqueness up to natural isomorphism is then the uniqueness up to homotopy of those comparison maps (proposition 56.2.14).

(a word on composition)

56.3.2 Long Exact Sequences of Derived Functors

With the derived functor established and being the best candidate for holding (co)homology information, we proceed with extracting this informaiton: we may take $\mathbf{L}_i\mathscr{F} := H^{-i} \circ \mathbf{L}\mathscr{F}$. The reason for taking H^{-i} instead of i is since the indexing works out better. This produced a functor

$\mathbf{L}_i\mathscr{F} : D^-(\mathbf{A}) \to B$. Notice that B does not need to have enough projectives for:

$$\mathbf{L}_i\mathscr{F}(P^\bullet) = H^{-i}(\mathscr{P}_B(\mathrm{Ch}(\mathscr{F})(P^\bullet))) \cong H^{-i}(\mathrm{Ch}(\mathscr{F})(P^\bullet))$$

where the last isomorphism comes from $\mathscr{P}_B(\mathrm{Ch}(\mathscr{F})(P^\bullet)))$ being quasi-isomorphic to $\mathrm{Ch}(\mathscr{F})(P^\bullet)$. Though this abstract approach is useful, the following more concrete version of $\mathbf{L}_i\mathscr{F}$ shall prove more useful for computations.

Definition 56.3.5: ith Left-Derived Functor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between two abelian categories where $\mathbf{A}$ has enough projectives. Then the *ith left-derived functor* $\mathbf{L}_i\mathscr{F} : A \to B$ is given by:

$$\mathbf{L}_i\mathscr{F} := H^{-i} \circ \mathbf{L}\mathscr{F} \circ \mathscr{P}_A \circ \iota_A$$

The complex in $\mathrm{Ch}(\mathbf{B})$ with $\mathbf{L}_i\mathscr{F}(M)$ in the $-i$th degree with vanishing differentials is denoted $\mathbf{L}_\bullet\mathscr{F}(M)$.

To be precise, if $M \in \mathbf{A}$, then $\mathbf{L}_i(M)$ is found by

1. finding any projective resolution $P^\bullet_M$ of M
2. Applying $\mathrm{Ch}(\mathscr{F})$ to $P^\bullet_M$, $\mathrm{Ch}(\mathscr{F})(P^\bullet_M)$
3. take the $(-i)$th cohomology of this complex, $H^{-i}(\mathrm{Ch}(\mathscr{F})(P^\bullet_M))$

With all the build-up done so far, the resulting cohomology is independent of choice, for:

1. Any two projective resolutions are homotopy-equivalent
2. the image of homotopy-equivalent complexes via additive functors have isomorphic cohomology

Naturally, the *ith right-derived functor* $\mathbf{R}^i\mathscr{F}$ of an additive functor $\mathscr{F}$ and the assocaited complex $\mathbf{R}^\bullet\mathscr{F}$ is defined simplify (given $\mathbf{A}$ has enough injectives), namely

$$\mathbf{R}^i\mathscr{F} := H^i \circ \mathbf{R}\mathscr{F} \circ \mathscr{Q}_A \circ \iota_A$$

A note should be said about *contravriant functors*: since they can always be viewed as *covariant* functor $\mathbf{A}^{\mathrm{op}} \to B$, $\mathbf{A}$ would instead have to have the appropriate injectives or projectives swapped. The right-derived functor of an additive *contravariant functor* would need $\mathbf{A}$ to have enough *projectives*, since $\mathbf{A}^{\mathrm{op}}$ would have to have enough injectives. The $\mathbf{L}_i$ and $\mathbf{R}_i$ notation can be thought of as "looking" at the cohomology provided by $\mathscr{F}$. As mentioned earlier, if $\mathscr{F}$ is exact, then the derived functors are *trivial* in terms of cohomology, hence the derived functors are only interesting if $\mathscr{F}$ is not exact, at which point these functors give you interesting information.

Example 56.3.6: ith Derived Functors

It is finally time to bring back section 17.6

1. Let $\mathbf{A} = R\text{-}\mathbf{Mod}$ for a commutative ring R, pick an R-module N, and define

$$- \otimes_R N$$

The left-derived functor of $- \otimes_R N$ is labeled

$$- \overset{\mathbf{L}}{\otimes}_R N : D^-(R\text{-Mod}) \to D^-(R\text{-Mod})$$

The ith derived left-functor of $- \otimes_R N$ is denoted:

$$\operatorname{Tor}_i^R(- \otimes_R N) = H^{-i}((-)_\bullet \otimes N)$$

where the right hand side of the equality comes from the result elaborated in section 17.6. It was mentioned that a flat resolution may be used instead of a projective resolution, however this was does not currently fit within the theory. This shall be addressed in the next section.

2. Similarly, $\operatorname{Hom}_R(-, N)$ and $\operatorname{Hom}_R(N, -)$ admits a right derived functors

$$\operatorname{Ext}_R^i(M, N) = H^i(\operatorname{Hom}_R(M, N^\bullet))$$

For $\operatorname{Hom}_R(-, N)$, do not forget that one must take the opposite category and a projective resolution.

Commutativity of R is used here only so that the values are again R-modules. Over an arbitrary ring R the same definitions apply to $- \otimes_R N \colon \text{Mod-}R \to \mathbf{Ab}$ for a left R-module N, and to Hom_R between left R-modules, with values in $\mathbf{Ab}$.

The most important part of left-/right-derived functors is their use in fixing exactness after applying a not necessarily exact functor $\mathscr{F}$. On a high level, since the derived category there is not an abelian category (hence not necessarily containing kernels and cokernels, nor is it really feasible to investigate such categories), the notion of *triangulated categories* is useful for categories where given a "short exact sequence", we can create a long exact sequence (that is, a category in which snakes lemma can be applied). We shall not investigate the idea of triangulated categories, but the following is a concrete results needed for any rigorous exploration of triangulated categories.

Assuming the whole that that our category $\mathbf{A}$ has enough projectives, take a short exact sequence:

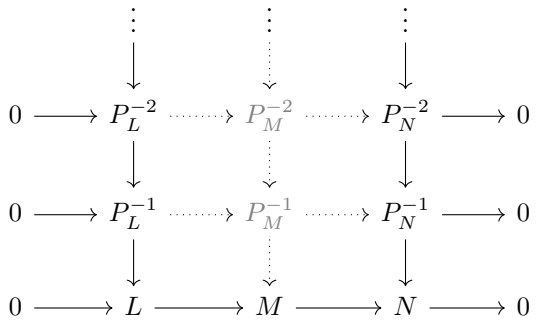
$$0 \to L \to M \to N \to 0$$

Since there is enough projectives, can the projective resolutions be arranged to create a short exact sequence? The answer is yes, and given the following apt name:

Lemma 56.3.7: Horseshoe Lemma

Let

$$0 \to L \to M \to N \to 0$$



be an exact sequence in an abelian category $\mathbf{A}$ with enough projectives, and let $P_L^\bullet, P_N^\bullet$ be projective resolutions of L, N respectively. Then there exists an exact sequence:

$$0 \to P_L^\bullet \to P_M^\bullet \to P_N^\bullet \to 0$$

where $P_M^\bullet$ is a projective resolution of M, inducing the original sequence in cohomology (i.e. applying H^0). Moreover the sequence is *degreewise split*: the construction produces $P_M^i = P_L^i \oplus P_N^i$ in each degree, with the two displayed maps the inclusion and the projection.

The dual statement holds in an abelian category with enough injectives: given injective resolutions $L \to I_L^\bullet$ and $N \to I_N^\bullet$, there is a degreewise split exact sequence $0 \to I_L^\bullet \to I_M^\bullet \to I_N^\bullet \to 0$ with $I_M^\bullet$ an injective resolution of M. It is this form that theorem 60.4.2 uses, and it follows by applying the projective statement in the opposite category.

***Proof*:**
Visually, we want to find objects and maps to fill in this commutative diagram:

where the dotted lines and the P_M^i are the goal (the name of the lemma comes from this horseshoe shaped diagram). I claim that $P_M^i = P_L^i \oplus P_N^i$ (which the reader should recall or reprove is projective) with the natural inclusion and projection maps shall work. The argument is done via induction. Since P_N^0 is projective and $M \to N$ is an epimorphism, the morphism $P_N^0 \to N$ lifts to a isomorphism m $\beta : P_N^0 \to M$. On the other hand, P_L^0 maps to M via $\alpha : P_L^0 \to L \to M$. Thus, there is a morphism:

$$\pi_M := \alpha \oplus \beta : P_L^0 \oplus P_N^0 \to M$$

diving us the diagram

$$\begin{array}{ccccccccc}
 & & \vdots & & \vdots & & \vdots & & \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
0 & \longrightarrow & P_L^{-2} & \cdots\cdots\rightarrow & P_M^{-2} & \cdots\cdots\rightarrow & P_N^{-2} & \longrightarrow & 0 \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
0 & \longrightarrow & P_L^{-1} & \cdots\cdots\rightarrow & P_M^{-1} & \cdots\cdots\rightarrow & P_N^{-1} & \longrightarrow & 0 \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
0 & \longrightarrow & P_L^{0} & \longrightarrow & P_L^0 \oplus P_N^0 & \longrightarrow & P_N^0 & \longrightarrow & 0 \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
0 & \longrightarrow & L & \longrightarrow & M & \longrightarrow & N & \longrightarrow & 0
\end{array}$$

The snake lemma and π_L being an epimorphism gives that the kernels of the vertical maps form an exact sequence, and hence we have an epimorphism from P_L^{-1} and P_N^{-1} to the respective kernels since the column of the original diagram are exact:

$$\begin{array}{ccccccccc}
 & & P_L^{-1} & & & & P_N^{-1} & & \\
 & & \downarrow{\scriptstyle \pi_L^{-1}} & & & & \downarrow{\scriptstyle \pi_N^{-1}} & & \\
0 & \longrightarrow & \ker \pi_L & \longrightarrow & \ker \pi_M & \longrightarrow & \ker \pi_N & \longrightarrow & 0
\end{array}$$

Now, repeat as before, defining $P_M^{-1} = P_L^{-1} \oplus P_N^{-1}$ and define $\pi_M^{-1} : P_L^{-1} \oplus P_N^{-1} \to \ker \pi_M \to P_L^0 \oplus P_N^0$ giving the diagram:

$$\begin{array}{ccccccccc}
0 & \longrightarrow & P_L^{-1} & \longrightarrow & P_L^{-1} \oplus P_N^{-1} & \longrightarrow & P_N^{-1} & \longrightarrow & 0 \\
 & & \downarrow{\scriptstyle \pi_L^{-1}} & & \downarrow{\scriptstyle \pi_M^{-1}} & & \downarrow{\scriptstyle \pi_N^{-1}} & & \\
0 & \longrightarrow & P_L^{0} & \longrightarrow & P_L^0 \oplus P_N^0 & \longrightarrow & P_N^0 & \longrightarrow & 0 \\
 & & \downarrow{\scriptstyle \pi_L} & & \downarrow{\scriptstyle \pi_M} & & \downarrow{\scriptstyle \pi_N} & & \\
0 & \longrightarrow & L & \longrightarrow & M & \longrightarrow & N & \longrightarrow & 0
\end{array}$$

By then by the snake lemma, $P_L^{-1} \oplus P_N^{-1} \to \ker \pi_M$ is an epimorphism, and hence we get exactness at $P_L^0 \oplus P_N^0$. Continuing inductively constructs the rest of the diagram.

It is tempting to say from this result that the mapping $\mathbf{A} \to K(\mathbf{A})$ is exact, however $K(\mathbf{A})$ is not abelian and hence this is simply undefined. The above is should instead be interpreted as follows: $P_M^\bullet$ is the mapping cone of a morphism: $\rho^\bullet : P_N[-1]^\bullet \to P_L^\bullet$, giving the distinguished triangle:

$$\begin{array}{ccc}
 & P_L^\bullet & \\
{\scriptstyle +1}\nearrow & & \searrow \\
P_N^\bullet & \longleftarrow & MC(\rho)^\bullet [= P_M^\bullet]
\end{array}$$

This is as close as we can get to preserving exactness.

The horseshoe construction is functorial in the short exact sequence it resolves. Once lifts of the two outer resolutions have been chosen, compatibility with the splitting leaves only one entry of the middle lift to be built, and that entry is what the following lemma constructs.

Lemma 56.3.8: Functoriality of the Horseshoe Construction

Consider a morphism of short exact sequences in an abelian category with enough injectives,

$$\begin{array}{ccccccccc} 0 & \longrightarrow & L & \longrightarrow & M & \longrightarrow & N & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle \lambda} & & \downarrow{\scriptstyle \mu} & & \downarrow{\scriptstyle \nu} & & \\ 0 & \longrightarrow & L' & \longrightarrow & M' & \longrightarrow & N' & \longrightarrow & 0 \end{array}$$

and injective resolutions $I_L^\bullet, I_N^\bullet, I_{L'}^\bullet, I_{N'}^\bullet$ of the four outer objects, and injective resolutions $I_M^\bullet$, $I_{M'}^\bullet$ of M and M' sitting in *degreewise split* short exact sequences $0 \to I_L^\bullet \to I_M^\bullet \to I_N^\bullet \to 0$ and $0 \to I_{L'}^\bullet \to I_{M'}^\bullet \to I_{N'}^\bullet \to 0$ lifting the two given rows. (This is what lemma 56.3.7 produces, but the argument uses only the splitting, which is automatic whenever the outer terms are injective.) Given lifts $\lambda^\bullet \colon I_L^\bullet \to I_{L'}^\bullet$ and $\nu^\bullet \colon I_N^\bullet \to I_{N'}^\bullet$ of λ and ν, there is a lift $\mu^\bullet \colon I_M^\bullet \to I_{M'}^\bullet$ of μ compatible with both, that is making the induced diagram of resolutions commute.

The dual statement holds in an abelian category with enough projectives: given a morphism of short exact sequences of the same shape, projective resolutions of the four outer objects, degreewise split short exact sequences $0 \to P_L^\bullet \to P_M^\bullet \to P_N^\bullet \to 0$ and $0 \to P_{L'}^\bullet \to P_{M'}^\bullet \to P_{N'}^\bullet \to 0$ lifting the two rows, and lifts $\lambda^\bullet$ of λ and $\nu^\bullet$ of ν, there is a lift $\mu^\bullet \colon P_M^\bullet \to P_{M'}^\bullet$ of μ compatible with both. It follows by applying the injective statement in the opposite category, and it is this form that theorem 56.3.11 uses.

***Proof*:**

By lemma 56.3.7 the middle resolutions are $I_M^q = I_L^q \oplus I_N^q$ and $I_{M'}^q = I_{L'}^q \oplus I_{N'}^q$ in each degree, with the displayed maps the inclusion and the projection. Compatibility with those two maps forces $\mu^\bullet$ to have the shape

$$\mu^q = \begin{pmatrix} \lambda^q & \sigma^q \\ 0 & \nu^q \end{pmatrix}$$

so the only freedom is the family $\sigma^q \colon I_N^q \to I_{L'}^q$, and the content of the lemma is that it can be chosen so that $\mu^\bullet$ is a chain map lifting μ.

Write the differential of $I_M^\bullet$ as $\begin{pmatrix} d_L & \tau \\ 0 & d_N \end{pmatrix}$ and that of $I_{M'}^\bullet$ as $\begin{pmatrix} d_{L'} & \tau' \\ 0 & d_{N'} \end{pmatrix}$, where τ and τ' are the off-diagonal terms the horseshoe construction produces. The chain-map condition $\mu^{q+1} d = d \mu^q$ reads, in the only entry that is not automatic,

$$\lambda^{q+1}\tau^q + \sigma^{q+1} d_N^q = d_{L'}^q \sigma^q + \tau'^q \nu^q$$

so, writing $\theta^q := d_{L'}^q \sigma^q + \tau'^q \nu^q - \lambda^{q+1}\tau^q$, the family σ must satisfy $\sigma^{q+1} \circ d_N^q = \theta^q$ for every q.

The base case. Write the augmentation of $I_M^\bullet$ through the splitting as $\varepsilon_M = (\varphi,\ \varepsilon_N \pi)^{\mathsf{T}}$, where

$\pi\colon M \to N$ is the given epimorphism and $\varphi\colon M \to I^0_L$ restricts to ε_L on L; similarly for M'. The morphism σ^0 is not given by the hypothesis, it has to be built. Set $\theta^{-1} := \varphi'\mu - \lambda^0\varphi\colon M \to I^0_{L'}$. On the subobject L this is $\varepsilon_{L'}\lambda - \varepsilon_{L'}\lambda = 0$, so θ^{-1} kills $L = \ker\pi$ and factors as $\bar\theta \circ \pi$ for a unique $\bar\theta\colon N \to I^0_{L'}$. Since $\varepsilon_N\colon N \to I^0_N$ is a monomorphism and $I^0_{L'}$ is injective, $\bar\theta$ extends along it to $\sigma^0\colon I^0_N \to I^0_{L'}$ with $\sigma^0\varepsilon_N\pi = \theta^{-1}$, which is the degree-zero instance of the required identity and is the only place the compatibility of μ with λ and ν is used.

The inductive step. Suppose $\sigma^{\le q}$ has been chosen. To extend θ^q along d^q_N it suffices that θ^q vanish on $\ker d^q_N = \mathrm{im} d^{q-1}_N$, and this is a direct computation. Squaring the differential of $I^\bullet_M$ gives $d_L\tau + \tau d_N = 0$, and likewise $d_{L'}\tau' + \tau' d_{N'} = 0$; using these, the inductive hypothesis $\sigma^q d^{q-1}_N = \theta^{q-1}$, the chain-map identities for λ and ν, and $d \circ d = 0$,

$$\theta^q \circ d^{q-1}_N = \left(\lambda^{q+1} d^q_L - d^q_{L'}\lambda^q\right) \circ \tau^{q-1} = 0$$

the last equality because $\lambda^\bullet$ is a chain map. For $q = 0$ the same conclusion holds with $\ker d^0_N = \mathrm{im}\varepsilon_N$ in place of $\mathrm{im} d^{-1}_N$: applying θ^0 to $\varepsilon_N\pi$ and using $d^0_L\varphi + \tau^0\varepsilon_N\pi = 0$, which is the first component of $d^0_M\varepsilon_M = 0$, together with the base case, gives $\theta^0\varepsilon_N\pi = (\lambda^1 d^0_L - d^0_{L'}\lambda^0)\varphi = 0$, and π is an epimorphism. Hence in every degree θ^q factors through $\mathrm{im} d^q_N$, and since $\mathrm{im} d^q_N \hookrightarrow I^{q+1}_N$ is a monomorphism and $I^{q+1}_{L'}$ is injective, definition 56.2.1 extends the factored morphism to $\sigma^{q+1}\colon I^{q+1}_N \to I^{q+1}_{L'}$ with $\sigma^{q+1} d^q_N = \theta^q$, as required.

The resulting $\mu^\bullet$ is a chain map by construction, is compatible with the inclusion and projection by its shape, and lifts μ because it does so in degree -1, that is on the augmentations, completing the proof.

Corollary 56.3.9: Resolution Of Projective Resolutions

Let $M^\bullet$ be a complex bounded from above in a category $\mathbf{A}$ with enough projectives. Then there exists a complex $P^b_{M^\bullet} b$:

$$\cdots \to P^\bullet_{M^{-3}} \to P^\bullet_{M^{-2}} \to P^\bullet_{M^{-1}} \to\!\!\to P^\bullet_{M^0} \to 0$$

where each $P^\bullet_{M^i}$ is a projection resolution of M^i and inducing $M^\bullet$ in cohomology. If $M^\bullet$ is exact, then $P^\bullet_{M^\bullet}$ can be chosen to be exact.

***Proof*:**
Since $M^\bullet$ is a complex, it can be broken down into two short exact sequences:

$$0 \to K^i \to M^i \to I^{i+1} \to 0 \qquad 0 \to I^i \to K^i \to H^i \to 0$$

where K^i is the kernel of $M^i \to M^{i+1}$, I^{i+1} is its image, and H^i the cohomology at M^i. Chose arbitrary projective resolutions for each I^i and H^i for all i. Then by the horseshoe lemma, we get a projective resolution for K^i that fits within the short exact sequence:

$$0 \to P^\bullet_{I^i} \to P^\bullet_{K^i} \to P^\bullet_{H^i} \to 0$$

Applying the horseshoe lemma gain, we get a short exact sequence:

$$0 \to P^\bullet_{K^i} \to P^\bullet_{M^i} \to P^\bullet_{I^{i+1}} \to 0$$

Using these, the $P^\bullet_{M^i}$ can be used to construct a cochain complex, the differentials obtains by composition. If $M^\bullet$ is exact, then $I^i = K^i$, and so the construction gives $P^\bullet_{I^i} = P^\bullet_{K^i}$, so that $P^\bullet_{M^\bullet}$ is also exact.

Lemma 56.3.10: Projective Resolution and Functors

Let $\mathbf{A}$ be an abelian category and let

$$0 \to L^\bullet \to M^\bullet \to P^\bullet \to 0$$

be an exact sequence of complexes in $\mathbf{A}$, where P^i is projective for all i. Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor between abelian categories. Then the sequence:

$$0 \to \mathscr{F}(L^\bullet) \to \mathscr{F}(M^\bullet) \to \mathscr{F}(P^\bullet) \to 0$$

is exact

Note that there is nothing about $\mathscr{F}$ being an exact functor! This can be thought of as the generalization of the properties of projective modules which preserve exactness!!

***Proof*:**

Fix i. By lemma 56.1.5 the sequence $0 \to L^i \xrightarrow{\iota} M^i \xrightarrow{\pi} P^i \to 0$ is exact. The cokernel of $0 \to L^i$ is id_{L^i}, so exactness at L^i makes $\ker \iota$ the zero morphism. A kernel is a monomorphism (lemma 55.1.3), and a zero monomorphism has a zero object as its source, so ι is a monomorphism (lemma 55.1.4). Dually, exactness at P^i makes π an epimorphism. Exactness at M^i gives $\pi\iota = 0$ and $\mathrm{coker}\iota \circ \ker \pi = 0$. The monomorphism ι is the kernel of some morphism (condition (2) of definition 55.1.6), hence the kernel of $\mathrm{coker}\iota$ (lemma 55.1.7). So $\ker \pi = \iota a$ for some a, and $\pi\iota = 0$ gives $\iota = (\ker \pi)\, b$ for some b. Then $\iota = \iota ab$ and $\ker \pi = (\ker \pi)\, ba$, and as both are monomorphisms, ab and ba are identities. So a is an isomorphism and ι is a kernel of π. Applying the exact functor $\mathrm{Hom}_{\mathbf{A}}(P^i, -)$ (definition 56.2.1) to it shows that $s \mapsto \pi s$ maps $\mathrm{Hom}_{\mathbf{A}}(P^i, M^i)$ onto $\mathrm{Hom}_{\mathbf{A}}(P^i, P^i)$, so there is $s\colon P^i \to M^i$ with $\pi s = \mathrm{id}_{P^i}$. Then $\pi(\mathrm{id}_{M^i} - s\pi) = \pi - \pi = 0$, so $\mathrm{id}_{M^i} - s\pi = \iota r$ for a unique $r\colon M^i \to L^i$. From $\iota r\iota = \iota - s\pi\iota = \iota$ and ι monic, $r\iota = \mathrm{id}_{L^i}$. So

$$\pi\iota = 0 \qquad r\iota = \mathrm{id}_{L^i} \qquad \pi s = \mathrm{id}_{P^i} \qquad \iota r + s\pi = \mathrm{id}_{M^i}$$

An additive functor preserves composites, identities, zero morphisms and sums of morphisms, so the same four identities hold for $\mathscr{F}(\iota)$, $\mathscr{F}(\pi)$, $\mathscr{F}(r)$ and $\mathscr{F}(s)$ in $\mathbf{B}$. They make $0 \to \mathscr{F}(L^i) \to \mathscr{F}(M^i) \to \mathscr{F}(P^i) \to 0$ exact: $\mathscr{F}(\iota)$ has the left inverse $\mathscr{F}(r)$, so it is a monomorphism, $\mathscr{F}(\pi)$ has the right inverse $\mathscr{F}(s)$, so it is an epimorphism, and $\mathscr{F}(\iota)$ is a kernel of $\mathscr{F}(\pi)$, because $\mathscr{F}(\pi)\mathscr{F}(\iota) = 0$ and every t with $\mathscr{F}(\pi)t = 0$ satisfies

$$t = \big(\mathscr{F}(\iota)\mathscr{F}(r) + \mathscr{F}(s)\mathscr{F}(\pi)\big)t = \mathscr{F}(\iota)\big(\mathscr{F}(r)t\big)$$

with the factorization unique as $\mathscr{F}(\iota)$ is monic. This holds in every degree i, so lemma 56.1.5 gives the exactness of the sequence of complexes, completing the proof.

Theorem 56.3.11: Long Exact Sequence From Derived Functor

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be an additive functor of abelian categories, and assume $\mathbf{A}$ has enough projective. Then every short exact sequence in $\mathbf{A}$

$$0 \to L \xrightarrow{\alpha} M \xrightarrow{\beta} N \to 0$$

[covariantly] functorially induces a long exact sequence in $\mathbf{B}$, whose unlabelled horizontal arrows are $L_i\mathscr{F}(\alpha)$ and $L_i\mathscr{F}(\beta)$:

$$\begin{array}{ccccccc}
0 & \longrightarrow & L_2\mathscr{F}(L) & \longrightarrow & L_2\mathscr{F}(M) & \longrightarrow & L_2\mathscr{F}(N) \\
 & & & \overset{\delta_2}{\searrow} & & & \\
 & & L_1\mathscr{F}(L) & \longrightarrow & L_1\mathscr{F}(M) & \longrightarrow & L_1\mathscr{F}(N) \\
 & & & \overset{\delta_1}{\searrow} & & & \\
 & & L_0\mathscr{F}(L) & \longrightarrow & L_0\mathscr{F}(M) & \longrightarrow & L_0\mathscr{F}(N) \longrightarrow 0
\end{array}$$

The assignment is natural in the short exact sequence. Given a commutative diagram with exact rows

$$\begin{array}{ccccccccc}
0 & \longrightarrow & L & \longrightarrow & M & \longrightarrow & N & \longrightarrow & 0 \\
 & & \downarrow{\scriptstyle \lambda} & & \downarrow{\scriptstyle \mu} & & \downarrow{\scriptstyle \nu} & & \\
0 & \longrightarrow & L' & \longrightarrow & M' & \longrightarrow & N' & \longrightarrow & 0
\end{array}$$

the two long exact sequences form a commutative ladder whose vertical morphisms are $L_i\mathscr{F}(\lambda)$, $L_i\mathscr{F}(\mu)$ and $L_i\mathscr{F}(\nu)$. Writing δ_i' for the connecting morphisms of the second row, the squares carrying the connecting morphisms read $\delta_i' \circ L_i\mathscr{F}(\nu) = L_{i-1}\mathscr{F}(\lambda) \circ \delta_i$.

***Proof*:**

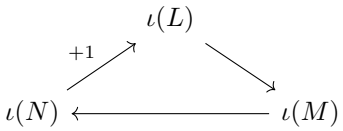
Choose projective resolutions $P_L^\bullet$ and $P_N^\bullet$. By lemma 56.3.7 the given short exact sequence lifts to a degreewise split short exact sequence $0 \to P_L^\bullet \to P_M^\bullet \to P_N^\bullet \to 0$ of projective resolutions, which by lemma 56.3.10 creates a short exact sequence:

$$0 \to \mathscr{F}(P_L^\bullet) \to \mathscr{F}(P_M^\bullet) \to \mathscr{F}(P_N^\bullet) \to 0$$

Since the cohomology of these complexes is precisely the left-derived functors of $\mathscr{F}$ (definition 56.3.5), the long exact cohomology sequence is given by theorem 56.1.18.

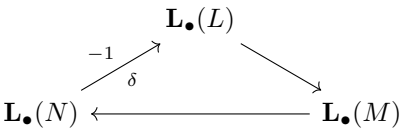
Naturality. Resolve the second row the same way, as $0 \to P_{L'}^\bullet \to P_{M'}^\bullet \to P_{N'}^\bullet \to 0$. By proposition 56.2.15 the morphisms λ and ν lift to morphisms of resolutions $\lambda^\bullet : P_L^\bullet \to P_{L'}^\bullet$ and $\nu^\bullet : P_N^\bullet \to P_{N'}^\bullet$, and the projective form of lemma 56.3.8 then produces a lift $\mu^\bullet : P_M^\bullet \to P_{M'}^\bullet$ of μ compatible with the inclusion and the projection. The three lifts form a morphism of short exact sequences of complexes, and $\mathscr{F}$, being a functor, carries the two commuting squares to

commuting squares:



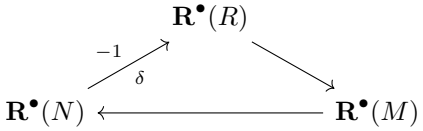
$$\begin{array}{ccccccccc} 0 & \longrightarrow & \mathscr{F}(P_L^\bullet) & \longrightarrow & \mathscr{F}(P_M^\bullet) & \longrightarrow & \mathscr{F}(P_N^\bullet) & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle \mathscr{F}(\lambda^\bullet)} & & \downarrow{\scriptstyle \mathscr{F}(\mu^\bullet)} & & \downarrow{\scriptstyle \mathscr{F}(\nu^\bullet)} & & \\ 0 & \longrightarrow & \mathscr{F}(P_{L'}^\bullet) & \longrightarrow & \mathscr{F}(P_{M'}^\bullet) & \longrightarrow & \mathscr{F}(P_{N'}^\bullet) & \longrightarrow & 0 \end{array}$$

Both rows are exact by lemma 56.3.10, so the naturality clause of theorem 56.1.18, read through $H_n = H^{-n}$, gives a commutative ladder between the two long exact sequences, the squares carrying the connecting morphisms included.



The vertical morphisms of that ladder are the asserted ones. By definition 56.3.5 the value of $L_i\mathscr{F}$ on a morphism is H^{-i} of the image under $\mathrm{Ch}(\mathscr{F})$ of a lift of that morphism to projective resolutions, and the value does not depend on the lift chosen: two lifts are homotopic by proposition 56.2.15, $\mathrm{Ch}(\mathscr{F})$ carries homotopic morphisms to homotopic morphisms by lemma 56.1.32, and homotopic morphisms agree on cohomology by proposition 56.1.29. Since $\lambda^\bullet$, $\mu^\bullet$ and $\nu^\bullet$ are such lifts, the vertical morphisms are $L_i\mathscr{F}(\lambda)$, $L_i\mathscr{F}(\mu)$ and $L_i\mathscr{F}(\nu)$.

The same argument identifies the horizontal arrows, which is what makes the sequence a long exact sequence *of the derived functors of α and β* rather than of unnamed induced maps. The horseshoe sequence $0 \to P_L^\bullet \to P_M^\bullet \to P_N^\bullet \to 0$ of lemma 56.3.7 induces the original short exact sequence on H^0, so its degreewise inclusion and projection are lifts of α and β to the chosen projective resolutions. Applying $\mathrm{Ch}(\mathscr{F})$ and H^{-i} to them therefore gives $L_i\mathscr{F}(\alpha)$ and $L_i\mathscr{F}(\beta)$, by the same independence of the lift, completing the proof.



The change from short exact sequence to long exact sequence can be unified under the notion of triangles, namely this theorem can be seen as the triangle:

inducing the triangle

where the vertices of this triangle are complexes in $C^{\leq 0}(\mathbf{B})$. Naturally, the dual situation happens for right derived functors for categories that have enough injectives, iin which case the above triangle induces a triangle:

where the vertices of this triangle are complexes in $C^{\geq 0}(\mathbf{B})$.

The dual statement is what the right-derived functors satisfy, and it is recorded separately because Ext in its second variable is computed that way.

Corollary 56.3.12: Long Exact Sequence From a Right-Derived Functor

Let $\mathscr{F}\colon \mathbf{A} \to \mathbf{B}$ be an additive functor of abelian categories with $\mathbf{A}$ having enough injectives. Then every short exact sequence $0 \to L \xrightarrow{\alpha} M \xrightarrow{\beta} N \to 0$ in $\mathbf{A}$ induces a long exact sequence

$$\begin{aligned} 0 &\to R^0\mathscr{F}(L) \\ &\to R^0\mathscr{F}(M) \\ &\to R^0\mathscr{F}(N) \xrightarrow{\delta^0} R^1\mathscr{F}(L) \\ &\to R^1\mathscr{F}(M) \\ &\to R^1\mathscr{F}(N) \xrightarrow{\delta^1} R^2\mathscr{F}(L) \\ &\to \cdots \end{aligned}$$

whose unlabelled arrows are $R^i\mathscr{F}(\alpha)$ and $R^i\mathscr{F}(\beta)$, and which is functorial in the short exact sequence: a morphism from it to a second short exact sequence $0 \to L' \to M' \to N' \to 0$, with components $\lambda\colon L \to L'$, $\mu\colon M \to M'$ and $\nu\colon N \to N'$, induces a commutative ladder between the two long exact sequences whose vertical morphisms are $R^i\mathscr{F}(\lambda)$, $R^i\mathscr{F}(\mu)$ and $R^i\mathscr{F}(\nu)$, the squares carrying the connecting morphisms included.

***Proof*:**
Apply theorem 56.3.11 in the opposite categories. An injective object of $\mathbf{A}$ is a projective object of $\mathbf{A}^{op}$, so $\mathbf{A}$ having enough injectives is $\mathbf{A}^{op}$ having enough projectives; the short exact sequence reverses to $0 \to N \to M \to L \to 0$ in $\mathbf{A}^{op}$; and the left-derived functors of $\mathscr{F}^{op}$ are the right-derived functors of $\mathscr{F}$ with the arrows reversed, by definition 56.3.1. Transporting the conclusion back gives the displayed sequence.

The naturality clause transports with it. A morphism of short exact sequences in $\mathbf{A}$ with components λ, μ, ν is, in $\mathbf{A}^{op}$, a morphism from the reversed second sequence to the reversed first with components $\nu^{op}, \mu^{op}, \lambda^{op}$, so theorem 56.3.11 produces a commutative ladder in $\mathbf{B}^{op}$ whose vertical morphisms are the left-derived functors of $\mathscr{F}^{op}$ applied to those three. Read in $\mathbf{B}$, that ladder is the asserted one, completing the proof.

These consideration were for general additive functors. In most cases we saw, there is usually a left-exact or right-exact functor (indeed, the nature of the left-derived and right-derived series almost force us to choose "a side"). If a functor is given to be either left- or right-exact, then it can be directly recovered from their derived functors, as we shall now show.

Proposition 56.3.13: Right-Exactness And Derived Functors

Let $\mathbf{A}$ be an abelian category with enough projectives and $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be a right-exact additive functor. Then

1. $\mathbf{L}_i\mathscr{F} = 0$ for $i < 0$
2. $L_0\mathscr{F}$ is naturally isomorphic to $\mathscr{F}$

The dual result holds for the category with enough injectives. Do note that the *right*-exact functor is associated to the *left* derived functors, and vice-versa for left-exact functors which would have the associated *right* derived functors. This is because the derived functors are "fixing" the exactness on the other side.

***Proof*:**

Since projective resolution $P^\bullet$ of an object M in $\mathbf{A}$ is in $C^{\leq 0}(\mathbf{A})$, $C(\mathscr{F})(P^\bullet)$ is 0 in positive degree, and hence so is its cohomology. Since $H_i = H^{-i}$, the first claim is immediate.

For the second, an exact sequence:

$$P^{-1} \to P^0 \to M \to 0$$

will map to an exact sequence by $\mathscr{F}$ (due to right-exactness)

$$\mathscr{F}(P^{-1}) \to \mathscr{F}(P^0) \to \mathscr{F}(M) \to 0$$

This induces an isomorphism: $\nu_M : \mathbf{L}_0\mathscr{F}(M) = H^0(C(\mathscr{F})(P^\bullet)) \xrightarrow{\sim} \mathscr{F}(M)$. If $\varphi : M_0 \to M_1$ is a morphism, then there exists a morphism of projective resolutions $\alpha^\bullet : P_0^\bullet \to P_1^\bullet$:

$$\begin{array}{ccccccccc} \cdots & \longrightarrow & P_0^{-1} & \longrightarrow & P_0^0 & \longrightarrow & M_0 & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle \alpha^{-1}} & & \downarrow{\scriptstyle \alpha^0} & & \downarrow{\scriptstyle \varphi} & & \\ \cdots & \longrightarrow & P_1^{-1} & \longrightarrow & P_1^0 & \longrightarrow & M_1 & \longrightarrow & 0 \end{array}$$

induced by φ where $H^0(\alpha^\bullet)$ agrees with φ. Applying $\mathscr{F}$ and truncating to $\alpha^\bullet$, we get the commutative diagram:

$$\begin{array}{ccccccc} \mathscr{F}(P_0^{-1}) & \longrightarrow & \mathscr{F}(P_0^0) & \longrightarrow & \mathscr{F}(M_0) & \longrightarrow & 0 \\ \downarrow{\scriptstyle \mathscr{F}(\alpha^{-1})} & & \downarrow{\scriptstyle \mathscr{F}(\alpha^0)} & & \downarrow{\scriptstyle \mathscr{F}(\varphi)} & & \\ \mathscr{F}(P_1^{-1}) & \longrightarrow & \mathscr{F}(P_1^0) & \longrightarrow & \mathscr{F}(M_1) & \longrightarrow & 0 \end{array}$$

with exact rows since $\mathscr{F}$ is right-exact. But then the following diagram commutes:

$$\begin{array}{ccc} \mathbf{L}_0\mathscr{F}(M_0) & \xrightarrow{\mathbf{L}_0\mathscr{F}(\varphi)} & \mathbf{L}_0\mathscr{F}(M_1) \\ \downarrow{\scriptstyle \nu_{M_0}} & & \downarrow{\scriptstyle \nu_{M_1}} \\ \mathscr{F}(M_0) & \xrightarrow[\mathscr{F}(\varphi)]{} & \mathscr{F}(M_1) \end{array}$$

The square commutes because $\mathbf{L}_0\mathscr{F}(\varphi) = H^0(C(\mathscr{F})(\alpha^\bullet))$ is the map that $\mathscr{F}(\alpha^0)$ induces on the cokernels of the maps $\mathscr{F}(P_i^{-1}) \to \mathscr{F}(P_i^0)$, each ν_{M_i} is the map that $\mathscr{F}(P_i^0) \to \mathscr{F}(M_i)$ induces on the same cokernel, and the right-hand square of the previous diagram commutes. This completes the proof.

This finally gives the desired recovery of exactness promised way back. Given a short exact sequence

$$0 \to L \to M \to N \to 0$$

then applying a right-exact functor

$$\mathscr{F}(L) \to \mathscr{F}(M) \to \mathscr{F}(N) \to 0$$

will give an exact sequence, which can be stretched out to form a long exact sequence using the derived functors:

$$\begin{array}{ccccccc} 0 & \longrightarrow & L_2\mathscr{F}(L) & \longrightarrow & L_2\mathscr{F}(M) & \longrightarrow & L_2\mathscr{F}(N) \\ & \xrightarrow{\delta_2} & L_1\mathscr{F}(L) & \longrightarrow & L_1\mathscr{F}(M) & \longrightarrow & L_1\mathscr{F}(N) \\ & \xrightarrow{\delta_1} & \mathscr{F}(L) & \longrightarrow & \mathscr{F}(M) & \longrightarrow & \mathscr{F}(N) \longrightarrow 0 \end{array}$$

In this way, $\mathbf{L}_1\mathscr{F}$ measures the extent to which $\mathscr{F}$ fails to be left-exact, and each progressive $\mathbf{L}_i\mathscr{F}$ gives further measurement, further information, about this failure. When in a geometrical setting, this failure is often thought of as some form of obstruction (famously, in algebraic topology, this obstruction is interpreted as "'holes", in K-theory).

Similarly, $\mathbf{R}^-\mathscr{F}$ is naturally isomorphic to $\mathscr{F}$ if $\mathscr{F}$ is left-exact and the right-derived functors fit into the diagram:

$$\begin{array}{ccccccc} 0 & \longrightarrow & \mathscr{F}(L) & \longrightarrow & \mathscr{F}(M) & \longrightarrow & \mathscr{F}(N) \\ & \xrightarrow{\delta_1} & R^1\mathscr{F}(R) & \longrightarrow & R^1\mathscr{F}(M) & \longrightarrow & R^1\mathscr{F}(N) \\ & \xrightarrow{\delta_0} & R^2\mathscr{F}(R) & \longrightarrow & R^2\mathscr{F}(M) & \longrightarrow & R^2\mathscr{F}(N) \longrightarrow \cdots \end{array}$$

Thus, we have successfully captured the cohomological information that a functor may provide!

Acyclic Functors

There still remain some questions to be answered, one that was mentioned was that instead of using a projective resolution for Tor, a flat resolution may be used instead and give the same answer.

Definition 56.3.14: Acyclic Functor

Let $\mathscr{F}$ be an additive functor. An object M of $\mathbf{A}$ is *$\mathscr{F}$-acyclic* (with respect to left-derived functors) if $\mathbf{L}_i\mathscr{F}(M) = 0$ for all $i \neq 0$.

Similarly, an object M is $\mathscr{F}$-acyclic with respect to right-derived functors if $\mathbf{R}^i\mathscr{F}(M) = 0$ for $i \neq 0$. Naturally, projectives are acyclic for every right-exact functor, and injective acyclic for every left-exact functor, however such a functor may admit other $\mathscr{F}$-acyclic objects.

Example 56.3.15: Functor-acyclic Objects

Let R be a commutative ring. Recall that an R-module M is *flat* if $- \otimes_R M$ is exact (equivalently, by symmetry of $\otimes$ that $M \otimes_R -$ is exact). Then flat modules are *acyclic* with respect to tensor products, namely if N is flat:

$$\mathrm{Tor}_R^i(M, N) = 0 \qquad \forall i \neq 0, \ \forall M$$

and symmetrically if M is flat. Thus, flat modules are $(- \otimes_R N)$-acyclic for all modules N.

What shall be built up to now is that $\mathscr{F}$-acyclic resolutions can be used to compute $\mathbf{L}_i\mathscr{F}$.

Theorem 56.3.16: Derived Functors And Acyclic Functors

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be a right-exact functor of abelian groups where $\mathbf{A}$ has enough projectives. Let $A^\bullet$ be a resolution of M where each A^i is $\mathscr{F}$-acyclic. Then for all i:

$$\mathbf{L}_i\mathscr{F}(M) \cong H^{-i}(\mathrm{Ch}(\mathscr{F})(A^\bullet))$$

Note that if each A^i is projective, the statement follows by definition.

***Proof*:**

The 0th and -1th position will be computed directly, and each successive position comes from induction. Take the exact sequence

$$A^{-1} \to A^0 \to M \to 0$$

which creates another exact sequence in $\mathbf{B}$ after applying the right-exact functor $\mathscr{F}$:

$$\mathscr{F}(A^{-1}) \to \mathscr{F}(A^0) \to \mathscr{F}(M) \to 0$$

Then:

$$H^0(\mathrm{Ch}(\mathscr{F})(A^\bullet)) \cong \mathscr{F}(M) \cong \mathbf{L}_0\mathscr{F}(M)$$

Now, if K is the kernel of $A^0 \to M$, then we have a short exact sequence:

$$0 \to K \to A^0 \to M \to 0$$

Thus applying the left-derived functors we form the long exact sequence:

$$\mathbf{L}_1\mathscr{F}(A^0) \to \mathbf{L}_1\mathscr{F}(M) \to \mathscr{F}(K) \to \mathscr{F}(A^0) \to \mathscr{F}(M) \to 0$$

Since A^0 is acyclic, $L_1\mathscr{F}(A^0) = 0$, hence by exactness

$$\mathbf{L}_1\mathscr{F}(M) \cong \ker(\mathscr{F}(K) \to \mathscr{F}(A^0)) \cong H^{-1}(\mathrm{Ch}(\mathscr{F})(A^\bullet))$$

where the last isomorphism is some manipulation of definition. For the rest, we do induction. Assume now that for all object of $\mathbf{A}$ and all indices $< i$. Truncating and shifting $\mathbf{A}^\bullet$ so that A^{-1} is in the 0 degree:

$$\cdots \to A^{-3} \to A^{-2} \to A^{-1} \to 0 \to \cdots$$

we get an $\mathscr{F}$-acyclic resolution of K, and so by the induction hypothesis $\mathbf{L}_{i-1}\mathscr{F}(K)$ can be computed by applying $\mathrm{Ch}(\mathscr{F})$ to the complex and taking cohomology, namely:

$$\mathbf{L}_{i-1}\mathscr{F}(K) \cong H^{-i}(A^\bullet)$$

On the other hand, the other terms in the long exact sequence obtained using the left derived functors gives:

$$\cdots \to \mathbf{L}_i\mathscr{F}(A^0) \to L_i\mathscr{F}(M) \to \mathbf{L}_{i-1}\mathscr{F}(K) \to \mathbf{L}_{i-1}\mathscr{F}(A^0) \to \cdots$$

since A^0 is $\mathscr{F}$-acyclic and $i > 1$, we get:

$$\mathbf{L}_i\mathscr{F}(M) \cong \mathbf{L}_{i-1}\mathscr{F}(K)$$

giving the desired result.

Thus, for the Tor functor, we may use a flat resolution to compute it the left-derived functors. Since $\mathscr{F}$-acyclic objects suffice in the computation, one can imagine that there is not need for $\mathbf{A}$ to have enough projectives to compute it. This is indeed the case, given that $\mathbf{A}$ has "enough $\mathscr{F}$-acyclic's". (this is an exercise in Aluffi, 8.14, with bifunctors).

56.4 δ-Functors and Grothendieck's Effaceability Criterion

The right-derived functors of section 56.3 are built from an injective resolution, and the resolution is a choice. The construction does not depend on that choice, but two constructions that look nothing alike cannot be compared by inspecting resolutions, and comparisons of that kind are what the theory is used for. Grothendieck's answer, in the 1957 Tôhoku paper, is to axiomatize what the derived functors do rather than how they are made. What they do is corollary 56.3.12: a family of functors $(T^i)_{i\geq 0}$ turns each short exact sequence into a long exact sequence, compatibly with morphisms of short exact sequences. A family with that structure is a δ-functor.

The two axioms do not determine the higher terms from the degree-zero one, as example 56.4.2 below shows. What determines them is a universal property inside the category of δ-functors, and a universal δ-functor is determined by its degree-zero term alone. That property cannot be checked by inspection, and this is where the criterion of the section enters: a δ-functor whose positive-degree terms are killed by embedding each object into a larger one is universal. The hypothesis, effaceability, asks for one embedding per object, and it is what makes two theories agreeing in degree zero isomorphic in every degree.

Definition 56.4.1: δ-Functor

Let $\mathcal{A}$ and $\mathcal{B}$ be abelian categories. A *δ-functor* T from $\mathcal{A}$ to $\mathcal{B}$ consists of a family $(T^i)_{i\geq 0}$ of additive functors $T^i\colon \mathcal{A}\to\mathcal{B}$ together with, for every short exact sequence

$$\xi\colon \qquad 0\to A'\xrightarrow{\alpha} A\xrightarrow{\beta} A''\to 0$$

in $\mathcal{A}$ and every $i\geq 0$, a morphism $\delta^i_\xi\colon T^i(A'')\to T^{i+1}(A')$ in $\mathcal{B}$, subject to two conditions.

1. (Exactness.) For every such ξ the sequence

$$\begin{aligned}0\to T^0(A')\to T^0(A)\to T^0(A'')\xrightarrow{\delta^0_\xi} T^1(A')\to T^1(A)\to T^1(A'')\\ \xrightarrow{\delta^1_\xi} T^2(A')\to T^2(A)\to\cdots\end{aligned}$$

   is exact, the unlabelled arrows being $T^i(\alpha)$ and $T^i(\beta)$.

2. (Naturality of δ.) For every commutative diagram with exact rows

$$\begin{array}{cccccccccc}\xi\colon & 0 & \longrightarrow & A' & \xrightarrow{\alpha} & A & \xrightarrow{\beta} & A'' & \longrightarrow & 0\\ & & & \downarrow{\scriptstyle g'} & & \downarrow{\scriptstyle g} & & \downarrow{\scriptstyle g''} & & \\ \eta\colon & 0 & \longrightarrow & B' & \longrightarrow & B & \longrightarrow & B'' & \longrightarrow & 0\end{array}$$

   and every $i\geq 0$, the square

$$\begin{array}{ccc}T^i(A'') & \xrightarrow{\delta^i_\xi} & T^{i+1}(A')\\ \downarrow{\scriptstyle T^i(g'')} & & \downarrow{\scriptstyle T^{i+1}(g')}\\ T^i(B'') & \xrightarrow[\delta^i_\eta]{} & T^{i+1}(B')\end{array}$$

   commutes.

Condition (1) has an immediate consequence: its opening segment $0\to T^0(A')\to T^0(A)\to T^0(A'')$ says that T^0 is left exact, in the sense fixed by proposition 17.2.1(2): a short exact sequence is carried to an exact sequence of that three-term shape. A δ-functor is therefore a left exact functor together with a chosen way of continuing its exact sequence to the right, and the question the section answers is how much freedom that continuation has. The indexing above is the cohomological one, matching corollary 56.3.12. The homological variant, in which the connecting morphisms lower the index, is this notion transported to the opposite categories, and only the cohomological form is written out below.

Example 56.4.2: The Constant δ-Functor on Ab

Take $\mathcal{A}=\mathcal{B}=\mathbf{Ab}$, set $T^i=\mathrm{id}_{\mathbf{Ab}}$ for every $i\geq 0$, and let every δ^i_ξ be the zero morphism. This is a δ-functor. Each T^i is additive, and for $\xi\colon 0\to A'\to A\to A''\to 0$ the sequence of condition (1) reads

$$0\to A'\to A\to A''\xrightarrow{0} A'\to A\to A''\xrightarrow{0} A'\to\cdots$$

> Exactness at the first A' is injectivity of $A' \to A$, and at each copy of A it is exactness of ξ. At each copy of A'' the image of $A \to A''$ is all of A'' by surjectivity, and the kernel of the zero map out of A'' is also all of A''. At each copy of A' after the first, the image of the zero map is 0, which is the kernel of the monomorphism $A' \to A$. Condition (2) holds because both composites in its square are zero.

The example uses no resolutions and no derived functors, and it shows that conditions (1) and (2) do not determine $(T^i)_{i>0}$ from T^0. Indeed the family with $T^0 = \mathrm{id}_{\mathbf{Ab}}$, with $T^i = 0$ for $i > 0$ and with all connecting morphisms zero, is a second δ-functor on $\mathbf{Ab}$ with the same degree-zero term: its long exact sequence is $0 \to A' \to A \to A'' \to 0 \to 0 \to \cdots$, exact at A'' because $A \to A''$ is an epimorphism. Pinning the higher terms down needs a comparison between δ-functors, so morphisms come first.

Definition 56.4.3: Morphism of δ-Functors

Let S and T be δ-functors from $\mathcal{A}$ to $\mathcal{B}$, with connecting morphisms written δ_S and δ_T. A *morphism of δ-functors* $f\colon T \to S$ is a family $(f^i)_{i\geq 0}$ of natural transformations $f^i\colon T^i \Rightarrow S^i$ such that for every short exact sequence $\xi\colon 0 \to A' \to A \to A'' \to 0$ and every $i \geq 0$ the square

$$\begin{array}{ccc} T^i(A'') & \xrightarrow{\delta^i_{T,\xi}} & T^{i+1}(A') \\ {\scriptstyle f^i_{A''}}\downarrow & & \downarrow{\scriptstyle f^{i+1}_{A'}} \\ S^i(A'') & \xrightarrow[\delta^i_{S,\xi}]{} & S^{i+1}(A') \end{array}$$

commutes.

Degreewise composition of two morphisms of δ-functors is again one, since the two commuting squares stack, and the identity natural transformations form a morphism, so the δ-functors from $\mathcal{A}$ to $\mathcal{B}$ form a category. The universal property below is initiality in that category among the δ-functors with a prescribed degree-zero term.

Definition 56.4.4: Universal δ-Functor

A δ-functor T from $\mathcal{A}$ to $\mathcal{B}$ is *universal* if for every δ-functor S from $\mathcal{A}$ to $\mathcal{B}$ and every natural transformation $\varphi\colon T^0 \Rightarrow S^0$ there is exactly one morphism of δ-functors $f\colon T \to S$ with $f^0 = \varphi$.

The quantifier runs over all δ-functors S and all φ, and the morphism produced goes out of T. So universality of T says that any competing family carrying long exact sequences receives a canonical comparison from T, determined by its degree-zero component alone.

Example 56.4.2 is not universal, and the failure is in uniqueness rather than existence. Take $S = T$ there and $\varphi = \mathrm{id}_{T^0}$. The identity morphism of T extends φ, and so does the family that is the identity in degree zero and multiplication by 2 in every positive degree: multiplication by 2 is a natural transformation $\mathrm{id}_{\mathbf{Ab}} \Rightarrow \mathrm{id}_{\mathbf{Ab}}$ because every homomorphism of abelian groups commutes with it, and the square of definition 56.4.3 commutes because all the connecting morphisms are zero. The two extensions differ on $T^1(\mathbb{Z}) = \mathbb{Z}$.

Definition 56.4.5: Effaceable Functor

An additive functor $T\colon \mathcal{A} \to \mathcal{B}$ is *effaceable* if for every object A of $\mathcal{A}$ there is a monomorphism $u\colon A \hookrightarrow M$ in $\mathcal{A}$ with $T(u) = 0$. Such a u is said to *efface* T at A. A δ-functor $(T^i)_{i\geq 0}$ is *effaceable in positive degrees* if T^i is effaceable for every $i > 0$.

The condition asks that the morphism $T^i(u)$ vanish, not that the object $T^i(M)$ vanish. The second is strictly stronger, and it is what happens whenever M can be taken injective, but the proof below uses only the first. Nothing in the definition asks for a functorial choice of u either: one monomorphism per object is enough, and different objects may be effaced by embeddings with no relation to each other.

The criterion has a hypothesis that is checked object by object and a conclusion about every δ-functor at once.

Theorem 56.4.6: An Effaceable δ-Functor Is Universal

Let $\mathcal{A}$ and $\mathcal{B}$ be abelian categories and let $T = (T^i)_{i\geq 0}$ be a δ-functor from $\mathcal{A}$ to $\mathcal{B}$ that is effaceable in positive degrees. Then T is universal.

***Proof*:**
Let S be a δ-functor from $\mathcal{A}$ to $\mathcal{B}$ and $\varphi\colon T^0 \Rightarrow S^0$ a natural transformation. Set $f^0 := \varphi$ and construct f^{n+1} from f^n by induction on $n \geq 0$, the induction hypothesis being that $f^n\colon T^n \Rightarrow S^n$ is a natural transformation. Two facts about abelian categories are used repeatedly, both read off theorem 55.1.9: applied to an epimorphism ϵ, that theorem factors ϵ through $\operatorname{coker}(\ker \epsilon)$ by an isomorphism, so ϵ is a cokernel of its kernel; applied to a monomorphism μ, it factors μ through $\ker(\operatorname{coker}\mu)$ by an isomorphism, so μ is a kernel of its cokernel.

Step 1: Effacing short exact sequences. Fix $n \geq 0$ and an object A of $\mathcal{A}$, and let $u\colon A \to M$ be a monomorphism with $T^{n+1}(u) = 0$, which exists because T^{n+1} is effaceable. Put $N := \operatorname{coker} u$, so that

$$\xi_u\colon \qquad 0 \to A \xrightarrow{u} M \xrightarrow{v} N \to 0$$

is a short exact sequence. The relevant segment of the long exact sequence of T at ξ_u is

$$T^n(M) \xrightarrow{T^n(v)} T^n(N) \xrightarrow{\delta^n_{T,\xi_u}} T^{n+1}(A) \xrightarrow{T^{n+1}(u)} T^{n+1}(M)$$

The last morphism is zero, so exactness at $T^{n+1}(A)$ makes the image of δ^n_{T,ξ_u} all of $T^{n+1}(A)$, that is, δ^n_{T,ξ_u} is an epimorphism. Exactness at $T^n(N)$ identifies its kernel with the image of $T^n(v)$.

Step 2: The construction. Keep u and ξ_u, and consider $\delta^n_{S,\xi_u} \circ f^n_N\colon T^n(N) \to S^{n+1}(A)$. Naturality of f^n applied to v gives $f^n_N \circ T^n(v) = S^n(v) \circ f^n_M$, and $\delta^n_{S,\xi_u} \circ S^n(v) = 0$ because those two morphisms are consecutive in the long exact sequence of S at ξ_u. Hence $\delta^n_{S,\xi_u} \circ f^n_N \circ T^n(v) = 0$. Write $k\colon K \to T^n(N)$ for the kernel of δ^n_{T,ξ_u}, which by Step 1 is the image of $T^n(v)$. The induced morphism $T^n(M) \to K$ is an epimorphism (proposition 55.1.12), so the displayed vanishing gives $\delta^n_{S,\xi_u} \circ f^n_N \circ k = 0$. As δ^n_{T,ξ_u} is an epimorphism it is a cokernel of k, so there is exactly one

morphism

$$f^{n+1}_{A,u}\colon T^{n+1}(A) \longrightarrow S^{n+1}(A) \qquad \text{with} \qquad f^{n+1}_{A,u} \circ \delta^n_{T,\xi_u} = \delta^n_{S,\xi_u} \circ f^n_N$$

Step 3: Comparison of two effacements. Suppose given a commutative diagram with exact rows

$$\begin{array}{lccccccccc} \xi_u\colon & 0 & \longrightarrow & A & \xrightarrow{u} & M & \xrightarrow{v} & N & \longrightarrow & 0 \\ & & & \downarrow{\scriptstyle a} & & \downarrow & & \downarrow{\scriptstyle c} & & \\ \xi_w\colon & 0 & \longrightarrow & B & \xrightarrow{w} & P & \longrightarrow & Q & \longrightarrow & 0 \end{array}$$

in which $T^{n+1}(u) = 0$ and $T^{n+1}(w) = 0$. Then $S^{n+1}(a) \circ f^{n+1}_{A,u} = f^{n+1}_{B,w} \circ T^{n+1}(a)$. Since δ^n_{T,ξ_u} is an epimorphism, it is enough to check that the two sides agree after composing with it. For the first, Step 2, naturality of δ_S for the displayed morphism, and naturality of f^n applied to c give

$$S^{n+1}(a) f^{n+1}_{A,u} \delta^n_{T,\xi_u} = S^{n+1}(a) \delta^n_{S,\xi_u} f^n_N = \delta^n_{S,\xi_w} S^n(c) f^n_N = \delta^n_{S,\xi_w} f^n_Q T^n(c)$$

For the second, naturality of δ_T for the same morphism, followed by Step 2 for w, gives

$$f^{n+1}_{B,w} T^{n+1}(a) \delta^n_{T,\xi_u} = f^{n+1}_{B,w} \delta^n_{T,\xi_w} T^n(c) = \delta^n_{S,\xi_w} f^n_Q T^n(c)$$

The two agree.

Step 4: Independence of the effacement. Let $u\colon A \to M$ and $u'\colon A \to M'$ both efface T^{n+1} at A. The morphism $(u, u')\colon A \to M \oplus M'$ is a monomorphism, because composing it with the projection to M gives u. Writing ι_M and $\iota_{M'}$ for the two inclusions, $(u, u') = \iota_M u + \iota_{M'} u'$, so additivity of T^{n+1} gives

$$T^{n+1}\big((u, u')\big) = T^{n+1}(\iota_M) T^{n+1}(u) + T^{n+1}(\iota_{M'}) T^{n+1}(u') = 0$$

and (u, u') effaces T^{n+1} at A as well. The projection $M \oplus M' \to M$ carries (u, u') to u, hence induces a morphism from the effacing short exact sequence of (u, u') to that of u whose left-hand vertical map is id_A. Step 3 with $a = \mathrm{id}_A$ then gives $f^{n+1}_{A,(u,u')} = f^{n+1}_{A,u}$, and the other projection gives $f^{n+1}_{A,(u,u')} = f^{n+1}_{A,u'}$ in the same way. So the morphism of Step 2 does not depend on the effacement, and it is written f^{n+1}_A from now on.

Step 5: Naturality. Let $g\colon A \to B$ be a morphism of $\mathcal{A}$, and choose effacements $u\colon A \to M$ of T^{n+1} at A and $w\colon B \to P$ at B. The morphism $(u, wg)\colon A \to M \oplus P$ is a monomorphism, again because its composite with the projection to M is u, and

$$T^{n+1}\big((u, wg)\big) = T^{n+1}(\iota_M) T^{n+1}(u) + T^{n+1}(\iota_P) T^{n+1}(w) T^{n+1}(g) = 0$$

since $T^{n+1}(u) = 0$ and $T^{n+1}(w) = 0$. So (u, wg) effaces T^{n+1} at A. The projection $M \oplus P \to P$ carries (u, wg) to $wg = w \circ g$, so it induces a morphism from the effacing short exact sequence of (u, wg) to that of w whose left-hand vertical map is g. Step 3 gives $S^{n+1}(g) \circ f^{n+1}_{A,(u,wg)} = f^{n+1}_{B,w} \circ T^{n+1}(g)$, and by Step 4 the two subscripted morphisms are f^{n+1}_A and f^{n+1}_B. Hence f^{n+1} is a natural transformation $T^{n+1} \Rightarrow S^{n+1}$, which is the induction hypothesis one degree up.

Step 6: Compatibility with every connecting morphism. Let $\xi\colon 0 \to A \xrightarrow{a} M \xrightarrow{b} N \to 0$ be an arbitrary short exact sequence, choose an effacement $u\colon A \to E$ of T^{n+1} at A, and form the pushout of a along u,

$$P := \operatorname{coker}\Big(A \xrightarrow{(a,-u)} M \oplus E\Big)$$

with structure morphisms $m\colon M \to P$ and $e\colon E \to P$, so that $ma = eu$.

The morphism m is a monomorphism. Let $k\colon K \to M$ satisfy $mk = 0$. Then the composite of $(k,0)\colon K \to M \oplus E$ with the cokernel morphism $\pi\colon M \oplus E \to P$ vanishes, so $(k,0)$ factors through $\ker \pi$. Now $(a,-u)$ is a monomorphism, because its composite with the projection to M is a, and π is its cokernel, so $(a,-u)$ is a kernel of π. Hence there is $h\colon K \to A$ with $ah = k$ and $-uh = 0$. As u is a monomorphism $h = 0$, and therefore $k = 0$. So $0 \to M$ is a kernel of m, and lemma 55.1.4(1) makes m a monomorphism.

Consequently $a_1 := ma = eu$ is a monomorphism, being a composite of two, and $T^{n+1}(a_1) = T^{n+1}(e)T^{n+1}(u) = 0$. So

$$\xi_1\colon \qquad 0 \to A \xrightarrow{a_1} P \to \operatorname{coker}(a_1) \to 0$$

effaces T^{n+1} at A, and the identity of A together with m and the induced morphism $\gamma\colon N \to \operatorname{coker}(a_1)$ on cokernels is a morphism of short exact sequences $\xi \to \xi_1$. Steps 2 and 4 give $f_A^{n+1} \circ \delta^n_{T,\xi_1} = \delta^n_{S,\xi_1} \circ f^n_{\operatorname{coker}(a_1)}$, while naturality of δ_T and of δ_S for that morphism gives $\delta^n_{T,\xi_1} \circ T^n(\gamma) = \delta^n_{T,\xi}$ and $\delta^n_{S,\xi_1} \circ S^n(\gamma) = \delta^n_{S,\xi}$, since that morphism is the identity on A. Therefore

$$f_A^{n+1}\delta^n_{T,\xi} = f_A^{n+1}\delta^n_{T,\xi_1}T^n(\gamma) = \delta^n_{S,\xi_1}f^n_{\operatorname{coker}(a_1)}T^n(\gamma) = \delta^n_{S,\xi_1}S^n(\gamma)f^n_N = \delta^n_{S,\xi}f^n_N$$

the third equality being naturality of f^n applied to γ. The induction therefore produces a family $f = (f^i)_{i\geq 0}$ of natural transformations satisfying the condition of definition 56.4.3, that is, a morphism of δ-functors with $f^0 = \varphi$.

Step 7: Uniqueness. Let f and g be morphisms of δ-functors $T \to S$ with $f^0 = g^0 = \varphi$, and suppose $f^j = g^j$ for all $j \leq n$. Given an object A, choose an effacement $u\colon A \to M$ of T^{n+1} at A and form ξ_u as in Step 1. Both f_A^{n+1} and g_A^{n+1} satisfy $h \circ \delta^n_{T,\xi_u} = \delta^n_{S,\xi_u} \circ f^n_N$, by definition 56.4.3 and the induction hypothesis, and δ^n_{T,ξ_u} is an epimorphism by Step 1, so $f_A^{n+1} = g_A^{n+1}$. Hence $f = g$, and T is universal, as we sought to show.

The hypothesis is one embedding per object and per positive degree, and the conclusion quantifies over every δ-functor at once. Step 1 is what makes that exchange possible: an effacing embedding makes δ^n an epimorphism, so a morphism out of $T^{n+1}(A)$ is pinned down by its effect on T^n of the quotient, one degree lower. Without effaceability the induction has nothing to descend on, and example 56.4.2 is the failing case: there $T^1 = \mathrm{id}_{\mathbf{Ab}}$, so a monomorphism $u\colon A \to M$ has $T^1(u) = u$, which vanishes only when $A = 0$.

The use of universality is that it turns a comparison in degree zero into a comparison in every degree.

Corollary 56.4.7: A Universal δ-Functor Is Determined by Its Degree-Zero Part

Let S and T be universal δ-functors from $\mathcal{A}$ to $\mathcal{B}$ and let $\varphi\colon T^0 \Rightarrow S^0$ be a natural isomorphism. Then the unique morphism of δ-functors $f\colon T \to S$ with $f^0 = \varphi$ has every f^i a natural isomorphism. Equivalently, *any* morphism of δ-functors between universal δ-functors whose degree-zero component is a natural isomorphism is itself an isomorphism. In particular, a universal δ-functor with a prescribed degree-zero term is unique up to a unique isomorphism of δ-functors.

***Proof*:**
Universality of T gives a unique morphism $f\colon T \to S$ with $f^0 = \varphi$, and universality of S a unique morphism $g\colon S \to T$ with $g^0 = \varphi^{-1}$. The degreewise composite $g \circ f\colon T \to T$ is a morphism of δ-functors with $(g \circ f)^0 = \varphi^{-1} \circ \varphi = \mathrm{id}_{T^0}$, and id_T is another one. Applying definition 56.4.4 to T with S taken to be T itself and φ taken to be id_{T^0}, the two coincide, so $g \circ f = \mathrm{id}_T$. The same argument in S gives $f \circ g = \mathrm{id}_S$. Hence each f^i is a natural isomorphism with inverse g^i. For the second sentence of the statement, a morphism of δ-functors $h\colon T \to S$ whose component h^0 is a natural isomorphism is, by universality of T, the unique morphism extending h^0, so it is the f just treated with $\varphi = h^0$, completing the proof.

The corollary is what makes universality usable: to identify two families of functors in all degrees it is enough to identify them in degree zero, provided both are universal. The criterion of theorem 56.4.6 is what verifies that proviso, and the family it applies to most often is the one built in section 56.3.

Corollary 56.4.8: The Right-Derived Functors Form a Universal δ-Functor

Let $\mathcal{A}$ be an abelian category with enough injectives, let $\mathcal{B}$ be an abelian category, and let $F\colon \mathcal{A} \to \mathcal{B}$ be an additive functor. Then:

1. the family $(R^iF)_{i\geq 0}$, equipped with the connecting morphisms of corollary 56.3.12, is a δ-functor from $\mathcal{A}$ to $\mathcal{B}$;
2. $R^iF(I) = 0$ for every injective object I of $\mathcal{A}$ and every $i > 0$; consequently $(R^iF)_{i\geq 0}$ is effaceable in positive degrees and therefore universal;
3. if F is left exact then R^0F is naturally isomorphic to F, and $(R^iF)_{i\geq 0}$ is then, up to a unique isomorphism of δ-functors, the only universal δ-functor from $\mathcal{A}$ to $\mathcal{B}$ whose degree-zero term is naturally isomorphic to F.

***Proof*:**

1. Each R^iF is additive. Let $\varphi, \psi\colon A \to B$, and choose injective resolutions $A \to I^\bullet$ and $B \to J^\bullet$. Applying proposition 56.2.15 in the opposite category, φ and ψ lift to morphisms of resolutions $\varphi^\bullet, \psi^\bullet\colon I^\bullet \to J^\bullet$, unique up to homotopy, and $\varphi^\bullet + \psi^\bullet$ is then a lift of $\varphi + \psi$. Since F is additive, $\mathrm{Ch}(F)(\varphi^\bullet + \psi^\bullet) = \mathrm{Ch}(F)(\varphi^\bullet) + \mathrm{Ch}(F)(\psi^\bullet)$ degreewise, and H^i carries a sum of morphisms of complexes to the sum of the induced morphisms, so $R^iF(\varphi + \psi) = R^iF(\varphi) + R^iF(\psi)$. Condition (1) of definition 56.4.1 is the exactness assertion of corollary 56.3.12 together with its identification of the unlabelled arrows as $R^iF(\alpha)$ and $R^iF(\beta)$, and condition (2) is its functoriality in the short exact sequence.

2. Let I be injective. The complex with I in degree 0 and 0 elsewhere, augmented by id_I, is an injective resolution of I, so $R^iF(I) = H^i(F(I) \to 0 \to \cdots)$, which is 0 for $i > 0$. Given an object A and $i > 0$, enough injectives gives a monomorphism $A \hookrightarrow I$ with I injective (definition 56.2.3(2)), and the induced morphism $R^iF(A) \to R^iF(I) = 0$ is zero because its target is. So R^iF is effaceable for every $i > 0$, and theorem 56.4.6 applies.

3. Let $0 \to A \xrightarrow{\varepsilon_A} I^0 \xrightarrow{d^0} I^1 \to \cdots$ be an injective resolution. Left exactness is a hypothesis about short exact sequences, and $0 \to A \to I^0 \xrightarrow{d^0} I^1$ is not one, so the passage to $\ker F(d^0)$ takes two steps. First, F preserves monomorphisms: a monomorphism $\nu\colon X \to Y$ is a kernel of its cokernel (theorem 55.1.9), so $0 \to X \xrightarrow{\nu} Y \to \operatorname{coker}\nu \to 0$ is short exact and left exactness makes $F(\nu)$ a monomorphism. Second, factor $d^0 = \mu \circ p$ with $p\colon I^0 \to \operatorname{im}d^0$ an epimorphism and $\mu\colon \operatorname{im}d^0 \to I^1$ a monomorphism (theorem 55.1.9). Exactness of the resolution at A and at I^0 makes ε_A a kernel of d^0, hence of p since μ is a monomorphism, so $0 \to A \xrightarrow{\varepsilon_A} I^0 \xrightarrow{p} \operatorname{im}d^0 \to 0$ is short exact and $0 \to F(A) \to F(I^0) \xrightarrow{F(p)} F(\operatorname{im}d^0)$ is exact. Since $F(\mu)$ is a monomorphism, $\ker F(d^0) = \ker F(p)$, and that kernel is the image of the monomorphism $F(\varepsilon_A)$. Hence $F(A) \cong \ker F(d^0) = H^0\big(\mathrm{Ch}(F)(I^\bullet)\big) = R^0F(A)$, the isomorphism being induced by $F(\varepsilon_A)$. For a morphism $\varphi\colon A \to B$ and a lift $\varphi^\bullet$ of φ to the chosen resolutions, the augmentation square $\varepsilon_B \circ \varphi = \varphi^0 \circ \varepsilon_A$ gives $F(\varepsilon_B)F(\varphi) = F(\varphi^0)F(\varepsilon_A)$, and $R^0F(\varphi)$ is the restriction of $F(\varphi^0)$ to the two kernels, so the isomorphism is natural in A. For the final clause, $(R^iF)_{i\geq 0}$ is universal by (2) and its degree-zero term is F up to the isomorphism just produced, so corollary 56.4.7 gives the uniqueness, completing the proof.

Part (3) is the form in which the corollary is applied: a family of functors carrying long exact sequences, agreeing with F in degree zero and effaceable in positive degrees, *is* the family of right-derived functors of F, by a canonical isomorphism compatible with every connecting morphism. The converse question, whether universality forces effaceability, has an affirmative answer as soon as enough injectives are available.

Corollary 56.4.9: Universality and Effaceability Agree When There Are Enough Injectives

Let $\mathcal{A}$ be an abelian category with enough injectives, let $\mathcal{B}$ be an abelian category, and let T be a δ-functor from $\mathcal{A}$ to $\mathcal{B}$. Then the following are equivalent:

1. T is universal;
2. $T^i(I) = 0$ for every injective object I of $\mathcal{A}$ and every $i > 0$;
3. T^i is effaceable for every $i > 0$.

***Proof*:**
That (3) implies (1) is theorem 56.4.6. For (1) implies (2), let T be universal. Condition (1) of definition 56.4.1 makes T^0 left exact, so by corollary 56.4.8(2) and (3) the family $(R^iT^0)_{i\geq 0}$ is a universal δ-functor with R^0T^0 naturally isomorphic to T^0. Both T and $(R^iT^0)_{i\geq 0}$ are universal and their degree-zero terms are naturally isomorphic, so corollary 56.4.7 gives an isomorphism of δ-functors $T \cong (R^iT^0)_{i\geq 0}$. For I injective and $i > 0$ this gives $T^i(I) \cong R^iT^0(I) = 0$ by corollary 56.4.8(2). For (2) implies (3), let $i > 0$ and let A be an object. Enough injectives gives

a monomorphism $A \hookrightarrow I$ with I injective, and $T^i(A) \to T^i(I) = 0$ is zero because its target is. Hence T^i is effaceable, completing the proof.

A worked case shows the two corollaries, and it can be carried out to the end because the functor below has an injective resolution of length one available at every object.

Example 56.4.10: The δ-Functor $\operatorname{Ext}^\bullet_{\mathbb{Z}}(\mathbb{Z}/n, -)$

Fix an integer $n \geq 1$ and let $F = \operatorname{Hom}_{\mathbb{Z}}(\mathbb{Z}/n, -)\colon \mathbf{Ab} \to \mathbf{Ab}$, which is left exact. The category $\mathbf{Ab}$ is $\mathbb{Z}$-$\mathbf{Mod}$ and has enough injectives by example 56.2.2(4), and $R^iF = \operatorname{Ext}^i_{\mathbb{Z}}(\mathbb{Z}/n, -)$ by example 56.3.6(2), so corollary 56.4.8 makes $\big(\operatorname{Ext}^i_{\mathbb{Z}}(\mathbb{Z}/n, -)\big)_{i\geq 0}$ a universal δ-functor whose degree-zero term is naturally isomorphic to F.

Its values can be written down. By theorem 17.3.5(2), applied to the principal ideal domain $\mathbb{Z}$, an abelian group is injective if and only if it is divisible. Every abelian group embeds in a divisible one: write $A = L/K$ with L the free abelian group on the underlying set of A, note that $L \subseteq L \otimes_{\mathbb{Z}} \mathbb{Q}$ and that $K \subseteq L$, and observe that the kernel of $A = L/K \to (L \otimes_{\mathbb{Z}} \mathbb{Q})/K$ consists of the classes of elements of L that lie in K, hence is zero, while the target is a quotient of the divisible group $L \otimes_{\mathbb{Z}} \mathbb{Q}$ and is therefore divisible. Fix such an embedding $A \hookrightarrow D$ with D divisible. The quotient D/A is divisible as well, so

$$0 \to A \to D \to D/A \to 0$$

is an injective resolution of A of length one, and $\operatorname{Ext}^i_{\mathbb{Z}}(\mathbb{Z}/n, A) = 0$ for $i \geq 2$.

For any abelian group B a homomorphism $\mathbb{Z}/n \to B$ is determined by the image of 1, which may be any element killed by n, so $\operatorname{Hom}_{\mathbb{Z}}(\mathbb{Z}/n, B) = B[n] := \{b \in B \,|\, nb = 0\}$. Applying F to the resolution leaves the two-term complex $D[n] \to (D/A)[n]$, whence

$$\operatorname{Ext}^0_{\mathbb{Z}}(\mathbb{Z}/n, A) = \ker\big(D[n] \to (D/A)[n]\big) = D[n] \cap A = A[n]$$

which agrees with left exactness, and $\operatorname{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, A) = \operatorname{coker}\big(D[n] \to (D/A)[n]\big)$. That cokernel is A/nA. Send the class of $d + A$, where $nd \in A$, to $nd + nA$. This is well defined, since replacing d by $d + a$ with $a \in A$ changes nd by $na \in nA$, and it kills the image of $D[n]$, on which $nd = 0$. It is surjective because D is divisible: given $a \in A$ choose $d \in D$ with $nd = a$, and then $d + A$ lies in $(D/A)[n]$ and maps to $a + nA$. It is injective because $nd \in nA$, say $nd = na$ with $a \in A$, forces $n(d - a) = 0$, so that $d + A = (d - a) + A$ lies in the image of $D[n]$.

The universal δ-functor extending $A \mapsto A[n]$ is therefore

$$\operatorname{Ext}^0_{\mathbb{Z}}(\mathbb{Z}/n, A) = A[n], \qquad \operatorname{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, A) = A/nA, \qquad \operatorname{Ext}^i_{\mathbb{Z}}(\mathbb{Z}/n, A) = 0 \quad (i \geq 2)$$

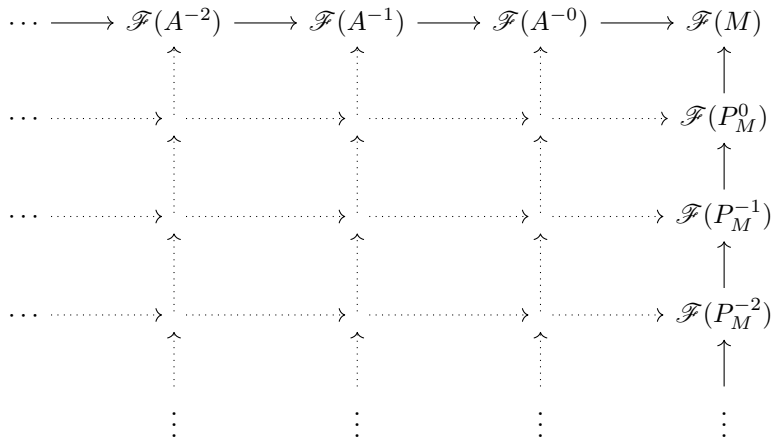
and the long exact sequence attached to $0 \to A' \to A \to A'' \to 0$ has only six nonzero terms,

$$0 \to A'[n] \to A[n] \to A''[n] \xrightarrow{\delta^0} A'/nA' \to A/nA \to A''/nA'' \to 0$$

Effaceability is visible in this display: for D divisible $D/nD = 0$, so the morphism $\operatorname{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, A) \to \operatorname{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, D)$ induced by $A \hookrightarrow D$ is zero, and in degrees $i \geq 2$ both groups vanish.

Applications of the criterion follow one pattern. Two families of functors are each shown to carry long

exact sequences functorial in the short exact sequence; each is shown effaceable in positive degrees, possibly by different classes of effacing objects; and the two degree-zero terms are matched by a natural isomorphism. Theorem 56.4.6 makes both universal, and corollary 56.4.7 then upgrades the degree-zero match to an isomorphism in every degree, compatible with every connecting morphism. The two classes of effacing objects need not be related, and neither has to consist of injective objects, since definition 56.4.5 asks only that the induced morphism vanish.

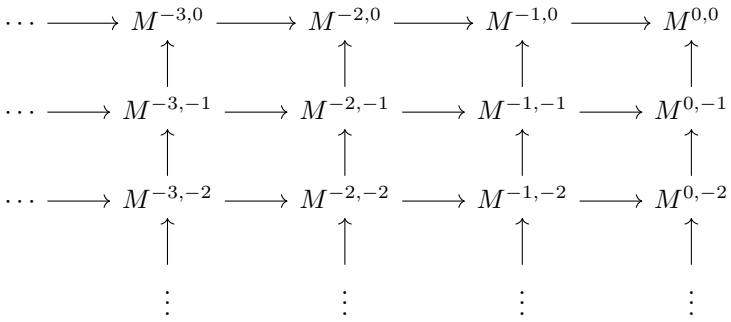


Exercise 56.4.1

1. Let $G\colon \mathcal{A} \to \mathcal{B}$ be an exact additive functor. Show that setting $T^i := G$ for every $i \geq 0$, with all connecting morphisms zero, defines a δ-functor from $\mathcal{A}$ to $\mathcal{B}$, and that this δ-functor is universal if and only if G is the zero functor.
2. Show that a universal δ-functor T with $T^0 = 0$ has $T^i = 0$ for every $i \geq 0$.
3. Let $\mathcal{A}$ be an abelian category with enough injectives and let $F, G\colon \mathcal{A} \to \mathcal{B}$ be left exact additive functors admitting a natural isomorphism $\eta\colon F \Rightarrow G$. Show that there is exactly one isomorphism of δ-functors $(R^iF)_{i\geq 0} \to (R^iG)_{i\geq 0}$ whose degree-zero component corresponds to η, and give the argument without choosing a single resolution.
4. Fix integers $m, n \geq 1$ and put $d = \gcd(m, n)$. Write out the six-term exact sequence of example 56.4.10 for the short exact sequence $0 \to \mathbb{Z} \xrightarrow{m} \mathbb{Z} \to \mathbb{Z}/m \to 0$, computing each of the six groups, and verify the exactness of the resulting sequence directly.
5. Let $\mathcal{A}$ be an abelian category with enough injectives, let $F\colon \mathcal{A} \to \mathcal{B}$ be additive, and let $0 \to A \to I \to C \to 0$ be exact with I injective. Show that $R^iF(C) \cong R^{i+1}F(A)$ for every $i \geq 1$ and that $R^1F(A) \cong \operatorname{coker}\big(R^0F(I) \to R^0F(C)\big)$.
6. Let T be a δ-functor from $\mathcal{A}$ to $\mathcal{B}$ and let $E\colon \mathcal{B} \to \mathcal{C}$ be an exact additive functor. Show that $(E \circ T^i)_{i\geq 0}$, with connecting morphisms $E(\delta^i_\xi)$, is a δ-functor from $\mathcal{A}$ to $\mathcal{C}$, and that it is universal whenever T is effaceable in positive degrees.
7. Let T be a universal δ-functor from $\mathcal{A}$ to $\mathcal{B}$. Show that $f \mapsto f^0$ is a bijection from the set of morphisms of δ-functors $T \to T$ onto the set of natural transformations $T^0 \Rightarrow T^0$, and that it carries composition to composition.

56.5 Double Complexes

This final section shall be the basis for being able to compute many complexes. It was mentioned in box 56.2.12 that $\operatorname{Ext}^i_R(M, N)$ may be computed by using either a projective resolution of M or an injective resolution on N, both give the same answer. More generally, we may compute the resolution of either M or N and get the same value. This section will now prove this result. This will make many computations much simpler, for usually one object in is readily understandable while the other is being analyzed.



To motivate this, switching from projective to $\mathscr{F}$-acyclic resolutions can be viewed in the following important alternative way. Consider the following diagram where the top row and right column are cochain:

in some way, there was a reason to go from the top chain to the right chain, with the intermediate values "interpolating" the result. The natural candidate for this would be a complex of complex. Needing to bound it in one direction, say we are looking at $\mathrm{Ch}^{\leq 0}(\mathrm{Ch}^{\leq 0}(\mathbf{A}))$. Such an object would be of the form:

$$\cdots \to M^{-3,\bullet} \xrightarrow{d_h^{-3,\bullet}} M^{-2,\bullet} \xrightarrow{d_h^{-2,\bullet}} M^{-1,\bullet} \xrightarrow{d_h^{-1,\bullet}} M^{0,\bullet} \to 0 \to \cdots$$

The h in the subscript is to represent the fact we are going *horizontally*, and the respective morphism of each $d_h^{-i,\bullet}$ will be going vertically and are denoted $d_v^{i,j}$, or simply d_v to simply show the function's direction:

Given a complex of complex, it would be nice to reduce this to being a complex, a more familiar setting. One strategy the reader may come up with is to take:

$$\bigoplus_{i+j=n} M^{i,j}$$

with the natural morphisms between them. However these morphisms *almost* complexes: instead of commutativity for each square, they are *anti-commutative*. To fix this, create a new type of object that will satisfy this condition:

Definition 56.5.1: Double Complex

Let $A = \{A_{p,q}\}$ be a family of objects from $\mathbf{A}$. Then A together with maps

$$d^h : A_{p,q} \to A_{p-1,q} \qquad \delta^v : A_{p,q} \to A_{p,q-1}$$

satisfying $d^h \circ d^h = 0$, $\delta^v \circ \delta^v = 0$ and $d^h \circ \delta^v + \delta^v \circ d^h = 0$ is called a *double complex* or *bicomplex*.
Both differentials *lower* an index; this homological convention is the one used throughout, and in particular in chapter 60. A cochain double complex, whose differentials raise indices, is the same thing read through $A_{p,q} = A^{-p,-q}$.

We may visualize a double complex like so, with d^h running to the right and δ^v running downwards, each lowering its index:

$$\begin{array}{ccccccccc}
 & & \vdots & & \vdots & & \vdots & & \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
\cdots & \longrightarrow & A_{p+1,q+1} & \longrightarrow & A_{p,q+1} & \longrightarrow & A_{p-1,q+1} & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
\cdots & \longrightarrow & A_{p+1,q} & \longrightarrow & A_{p,q} & \longrightarrow & A_{p-1,q} & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
\cdots & \longrightarrow & A_{p+1,q-1} & \longrightarrow & A_{p,q-1} & \longrightarrow & A_{p-1,q-1} & \longrightarrow & \cdots \\
 & & \downarrow & & \downarrow & & \downarrow & & \\
 & & \vdots & & \vdots & & \vdots & &
\end{array} \tag{56.6}$$

Note this is not a commutative diagram but an *anti-commutative* one. That is a convention, not a restriction, and it is worth pinning down once because both forms occur in practice. A grid whose squares *commute*, which is what a complex of complexes literally gives, is converted into a double complex in the sense above by replacing the vertical differential with

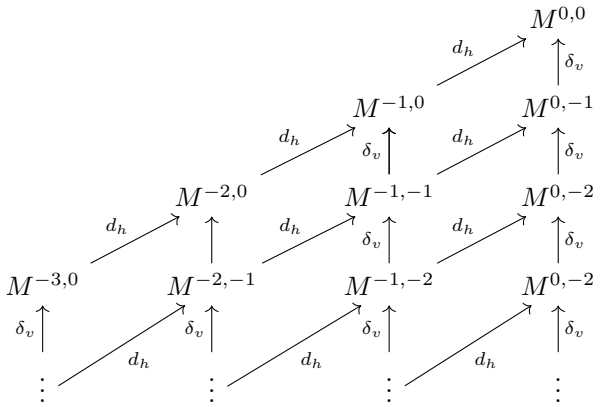
$$\delta^v_{p,q} := (-1)^p \, \tilde{\delta}^v_{p,q}$$

where $\tilde{\delta}^v$ is the commuting one. The sign makes the squares anticommute, which is exactly what makes $d^h + \delta^v$ square to zero on the total complex. Every later construction, here and in chapter 60, assumes the anticommuting form; when a source of double complexes produces commuting squares, this twist is understood to have been applied.

As mentioned, we can form a total complex from this:

Proposition 56.5.2: Total Complex

Let $A = \{A^{p,q}\}$ be a double complex. Then define the total complex $\mathrm{Tot}^{\Pi}(A)$ and $\mathrm{Tot}^{\oplus}(A)$ by:



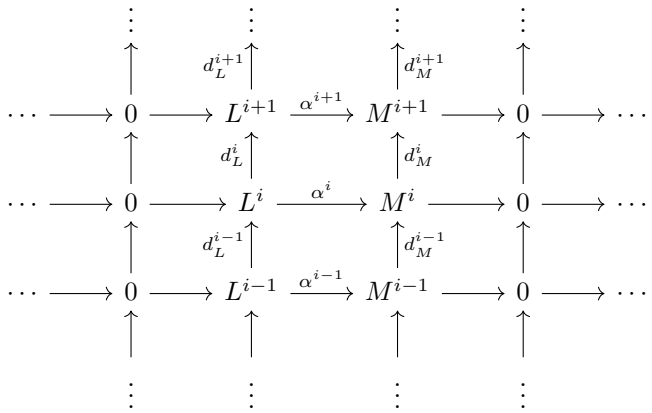
$$\mathrm{Tot}^{\Pi}(A)_n = \prod_{p+q=n} A_{p,q} \qquad \mathrm{Tot}^{\oplus}(A)_n = \bigoplus_{p+q=n} A_{p,q}$$

with $d^{\mathrm{tot}} = d^h + \delta^v$, which squares to zero precisely because the two differentials anticommute. The two agree whenever only finitely many $A_{p,q}$ are nonzero on each diagonal $p+q=n$, as for bounded-above tensor and Hom grids.

***Proof*:**
Computing:

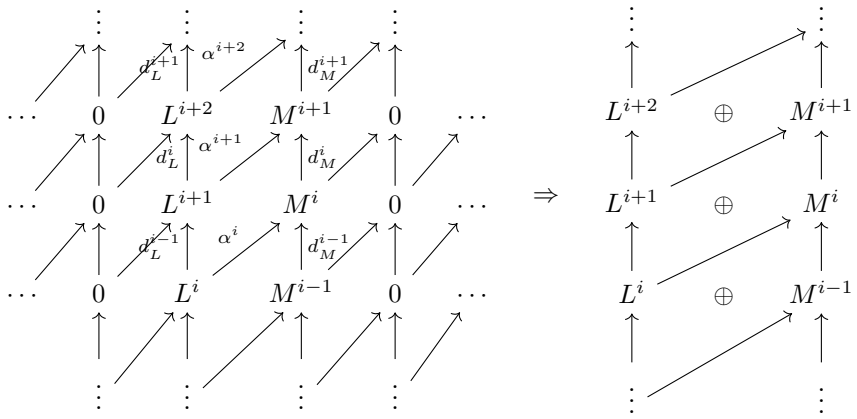
$$d_{tot} \circ d_{tot} = (d_h + \delta_v) \circ (d_h + \delta_v) = d_h \circ d_h + d_h \circ \delta_v + \delta_v \circ d_h + \delta_v \circ \delta_v = 0$$

Note that the total complex does not exist in all categories, namely it may not exist in categories which are not closed under infinite products and coproducts (ex. in the category of finite abelian groups). A category which is closed for infinite products is called *complete* and *cocomplete* if it is closed for infinite sums. We can visualize a total complex by taking the diagram in equation (56.6) and moving it like so:



It is then easy to visualize how we get a total complex form this.

Example 56.5.3: Total Complexes



1. Consider a double complex:

$$\cdots \to 0 \to L^\bullet \xrightarrow{\alpha^\bullet} M^\bullet \to 0 \to \cdots$$

which we may represent as:

we shall get the following:

which is exactly the definition of a mapping cone!

2. The operators $\mathrm{Hom}_A(-,-)$ and $-\otimes-$ both give rise to double complexes. Focusing on the $\mathrm{Hom}_A(-,-)$ example, consider a chain in $L^\bullet \in \mathrm{Ch}^{\leq 0}(\mathbf{A})$ and $M^\bullet \in \mathrm{Ch}^{\geq 0}(\mathbf{A})$. These can be used to form a double complex, or isomorphically a complex in $\mathrm{Ch}^{\leq 0}(\mathrm{Ch}^{\leq 0}(\mathbf{A}))$:

$$\cdots \to \mathrm{Hom}_A(L^\bullet, M^0) \to \mathrm{Hom}_A(L^\bullet, M^1) \to \mathrm{Hom}_A(L^\bullet, M^2) \to \cdots$$

which creates the following upper-quadrant grid:

$$\begin{array}{ccccccc}
\vdots & & \vdots & & \vdots & & \\
\uparrow & & \uparrow & & \uparrow & & \\
\mathrm{Hom}_A(L^{-2}, M^0) & \longrightarrow & \mathrm{Hom}_A(L^{-2}, M^1) & \longrightarrow & \mathrm{Hom}_A(L^{-2}, M^2) & \longrightarrow & \cdots \\
\uparrow & & \uparrow & & \uparrow & & \\
\mathrm{Hom}_A(L^{-1}, M^0) & \longrightarrow & \mathrm{Hom}_A(L^{-1}, M^1) & \longrightarrow & \mathrm{Hom}_A(L^{-1}, M^2) & \longrightarrow & \cdots \\
\uparrow & & \uparrow & & \uparrow & & \\
\mathrm{Hom}_A(L^0, M^0) & \longrightarrow & \mathrm{Hom}_A(L^0, M^1) & \longrightarrow & \mathrm{Hom}_A(L^0, M^2) & \longrightarrow & \cdots
\end{array}$$

Flipping the above diagram across the main diagonal, we would get the double complex:

$$\cdots \to \mathrm{Hom}_A(L^0, M^\bullet) \to \mathrm{Hom}_A(L^{-1}, M^\bullet) \to \mathrm{Hom}_A(L^{-2}, M^\bullet) \to \cdots$$

These two double complexes are isomorphic (as the reader should check). Due to this, by slight abuse of notation the total complex of both can be denoted $TC(\mathrm{Hom}_A(L, M))^\bullet$, where the degree i term is:

$$\mathrm{Hom}_A(L^{-i}, M^0) \oplus \mathrm{Hom}_A(L^{-i+1}, M^1) \oplus \cdots \oplus 0\mathrm{Hom}_A(L^{-1}, M^{i-1}) \oplus 0\mathrm{Hom}_A(L^0, M^i)$$

The reader should verify that:

(a) $\ker d^i_{tot}$ is equal to morphisms of cochains $L^\bullet \to M[i]^\bullet$

(b) The image $\mathrm{im} d^{i-1}_{tit}$ consists of morphisms that are homotopy equivalent to 0

(c) Thus, the cohomology of $TC(\mathrm{Hom}_A(M, N))^\bullet$ "paramaterizes" the morphisms in the homotopic category

To ground this, consider $TC(\mathrm{Hom}_A(M, N))^0 = \mathrm{Hom}_A(L^0, M^0)$. Then $d_{tot}(\alpha) = 0$ means that both $\alpha \circ d^{-1}_{L^\bullet} \in \mathrm{Hom}_A(L^{-1}, M^0)$ and $d^0_{M^\bullet} \in \mathrm{Hom}_A(L^0, M^1)$ both vanish. The reader should draw out this diagram, and notice that this will make α have the condition to be a morphism of cochain complexes $L^\bullet \to M^\bullet$!

$$H^0(TC(\mathrm{Hom}_A(M, N))^\bullet) = \mathrm{Hom}_{\mathrm{Ch}(\mathbf{A})}(L^\bullet, M^\bullet) \overset{!}{=} \mathrm{Hom}_{K(\mathbf{A})}(L^\bullet, M^\bullet)$$

where the $\overset{!}{=}$ equality comes from the fact that there is no nontrivial homotopies in this case! For $H^i(TC(\mathrm{Hom}_A(M, N))^\bullet)$, with some care for signs, it can be identified with $\mathrm{Hom}_{K(\mathbf{A})}(L^\bullet, M[i]^\bullet)$

The cohomology of double complexes requires some book-keeping through the use of *spectral sequences*, which shall be explored in greater depth in chapter 60. For the current goal, it is enough to consider when a double-complex is exact:

Proposition 56.5.4: Exactness Of Complex Of Complex

Let $\mathbf{A}$ be an abelian category and let

$$\cdots \to M^{-3,\bullet} \to M^{-2,\bullet} \to M^{-1,\bullet} \to M^{0,\bullet} \to 0$$

be a complex in $\mathrm{Ch}^{\leq 0}(\mathrm{Ch}^{\leq 0}(\mathbf{A}))$, regarded as a double complex $M^{\bullet,\bullet}$ with $M^{p,q} = 0$ unless $p \leq 0$ and $q \leq 0$, and let $T^\bullet$ denote its total complex. Then $T^\bullet$ is exact if *either* of the following holds:

1. the displayed complex is exact in $\mathrm{Ch}^{\leq 0}(\mathbf{A})$, equivalently every row $M^{\bullet,q}$ is exact;
2. every column $M^{p,\bullet}$ is exact.

Neither hypothesis implies the other, and either one alone suffices; this is the form in which the result is used below and in chapter 60. The same statement holds in $\mathrm{Ch}^{\geq 0}(\mathrm{Ch}^{\geq 0}(\mathbf{A}))$, by reversing the direction of every index. Note further that only one of the two directions need be bounded: case (2) uses only $p \leq 0$ and case (1) only $q \leq 0$, the bound being what makes the following staircase terminate; with only one bound the diagonals are infinite, so there the total complex must be taken to be $\mathrm{Tot}^{\oplus}$, since the staircase needs a least index in the support of a given element. The result is known as the *acyclic assembly lemma*; see *An Introduction to Homological Algebra* [101] for the variants in the other quadrants and for the distinction between Tot^{Π} and $\mathrm{Tot}^{\oplus}$, which does not arise here because each diagonal of $M^{\bullet,\bullet}$ carries only finitely many nonzero terms.

***Proof*:**

Step 1: Reduction to case (2). Transposing the double complex, that is exchanging the two indices and the two differentials, converts rows into columns and leaves the total complex unchanged up to the sign of the differential, which does not affect exactness. So case (1) follows from case (2) applied to the transpose, and only the latter needs proof.

Step 2: The staircase. Assume every column is exact, write d_h and d_v for the two differentials and $d = d_h + d_v$ for the differential of $T^\bullet$. Let $x \in T^n$ satisfy $dx = 0$; the claim is that $x = dy$ for some $y \in T^{n-1}$. Write $x = \sum_{p+q=n} x^{p,q}$, a finite sum.

Let p_1 be least with $x^{p_1,q_1} \neq 0$, where $q_1 = n - p_1$; if there is no such p_1 then $x = 0$ and there is nothing to prove. Consider the component of the equation $dx = 0$ in bidegree $(p_1, q_1 + 1)$. Only two terms can contribute to it, namely $d_v x^{p_1,q_1}$ and $d_h x^{p_1-1,q_1+1}$, and the second vanishes because $p_1 - 1 < p_1$ and p_1 was least. Hence

$$d_v x^{p_1,q_1} = 0$$

so x^{p_1,q_1} is a cocycle in the column $M^{p_1,\bullet}$. That column is exact, so there is $y^{p_1,q_1-1} \in M^{p_1,q_1-1}$ with $d_v y^{p_1,q_1-1} = x^{p_1,q_1}$.

Step 3: Termination. Replace x by

$$x' = x - d\big(y^{p_1,q_1-1}\big) = x - d_v y^{p_1,q_1-1} - d_h y^{p_1,q_1-1}$$

This is again a cocycle, since it differs from x by a coboundary. Its component in bidegree (p_1, q_1) is $x^{p_1,q_1} - d_v y^{p_1,q_1-1} = 0$, and $d_h y^{p_1,q_1-1}$ lives in bidegree $(p_1 + 1, q_1 - 1)$, so no component

with $p < p_1$ is disturbed and all of those were already zero. The least index with a nonzero component has therefore increased by at least one.

Because $M^{p,q} = 0$ for $p > 0$, this least index cannot exceed 0, so after at most $|p_1| + 1$ repetitions every component vanishes. Summing the finitely many y's produced along the way gives $y \in T^{n-1}$ with $dy = x$, so $T^\bullet$ is exact at degree n. As n was arbitrary, this completes the proof.

Example 56.5.5: Exactness Of Double Complex

Let $P^\bullet \in C^{\leq 0}(\mathbf{A})$ be a complex and $L^\bullet \in C^{\geq 0}(\mathbf{A})$ an exact complex. Since each P^i is projective, $\mathrm{Hom}_{\mathbf{A}}(P^i, L^\bullet)$ for each i. Hence, the complex:

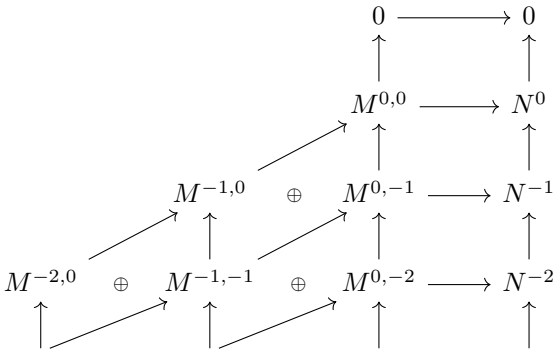
$$0 \to \mathrm{Hom}_{\mathbf{A}}(P^0, L^\bullet) \to \mathrm{Hom}_{\mathbf{A}}(P^{-1}, L^\bullet) \to \mathrm{Hom}_{\mathbf{A}}(P^{-2}, L^\bullet) \to \cdots$$

is exact. Using example 56.5.3, we see that:

$$\mathrm{Hom}_{K(\mathbf{A})}(P^\bullet, L[i]^\bullet) = 0 \qquad \forall i \in \mathbb{Z}$$

This implies that every cochain morphism from a bounded-above projective complex to a bounded-bellow exact complex is homotopic to 0. This just proved corollary 56.2.5 (with an extra boundedness condition)! In some textbooks, due to the speed at which some results can be proved using double-complexes, they are introduced earlier. However, the more "down-to-earth" introduction has is favored in this chapter since it demonstrated key homological concepts.

Next, we look at resolutions of complexes.. As we saw in definition 56.2.11, a (projective) resolution is a quasi-isomorphism $M^\bullet \to \iota(A)$ for some complex $M^\bullet \in \mathrm{Obj}(\mathrm{Ch}(\mathbf{A}))$, and more generally a projective resolution for a general complex is a quasi-isomorphism $P^\bullet \to C^\bullet$ for some projective complex $P^\bullet$. Generalizing the definition of resolution of the first kind, $\iota(A)$, and say that resolution of a complex $N^\bullet \in \mathrm{Ch}^\bullet(A) = A'$ is a complex of complex $M^{\bullet,\bullet} \in \mathrm{Ch}^{\leq 0}(A')$ and a quasi-isomorphism

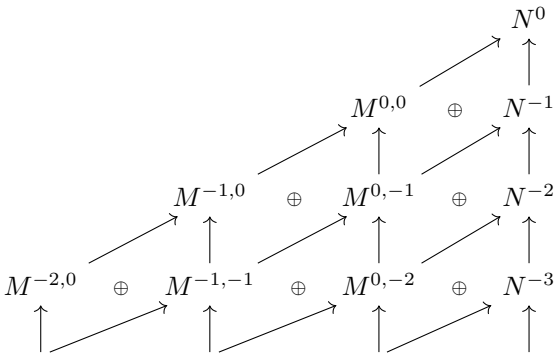


$$\begin{array}{ccccccccc} \cdots & \longrightarrow & M^{-2,\bullet} & \xrightarrow{d_h} & M^{-2,\bullet} & \xrightarrow{d_h} & M^{-2,\bullet} & \longrightarrow & 0 & \longrightarrow & \cdots \\ & & \downarrow & & \downarrow & & \downarrow & & \downarrow & & \\ \cdots & \longrightarrow & 0 & \longrightarrow & 0 & \longrightarrow & N^\bullet & \longrightarrow & 0 & \longrightarrow & \cdots \end{array} \tag{56.7}$$

where the diagram commutes. We shall show that this definition of a resolution induces a resolution as given in theorem 56.2.17. To see this, notice that in equation (56.7), $\alpha^\bullet \circ d_h = 0$, hence we can collapse the diagram like so:

$$\cdots \to M^{-2,\bullet} \xrightarrow{-d_h} M^{-1,\bullet} \xrightarrow{d_h} M^{0,\bullet} \xrightarrow{\alpha^\bullet} N^\bullet \to 0 \cdots$$

Call this complex $M_N^{\bullet,\bullet}$. Two important diagrams can be derived here. The first is by taking the



total complex of $M^{\bullet,\bullet}$ and taking a morphism from this to $N^\bullet$:

This gives a morphism:

$$TC(\alpha^\bullet) : TC(M^{\bullet,\bullet}) \to N^\bullet$$

where the morphism is defined since $TC(-)$ is a functorial. Another diagram we can create is by considering the total complex of $M_N^{\bullet,\bullet}$:

These two are related in the following way:

Proposition 56.5.6: Total Complex Of Resolution

Let $M^{\bullet,\bullet}$ be a resolution of $N^\bullet$ and let $M_N^{\bullet,\bullet}$ be defined as above. Then

$$TC(M_N)^\bullet \cong MC\big(TC(\alpha)\big)[-1]^\bullet$$

canonically, equivalently $TC(M_N)[1]^\bullet \cong MC(TC(\alpha))^\bullet$.

***Proof*:**
Both sides are computed degreewise, so it suffices to match the terms and the differentials.

Step 1: The terms. The complex $M_N^{\bullet,\bullet}$ is $M^{\bullet,\bullet}$ with $N^\bullet$ appended in the column $p = 1$, to the right of $M^{0,\bullet}$ and joined to it by the augmentation $\alpha^\bullet$. A term N^j therefore sits in total degree

$1+j$, so its contribution to total degree n is N^{n-1} and

$$TC(M_N)^n = \Big(\bigoplus_{i+j=n} M^{i,j}\Big) \oplus N^{n-1} = TC(M)^n \oplus N^{n-1}$$

which is what the diagram above the proposition displays, $M^{0,0}$ being grouped with N^{-1}. On the other side $TC(\alpha)\colon TC(M)^\bullet \to N^\bullet$ is the totalized augmentation, and since definition 56.1.21 puts the *source* of a morphism in the shifted slot,

$$MC\big(TC(\alpha)\big)^n = TC(M)^{n+1} \oplus N^n$$

Comparing the two, $TC(M_N)^n = MC(TC(\alpha))^{n-1}$, which is the shift asserted in the statement.

Step 2: The differentials. On $TC(M_N)^\bullet$ the differential is the total differential of the augmented double complex: on the M part it is $d_h + d_v$, the component carrying $M^{0,\bullet}$ into the appended column is $\alpha^\bullet$, and on the N part it is $-d_N$, the sign being the $(-1)^p$ twist at $p=1$ that makes the augmented grid anticommute. So $d_{TC(M_N)}(m,n) = (d_{TC(M)}m,\ \alpha(m) - d_N n)$. By definition 56.1.21 the cone differential is $d_{MC}(l,n) = (-d_{TC(M)}l,\ \alpha(l) + d_N n)$, so under the identification of Step 1 the two differ by an overall sign.

The shift convention $d_{[r]} = (-1)^r d$ gives $d_{MC(TC(\alpha))[-1]}(m,n) = -\big(-d_{TC(M)}m,\ \alpha(m) + d_N n\big) = (d_{TC(M)}m,\ -\alpha(m) - d_N n)$, so the two differentials agree in the $TC(M)$ component and differ exactly in the sign of the α-component. They are therefore not equal on the nose, but the map

$$\varphi(m,n) = (m,-n)$$

is an isomorphism of complexes intertwining them: $\varphi\big(d_{TC(M_N)}(m,n)\big) = (d_{TC(M)}m,\ -\alpha(m) + d_N n) = d_{MC(TC(\alpha))[-1]}\big(\varphi(m,n)\big)$. Hence $TC(M_N)^\bullet \cong MC(TC(\alpha))[-1]^\bullet$, canonically, completing the proof.

Using this, we can see how the resolution in $\mathrm{Ch}^{\leq 0}(A')$ leads to a resolution as defined in theorem 56.2.17:

Theorem 56.5.7: Total Complexes And Resolution Of Complexes

Let $\mathbf{A}$ be an abelian category, $\mathbf{A}' = \mathrm{Ch}^{\leq 0}(\mathbf{A})$, and $N^\bullet \in A'$. Let $M^{\bullet,\bullet} \in \mathrm{Ch}^{\leq 0}(\mathbf{A}')$ with total complex $T^\bullet$.

1. Assume that $M^{\bullet,\bullet}$ is a resolution of $N^\bullet$ in $\mathrm{Ch}^{\leq 0}(\mathbf{A}')$. Then $T^\bullet$ is quasi-isomorphic to $N^\bullet$ in $\mathbf{A}'$.
2. Assuming the cohomology of $M^{i,\bullet}$ is concentrated at 0. Then $T^\bullet$ is quasi-isomorphic to the complex of cohomology objects induced by the complex $M^{\bullet,\bullet}$:

$$\cdots \to H^0(M^{-3,\bullet}) \to H^0(M^{-2,\bullet}) \to H^0(M^{-1,\bullet}) \to H^0(M^{0,\bullet}) \to 0 \cdots$$

Notice that this theorem is a direct extensions of proposition 56.5.4. This is also a special case of results we shall see in chapter 60

***Proof*:**
Notice that (2) follows from (1) by flipping the corresponding double-complex across the diagonal, hence we prove the first. For the first, if $M_N^{\bullet,\bullet}$ is quasi-isomorphic, then $TC(M_N)^\bullet$ is exact by proposition 56.5.4, which by proposition 56.5.6 is the mapping cone of the morphism $T^\bullet \to N^\bullet$, which by proposition 56.1.24 shows that $\alpha^\bullet : T^\bullet \to N^\bullet$ is a quasi-isomorphism, as we sought to show.

Using this theorem, a simple alternative to resolving complexes (theorem 56.2.17). By the horseshoe lemma, every bounded-above complex $N^\bullet$ in an abelian category with enough projectives may be viewed as a complex induced by H^0 from a complex:

$$\cdots \to P^{-3,\bullet} \to P^{-2,\bullet} \to P^{-1,\bullet} \to P^{0,\bullet} \to 0$$

where $P^{i,\bullet}$ are projective resolutions of N^i. Then by theorem 56.5.7(2) the total complex of $P^{\bullet,\bullet}$ is a projective resolution of $N^\bullet$. This then can give theorem 56.2.17. It is still worth presenting theorem 56.2.17 to firmly grasp the fundamentals of homological algebra.

56.5.1 Applications to Computations of Ext and Tor

Let us now show that we may compute $\text{Ext}(M,N)$ or $\text{Tor}(M,N)$ using a resolution of either term. Going back to the $\mathscr{F}$-acyclic resolution of an object M:

$$\cdots \to A^{-2} \to A^{-1} \to A^0 \to M \to 0 \to \cdots$$

We may create a complex of projective resolution by corollary 56.3.9:

$$\cdots \to P^{-2,\bullet} \to P^{-1,\bullet} \to P^{0,\bullet} \to P_M^\bullet \to 0 \to \cdots$$

where $P^{i,\bullet}$ is a projective resolution of A^{-i}. Since the resolution by projective resolution's is exact, the rows of the double-complex corresponding to $P^{\bullet,\bullet}$ are projective resolutions of P_M^i. Now, applying the functor $\mathscr{F}$, we get the diagram:

$$\begin{array}{ccccccccc}
\cdots & \longrightarrow & \mathscr{F}(A^{-2}) & \longrightarrow & \mathscr{F}(A^{-1}) & \longrightarrow & \mathscr{F}(A^0) & \longrightarrow & \mathscr{F}(M) \\
 & & \uparrow & & \uparrow & & \uparrow & & \uparrow \\
\cdots & \longrightarrow & \mathscr{F}(P_M^{-2,0}) & \longrightarrow & \mathscr{F}(P_M^{-1,0}) & \longrightarrow & \mathscr{F}(P_M^{0,0}) & \longrightarrow & \mathscr{F}(P_M^0) \\
 & & \uparrow & & \uparrow & & \uparrow & & \uparrow \\
\cdots & \longrightarrow & \mathscr{F}(P_M^{-2,-1}) & \longrightarrow & \mathscr{F}(P_M^{-1,-1}) & \longrightarrow & \mathscr{F}(P_M^{0,-1}) & \longrightarrow & \mathscr{F}(P_M^{-1}) \\
 & & \uparrow & & \uparrow & & \uparrow & & \uparrow \\
\cdots & \longrightarrow & \mathscr{F}(P_M^{-2,-2}) & \longrightarrow & \mathscr{F}(P_M^{-1,-2}) & \longrightarrow & \mathscr{F}(P_M^{0,-2}) & \longrightarrow & \mathscr{F}(P_M^{-2}) \\
 & & \uparrow & & \uparrow & & \uparrow & & \uparrow \\
 & & \vdots & & \vdots & & \vdots & & \vdots
\end{array}$$

Since each row and column of this diagram (excluding the top row and right column) is exact, by theorem 56.5.7 the total complex of:

$$\cdots \mathscr{F}(P^{-2,\bullet}) \to \mathscr{F}(P^{-1,\bullet}) \to \mathscr{F}(P^{0,\bullet}) \to 0 \to \cdots$$

is quasi-isomorphic to both $\mathrm{Ch}(\mathscr{F})(A^\bullet)$ and $\mathrm{Ch}(\mathscr{F})(P^\bullet)$, that is:

$$TC(\mathscr{F}(P))^\bullet \sim \mathrm{Ch}(\mathscr{F})(A^\bullet) \sim \mathrm{Ch}(\mathscr{F})(P^\bullet)$$

Thus, by definition of quasi-isomorphism

$$\mathbf{L}_i\mathscr{F}(M) \cong H^{-i}(\mathrm{Ch}(\mathscr{F})(A^\bullet)) \cong H^{-i}(\mathrm{Ch}(\mathscr{F})(P^\bullet))$$

Applying these results to Ext and Tor will finally give us the following results:

Theorem 56.5.8: Computation Of Tor and Ext

Let R be a ring. If M is a right and N a left R-module, with projective resolutions $P^\bullet_M$ and $P^\bullet_N$, then

$$\mathrm{Tor}^R_i(M,N) \cong H^{-i}(P^\bullet_M \otimes_R N) \cong H^{-i}(M \otimes_R P^\bullet_N)$$

If M and N are left R-modules, $P^\bullet_M$ is a projective resolution of M and $Q^\bullet_N$ an injective resolution of N, then

$$\mathrm{Ext}^i_R(M,N) \cong H^i(\mathrm{Hom}_R(P^\bullet_M, N)) \cong H^i(\mathrm{Hom}_R(M, Q^\bullet_N))$$

The index for Tor is $-i$ because a projective resolution sits in nonpositive degrees (definition 56.2.11), so that $P^{-i}_M \otimes_R N$ is the term of degree $-i$.

***Proof*:**
We first treat Tor. Take the complex:

$$\cdots \to P^{-2}_M \otimes_R P^\bullet_N \to P^{-1}_M \otimes_R P^\bullet_N \to P^0_M \otimes_R P^\bullet_N \to 0 \cdots$$

Each P^j_N is projective, hence flat (corollary 17.5.5), so $- \otimes_R P^j_N$ is exact, and the cohomology of the complex is concentrated at 0 and equals $M \otimes_R P^\bullet_N$. By theorem 56.5.7 we have that :

$$TC(P^\bullet_M \otimes_R P^\bullet_N)^\bullet \qquad \text{is quasi-isomorphic to} \qquad M \otimes_R P^\bullet_N$$

Similarly, since each P^i_M is projective, hence flat, the complex $P^i_M \otimes_R P^\bullet_N$ is a resolution of $P^i_M \otimes N$, i.e. the cohomology of each $P^i_M \otimes_R P^\bullet_N$ is concentrated at degree 0 and equals $P^i_M \otimes_R N$. By theorem 56.5.7 we have that :

$$TC(P^\bullet_M \otimes_R P^\bullet_N)^\bullet \qquad \text{is quasi-isomorphic to} \qquad P^\bullet_M \otimes_R N$$

but then, the cohomologies are identical.

For Ext the double complex is $\mathrm{Hom}_R(P^{-p}_M, Q^q_N)$. Each $\mathrm{Hom}_R(-, Q^q_N)$ is exact, Q^q_N being injective, so the complex $\mathrm{Hom}_R(P^\bullet_M, Q^q_N)$ is a resolution of $\mathrm{Hom}_R(M, Q^q_N)$. Each $\mathrm{Hom}_R(P^{-p}_M, -)$ is exact, P^{-p}_M being projective, so $\mathrm{Hom}_R(P^{-p}_M, Q^\bullet_N)$ is a resolution of $\mathrm{Hom}_R(P^{-p}_M, N)$. The same two applications of theorem 56.5.7, with every index reversed as after proposition 56.5.4, identify both $\mathrm{Hom}_R(M, Q^\bullet_N)$ and $\mathrm{Hom}_R(P^\bullet_M, N)$ up to quasi-isomorphism with the total complex, as we sought to show.

57

The Derived Category

Every derived functor in chapter 56 was computed by choosing a resolution and then proving the answer independent of the choice. That pattern is a symptom. The object of the theory is not the module A but the complex that resolves it, and not the complex but its class up to quasi-isomorphism. The resolutions are representatives, and the independence proofs are what working with representatives costs. The derived category is the category in which that thing is an object. Its construction was already carried out in section 55.2 and recorded as corollary 55.2.6: it is the localization $D(\mathbf{A}) = \mathrm{Ch}(\mathbf{A})[\mathrm{qis}^{-1}]$, and it needs no hypothesis on projectives or injectives.

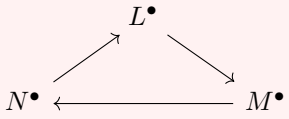
What that construction does not say is what kind of category results. In general it is not abelian, and the failure is not a technicality: kernels and cokernels are the first casualties of inverting quasi-isomorphisms. Something weaker survives, strong enough to carry every long exact sequence the subject uses, and it has a name and a short list of axioms. This chapter states them, builds $D(\mathbf{A})$ inside that framework, and then recovers Ext, Tor and the Grothendieck spectral sequence as statements about it. Its notation follows Weibel and Gelfand-Manin. section 57.1 flags the one place where the two disagree.

57.1 Triangulated Categories

A homotopy category is in general not abelian. The kernel and cokernel of a homotopy class of maps depend on the representative, so neither is well defined on the class. Yet a derived functor $\mathrm{D}(\mathscr{F})$ still carries a long exact sequence, so some structure survives. Locating it starts from a short exact sequence of complexes

$$0 \to L^\bullet \to M^\bullet \to N^\bullet \to 0$$

The snake lemma (theorem 56.1.18) relates $N^\bullet$ and $L^\bullet$ after passing to cohomology, through the connecting morphism. Before passing to cohomology there is no map between them at all. Adjoining



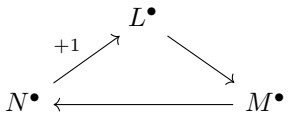
the zero morphism $N^\bullet \xrightarrow{0} L^\bullet$ closes the sequence into a cycle, and the one short exact sequence becomes three:

$$N^\bullet \xrightarrow{0} L^\bullet \to M^\bullet$$
$$L^\bullet \to M^\bullet \to N^\bullet$$
$$M^\bullet \to N^\bullet \xrightarrow{0} L^\bullet$$

These carry the same information, and folding any one of them gives a triangle.

Definition 57.1.1: Exact Triangle

Let $L^\bullet, M^\bullet, N^\bullet \in \mathrm{Ch}(\mathbf{A})$ be three complexes. If there exist morphisms such that the following diagram is exact (at each vertex):



Then the diagram is called an *exact triangle* of $\mathrm{Ch}(\mathbf{A})$. This diagram is also sometimes denoted

$$L^\bullet \to M^\bullet \to N^\bullet \to$$

if it is easier to write it out flat.

The particular triangle obtained by folding the three sequences above is

where the $+1$ morphism is the zero map. The label anticipates what that map becomes once the construction is done properly: not zero, but a map $N^\bullet \to L[1]^\bullet$ raising cohomological degree by one. Stretched out, the triangle is a single long sequence

$$\cdots \to N^{i-1} \xrightarrow{0} L^i \to M^i \to N^i \xrightarrow{0} L^{i+1} \to \cdots$$

Applying the cohomology functor and replacing the zero maps by the connecting morphism gives

$$\cdots \to H^{i-1}(N^\bullet) \xrightarrow{\delta^{i-1}} H^i(L^\bullet) \to H^i(M^\bullet) \to H^i(N^\bullet) \xrightarrow{\delta^i} H^{i+1}(L^\bullet) \to \cdots$$

The maps δ^i do not come from the cohomology functor, which is the precise sense in which $\mathrm{Ch}(\mathbf{A})$ is the wrong category to apply it in. The axioms below name the structure that carries δ as part of its data.

The translation functor on $\mathrm{Ch}(\mathbf{A})$, $\mathrm{K}(\mathbf{A})$ and $D(\mathbf{A})$ is the shift of definition 56.1.21. For $n \in \mathbb{Z}$, a complex X and a chain map f it is

$$X[n]^i := X^{i+n}, \qquad d^i_{X[n]} := (-1)^n d^{i+n}_X, \qquad f[n]^i := f^{i+n} \tag{57.1}$$

so that $H^i(X[n]^\bullet) = H^{i+n}(X^\bullet)$. For $n = 1$ this is the shift definition 56.1.21 uses: its projection $MC(\alpha) \to L[1]$ is a chain map because $d_{L[1]} = -d_L$. It is an automorphism of each of these categories, with inverse $X \mapsto X[-1]$.

57.1.2 Warning: Two Conventions for the Translation Weibel writes the translation functor T and reserves the bracket for the opposite shift, so that his T is his $[-1]$ and his identification reads $H^i(A[-1]) \cong H^{i+1}(A)$. This book writes the translation as $[1]$ throughout. *The functors agree*: both raise cohomological degree by one, and $[1]$ here is T there. Only the bracket differs. A reader checking an axiom against Weibel §10.2 should translate $T \rightsquigarrow [1]$ and leave the signs unchanged.

With the translation fixed, the axioms can be stated. A *triangle* on an ordered triple (A, B, C) of objects of an additive category $\mathcal{K}$ equipped with an automorphism $[1]$ is a triple of morphisms $u\colon A \to B$, $v\colon B \to C$, $w\colon C \to A[1]$, displayed

$$A \xrightarrow{u} B \xrightarrow{v} C \xrightarrow{w} A[1]$$

A *morphism of triangles* (f, g, h) from (u, v, w) on (A, B, C) to (u', v', w') on (A', B', C') is a triple of morphisms making the three squares of

$$\begin{array}{ccccccc} A & \xrightarrow{u} & B & \xrightarrow{v} & C & \xrightarrow{w} & A[1] \\ {\scriptstyle f}\downarrow & & {\scriptstyle g}\downarrow & & {\scriptstyle h}\downarrow & & \downarrow{\scriptstyle f[1]} \\ A' & \xrightarrow[u']{} & B' & \xrightarrow[v']{} & C' & \xrightarrow[w']{} & A'[1] \end{array}$$

commute.

Definition 57.1.3: Triangulated Category

A *triangulated category* is an additive category $\mathcal{K}$ together with an automorphism $[1]\colon \mathcal{K} \to \mathcal{K}$ (the *translation*) and a class of triangles called *distinguished*, satisfying:

(TR1) Every morphism $u\colon A \to B$ embeds in a distinguished triangle (u, v, w). For every object A the triangle $(\mathrm{id}_A, 0, 0)$ on $(A, A, 0)$ is distinguished. Any triangle isomorphic to a distinguished triangle is distinguished.

(TR2) *(Rotation.)* If (u, v, w) is distinguished on (A, B, C), then so are

$$\big(v,\ w,\ -u[1]\big) \text{ on } (B, C, A[1]) \qquad \text{and} \qquad \big(-w[-1],\ u,\ v\big) \text{ on } (C[-1], A, B)$$

(TR3) *(Morphisms.)* Given distinguished triangles (u, v, w) on (A, B, C) and (u', v', w') on (A', B', C') and morphisms $f\colon A \to A'$, $g\colon B \to B'$ with $gu = u'f$, there exists $h\colon C \to C'$ making (f, g, h) a morphism of triangles.

(TR4) *(The octahedral axiom.)* Let $u\colon A \to B$ and $v\colon B \to C$ be morphisms, and suppose given distinguished triangles

$$(u,\ j,\ \delta) \text{ on } (A, B, C'), \quad (v,\ x,\ i) \text{ on } (B, C, A'), \quad (vu,\ y,\ \varepsilon) \text{ on } (A, C, B')$$

Then there is a distinguished triangle $\big(f,\ g,\ (j[1])\, i\big)$ on (C', B', A') such that

$$\delta = \varepsilon f, \qquad x = gy, \qquad yv = fj, \qquad u[1]\,\varepsilon = ig$$

The four axioms are Verdier's. A triangulated category is *not* an abelian category, and the distinguished triangles are what stand in for its short exact sequences.

Three comments on the axioms, in the order a reader meets the difficulties.

The sign in (TR2) is not decoration, and what it does is easy to misstate. Rotating three times returns $(-u[1], -v[1], -w[1])$, and $(-\mathrm{id}, \mathrm{id}, -\mathrm{id})$ is an isomorphism of triangles from that to $(u[1], v[1], -w[1])$: the translate carrying a single sign. That sign does not in general come off. For a diagonal $(\varepsilon_1, \varepsilon_2, \varepsilon_3)$ with $\varepsilon_i = \pm\mathrm{id}$ landing on $(u[1], v[1], w[1])$, the three squares read

$$(\varepsilon_1 + \varepsilon_2)\, u[1] = 0, \qquad (\varepsilon_2 + \varepsilon_3)\, v[1] = 0, \qquad (\varepsilon_3 + \varepsilon_1)\, w[1] = 0$$

Where an edge is not annihilated by 2, its square forces the corresponding $\varepsilon_k = -\varepsilon_{k+1}$, and the three relations together give $2\varepsilon_1 = 0$, which no diagonal satisfies. Where an edge *is* killed by 2 the constraint is vacuous and a diagonal can exist: on the triangle $(\mathrm{id}_A, 0, 0)$ of (TR1), whose second and third edges vanish, $(\mathrm{id}, -\mathrm{id}, \mathrm{id})$ is such an isomorphism. In particular $(-\mathrm{id}, -\mathrm{id}, -\mathrm{id})$ is not such an isomorphism: conjugating every vertex by $-\mathrm{id}$ fixes every edge, so it is an automorphism of a triangle and not a map to the sign-flipped one. What forces the sign in the first place is the model, exercise 57.1.1 (1) producing $-\alpha[1]$ from the cone construction, so an axiom without it would fail for $\mathrm{K}(\mathbf{A})$.

(TR3) asserts existence of the filler h and not uniqueness, and the failure of uniqueness is the standing defect of triangulated categories, the reason the axioms hand back no functorial cone and the reason the theory does not by itself glue. What (TR3) does give is proposition 57.1.10, recorded below once the tools to prove it are in place.

The octahedral axiom (TR4) is the one that resists reading. Its content is a compatibility between the three cones attached to a composable pair $A \xrightarrow{u} B \xrightarrow{v} C$: the cones of u, of v, and of vu are not independent, and (TR4) says the first and third fit into a distinguished triangle whose third vertex is the second. In the abelian setting the corresponding statement is the third isomorphism theorem, $(C/A)/(B/A) \cong C/B$, and (TR4) is what survives of it. The four displayed identities say that the octahedron built from the four triangles has its remaining four faces commuting.

57.1.4 Note: What the Axioms Do Not Give The axioms give no limits or colimits beyond finite direct sums, no functorial cone, and no notion of exactness for a general diagram. A particular triangulated category may still have some of this. $\mathrm{K}(R\text{-Mod})$ has all small products and coproducts, formed degreewise, since a family of null-homotopies assembles componentwise. But nothing in definition 57.1.3 produces them, so no argument from the axioms may use them. Restoring the missing structure canonically is what the enhancements of a triangulated category (differential graded, or stable ∞-categorical, [27]) exist for.

Two kinds of functor are relevant, one preserving the triangulated structure and one converting it into exactness in an abelian category.

Definition 57.1.5: Triangulated Functor

Let $\mathcal{K}$ and $\mathcal{K}'$ be triangulated categories. A *triangulated functor* (or *exact functor* of triangulated categories) is an additive functor $F\colon \mathcal{K} \to \mathcal{K}'$ together with a natural isomorphism $F(A[1]) \cong F(A)[1]$, carrying distinguished triangles to distinguished triangles.

Definition 57.1.6: Cohomological Functor

Let $\mathcal{K}$ be a triangulated category and $\mathbf{A}$ an abelian category. An additive functor $H\colon \mathcal{K} \to \mathbf{A}$ is *cohomological* if for every distinguished triangle (u, v, w) on (A, B, C) the sequence

$$H(A) \xrightarrow{H(u)} H(B) \xrightarrow{H(v)} H(C)$$

is exact at $H(B)$.

The definition asks for exactness at one spot, and rotation delivers the rest: applying H to every rotate of a distinguished triangle and splicing gives the long exact sequence

$$\cdots \to H(A[n]) \to H(B[n]) \to H(C[n]) \to H(A[n+1]) \to \cdots$$

This is the mechanism promised at the start of the section. The connecting morphism δ is no longer constructed by a diagram chase. It is the image under H of the third edge w, which the triangle carried all along.

Lemma 57.1.7: Consecutive Maps of a Distinguished Triangle Compose to Zero

Let (u, v, w) be a distinguished triangle on (A, B, C) in a triangulated category $\mathcal{K}$. Then $vu = 0$, $wv = 0$ and $u[1]\, w = 0$.

***Proof*:**
By (TR1) the triangle $(\mathrm{id}_A, 0, 0)$ on $(A, A, 0)$ is distinguished. Take $f = \mathrm{id}_A$ and $g = u$ in (TR3), against the two distinguished triangles

$$A \xrightarrow{\mathrm{id}_A} A \xrightarrow{0} 0 \xrightarrow{0} A[1] \qquad \text{and} \qquad A \xrightarrow{u} B \xrightarrow{v} C \xrightarrow{w} A[1]$$

The required square commutes, since $u \circ \mathrm{id}_A = u = u \circ \mathrm{id}_A$. So (TR3) gives $h\colon 0 \to C$ making the triple a morphism of triangles, and commutativity of the middle square reads $v \circ u = h \circ 0 = 0$. This is $vu = 0$.

Rotating the triangle once by (TR2) gives the distinguished triangle $(v, w, -u[1])$ on $(B, C, A[1])$. Its first two maps compose to zero by the case already proved, so $wv = 0$. Rotating once more gives $(w, -u[1], -v[1])$, whence $(-u[1])w = 0$ and so $u[1]\, w = 0$.

Proposition 57.1.8: Hom Is Cohomological

Let $\mathcal{K}$ be a triangulated category and $X \in \mathcal{K}$. Then $\mathrm{Hom}_{\mathcal{K}}(X, -)\colon \mathcal{K} \to \mathbf{Ab}$ is cohomological, and $\mathrm{Hom}_{\mathcal{K}}(-, X)\colon \mathcal{K}^{\mathrm{op}} \to \mathbf{Ab}$ is cohomological.

***Proof*:**
Let (u, v, w) be distinguished on (A, B, C) and let $X \in \mathcal{K}$. Write $u_* = \mathrm{Hom}(X, u)$ and similarly for v.

Step 1: $v_* u_* = 0$. By lemma 57.1.7 the composite vu is zero, so $v_* u_*(\varphi) = vu\varphi = 0$ for every $\varphi \in \mathrm{Hom}(X, A)$. Hence $\mathrm{im} u_* \subseteq \ker v_*$.

Step 2: $\ker v_* \subseteq \mathrm{im} u_*$. Let $\psi \in \mathrm{Hom}(X, B)$ with $v\psi = 0$. Consider the distinguished triangle $(\mathrm{id}_X, 0, 0)$ on $(X, X, 0)$ from (TR1) and the triangle (u, v, w), and rotate both once by (TR2) to get distinguished triangles on $(X, 0, X[1])$ and $(B, C, A[1])$. The square

$$\begin{array}{ccc} X & \longrightarrow & 0 \\ {\scriptstyle \psi}\downarrow & & \downarrow \\ B & \xrightarrow[v]{} & C \end{array}$$

commutes precisely because $v\psi = 0$, so (TR3) gives a morphism $X[1] \to A[1]$ completing it to a morphism of triangles. Since $[1]$ is an automorphism, that morphism is $\varphi[1]$ for a unique $\varphi\colon X \to A$, and commutativity of the remaining square gives $u\varphi = \psi$. Hence $\psi \in \mathrm{im} u_*$.

The two inclusions give exactness at $\mathrm{Hom}(X, B)$, which is the definition. The contravariant statement is the same argument applied in $\mathcal{K}^{\mathrm{op}}$, which is triangulated with translation $[-1]$.

Two consequences follow at once, and the second is the substitute for functoriality promised above.

Corollary 57.1.9: The Five Lemma for Distinguished Triangles

Let (f, g, h) be a morphism of distinguished triangles in $\mathcal{K}$, from (u, v, w) on (A, B, C) to (u', v', w') on (A', B', C'). If f and g are isomorphisms, so is h.

***Proof*:**
Fix $X \in \mathcal{K}$ and apply $\mathrm{Hom}_{\mathcal{K}}(X, -)$. By proposition 57.1.8 and rotation, each triangle gives a long exact sequence of abelian groups, and (f, g, h) induces a morphism between them. In the five consecutive terms

$$\mathrm{Hom}(X, A) \to \mathrm{Hom}(X, B) \to \mathrm{Hom}(X, C) \to \mathrm{Hom}(X, A[1]) \to \mathrm{Hom}(X, B[1])$$

the maps induced by f, g, $f[1]$ and $g[1]$ are isomorphisms, $[1]$ being an automorphism of $\mathcal{K}$. The five lemma (lemma 56.1.20) in $\mathbf{Ab}$ gives that $h_* \colon \mathrm{Hom}(X, C) \to \mathrm{Hom}(X, C')$ is an isomorphism.

It remains to produce an inverse for h itself, which needs no Yoneda argument. Take $X = C'$: surjectivity of h_* gives $k \colon C' \to C$ with $hk = \mathrm{id}_{C'}$. Take $X = C$: both kh and id_C are carried by h_* to h, since $h(kh) = (hk)h = h$, so injectivity of h_* forces $kh = \mathrm{id}_C$. Thus k is a two-sided inverse and h is an isomorphism.

Proposition 57.1.10: A Distinguished Triangle Is Determined by Any One of Its Maps

Let (u, v, w) on (A, B, C) and (u, v', w') on (A, B, C') be distinguished triangles sharing the morphism $u \colon A \to B$. Then there is an isomorphism $h \colon C \to C'$ with $(\mathrm{id}_A, \mathrm{id}_B, h)$ a morphism of triangles.

***Proof*:**
Apply (TR3) with $f = \mathrm{id}_A$ and $g = \mathrm{id}_B$. The required square commutes, both composites being u, so there is $h \colon C \to C'$ making $(\mathrm{id}_A, \mathrm{id}_B, h)$ a morphism of triangles. Its two outer maps are identities, hence isomorphisms, so corollary 57.1.9 gives that h is an isomorphism.

The cone of a morphism is therefore unique up to isomorphism, and that is all: the isomorphism h is produced by (TR3), which does not claim it is unique, so the axioms provide no functorial choice of cone. Everything awkward about triangulated categories descends from this one gap.

One fact the verification needs is used twice more in this chapter and is stated nowhere earlier, so it is recorded here.

Lemma 57.1.11: The Cone on an Identity Is Null-Homotopic

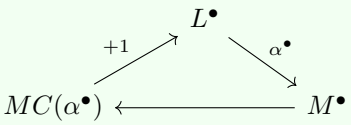
Let $L^\bullet \in \mathrm{Ch}(\mathbf{A})$. Then $MC(\mathrm{id}_{L^\bullet})$ is null-homotopic, hence exact, and is isomorphic to 0 in $\mathrm{K}(\mathbf{A})$.

***Proof*:**
By definition 56.1.21, $MC(\mathrm{id}_L)^i = L^{i+1} \oplus L^i$ with

$$d^i(a,b) = \big(-d_L^{i+1}(a),\ a + d_L^i(b)\big)$$

Define $s^i \colon MC(\mathrm{id}_L)^i \to MC(\mathrm{id}_L)^{i-1} = L^i \oplus L^{i-1}$ by $s^i(a,b) := (b,0)$. Then

$$\begin{aligned} d^{i-1}s^i(a,b) &= d^{i-1}(b,0) = \big(-d_L^i(b),\ b\big), \\ s^{i+1}d^i(a,b) &= s^{i+1}\big(-d_L^{i+1}(a),\ a + d_L^i(b)\big) = \big(a + d_L^i(b),\ 0\big) \end{aligned}$$



Adding, $\big(ds + sd\big)(a,b) = \big(-d_L^i(b) + a + d_L^i(b),\ b\big) = (a,b)$, so $ds + sd = \mathrm{id}$ and s is a contracting homotopy for the identity.

Exactness follows: by proposition 56.1.27 a null-homotopic map induces the zero map on cohomology, so $H^i(\mathrm{id}) = 0$ for every i. But H^i is a functor, so $H^i(\mathrm{id}) = \mathrm{id}_{H^i(MC(\mathrm{id}_L))}$. An identity that is also the zero map forces $H^i\big(MC(\mathrm{id}_L)\big) = 0$. In $\mathrm{K}(\mathbf{A})$ the identity of $MC(\mathrm{id}_L)$ and the zero morphism are the same homotopy class, which is what it means for the object to be isomorphic to 0 there.

The example the chapter is built on is $\mathrm{K}(\mathbf{A})$, the homotopy category of definition 56.1.36. Its translation is the shift, and its distinguished triangles are declared by the mapping cone.

Theorem 57.1.12: The Homotopy Category Is Triangulated

Let $\mathbf{A}$ be an abelian category. Then $\mathrm{K}(\mathbf{A})$ is a triangulated category, with translation the shift [1] and with distinguished triangles those isomorphic in $\mathrm{K}(\mathbf{A})$ to a *mapping cone triangle*

for some chain map $\alpha^\bullet \colon L^\bullet \to M^\bullet$. The same holds for the bounded variants $\mathrm{K}^+(\mathbf{A})$, $\mathrm{K}^-(\mathbf{A})$ and $\mathrm{K}^b(\mathbf{A})$.

***Proof*:**
That $\mathrm{K}(\mathbf{A})$ is additive is lemma 56.1.37, and the shift is an automorphism of it because it is an automorphism of $\mathrm{Ch}(\mathbf{A})$ carrying chain homotopies to chain homotopies.

(TR1). Every $\alpha^\bullet$ embeds in its own mapping cone triangle, which is distinguished by definition. The triangle $(\mathrm{id}_A, 0, 0)$ is distinguished because $MC(\mathrm{id}_A)$ is null-homotopic (lemma 57.1.11), hence zero in $\mathrm{K}(\mathbf{A})$, so the cone triangle on id_A is isomorphic to it. Closure under isomorphism holds by fiat, the class being defined as the isomorphism closure.

(TR2), (TR3), (TR4). Neither (TR2) nor (TR4) holds in $\mathrm{Ch}(\mathbf{A})$ on the nose. The rotate of a cone triangle, and the octahedron's fourth triangle, are cone triangles only up to an explicit homotopy

equivalence between cones, the underlying graded objects being different in general. (TR3) is not like that. Its filler is $h(l,m)=(f(l),g(m))$, a chain map exactly because the hypothesis square $gu=u'f$ closes the second component, so (TR3) holds at the chain level whenever that square commutes strictly. What changes in $\mathrm{K}(\mathbf{A})$ is that the square commutes only up to homotopy, and the filler must absorb the chosen homotopy. The constructions are in Weibel [101], rotation at Example 10.1.6 in §10.1 and (TR3) with the octahedral axiom at Proposition 10.2.4, whose closing homotopy check that book also leaves to its reader. Exercise 57.1.1 (1) asks for the rotation case here, whose sign is the one worth seeing produced.

The theorem also settles a question the mapping cone raises. $\mathrm{Ch}(\mathbf{A})$ itself is *not* triangulated, and the obstruction is visible in one line: (TR1) forces $(\mathrm{id}_{L^\bullet},0,0)$ to be distinguished, so by rotation $L^\bullet$ must be the cone of $0\to L^\bullet$ up to isomorphism, which it is, but (TR1) applied to $\mathrm{id}_{L^\bullet}$, together with proposition 57.1.10 comparing the two distinguished triangles that share $\mathrm{id}_{L^\bullet}$, forces $MC(\mathrm{id}_{L^\bullet})$ to be isomorphic to 0. The cone of the identity is not the zero complex. It is only null-homotopic, so the isomorphism exists in $\mathrm{K}(\mathbf{A})$ and not in $\mathrm{Ch}(\mathbf{A})$. Passing to homotopy classes is exactly what is needed, and no less.

What remains is that $D(\mathbf{A})$ is triangulated too, and that in $D(\mathbf{A})$, unlike in $\mathrm{K}(\mathbf{A})$, every short exact sequence of complexes yields a distinguished triangle. Both are taken up in section 57.2.

Exercise 57.1.1

1. Verify (TR2) for $\mathrm{K}(\mathbf{A})$ in the rotation direction. Given a chain map $\alpha^\bullet\colon L^\bullet\to M^\bullet$, construct a homotopy equivalence $MC\big(M^\bullet\to MC(\alpha^\bullet)\big)\to L[1]^\bullet$, and check that under it the third map of the rotated triangle is $-\alpha[1]^\bullet$ and not $\alpha[1]^\bullet$. Where in the construction does the sign enter?

2. Rotate a distinguished triangle (u,v,w) three times using (TR2) and write down the result. Show that it is $(-u[1],-v[1],-w[1])$ on $(A[1],B[1],C[1])$, and check that $(-\mathrm{id},\mathrm{id},-\mathrm{id})$ is an isomorphism of triangles from it to $(u[1],v[1],-w[1])$. Then read off the three squares as conditions $(\varepsilon_k+\varepsilon_{k+1})e_k=0$ on the edges e_k, and show that no diagonal $(\varepsilon_1,\varepsilon_2,\varepsilon_3)$ with $\varepsilon_i=\pm\mathrm{id}$ is an isomorphism onto $(u[1],v[1],w[1])$ *provided no edge is annihilated by* 2. Then check that the diagonal $(\mathrm{id},-\mathrm{id},\mathrm{id})$ given above for $(\mathrm{id}_A,0,0)$ satisfies all three squares, and say why it does not contradict the general case. Where would the argument break if (TR2) carried no sign?

3. Let (u,v,w) be a distinguished triangle on (A,B,C) with $C=0$. Show that u is an isomorphism. (Use proposition 57.1.8 and the argument that closes corollary 57.1.9.)

4. Show that a distinguished triangle (u,v,w) with $w=0$ splits, in the sense that v admits a section $s\colon C\to B$ and $B\cong A\oplus C$ compatibly with u and v. Deduce that in $\mathrm{K}(\mathbf{A})$ a short exact sequence of complexes that is degreewise split gives a distinguished triangle, and find a short exact sequence of complexes that does not.

5. Let $A\subseteq B\subseteq C$ be subobjects in an abelian category, and consider the three quotient maps. Identify the objects C', A' and B' of (TR4) in this situation, and check that the fourth distinguished triangle it produces is

$$B/A\longrightarrow C/A\longrightarrow C/B$$

This is the third isomorphism theorem, and it is what (TR4) abstracts. Verify the four identities of (TR4) against it.

57.2 The Derived Category as a Triangulated Category

The derived category was produced in section 55.2 as a localization and recorded as corollary 55.2.6. That construction is universal and says nothing about how a morphism of $D(\mathbf{A})$ looks. This section gives the concrete description, shows that $D(\mathbf{A})$ inherits the structure of definition 57.1.3, and proves the property that motivated the whole apparatus: in $D(\mathbf{A})$, and not in $\mathrm{K}(\mathbf{A})$, every short exact sequence of complexes becomes a distinguished triangle. The treatment follows Aluffi's *Algebra: Chapter 0* [3] and Weibel [101] §10.4.

The objects of $D(\mathbf{A})$ are those of $\mathrm{Ch}(\mathbf{A})$. What changes is the morphisms, because the quasi-isomorphisms must become invertible. A first attempt would localize $\mathrm{Ch}(\mathbf{A})$ directly. It fails, and for a reason already recorded in box 55.2.3: the quasi-isomorphisms of $\mathrm{Ch}(\mathbf{A})$ do not form a multiplicative system, so theorem 55.2.5 does not apply and the localization is produced only as a category whose Hom-classes need not be sets. In $\mathrm{K}(\mathbf{A})$ they do form a multiplicative system, and the calculus of fractions then presents every morphism concretely.

Definition 57.2.1: Roof

Let $L^\bullet, M^\bullet \in \mathrm{K}(\mathbf{A})$. A *roof* from $L^\bullet$ to $M^\bullet$ is a diagram

$$\begin{array}{ccc} & N^\bullet & \\ {\scriptstyle s}\swarrow & & \searrow{\scriptstyle f} \\ L^\bullet & & M^\bullet \end{array}$$

in $\mathrm{K}(\mathbf{A})$ in which s is a quasi-isomorphism. Two roofs $(N^\bullet, s, f)$ and $(N'^\bullet, s', f')$ are *equivalent* if there is a third roof $(N''^\bullet, t, g)$ and morphisms $a\colon N''^\bullet \to N^\bullet$ and $b\colon N''^\bullet \to N'^\bullet$ with $sa = t = s'b$ and $fa = g = f'b$ in $\mathrm{K}(\mathbf{A})$. The maps a and b are then automatically quasi-isomorphisms, by two-out-of-three applied to $sa = t$ and $s'b = t$, so nothing is lost by not requiring it.

The roof is the fraction $f \circ s^{-1}$ written before s^{-1} exists. Composition is where the multiplicative system earns its place: to compose fs^{-1} with gt^{-1} one must rewrite $s^{-1}g$ as $g'(s')^{-1}$ for some new roof, and the Ore condition inside theorem 55.2.5 is exactly the hypothesis that this is always possible.

Everything in this section rests on one theorem, and it is the reason the passage from $\mathrm{Ch}(\mathbf{A})$ to $\mathrm{K}(\mathbf{A})$ is made at all. In $\mathrm{Ch}(\mathbf{A})$ the quasi-isomorphisms are not a multiplicative system, as box 55.2.3 shows by example. In $\mathrm{K}(\mathbf{A})$ they are, and the proof is where the triangulated structure of section 57.1 first does work.

One preliminary is needed. Proposition 56.1.22 gives a long exact cohomology sequence for a mapping cone triangle, and since every distinguished triangle of $\mathrm{K}(\mathbf{A})$ is isomorphic to one, that is a statement about all of them.

Lemma 57.2.2: Cohomology Is Cohomological on the Homotopy Category

For each n the functor $H^n\colon \mathrm{K}(\mathbf{A}) \to \mathbf{A}$ is cohomological in the sense of definition 57.1.6. In particular, if (u, v, w) is a distinguished triangle of $\mathrm{K}(\mathbf{A})$ on (A, B, C) with C exact, then u is a quasi-isomorphism.

***Proof*:**
H^n is well defined on $\mathrm{K}(\mathbf{A})$ because homotopic maps induce the same map on cohomology (proposition 56.1.29).

Let (u, v, w) be distinguished. By theorem 57.1.12 it is isomorphic to a mapping cone triangle, for which proposition 56.1.22 gives the long exact cohomology sequence, exact in particular at the middle term. An isomorphism of triangles induces isomorphisms on each H^n, and exactness transports along them, so the sequence $H^n(A) \to H^n(B) \to H^n(C)$ is exact for (u, v, w) as well.

For the consequence, rotate by (TR2) and splice as after definition 57.1.6 to obtain

$$H^{n-1}(C) \to H^n(A) \xrightarrow{H^n(u)} H^n(B) \to H^n(C)$$

exact for every n. If C is exact the outer terms vanish, so each $H^n(u)$ is an isomorphism.

The theorem itself is Weibel [101] Proposition 10.4.1(1). Both substantial conditions follow the same pattern: replace a quasi-isomorphism by the triangle it sits in, note that the third vertex is exact, and use the exactness of Hom on that triangle to factor the morphism that must be killed.

Theorem 57.2.3: Quasi-Isomorphisms Form a Multiplicative System

Let $\mathbf{A}$ be an abelian category. The class of quasi-isomorphisms in $\mathrm{K}(\mathbf{A})$ is a multiplicative system in the sense of definition 55.2.4.

***Proof*:**
Throughout, if t is a quasi-isomorphism then any distinguished triangle on t has exact third vertex: the mapping cone triangle on t has third vertex $MC(t)$, exact by proposition 56.1.24, and any other is isomorphic to it by proposition 57.1.10, an isomorphism of $\mathrm{K}(\mathbf{A})$ being a homotopy equivalence and so preserving cohomology (proposition 56.1.31).

Condition (1). Each $H^n(\mathrm{id})$ is an identity, and $H^n(gf) = H^n(g)H^n(f)$, so identities are quasi-isomorphisms and a composite of two is one.

Condition (2), the Ore condition. Let $f\colon Z \to B$ be any morphism and $t\colon V \to B$ a quasi-isomorphism. Embed t in a distinguished triangle

$$V \xrightarrow{t} B \xrightarrow{g} C \longrightarrow V[1]$$

by (TR1). By the paragraph above, C is exact. Apply (TR1) to $gf\colon Z \to C$ and rotate backwards by (TR2) to obtain a distinguished triangle

$$Z' \xrightarrow{t'} Z \xrightarrow{gf} C \longrightarrow Z'[1]$$

Its third vertex C is exact, so t' is a quasi-isomorphism by lemma 57.2.2.

It remains to factor ft' through t. By lemma 57.1.7 applied to the second triangle, $(gf)t' = 0$,

that is $g(ft') = 0$. Apply $\mathrm{Hom}_{\mathrm{K}(\mathbf{A})}(Z', -)$ to the first triangle: by proposition 57.1.8 the sequence

$$\mathrm{Hom}(Z', V) \xrightarrow{t_*} \mathrm{Hom}(Z', B) \xrightarrow{g_*} \mathrm{Hom}(Z', C)$$

is exact at the middle term. Since ft' lies in $\ker g_*$, there is $f' \colon Z' \to V$ with $tf' = ft'$, which is condition (2).

Condition (3). Let $f, g \colon X \to Y$ and let $s \colon Y \to Y'$ be a quasi-isomorphism with $sf = sg$. Put $h := f - g$, using that $\mathrm{K}(\mathbf{A})$ is additive (lemma 56.1.37). Then $sh = 0$, and it suffices to find a quasi-isomorphism t with $ht = 0$.

Embed s in a distinguished triangle and rotate backwards to put s in the middle:

$$W \xrightarrow{r} Y \xrightarrow{s} Y' \longrightarrow W[1]$$

The third vertex of a triangle on s is exact, and W is its shift, so W is exact as well. Applying $\mathrm{Hom}_{\mathrm{K}(\mathbf{A})}(X, -)$ and proposition 57.1.8 gives exactness of

$$\mathrm{Hom}(X, W) \xrightarrow{r_*} \mathrm{Hom}(X, Y) \xrightarrow{s_*} \mathrm{Hom}(X, Y')$$

at the middle term, and $h \in \ker s_*$, so $h = rh'$ for some $h' \colon X \to W$.

Now apply (TR1) to h' and rotate backwards, giving a distinguished triangle

$$X' \xrightarrow{t} X \xrightarrow{h'} W \longrightarrow X'[1]$$

whose third vertex W is exact, so t is a quasi-isomorphism by lemma 57.2.2. By lemma 57.1.7, $h't = 0$, whence

$$ht = rh't = 0$$

that is, $ft = gt$. This is condition (3), and the three conditions together are the definition.

The theorem discharges an obligation the book has carried since corollary 55.2.6. That proof observed that localizing $\mathrm{K}(\mathbf{A})$ is the route repairing the set-theoretic defect in localizing $\mathrm{Ch}(\mathbf{A})$, and pointed here for the reason the route is available.

Theorem 57.2.4: Roofs Compute the Derived Category

Let $\mathbf{A}$ be an abelian category. Then every morphism $L^\bullet \to M^\bullet$ of $D(\mathbf{A})$ is represented by a roof, two roofs represent the same morphism exactly when they are equivalent, composition is induced by the Ore condition, and the localization functor $Q \colon \mathrm{K}(\mathbf{A}) \to D(\mathbf{A})$ sends f to the class of the roof $(L^\bullet, \mathrm{id}, f)$.
The equivalence classes form a *set* when $\mathbf{A}$ is such that the quasi-isomorphisms into each complex admit a cofinal set. Without that hypothesis they are not guaranteed to be sets. The hypothesis is sufficient and is not necessary for a particular Hom-class to be a set: $\mathrm{Hom}_{D(\mathbf{A})}(0, M^\bullet)$ is a singleton for every $\mathbf{A}$, since any two roofs out of 0 are equivalent through the roof $(0, \mathrm{id}_0, 0)$.

***Proof*:**
By theorem 57.2.3 the quasi-isomorphisms of $\mathrm{K}(\mathbf{A})$ form a multiplicative system, so theorem 55.2.5 applies and gives this description of $\mathrm{K}(\mathbf{A})[\mathrm{qis}^{-1}]$.

It remains to identify that localization with $D(\mathbf{A})$, which corollary 55.2.6 defines as $\mathrm{Ch}(\mathbf{A})[\mathrm{qis}^{-1}]$ and so does not do on its own. The bridge is proposition 56.1.38: *any* functor out of $\mathrm{Ch}(\mathbf{A})$ inverting quasi-isomorphisms factors uniquely through $\mathrm{K}(\mathbf{A})$, and the factored functor inverts the quasi-isomorphisms there, those being the images of quasi-isomorphisms. So a functor out of $\mathrm{Ch}(\mathbf{A})$ inverting quasi-isomorphisms is the same thing as a functor out of $\mathrm{K}(\mathbf{A})$ doing so, compatibly with composition, and the two localizations satisfy the same universal property of definition 55.2.1 over *all* functors. They are therefore canonically isomorphic.

The quantifier matters. Restricting the comparison to *additive* functors would be circular, since the additive structure on $D(\mathbf{A})$ is derived in theorem 57.2.7 from the roof description being established here.

Inverting a single morphism is the case $M^\bullet = N^\bullet$, $f = \mathrm{id}$: the roof $(N^\bullet, s, \mathrm{id})$ is the inverse of $Q(s)$.

The set-hood clause is not a formality, and box 55.2.3 is where the difficulty was recorded: a calculus of fractions replaces zigzags by roofs without bounding anything, the roofs over a fixed object being indexed by a proper class. What bounds them is a *set* of quasi-isomorphisms cofinal among those into each complex. Every construction in this chapter is stated for $D(\mathbf{A})$ as a category. Only the statements quantifying over its Hom-*sets* need the hypothesis, and they say so. For a Grothendieck abelian category, which includes R-Mod and the categories of sheaves of abelian groups on a site (example 59.1.5), every Hom-class of $D(\mathbf{A})$ is a set by corollary 59.1.21, whose proof uses K-injective resolutions and no cofinality hypothesis.

57.2.5 Note: What the Bounded Variants Are For Writing $D^+(\mathbf{A})$, $D^-(\mathbf{A})$ and $D^b(\mathbf{A})$ for the full subcategories of $D(\mathbf{A})$ on the complexes with cohomology bounded below, bounded above, and bounded respectively, each is *equivalent* to the localization of the corresponding $\mathrm{K}^{\pm}(\mathbf{A})$ at its quasi-isomorphisms. Equivalent and not equal: the localization of $\mathrm{K}^b(\mathbf{A})$ has only bounded complexes as objects, whereas $D^b(\mathbf{A})$ as defined here contains every complex with bounded cohomology, such as the exact 2-periodic complex $\cdots \to \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \to \cdots$. Truncation gives essential surjectivity: if $H^i(X) = 0$ for $i < m$, then $p_m \colon X \to \tau^{\geq m} X$ of definition 56.1.12 is a quasi-isomorphism onto a bounded-below complex by proposition 56.1.14, and dually $i_m \colon \tau^{\leq m} X \to X$ when $H^i(X) = 0$ for $i > m$. For the bounded case, if $H^i(X) = 0$ outside $[m, M]$ then $i_M \colon \tau^{\leq M} X \to X$ is a quasi-isomorphism, and so is $p_m \colon \tau^{\leq M} X \to \tau^{\geq m} \tau^{\leq M} X$, since $H^i(\tau^{\leq M} X) \cong H^i(X) = 0$ for $i < m$ by proposition 56.1.14, and $\tau^{\geq m} \tau^{\leq M} X$ is bounded. The equivalence is Weibel [101] 10.3.15. The bound is what makes derived functors constructible: a resolution of a bounded-above complex by projectives is again bounded above, and section 55.2's machinery has something to run on. Chapter 57 states results for $D(\mathbf{A})$ where no bound is needed and says so explicitly where one is.

When $\mathbf{A}$ has enough projectives the bounded-above derived category has a second, entirely computational, description, and the book already has it.

Proposition 57.2.6: Enough Projectives Computes D^-

Let $\mathbf{A}$ be an abelian category with enough projectives and let $\mathbf{P}$ be its full subcategory of projectives. Then $\mathrm{K}^-(\mathbf{P})$ satisfies the universal property of $D^-(\mathbf{A})$: every additive functor out of $C^-(\mathbf{A})$ carrying quasi-isomorphisms to isomorphisms factors through $\mathrm{K}^-(\mathbf{P})$, uniquely up to natural isomorphism.

***Proof*:**
This is theorem 56.2.18, whose part (1) gives that a quasi-isomorphism of $C^-(\mathbf{A})$ becomes an isomorphism in $\mathrm{K}^-(\mathbf{P})$ and whose part (2) is the factorization. That quasi-isomorphisms are already isomorphisms in $\mathrm{K}^-(\mathbf{P})$, so that no further localization is needed, is corollary 56.2.10.

The point is worth stating plainly because it is easy to misremember in a form that is false. In general $\mathrm{K}(\mathbf{A})$ is *not* the localization of $\mathrm{Ch}(\mathbf{A})$ at the quasi-isomorphisms, with or without enough projectives. It inverts the homotopy equivalences, and for $\mathbf{A} = \mathbf{Ab}$ those are strictly fewer: example 56.1.16 exhibits a quasi-isomorphism with no inverse in $\mathrm{K}(\mathbf{Ab})$. What enough projectives gives is that the homotopy category of *projective* complexes, $\mathrm{K}^-(\mathbf{P})$, already has the quasi-isomorphisms inverted, and that is a statement about $\mathbf{P}$ and not about $\mathbf{A}$.

The hedge *in general* is doing work. Over a semisimple $\mathbf{A}$, say Vect_k, which has enough projectives, every complex splits as the direct sum of its cohomology and contractible pieces, so every quasi-isomorphism is already a homotopy equivalence and the two classes coincide. There $\mathrm{K}(\mathbf{A})$ *is* the localization, so over such an $\mathbf{A}$ the claim above is false there. That is why the general statement is given with a cited witness.

With the morphisms described, the structure of section 57.1 transfers.

Theorem 57.2.7: The Derived Category Is Triangulated

Let $\mathbf{A}$ be an abelian category. Then $D(\mathbf{A})$ is a triangulated category, with translation the shift $[1]$ and with distinguished triangles those isomorphic in $D(\mathbf{A})$ to the image under Q of a distinguished triangle of $\mathrm{K}(\mathbf{A})$. The localization functor $Q\colon \mathrm{K}(\mathbf{A}) \to D(\mathbf{A})$ is a triangulated functor in the sense of definition 57.1.5. The same holds for D^+, D^- and D^b.

***Proof*:**
The shift commutes with localization, since it carries quasi-isomorphisms to quasi-isomorphisms, and so descends to an automorphism of $D(\mathbf{A})$. $D(\mathbf{A})$ is additive because $\mathrm{K}(\mathbf{A})$ is (lemma 56.1.37) and the localization of an additive category at a multiplicative system is again additive, sums of roofs being formed over a common denominator and biproducts surviving. Theorem 55.2.5 is a statement about categories with no additive content, and the fact used here is Weibel [101] 10.3.11.

(TR1). A morphism of $D(\mathbf{A})$ is a roof fs^{-1}, and $Q(s)$ is invertible, so it is enough to embed f. Theorem 57.1.12 does that in $\mathrm{K}(\mathbf{A})$, and applying Q and composing with the isomorphism $Q(s)$ gives a distinguished triangle on fs^{-1}. The triangle $(\mathrm{id}, 0, 0)$ is the Q-image of the corresponding triangle of $\mathrm{K}(\mathbf{A})$, and closure under isomorphism holds because the class was defined as an isomorphism closure.

(TR2), (TR3), (TR4). These are Weibel [101] Proposition 10.4.1(2), and the deferral is deliberate. The obstacle is that a distinguished triangle of $D(\mathbf{A})$ is only *isomorphic* to a Q-image, and that (TR3)'s hypothesis square commutes in $D(\mathbf{A})$ and so only up to homotopy after lifting. Verdier's argument straightens the data with the Ore condition, rebuilds the triangles over the refined vertices using (TR1), (TR3) and corollary 57.1.9, applies the axiom in $\mathrm{K}(\mathbf{A})$, and conjugates back. Weibel calls the verification straightforward but lengthy, and it needs two-sided fractions, which definition 55.2.4 does not carry. No argument in this book depends on reproducing it.

Q carries distinguished triangles to distinguished triangles by the definition given, and commutes with the shift by the first paragraph, so it is a triangulated functor. The bounded cases are the same argument applied to $\mathrm{K}^{\pm}(\mathbf{A})$.

Proposition 57.2.8: Cohomology Is Cohomological on $D(\mathbf{A})$

For each n the functor $H^n\colon D(\mathbf{A}) \to \mathbf{A}$ is well defined and cohomological in the sense of definition 57.1.6.

***Proof*:**
H^n is well defined on $D(\mathbf{A})$ because a quasi-isomorphism induces an isomorphism on H^n by definition, so H^n inverts the class being localized and factors through Q by the universal property of theorem 55.2.2.

For the cohomological property, let (u, v, w) be distinguished in $D(\mathbf{A})$. By definition it is isomorphic to Q of a distinguished triangle of $\mathrm{K}(\mathbf{A})$, which by theorem 57.1.12 is isomorphic to a mapping cone triangle. For a mapping cone triangle the required exactness at the middle term is proposition 56.1.22, which produces exactly the long exact cohomology sequence of the cone. Exactness is preserved along the isomorphisms, so it holds for (u, v, w).

The failure that section 57.1 opened with can now be repaired. A short exact sequence of complexes has a connecting morphism on cohomology but, in $\mathrm{K}(\mathbf{A})$, need not have any morphism $N^\bullet \to L[1]^\bullet$ at all. The cone gives a candidate, and in $D(\mathbf{A})$ the candidate is an isomorphism.

Lemma 57.2.9: The Cone of an Injection Computes the Quotient

Let

$$0 \to L^\bullet \xrightarrow{u} M^\bullet \xrightarrow{v} N^\bullet \to 0$$

be a short exact sequence in $\mathrm{Ch}(\mathbf{A})$, meaning exact in each degree. Define $\varphi\colon MC(u)^\bullet \to N^\bullet$ by $\varphi^i(l, m) := v^i(m)$, where $MC(u)^i = L^{i+1} \oplus M^i$ as in definition 56.1.21. Then φ is a chain map and a quasi-isomorphism.

***Proof*:**
Step 1: φ is a chain map. With the differential of definition 56.1.21,

$$\varphi^{i+1}\big(d^i_{MC(u)}(l, m)\big) = \varphi^{i+1}\big(-d^{i+1}_L(l),\ u^{i+1}(l) + d^i_M(m)\big) = v^{i+1}u^{i+1}(l) + v^{i+1}d^i_M(m)$$

The first term vanishes because $vu = 0$, the sequence being exact at $M^\bullet$. The second is $d^i_N v^i(m)$

because v is a chain map. So $\varphi^{i+1} d^i_{MC(u)} = d^i_N \varphi^i$.

Step 2: the kernel of φ. In degree i, $\ker \varphi^i = \{(l, m) : v^i(m) = 0\} = L^{i+1} \oplus \ker v^i = L^{i+1} \oplus u^i(L^i)$, using exactness at $M^\bullet$. Since u is a monomorphism, $u^i(L^i) \cong L^i$, so $\ker \varphi^\bullet$ is the complex with $(\ker \varphi)^i = L^{i+1} \oplus L^i$ and differential $(l, l') \mapsto (-d^{i+1}_L(l),\ l + d^i_L(l'))$ read through u. This is exactly $MC(\mathrm{id}_{L^\bullet})$.

Step 3: φ is surjective in each degree, since v is. So

$$0 \to MC(\mathrm{id}_{L^\bullet}) \to MC(u)^\bullet \xrightarrow{\varphi} N^\bullet \to 0$$

is a short exact sequence of complexes. By lemma 57.1.11 the cone on an identity map is null-homotopic, hence exact, so $H^i\big(MC(\mathrm{id}_{L^\bullet})\big) = 0$ for every i. The long exact cohomology sequence of the displayed short exact sequence (theorem 56.1.18) then has zeroes flanking every $H^i(\varphi)$, forcing each $H^i(\varphi)$ to be an isomorphism. Thus φ is a quasi-isomorphism.

Theorem 57.2.10: Every Short Exact Sequence Gives a Distinguished Triangle in $D(\mathbf{A})$

Let $0 \to L^\bullet \xrightarrow{u} M^\bullet \xrightarrow{v} N^\bullet \to 0$ be a short exact sequence in $\mathrm{Ch}(\mathbf{A})$. Then there is a morphism $w\colon N^\bullet \to L[1]^\bullet$ in $D(\mathbf{A})$ for which

$$L^\bullet \xrightarrow{u} M^\bullet \xrightarrow{v} N^\bullet \xrightarrow{w} L[1]^\bullet$$

is a distinguished triangle of $D(\mathbf{A})$, and $H^\bullet(w) = -\delta$, where δ is the connecting morphism of theorem 56.1.18.

***Proof*:**
Let $\iota\colon M^\bullet \to MC(u)^\bullet$ and $\pi\colon MC(u)^\bullet \to L[1]^\bullet$ be the two natural chain maps of definition 56.1.21, so that (u, ι, π) is the mapping cone triangle on u and is distinguished in $\mathrm{K}(\mathbf{A})$ by theorem 57.1.12. Let $\varphi\colon MC(u)^\bullet \to N^\bullet$ be the quasi-isomorphism of lemma 57.2.9.

Step 1: φ is invertible in $D(\boldsymbol{A})$. It is a quasi-isomorphism, and Q inverts exactly those.

Step 2: the triangle. Set $w := Q(\pi) \circ Q(\varphi)^{-1}\colon N^\bullet \to L[1]^\bullet$. The triple $(\mathrm{id}_{L^\bullet}, \mathrm{id}_{M^\bullet}, Q(\varphi))$ is an isomorphism of triangles from $Q(u, \iota, \pi)$ to (u, v, w), provided the middle square commutes, that is $\varphi \circ \iota = v$. In degree i, $\iota^i(m) = (0, m)$ and $\varphi^i(0, m) = v^i(m)$, so the square commutes on the nose in $\mathrm{Ch}(\mathbf{A})$.

The third square commutes by the definition of w. Since $Q(u, \iota, \pi)$ is distinguished in $D(\mathbf{A})$ by theorem 57.2.7, and distinguished triangles are closed under isomorphism by (TR1), the triangle (u, v, w) is distinguished.

Step 3: the sign. Let $x \in N^n$ be a cocycle. Choose $m \in M^n$ with $v(m) = x$. Then $v(d_M m) = d_N x = 0$, so $d_M m = u(\lambda)$ for a unique $\lambda \in L^{n+1}$, and $\delta[x] = [\lambda]$ by the construction in

theorem 56.1.18. Now compute $H^n(w)[x]$ directly. A cocycle of $MC(u)^n$ lying over x is a pair (l, m) with $\varphi(l, m) = v(m) = x$ and

$$0 = d_{MC(u)}(l, m) = \big(-d_L(l),\ u(l) + d_M(m)\big)$$

The second component forces $u(l) = -d_M m = -u(\lambda)$, and u is a monomorphism, so $l = -\lambda$. Such a pair does exist: the first component asks $d_L(\lambda) = 0$, which holds because $u(d_L\lambda) = d_M(u\lambda) = d_M d_M m = 0$ and u is a monomorphism. Since $w = Q(\pi) \circ Q(\varphi)^{-1}$ and $\pi(l, m) = l$ carries no sign in definition 56.1.21,

$$H^n(w)[x] = [l] = [-\lambda] = -\delta[x]$$

so $H^\bullet(w) = -\delta$.

The sign is not an artifact of this book's conventions, which is the natural thing to assume and is wrong. Definition 56.1.21 puts the sign on d_L and none on α or on the projection π. Weibel flips both: his cone differential carries $-\alpha$ and his projection carries a minus. Under his conventions the second component forces $u(l) = +d_M m$, so $l = +\lambda$, and the signed projection returns $-\lambda$ again. The two flips cancel each other, and $-\delta$ is what both conventions produce. A mixed convention, flipping exactly one of the two, is what would give $+\delta$.

Nor is the sign available to be absorbed into w. The diagonal comparison of exercise 57.1.1 (2) fails for $(u, v, -w)$ against (u, v, w), so $(u, v, -w)$ is not known to be distinguished.

The contrast with $\mathrm{K}(\mathbf{A})$ is not a matter of the argument being harder there. It is false there.

Example 57.2.11: A Short Exact Sequence That Is No Triangle in $\mathrm{K}(\mathbf{Ab})$

Regard $\mathbb{Z}/2$ and $\mathbb{Z}/4$ as complexes concentrated in degree 0, and take the short exact sequence of abelian groups

$$0 \to \mathbb{Z}/2 \xrightarrow{\cdot 2} \mathbb{Z}/4 \to \mathbb{Z}/2 \to 0$$

There is no morphism w in $\mathrm{K}(\mathbf{Ab})$ making $(\cdot 2, \pi, w)$ a distinguished triangle on $(\mathbb{Z}/2, \mathbb{Z}/4, \mathbb{Z}/2)$.

Suppose there were, and apply $\mathrm{Hom}_{\mathrm{K}(\mathbf{Ab})}(\mathbb{Z}/2, -)$, which is cohomological by proposition 57.1.8. Every complex in sight is concentrated in degree 0, so $\mathbb{Z}/2[1]$ and $\mathbb{Z}/2[-1]$ are concentrated in degrees -1 and 1, and a chain map between complexes concentrated in different degrees is zero. Both outer terms of the long exact sequence therefore vanish, leaving

$$0 \to \mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}/2) \to \mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}/4) \to \mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}/2) \to 0$$

exact in $\mathbf{Ab}$, homotopies between degree-0 complexes being zero. Counting: the two outer groups have order 2, so the middle must have order 4. But $\mathrm{Hom}_{\mathbf{Ab}}(\mathbb{Z}/2, \mathbb{Z}/4)$ consists of the maps sending 1 to an element killed by 2, namely 0 and 2, so it has order 2. The contradiction shows no such w exists.

The argument used nothing about w itself, which is the point. The obstruction is not that the third map is hard to write down. It is that no *morphism* closes the triangle at all, whatever is placed at the third edge. The object $\mathbb{Z}/2$ does sit at that vertex in other distinguished triangles, and $\cdot 2$ does embed in one, namely its own cone triangle with third vertex $MC(\cdot 2)$.

In $D(\mathbf{Ab})$ the triangle exists, by theorem 57.2.10. What differs is not the category's objects but its morphisms: w is a roof, invisible from $\mathrm{K}(\mathbf{Ab})$.

Two criteria fall out of the roof description and are used constantly.

Proposition 57.2.12: Recognizing Zero in the Derived Category

Let $\mathbf{A}$ be an abelian category.

1. A complex $X^\bullet$ is isomorphic to 0 in $D(\mathbf{A})$ if and only if $X^\bullet$ is exact.
2. A chain map $f\colon X^\bullet \to Y^\bullet$ becomes the zero morphism in $D(\mathbf{A})$ if and only if there is a quasi-isomorphism $t\colon X''^\bullet \to X^\bullet$ with ft null-homotopic.

***Proof*:**
(1) If $X^\bullet$ is exact then $X^\bullet \to 0$ is a quasi-isomorphism, which Q inverts, so $X^\bullet \cong 0$ in $D(\mathbf{A})$. Conversely, if $X^\bullet \cong 0$ there, then $H^i(X^\bullet) \cong H^i(0) = 0$ for every i, since H^i is a functor on $D(\mathbf{A})$ by proposition 57.2.8. So $X^\bullet$ is exact.

(2) By theorem 57.2.4 the morphism $Q(f)$ is the class of the roof $(X^\bullet, \mathrm{id}, f)$ and the zero morphism is the class of $(X^\bullet, \mathrm{id}, 0)$. Two roofs with the same left leg represent the same morphism exactly when their right legs agree after precomposition with a quasi-isomorphism, which is the equivalence of definition 57.2.1. So $Q(f) = 0$ exactly when there is a quasi-isomorphism t with $ft = 0$ in $\mathrm{K}(\mathbf{A})$, and equality in $\mathrm{K}(\mathbf{A})$ is null-homotopy in $\mathrm{Ch}(\mathbf{A})$.

The criterion is stated with t on the *source* because that is the side definition 55.2.4 controls: its condition (3) cancels a quasi-isomorphism on the target and returns one on the source, and not conversely. The dual form, a quasi-isomorphism s on the target with sf null-homotopic, is equivalent, but deriving it needs the opposite cancellation condition, which the definition used here does not carry. Weibel [101] states the axioms in self-dual form for exactly this reason.

57.2.13 Note: Recovering A from $D(\mathbf{A})$ Distinct abelian categories can have equivalent derived categories, so $\mathbf{A}$ is not recovered from $D(\mathbf{A})$ on its own. What recovers it is an extra piece of data, a *t-structure*, whose heart is an abelian category. Section 59.3 constructs the standard t-structure on $D(\mathbf{A})$, whose heart is equivalent to $\mathbf{A}$, and section 59.4 develops the general theory. The middle-perversity t-structure, whose heart is the category of perverse sheaves, is the subject of the *Perverse Sheaves* volume [38].

57.2.1 Stable Module Theory

Two maps $f, g : M \to N$ of R-modules are *projectively homotopic* when $f - g$ factors through a projective module, $f - g : M \to P \to N$. This is the module-level form of the chain homotopy of section 56.1, and it recovers the geometric intuition directly: two modules can be homotopy equivalent without either one being resolved first. The associated equivalence on objects is *stable equivalence*:

modules M and N are stably equivalent when

$$M \oplus P \cong N \oplus P$$

for some projective P. This relation is the starting point of K_0, developed in [14].

Exercise 57.2.1

1. Let $s\colon N^\bullet \to L^\bullet$ be a quasi-isomorphism. Show that the roof $(N^\bullet, s, \mathrm{id}_{N^\bullet})$ represents a two-sided inverse to $Q(s)$ in $D(\mathbf{A})$, and that the equivalence relation of definition 57.2.1 is what makes the two composites equal to the identity roofs.
2. Give a complex of abelian groups that is exact, nonzero in infinitely many degrees, and therefore isomorphic to 0 in $D(\mathbf{Ab})$ while being isomorphic to 0 in neither $\mathrm{Ch}(\mathbf{Ab})$ nor $\mathrm{K}(\mathbf{Ab})$. (For the last point, exhibit the failure of a contracting homotopy, or cite exercise 57.1.1 (4).)
3. Lemma 57.1.11 shows $MC(\mathrm{id}_{L^\bullet})$ is null-homotopic, hence isomorphic to 0 in $\mathrm{K}(\mathbf{A})$. Show that it is nevertheless *not* the zero complex in $\mathrm{Ch}(\mathbf{A})$ whenever $L^\bullet \neq 0$. Then explain why lemma 57.2.9 concludes only that φ is a *quasi-isomorphism*, and not that it is an isomorphism of complexes, even though its kernel is isomorphic to 0 in $\mathrm{K}(\mathbf{A})$.
4. Find chain maps f and g of abelian groups such that f is zero in $D(\mathbf{Ab})$ without being null-homotopic, and g induces the zero map on every cohomology group without being zero in $D(\mathbf{Ab})$. (For the second, complexes of length two and a map built from multiplication by an integer will do.)
5. Show that $Q\colon \mathrm{K}(\mathbf{Ab}) \to D(\mathbf{Ab})$ is not full by producing a morphism of $D(\mathbf{Ab})$ that is not Q of any chain map. (Example 57.2.11 contains one.)

57.3 Adapted Classes and Total Derived Functors

Section 56.3 built $R^n\mathscr{F}$ by choosing a resolution, applying $\mathscr{F}$ term by term, taking cohomology, and then proving the answer independent of the choice. The derived category was introduced to make that last step unnecessary, so the natural thing to want now is a single functor $R\mathscr{F}$ on $D^+(\mathbf{A})$ whose cohomology returns the $R^n\mathscr{F}$. The obstacle is immediate: $\mathscr{F}$ applied term by term does *not* descend to $D^+(\mathbf{A})$, because a left exact functor need not carry quasi-isomorphisms to quasi-isomorphisms. If it did, all its higher derived functors would vanish.

Example 57.3.1: Termwise Application Does Not Descend
Let $\mathscr{F} = \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/2, -)$ on $\mathbf{Ab}$, which is left exact. The chain map

$$\begin{array}{ccc} \mathbb{Z} & \xrightarrow{2} & \mathbb{Z} \\ \downarrow & & \downarrow \\ 0 & \longrightarrow & \mathbb{Z}/2 \end{array}$$

from the complex $(\mathbb{Z} \xrightarrow{2} \mathbb{Z})$ in degrees $-1, 0$ to $\mathbb{Z}/2$ in degree 0 is a quasi-isomorphism. Both complexes have cohomology only in degree 0, and there the induced map is the reduction $\mathbb{Z}/2\mathbb{Z} \to \mathbb{Z}/2$, an isomorphism. Apply $\mathscr{F}$ term by term. The upper complex becomes $\mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}) \to$

$\mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z})$, which is $0 \to 0$. The lower becomes $\mathrm{Hom}(\mathbb{Z}/2, \mathbb{Z}/2) = \mathbb{Z}/2$ in degree 0. The induced map on H^0 is $0 \to \mathbb{Z}/2$, not an isomorphism.

So the termwise functor does not send this quasi-isomorphism to an isomorphism, and by the universal property of definition 55.2.1 it does not factor through $D^+(\mathbf{Ab})$.

The upper complex is a *projective* resolution of $\mathbb{Z}/2$, and that is the diagnosis. Projective resolutions compute the derived functors of right exact functors. But $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/2, -)$ is left exact, and the complexes on which it behaves are the injective ones. What follows makes that choice of complexes part of the construction.

The repair is to apply $\mathscr{F}$ only to complexes drawn from a class of objects on which it behaves, and then to check that no information is lost by the restriction. Both halves are packaged in the following definition, which is Gelfand-Manin [53] III.6.3.

Definition 57.3.2: Adapted Class

Let $\mathscr{F} : \mathbf{A} \to \mathbf{B}$ be a left exact additive functor. A class $\mathcal{R} \subseteq \mathrm{Ob}\,\mathbf{A}$, stable under finite direct sums, is *adapted* to $\mathscr{F}$ if

1. $\mathscr{F}$ carries every acyclic complex in $\mathrm{K}^+(\mathcal{R})$ to an acyclic complex, and
2. every object of $\mathbf{A}$ is a subobject of an object of $\mathcal{R}$.

For a right exact $\mathscr{F}$ the two conditions are dualized: $\mathscr{F}$ carries acyclic complexes in $\mathrm{K}^-(\mathcal{R})$ to acyclic complexes, and every object of $\mathbf{A}$ is a quotient of an object of $\mathcal{R}$.

Condition (2) is what makes the restriction harmless, since it lets every bounded-below complex be replaced by one built from $\mathcal{R}$. Condition (1) is what makes it useful.

Example 57.3.3: Adapted Classes

1. If $\mathbf{A}$ has enough injectives, the class of injective objects is adapted to every left exact $\mathscr{F}$. It is stable under finite direct sums, since $\mathrm{Hom}(-, I_1 \oplus I_2) \cong \mathrm{Hom}(-, I_1) \oplus \mathrm{Hom}(-, I_2)$ is exact when both summands are. Condition (2) is the definition of enough injectives. For condition (1), an acyclic bounded-below complex I of injectives is homotopy equivalent to 0 by the injective case of corollary 56.2.6, so id_I is null-homotopic. The additive functor $\mathscr{F}$ carries that null-homotopy to one of $\mathrm{id}_{\mathscr{F}(I)}$ (lemma 56.1.32), and a complex whose identity is null-homotopic is exact by proposition 56.1.27.

2. Dually, with enough projectives the projectives are adapted to every right exact $\mathscr{F}$.

3. Let R be a ring and N a left R-module. The flat right R-modules form a class adapted to $- \otimes_R N : \text{Mod-}R \to \mathbf{Ab}$. The class is stable under finite direct sums, since $(F_1 \oplus F_2) \otimes_R -$ is the direct sum of the exact functors $F_1 \otimes_R -$ and $F_2 \otimes_R -$. Every module is a quotient of a free module, and free modules are flat by corollary 17.5.5, which is the quotient form of condition (2).

   For condition (1), let K be an acyclic bounded-above complex of flat right modules, with $K^i = 0$ for $i > a$, let $\pi : P \to N$ be a projective resolution with $P^j = 0$ for $j > 0$, and let C be the exact complex $\cdots \to P^{-1} \to P^0 \xrightarrow{\pi} N$ with N in degree 1. Let T be the total

complex of the double complex $K^i \otimes_R C^j$, with differentials $d_K \otimes 1$ and $(-1)^i(1 \otimes d_C)$. Each column $K^i \otimes_R C$ is exact because K^i is flat, so T is exact by proposition 56.5.4, applied after re-indexing so that K and C vanish in positive degrees. After this re-indexing the twist of section 56.5 is $(-1)^{i-a}$, which differs from the sign $(-1)^i$ above by the constant $(-1)^a$, and $x \otimes y \mapsto (-1)^{aj}\, x \otimes y$ for $y \in C^j$ is an isomorphism between the two total complexes, so exactness transfers. The same holds for the quotient below. The terms with $j = 1$ form a subcomplex S with $S^n = K^{n-1} \otimes_R N$ and differential $d_K \otimes 1$, because d_C vanishes on C^1. The quotient T/S is the total complex of $K^i \otimes_R P^j$, whose rows $K \otimes_R P^j$ are exact because each P^j is projective, hence flat. So T/S is exact by proposition 56.5.4 again, and the long exact sequence of theorem 56.1.18 for $0 \to S \to T \to T/S \to 0$ makes S exact, which says that $K \otimes_R N$ is exact.

This class can be strictly larger than the class of projectives: over $\mathbb{Z}$ the module $\mathbb{Q}$ is flat and not projective (example 17.5.8). That is the point of allowing a class: a flat resolution, projective or not, computes $L(- \otimes_R N)$.

An adapted class computes the derived category, in the following precise sense. Write $S_{\mathcal{R}}$ for the class of quasi-isomorphisms in $\mathrm{K}^+(\mathcal{R})$.

Theorem 57.3.4: An Adapted Class Computes D^+

Let $\mathcal{R}$ be adapted to a left exact $\mathscr{F}\colon \mathbf{A} \to \mathbf{B}$. Then $S_{\mathcal{R}}$ is a multiplicative system in $\mathrm{K}^+(\mathcal{R})$, and the canonical functor

$$\mathrm{K}^+(\mathcal{R})\big[S_{\mathcal{R}}^{-1}\big] \longrightarrow D^+(\mathbf{A})$$

is an equivalence of categories. The corresponding statement with K^- and D^- holds for a right exact $\mathscr{F}$.

The proof is Gelfand-Manin [53] III.6.4. It repeats their construction of injective resolutions of complexes (III.5.22) with $\mathcal{R}$ in place of the injectives, and its input is the single fact about $\mathcal{R}$ that condition (2) is for: every bounded-below complex K admits a quasi-isomorphism $K \to L$ with L in $\mathrm{K}^+(\mathcal{R})$ (property $(*)$ in that proof). Full faithfulness follows through Gelfand-Manin's criterion III.2.10, condition b2: for every quasi-isomorphism $s\colon L' \to K$ with L' in $\mathrm{K}^+(\mathcal{R})$ there is a quasi-isomorphism $t\colon K \to L$ with ts in $S_{\mathcal{R}}$, which $(*)$ provides. That criterion uses fractions with the quasi-isomorphism on the target, the form theorem 57.2.3 takes when applied to $\mathbf{A}^{\mathrm{op}}$. Essential surjectivity follows from $(*)$ once an object of $D^+(\mathbf{A})$ has been replaced by a bounded-below complex, which is the truncation step of box 57.2.5, by the canonical truncation $\tau^{\geq m}$ of definition 56.1.12 (Weibel [101] 10.3.15).

With the equivalence in hand the construction is short.

Definition 57.3.5: Total Derived Functor

Let $\mathscr{F}\colon \mathbf{A} \to \mathbf{B}$ be left exact and $\mathcal{R}$ a class adapted to it. Define $R\mathscr{F}$ on $\mathrm{K}^+(\mathcal{R})$ term by term,

$$\big(R\mathscr{F}\big)(K^\bullet)^i := \mathscr{F}(K^i)$$

Condition (1) of definition 57.3.2 makes $R\mathscr{F}$ carry the quasi-isomorphisms of $\mathrm{K}^+(\mathcal{R})$ to isomorphisms, so it descends to $\mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}] \to D^+(\mathbf{B})$. Composing with an inverse $\Phi\colon D^+(\mathbf{A}) \to \mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]$ of the equivalence of theorem 57.3.4 gives the *total right derived functor*

$$R\mathscr{F}\colon D^+(\mathbf{A}) \longrightarrow D^+(\mathbf{B})$$

The total left derived functor $L\mathscr{F}$ of a right exact $\mathscr{F}$ is defined dually, on D^-.

That $R\mathscr{F}$ carries quasi-isomorphisms to isomorphisms is where condition (1) enters. A morphism $u\colon K \to L$ of $\mathrm{K}^+(\mathcal{R})$ is a quasi-isomorphism exactly when its cone is acyclic (proposition 56.1.24). The cone has terms $K^{n+1} \oplus L^n$, which lie in $\mathcal{R}$ because $\mathcal{R}$ is stable under finite direct sums, so it is a complex of $\mathrm{K}^+(\mathcal{R})$ and condition (1) makes its image under $\mathscr{F}$ acyclic. Being additive, $\mathscr{F}$ commutes with the formation of cones, so $\mathscr{F}(u)$ has acyclic cone and is a quasi-isomorphism.

The definition depends on two choices, $\mathcal{R}$ and Φ, and neither is canonical. What makes $R\mathscr{F}$ well defined regardless is a universal property. To state it, write $\Psi\colon \mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}] \to D^+(\mathbf{A})$ for the equivalence of theorem 57.3.4, $\beta\colon \mathrm{id} \to \Psi\Phi$ for the natural isomorphism that makes Φ an inverse of Ψ, $Q_{\mathcal{R}}$ for the localization functor of $\mathrm{K}^+(\mathcal{R})$, and $\bar{\mathscr{F}}\colon \mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}] \to D^+(\mathbf{B})$ for the functor induced by $\mathscr{F}$ term by term, so that $R\mathscr{F} = \bar{\mathscr{F}}\Phi$.

Theorem 57.3.6: The Total Derived Functor Is Universal

Let $\mathscr{F}\colon \mathbf{A} \to \mathbf{B}$ be left exact, let $\mathcal{R}$ be adapted to $\mathscr{F}$, and let $R\mathscr{F}$ be built from $\mathcal{R}$ and Φ as in definition 57.3.5. Write $Q_{\mathbf{A}}$ and $Q_{\mathbf{B}}$ for the localization functors of $\mathrm{K}^+(\mathbf{A})$ and $\mathrm{K}^+(\mathbf{B})$. For $X \in \mathrm{K}^+(\mathbf{A})$ put $Y := \Phi(Q_{\mathbf{A}}X)$, choose a quasi-isomorphism $s\colon X \to Z$ with Z in $\mathrm{K}^+(\mathcal{R})$, let $\gamma\colon Y \to Z$ be the isomorphism of $\mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]$ with $\Psi(\gamma) = Q_{\mathbf{A}}(s)\,\beta_X^{-1}$, and set

$$\varepsilon_{\mathscr{F}}(X) := \bar{\mathscr{F}}(\gamma)^{-1} \circ Q_{\mathbf{B}}\big(\mathscr{F}(s)\big)\colon \mathscr{F}(X) \longrightarrow \bar{\mathscr{F}}(Y) = R\mathscr{F}(Q_{\mathbf{A}}X)$$

1. $R\mathscr{F}$ is a triangulated functor. The morphism $\varepsilon_{\mathscr{F}}(X)$ does not depend on the choice of s, and these morphisms form a natural transformation $\varepsilon_{\mathscr{F}}\colon Q_{\mathbf{B}} \circ \mathrm{K}^+(\mathscr{F}) \to R\mathscr{F} \circ Q_{\mathbf{A}}$.
2. The pair $(R\mathscr{F}, \varepsilon_{\mathscr{F}})$ is initial: for every triangulated $\mathcal{G}\colon D^+(\mathbf{A}) \to D^+(\mathbf{B})$ and every natural transformation $\varepsilon\colon Q_{\mathbf{B}} \circ \mathrm{K}^+(\mathscr{F}) \to \mathcal{G} \circ Q_{\mathbf{A}}$ there is a unique natural transformation $\eta\colon R\mathscr{F} \to \mathcal{G}$ with $\varepsilon = (\eta * Q_{\mathbf{A}}) \circ \varepsilon_{\mathscr{F}}$.
3. Consequently $R\mathscr{F}$ is independent of $\mathcal{R}$ and Φ, up to a unique natural isomorphism compatible with the transformations $\varepsilon_{\mathscr{F}}$.
4. Dually, let $\mathscr{F}$ be right exact and $\mathcal{R}$ adapted to it. The total left derived functor $L\mathscr{F}$ carries a natural transformation $\varepsilon_{\mathscr{F}}\colon L\mathscr{F} \circ Q_{\mathbf{A}} \to Q_{\mathbf{B}} \circ \mathrm{K}^-(\mathscr{F})$, defined dually, and the pair is terminal: for every triangulated $\mathcal{G}\colon D^-(\mathbf{A}) \to D^-(\mathbf{B})$ and every natural transformation $\varepsilon\colon \mathcal{G} \circ Q_{\mathbf{A}} \to Q_{\mathbf{B}} \circ \mathrm{K}^-(\mathscr{F})$ there is a unique natural transformation $\eta\colon \mathcal{G} \to L\mathscr{F}$ with $\varepsilon = \varepsilon_{\mathscr{F}} \circ (\eta * Q_{\mathbf{A}})$. In particular $L\mathscr{F}$ is independent of the choices up to a unique compatible natural isomorphism.

The morphism γ exists because Z and Y are objects of $\mathrm{K}^+(\mathcal{R})$ and Ψ is fully faithful, and it is an isomorphism because $\Psi(\gamma)$ is one. The quasi-isomorphism s exists by property $(*)$ of the proof of theorem 57.3.4. When γ is the class of a quasi-isomorphism $t\colon Y \to Z$ of $\mathrm{K}^+(\mathcal{R})$, so that $X \xrightarrow{s} Z \xleftarrow{t} Y$ represents β_X, the definition reads $\varepsilon_{\mathscr{F}}(X) = Q_{\mathbf{B}}(\mathscr{F}(t))^{-1} \circ Q_{\mathbf{B}}(\mathscr{F}(s))$, with $\mathscr{F}(t)$ a quasi-isomorphism by condition (1) of definition 57.3.2. That is the formula of Gelfand-Manin [53] III.6.10, whose text writes $\mathrm{K}^+(F)(s)$ at the point where t is meant.

The general case reduces to this one. By Gelfand-Manin III.6.4 the class $S_{\mathcal{R}}$ is localizing in their sense (III.2.6), which includes the Ore condition with the quasi-isomorphism on the target, so by their Remark III.2.9, the right-roof variant of Lemma III.2.8, the isomorphism γ is $Q_{\mathcal{R}}(u)^{-1}Q_{\mathcal{R}}(t)$ for some morphisms $t\colon Y \to W$ and $u\colon Z \to W$ of $\mathrm{K}^+(\mathcal{R})$ with u in $S_{\mathcal{R}}$. Then $Q_{\mathbf{A}}(t) = \Psi(Q_{\mathcal{R}}(t)) = Q_{\mathbf{A}}(u)\,\Psi(\gamma)$ is invertible, so t is a quasi-isomorphism too (proposition 57.2.8), and

$$Q_{\mathbf{A}}(t) = Q_{\mathbf{A}}(u)\,Q_{\mathbf{A}}(s)\,\beta_X^{-1} = Q_{\mathbf{A}}(us)\,\beta_X^{-1}$$

So $X \xrightarrow{us} W \xleftarrow{t} Y$ represents β_X as in Gelfand-Manin III.6.10, with W in $\mathrm{K}^+(\mathcal{R})$. Since $\bar{\mathscr{F}} \circ Q_{\mathcal{R}} = Q_{\mathbf{B}} \circ \mathscr{F}$ on $\mathrm{K}^+(\mathcal{R})$,

$$\bar{\mathscr{F}}(\gamma)^{-1}\,Q_{\mathbf{B}}(\mathscr{F}(s)) = Q_{\mathbf{B}}(\mathscr{F}(t))^{-1}\,Q_{\mathbf{B}}(\mathscr{F}(u))\,Q_{\mathbf{B}}(\mathscr{F}(s)) = Q_{\mathbf{B}}(\mathscr{F}(t))^{-1}\,Q_{\mathbf{B}}(\mathscr{F}(us))$$

which is their $\varepsilon_F(X)$ for that diagram. So $\varepsilon_{\mathscr{F}}$ as defined here is Gelfand-Manin's, and III.6.10, which proves that theirs does not depend on the diagram and is natural in X, gives the second and third assertions of (1).

The statement is Gelfand-Manin's Definition III.6.6, with the right exact form (4) stated after it. That the construction of definition 57.3.5 satisfies it is their Theorem III.6.8, proved in III.6.8 to

III.6.11: $R\mathscr{F}$ is triangulated by III.6.8(a) and Lemma III.6.9, $\varepsilon_{\mathscr{F}}$ is constructed and shown to be well defined and natural in III.6.10, and the universal property is verified in III.6.11. The proof is deferred to Gelfand-Manin: it is four pages of manipulation of roofs and introduces no idea used later. Independence of the choices is III.6.7: two constructions, each initial, have unique comparison maps between them, and these are mutually inverse.

The reconciliation with section 56.3 is a computation with the definitions.

Theorem 57.3.7: Classical Derived Functors Are the Cohomology of the Total One

Let $\mathbf{A}$ have enough injectives and let $\mathscr{F}$ be left exact. For every object A of $\mathbf{A}$, regarded as a complex concentrated in degree 0,

$$H^n\big(R\mathscr{F}(A)\big) \cong R^n\mathscr{F}(A)$$

natural in A, where $R^n\mathscr{F}$ is the nth right derived functor of section 56.3.

***Proof*:**

Step 1: the class. Take $\mathcal{R}$ to be the class of injectives, adapted to $\mathscr{F}$ by example 57.3.3(1). By theorem 57.3.6(3) this changes $R\mathscr{F}$ only by a canonical natural isomorphism, so it suffices to prove the theorem for this $\mathcal{R}$.

Step 2: the object. Let $\iota_A\colon A \to I_A$ be an injective resolution, which exists by hypothesis. It is a quasi-isomorphism from the complex A in degree 0 to $I_A \in \mathrm{K}^+(\mathcal{R})$, so $Q_{\mathbf{A}}(\iota_A)\,\beta_A^{-1}\colon \Psi\Phi(A) \to \Psi(I_A)$ is an isomorphism of $D^+(\mathbf{A})$. As Ψ is fully faithful, it is $\Psi(c_A)$ for a unique isomorphism $c_A\colon \Phi(A) \to I_A$ of $\mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]$. Applying $\bar{\mathscr{F}}$ gives an isomorphism $R\mathscr{F}(A) = \bar{\mathscr{F}}\Phi(A) \cong \bar{\mathscr{F}}(I_A) = \mathscr{F}(I_A)$, and so

$$H^n\big(R\mathscr{F}(A)\big) \cong H^n\big(\mathscr{F}(I_A)\big)$$

The right-hand side is canonically isomorphic to $R^n\mathscr{F}(A)$ as defined in section 56.3, the two injective resolutions of A involved being homotopy equivalent (proposition 56.2.14, injective case) and $\mathscr{F}$ carrying homotopy equivalences to homotopy equivalences (lemma 56.1.32).

Step 3: naturality. Let $\varphi\colon A \to A'$ be a morphism and $\tilde{\varphi}\colon I_A \to I_{A'}$ a lift of it, with $\tilde{\varphi}\,\iota_A$ homotopic to $\iota_{A'}\varphi$, which exists by the injective case of proposition 56.2.15. Then $Q_{\mathbf{A}}(\tilde{\varphi})\,Q_{\mathbf{A}}(\iota_A) = Q_{\mathbf{A}}(\iota_{A'})\,\varphi$ in $D^+(\mathbf{A})$, and with the naturality of β,

$$\begin{aligned}\Psi\big(c_{A'}\,\Phi(\varphi)\big) &= Q_{\mathbf{A}}(\iota_{A'})\,\beta_{A'}^{-1}\,\Psi\Phi(\varphi) = Q_{\mathbf{A}}(\iota_{A'})\,\varphi\,\beta_A^{-1}\\ &= Q_{\mathbf{A}}(\tilde{\varphi})\,Q_{\mathbf{A}}(\iota_A)\,\beta_A^{-1} = \Psi\big(Q_{\mathcal{R}}(\tilde{\varphi})\big)\,\Psi(c_A)\end{aligned}$$

the last step because Ψ agrees with $Q_{\mathbf{A}}$ on morphisms of $\mathrm{K}^+(\mathcal{R})$. As Ψ is faithful, $c_{A'}\,\Phi(\varphi) = Q_{\mathcal{R}}(\tilde{\varphi})\,c_A$. Applying $\bar{\mathscr{F}}$ and then H^n shows that the isomorphism of Step 2 carries $H^n\big(R\mathscr{F}(\varphi)\big)$ to $H^n\big(\mathscr{F}(\tilde{\varphi})\big)$, which is $R^n\mathscr{F}(\varphi)$ by the definition in section 56.3, completing the proof.

So nothing computed earlier is displaced. What is gained is that $R\mathscr{F}(A)$ exists before its cohomology is taken, and that the gain shows up immediately when two functors are composed.

Theorem 57.3.8: Derived Functor of a Composite

Let $\mathbf{A}, \mathbf{B}, \mathcal{C}$ be abelian categories with $\mathbf{A}$ and $\mathbf{B}$ having enough injectives, and let

$$\mathscr{F}\colon \mathbf{A} \to \mathbf{B}, \qquad \mathcal{G}\colon \mathbf{B} \to \mathcal{C}$$

be left exact additive functors. There is always a natural transformation

$$\zeta\colon R(\mathcal{G}\circ\mathscr{F}) \longrightarrow R\mathcal{G}\circ R\mathscr{F}$$

and it is an isomorphism whenever $\mathscr{F}$ carries injective objects of $\mathbf{A}$ to $\mathcal{G}$-acyclic objects of $\mathbf{B}$, in the sense of definition 60.4.4.

The natural transformation comes from the universal property of theorem 57.3.6(2) applied to $R(\mathcal{G}\circ\mathscr{F})$. The isomorphism comes from the observation that for A a bounded-below complex of injectives the three complexes involved already agree. $R(\mathcal{G}\circ\mathscr{F})(A)$ and $R\mathscr{F}(A)$ are computed term by term, and so is $R\mathcal{G}(\mathscr{F}(A))$, because $\mathscr{F}(A)$ is a bounded-below complex of $\mathcal{G}$-acyclic objects and the $\mathcal{G}$-acyclic objects form a class adapted to $\mathcal{G}$ (Gelfand-Manin [53] III.6.16(b)). Every object of $D^{+}(\mathbf{A})$ is isomorphic to such a complex. The transformation ζ is Weibel [101] 10.8.2(1), and the isomorphism under this hypothesis is his Corollary 10.8.3. His letters are the opposite of the ones used here: he writes the composite as FG with G applied first, so his $R(FG) \cong RF \circ RG$ is the statement above with the names exchanged. The convention here matches theorem 60.4.5, which is what this theorem feeds.

57.3.9 Note: This Is the Grothendieck Spectral Sequence, Before Indices Theorem 60.4.5 carries the same hypothesis, that $\mathscr{F}$ send injectives to $\mathcal{G}$-acyclics, and concludes with a spectral sequence

$$E_2^{p,q} = R^p\mathcal{G}\big(R^q\mathscr{F}(A)\big) \implies R^{p+q}(\mathcal{G}\circ\mathscr{F})(A)$$

The relation between the two is that theorem 57.3.8 is the statement at the level of the derived category, and the spectral sequence is what remains of it after cohomology is taken. Filtering $R\mathscr{F}(A)$ by its canonical truncations (definition 56.1.12), equivalently by the Cartan-Eilenberg filtration in the proof of theorem 60.4.5, and applying $R\mathcal{G}$ gives, after renumbering the pages (the canonical filtration's E_1 is the E_2 below), a spectral sequence with $E_2^{p,q} = R^p\mathcal{G}\big(R^q\mathscr{F}(A)\big)$. The isomorphism ζ is what says the abutment is $R^{p+q}(\mathcal{G}\circ\mathscr{F})(A)$ and not something else.
This is worth seeing in both directions. The spectral sequence is the computational form and is what chapter 60 uses. The derived-category form carries strictly more information, since a spectral sequence loses the extension data that $R\mathcal{G}\circ R\mathscr{F}$ retains as an object.

Exercise 57.3.1

1. Exhibit two different classes adapted to $-\otimes_R N$ over a commutative ring R, and check directly that the two resulting constructions of $L(-\otimes_R N)$ agree on a module with a short flat resolution. Which part of theorem 57.3.6 makes the agreement automatic?

2. Prove directly that an acyclic bounded-below complex of injectives is split exact, the fact behind example 57.3.3(1), and deduce condition (1) of definition 57.3.2 for the class of injectives. (Build the splittings by induction up the complex, using injectivity at each stage.)

3. Show that if $\mathscr{F}$ is exact then every class stable under finite direct sums and satisfying condition (2) of definition 57.3.2 is adapted to $\mathscr{F}$, and conclude that $R\mathscr{F}$ is the functor induced by $\mathscr{F}$ term by term, with $R^n\mathscr{F} = 0$ for $n \neq 0$. Show also that the stability hypothesis cannot be omitted: in $\mathbf{Ab}$, the groups not isomorphic to $\mathbb{Z} \oplus \mathbb{Z}$ form a class satisfying condition (2) that is not stable under finite direct sums.

4. Give left exact $\mathscr{F}$ and $\mathcal{G}$ for which $\mathscr{F}$ does *not* carry injectives to $\mathcal{G}$-acyclics, and show that the conclusion of theorem 57.3.8 fails for them, so the hypothesis is not decorative. (One source of examples: take $\mathcal{G}$ to be a functor with a nonvanishing R^1 on an object in the image of an injective under $\mathscr{F}$.)

5. Definition 57.3.5 produces $R\mathscr{F}$ on $D^+(\mathbf{A})$ and not on $D(\mathbf{A})$. Identify the step in the construction that uses the bound, and explain what would go wrong for an unbounded complex.

57.4 $R\mathrm{Hom}$ and the Derived Tensor Product

The functors Ext and Tor of section 56.3 have two variables, and section 56.5.1 computed each by resolving either one of them. Section 57.3 derives a functor of a single variable. This section derives Hom and $\otimes$ in both variables, to bifunctors $R\mathrm{Hom}$ and $\otimes^L$ on the bounded derived categories with

$$H^n R\mathrm{Hom}(A,B) \cong \mathrm{Ext}^n(A,B), \qquad H^{-n}\big(A \otimes^L_R B\big) \cong \mathrm{Tor}^R_n(A,B)$$

for objects A and B. The agreement of the two computations, resolving the first variable or the second, becomes an isomorphism in the derived category, and $\mathrm{Ext}^n(A,B)$ becomes the group of morphisms $A \to B[n]$ of $D(\mathcal{A})$, a description with no resolution in it.

The treatment follows Weibel [101] 10.6 and 10.7, with the sign conventions of Gelfand-Manin [53] III.6.14. By box 57.2.5 every object of $D^+(\mathcal{A})$ is isomorphic to a bounded-below complex, and $D^+(\mathcal{A})$ is equivalent to the localization of $\mathrm{K}^+(\mathcal{A})$ at its quasi-isomorphisms. Objects of $D^+(\mathcal{A})$ are therefore taken to be bounded-below complexes, and objects of $D^-(\mathcal{A})$ bounded-above ones. Complexes with no bound are treated in chapter 59.

The morphisms of $\mathrm{K}(\mathcal{A})$ from a complex X to the shifts of a complex Y are the cohomology groups of one complex of abelian groups.

Definition 57.4.1: Hom Complex

Let $X, Y \in \mathrm{Ch}(\mathcal{A})$. The *Hom complex* $\mathrm{Hom}^\bullet(X,Y)$ is the complex of abelian groups with

$$\mathrm{Hom}^n(X,Y) := \prod_{i\in\mathbb{Z}} \mathrm{Hom}_{\mathcal{A}}\big(X^i, Y^{i+n}\big)$$

whose elements are families $\varphi = (\varphi^i)_{i\in\mathbb{Z}}$, and with differential

$$D\varphi := d_Y \circ \varphi - (-1)^n \varphi \circ d_X, \qquad \text{that is} \qquad (D\varphi)^i = d_Y^{i+n}\varphi^i - (-1)^n \varphi^{i+1} d_X^i$$

for $\varphi \in \mathrm{Hom}^n(X,Y)$.

The product is taken in **Ab**, where it exists whatever $\mathcal{A}$ is. For φ of degree n,

$$D(D\varphi) = d_Y d_Y \varphi - (-1)^n d_Y \varphi d_X + (-1)^n d_Y \varphi d_X - \varphi d_X d_X = 0$$

so $\mathrm{Hom}^\bullet(X,Y)$ is a complex. The sign matches the shift convention (57.1), under which the differential of $Y[n]$ is $(-1)^n d_Y$.

Example 57.4.2: The Hom Complex of a Resolution of $\mathbb{Z}/2$

Let P be the complex $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ in degrees -1 and 0, with basis e of P^{-1} and f of P^0, so that $de = 2f$. It is a projective resolution of $\mathbb{Z}/2$. The group $\mathrm{Hom}^n(P,P)$ vanishes unless $-1 \le n \le 1$, and

$$\mathrm{Hom}^{-1}(P,P) = \mathrm{Hom}(P^0,P^{-1}) \cong \mathbb{Z}, \qquad \mathrm{Hom}^1(P,P) = \mathrm{Hom}(P^{-1},P^0) \cong \mathbb{Z},$$
$$\mathrm{Hom}^0(P,P) = \mathrm{Hom}(P^{-1},P^{-1}) \oplus \mathrm{Hom}(P^0,P^0) \cong \mathbb{Z}^2$$

where $h \in \mathbb{Z}$ stands for $f \mapsto he$, the pair (a,b) for $e \mapsto ae$ and $f \mapsto bf$, and c for $e \mapsto cf$. In degree -1 the differential is $Dh = dh + hd$, which sends e to $h(2f) = 2he$ and f to $d(he) = 2hf$, so $Dh = (2h, 2h)$. In degree 0 it is $D(a,b) = d(a,b) - (a,b)d$, which sends e to $2af - 2bf$. So $\mathrm{Hom}^\bullet(P,P)$ is

$$0 \to \mathbb{Z} \xrightarrow{h \mapsto (2h,2h)} \mathbb{Z}^2 \xrightarrow{(a,b) \mapsto 2a-2b} \mathbb{Z} \to 0$$

Its cohomology is 0 in degree -1, $\{(a,a)\}/\{(2h,2h)\} \cong \mathbb{Z}/2$ in degree 0, generated by the identity $(1,1)$, and $\mathbb{Z}/2\mathbb{Z}$ in degree 1, generated by the map φ with $\varphi(e) = f$.

Lemma 57.4.3: The Hom Complex Computes the Homotopy Category

Let $X, Y \in \mathrm{Ch}(\mathcal{A})$ and $n \in \mathbb{Z}$.

1. The n-cocycles of $\mathrm{Hom}^\bullet(X,Y)$ are the chain maps $X \to Y[n]$, with the shift of (57.1), the n-coboundaries are the null-homotopic ones, and so
$$H^n\mathrm{Hom}^\bullet(X,Y) = \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}\big(X, Y[n]\big)$$
2. Chain maps $f\colon X' \to X$ and $g\colon Y \to Y'$ induce chain maps $f^*\colon \varphi \mapsto \varphi f$ and $g_*\colon \varphi \mapsto g\varphi$, and homotopic chain maps induce homotopic ones. Hence $(X,Y) \mapsto \mathrm{Hom}^\bullet(X,Y)$ is a functor $\mathrm{K}(\mathcal{A})^{\mathrm{op}} \times \mathrm{K}(\mathcal{A}) \to \mathrm{K}(\mathbf{Ab})$.
3. Under the identification of (1), $H^n(f^*)$ is precomposition with f and $H^n(g_*)$ is post-composition with $g[n]$.

***Proof*:**
Step 1: cocycles and coboundaries. For $\varphi \in \mathrm{Hom}^n(X,Y)$ the equation $D\varphi = 0$ reads $(-1)^n d_Y \varphi = \varphi d_X$. Since $d_{Y[n]} = (-1)^n d_Y$ and $Y[n]^i = Y^{i+n}$ by (57.1), this says that the family $\varphi^i\colon X^i \to Y[n]^i$ is a chain map $X \to Y[n]$. Next, $\varphi = D\psi$ for $\psi \in \mathrm{Hom}^{n-1}(X,Y)$ means $\varphi = d_Y\psi + (-1)^n \psi d_X$. Putting $s := (-1)^n\psi$, so that $s^i\colon X^i \to Y[n]^{i-1}$, this is

$$\varphi = d_{Y[n]}\, s + s\, d_X$$

which by definition 56.1.25 says that φ is null-homotopic as a map $X \to Y[n]$. Conversely a

null-homotopy s gives $\varphi = D\big((-1)^n s\big)$. Two chain maps are equal in $\mathrm{K}(\mathcal{A})$ exactly when their difference is null-homotopic (definition 56.1.36), which gives the displayed equality.

Step 2: functoriality. Since $f d_{X'} = d_X f$,

$$D(\varphi f) = d_Y \varphi f - (-1)^n \varphi f d_{X'} = \big(d_Y \varphi - (-1)^n \varphi d_X\big) f = (D\varphi) f$$

and similarly $D(g\varphi) = g\, D\varphi$, so f^* and g_* are chain maps. If $g - g' = d_{Y'} k + k d_Y$, then $H(\varphi) := k\varphi$ satisfies

$$D(k\varphi) + k\, D\varphi = d_{Y'} k\varphi + (-1)^n k\varphi d_X + k d_Y \varphi - (-1)^n k \varphi d_X = (g - g')\varphi$$

so $g_* - g'_* = DH + HD$. If $f - f' = d_X k + k d_{X'}$, then $H(\varphi) := (-1)^n \varphi k$ satisfies

$$D\big((-1)^n \varphi k\big) + (-1)^{n+1} (D\varphi) k = (-1)^n d_Y \varphi k + \varphi k d_{X'} + (-1)^{n+1} d_Y \varphi k + \varphi d_X k = \varphi (f - f')$$

so $f^* - f'^* = DH + HD$. As $(g\varphi) f = g(\varphi f)$, the two kinds of induced map commute, and $\mathrm{Hom}^\bullet$ is a functor on the product of homotopy categories.

Step 3: the induced maps. $H^n(f^*)$ sends the class of a chain map $\varphi\colon X \to Y[n]$ to the class of φf, and $H^n(g_*)$ sends it to the class of $g\varphi$, which as a map $X \to Y'[n]$ is $g[n] \circ \varphi$, the shift $g[n]$ having the same components as g by (57.1), completing the proof.

For the complex P of example 57.4.2 the lemma gives $\mathrm{Hom}_{\mathrm{K}(\mathbf{Ab})}(P, P) \cong \mathbb{Z}/2$, generated by id_P, and $\mathrm{Hom}_{\mathrm{K}(\mathbf{Ab})}(P, P[1]) \cong \mathbb{Z}/2$, generated by the chain map φ with $\varphi(e) = f$, which is therefore not null-homotopic.

On a bounded-below complex of injectives, and out of a bounded-above complex of projectives, the homotopy category already computes the morphisms of the derived category. This is Weibel [101] Corollary 10.4.7.

Lemma 57.4.4: Complexes of Projectives and Injectives Compute $D(\mathcal{A})$

Let $\mathcal{A}$ be an abelian category and $X \in \mathrm{Ch}(\mathcal{A})$.

1. If P is a bounded-above complex of projectives, then $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(P, X) \to \mathrm{Hom}_{D(\mathcal{A})}(P, X)$ is bijective.
2. If I is a bounded-below complex of injectives, then $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X, I) \to \mathrm{Hom}_{D(\mathcal{A})}(X, I)$ is bijective.

***Proof*:**
Step 1: (1), surjectivity. By theorem 57.2.4 a morphism $P \to X$ of $D(\mathcal{A})$ is the class of a roof (N, s, f) with $s\colon N \to P$ a quasi-isomorphism, and that class is $Q(f)\, Q(s)^{-1}$. As P is a bounded-above complex of projectives and s is a quasi-isomorphism into it, proposition 56.2.8 gives a chain map $g\colon P \to N$ with sg homotopic to id_P. (Its proof runs through lemma 56.2.4, stated for complexes vanishing in positive degrees. A translation of degrees puts P in that form and changes neither hypothesis nor conclusion.) Applying Q gives $Q(s)Q(g) = \mathrm{id}_P$, and as $Q(s)$ is invertible, $Q(g) = Q(s)^{-1}$. The given morphism is therefore $Q(f)Q(g) = Q(fg)$.

Step 2: (1), injectivity. The functor Q is additive by theorem 57.2.7, so it suffices to show that $Q(h) = 0$ forces h to be null-homotopic, for a chain map $h\colon P \to X$. By proposition 57.2.12(2) there is a quasi-isomorphism $t\colon N \to P$ with ht null-homotopic, and proposition 56.2.8 gives $g\colon P \to N$ with tg homotopic to id_P. Composition is well defined on homotopy classes, so h is homotopic to htg, which is homotopic to 0.

Step 3: (2). Reindexing $X^n \mapsto X^{-n}$ identifies $\mathrm{Ch}(\mathcal{A}^{\mathrm{op}})$ with $\mathrm{Ch}(\mathcal{A})^{\mathrm{op}}$. It carries quasi-isomorphisms to quasi-isomorphisms and null-homotopies to null-homotopies, so it identifies $\mathrm{K}(\mathcal{A}^{\mathrm{op}})$ with $\mathrm{K}(\mathcal{A})^{\mathrm{op}}$ and, the universal property of definition 55.2.1 being self-dual, $D(\mathcal{A}^{\mathrm{op}})$ with $D(\mathcal{A})^{\mathrm{op}}$, compatibly with Q. An injective object of $\mathcal{A}$ is a projective object of $\mathcal{A}^{\mathrm{op}}$, so I becomes a bounded-above complex of projectives of $\mathcal{A}^{\mathrm{op}}$. Statement (1) for the abelian category $\mathcal{A}^{\mathrm{op}}$ is then statement (2) for $\mathcal{A}$, completing the proof.

Corollary 57.4.5: The Hom Complex Preserves Quasi-Isomorphisms

Let $s\colon X \to X'$ and $t\colon Y \to Y'$ be quasi-isomorphisms in $\mathrm{Ch}(\mathcal{A})$.

1. If I is a bounded-below complex of injectives, then $s^*\colon \mathrm{Hom}^\bullet(X', I) \to \mathrm{Hom}^\bullet(X, I)$ is a quasi-isomorphism.
2. If P is a bounded-above complex of projectives, then $t_*\colon \mathrm{Hom}^\bullet(P, Y) \to \mathrm{Hom}^\bullet(P, Y')$ is a quasi-isomorphism.

***Proof*:**
(1) Fix n. The shift $I[n]$ is again a bounded-below complex of injectives. By lemma 57.4.3(1) and (3), $H^n(s^*)$ is the map $\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X', I[n]) \to \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X, I[n])$, $\psi \mapsto \psi s$. The bijections Q of lemma 57.4.4(2) carry it to $\psi \mapsto \psi \circ Q(s)$ from $\mathrm{Hom}_{D(\mathcal{A})}(X', I[n])$ to $\mathrm{Hom}_{D(\mathcal{A})}(X, I[n])$, because Q is a functor, and that map is bijective with inverse $\psi \mapsto \psi \circ Q(s)^{-1}$.

(2) The same argument applies with lemma 57.4.4(1): $H^n(t_*)$ becomes postcomposition with $Q(t[n])$ on $\mathrm{Hom}_{D(\mathcal{A})}(P, Y[n])$, which is bijective because $t[n]$ is a quasi-isomorphism, $H^i(t[n])$ being $H^{i+n}(t)$, completing the proof.

When $\mathcal{A}$ has enough injectives, corollary 57.4.5(1) shows that resolving the second variable by injectives gives a functor of the first variable that inverts quasi-isomorphisms.

Definition 57.4.6: *R*Hom

Let $\mathcal{A}$ have enough injectives. For every bounded-below complex B fix an *injective resolution* $\iota_B\colon B \to I_B$, that is, a quasi-isomorphism into a bounded-below complex of injectives. For $A \in \mathrm{Ch}(\mathcal{A})$ set

$$R\mathrm{Hom}(A, B) := \mathrm{Hom}^\bullet(A, I_B)$$

regarded as an object of $D(\mathbf{Ab})$.

Injective resolutions exist: theorem 56.2.17, applied to $\mathcal{A}^{\mathrm{op}}$, which has enough projectives because $\mathcal{A}$ has enough injectives, gives one for every bounded-below complex. When A is an object of $\mathcal{A}$

placed in degree 0, the group $\mathrm{Hom}^n(A, I_B)$ has the single factor $\mathrm{Hom}_{\mathcal{A}}(A, I_B^n)$ and $D\varphi = d_{I_B}\varphi$. So $R\mathrm{Hom}(A, B)$ is the complex $\mathrm{Hom}_{\mathcal{A}}(A, I_B)$, the left exact functor $\mathrm{Hom}_{\mathcal{A}}(A, -)$ applied term by term to I_B, which is the value at B of the total derived functor of definition 57.3.5 for the functor $\mathrm{Hom}_{\mathcal{A}}(A, -)$ and the class of injectives, adapted to it by example 57.3.3(1).

Example 57.4.7: $R\mathrm{Hom}(\mathbb{Z}/n, \mathbb{Z})$

In **Ab** take $B = \mathbb{Z}$ and the injective resolution $\mathbb{Z} \to I_{\mathbb{Z}}$, where $I_{\mathbb{Z}}$ is $\mathbb{Q} \to \mathbb{Q}/\mathbb{Z}$ in degrees 0 and 1. The groups $\mathbb{Q}$ and $\mathbb{Q}/\mathbb{Z}$ are divisible, hence injective, as recorded in example 56.4.10, and $0 \to \mathbb{Z} \to \mathbb{Q} \to \mathbb{Q}/\mathbb{Z} \to 0$ is exact, so the inclusion is a quasi-isomorphism. For $n \geq 1$,

$$\mathrm{Hom}(\mathbb{Z}/n, \mathbb{Q}) = 0, \qquad \mathrm{Hom}(\mathbb{Z}/n, \mathbb{Q}/\mathbb{Z}) = \{x \in \mathbb{Q}/\mathbb{Z} : nx = 0\} \cong \mathbb{Z}/n$$

the first because $\mathbb{Q}$ has no nonzero element of finite order, the second generated by the class of $1/n$. So $R\mathrm{Hom}(\mathbb{Z}/n, \mathbb{Z})$ is the complex $0 \to \mathbb{Z}/n$ with $\mathbb{Z}/n$ in degree 1, which is $(\mathbb{Z}/n)[-1]$. Its cohomology is $\mathrm{Hom}(\mathbb{Z}/n, \mathbb{Z}) = 0$ in degree 0 and $\mathbb{Z}/n$ in degree 1, the values of $\mathrm{Ext}^0_{\mathbb{Z}}(\mathbb{Z}/n, \mathbb{Z})$ and $\mathrm{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, \mathbb{Z})$ found in example 56.4.10.

Up to a canonical isomorphism $R\mathrm{Hom}(A, B)$ does not depend on the chosen resolutions, and it is a functor of both variables at once. The statement is Weibel [101] Lemma 10.7.3 and Theorem 10.7.4.

Theorem 57.4.8: $R\mathrm{Hom}$ **Is a Bifunctor**

Let $\mathcal{A}$ have enough injectives.

1. For every morphism $\beta\colon B \to B'$ of $D^+(\mathcal{A})$ there is a unique morphism $\tilde{\beta}\colon I_B \to I_{B'}$ of $\mathrm{K}(\mathcal{A})$ with $Q(\tilde{\beta})\,Q(\iota_B) = Q(\iota_{B'})\,\beta$, and $\beta \mapsto \tilde{\beta}$ is a functor $D^+(\mathcal{A}) \to \mathrm{K}(\mathcal{A})$.
2. $R\mathrm{Hom}$ is a bifunctor
$$R\mathrm{Hom}\colon D(\mathcal{A})^{\mathrm{op}} \times D^+(\mathcal{A}) \longrightarrow D(\mathbf{Ab})$$
whose value on $Q(f)$, for a chain map $f\colon A' \to A$, and on β is $Q\big(\mathrm{Hom}^\bullet(f, \tilde{\beta})\big)$.
3. Replacing the injective resolutions by another choice $\iota'_B\colon B \to I'_B$ changes $R\mathrm{Hom}$ by the natural isomorphism $\mathrm{Hom}^\bullet(A, c_B)$, where $c_B\colon I_B \to I'_B$ is the unique morphism of $\mathrm{K}(\mathcal{A})$ with $Q(c_B)\,Q(\iota_B) = Q(\iota'_B)$.
4. If A is bounded above, then $R\mathrm{Hom}(A, B)$ is bounded below. Hence $R\mathrm{Hom}$ restricts to a bifunctor $D^-(\mathcal{A})^{\mathrm{op}} \times D^+(\mathcal{A}) \to D^+(\mathbf{Ab})$.

***Proof*:**

Step 1: the second variable. By lemma 57.4.4(2), with $X = I_B$ and the bounded-below complex of injectives $I_{B'}$, the map $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(I_B, I_{B'}) \to \mathrm{Hom}_{D(\mathcal{A})}(I_B, I_{B'})$ is bijective. As $Q(\iota_B)$ is invertible, $Q(\iota_{B'})\,\beta\,Q(\iota_B)^{-1}$ lies in the target, so it is $Q(\tilde{\beta})$ for exactly one $\tilde{\beta}$, and that is the stated condition. For $\beta'\colon B' \to B''$,

$$Q(\tilde{\beta}'\tilde{\beta})\,Q(\iota_B) = Q(\tilde{\beta}')\,Q(\iota_{B'})\,\beta = Q(\iota_{B''})\,\beta'\beta$$

so $\tilde{\beta}'\tilde{\beta}$ satisfies the condition defining $\widetilde{\beta'\beta}$ and the two are equal. Likewise $\widetilde{\mathrm{id}_B} = \mathrm{id}_{I_B}$. This is (1).

Step 2: the first variable. Fix B. By lemma 57.4.3(2), $A \mapsto \mathrm{Hom}^\bullet(A, I_B)$ is a functor $\mathrm{K}(\mathcal{A})^{\mathrm{op}} \to \mathrm{K}(\mathbf{Ab})$, and by corollary 57.4.5(1) it carries quasi-isomorphisms to quasi-isomorphisms. Followed by $Q\colon \mathrm{K}(\mathbf{Ab}) \to D(\mathbf{Ab})$ it carries the quasi-isomorphisms of $\mathrm{K}(\mathcal{A})$ to isomorphisms. By theorem 57.2.4, $D(\mathcal{A})$ is the localization of $\mathrm{K}(\mathcal{A})$ at its quasi-isomorphisms, so $D(\mathcal{A})^{\mathrm{op}}$ is that of $\mathrm{K}(\mathcal{A})^{\mathrm{op}}$, and the universal property of definition 55.2.1 factors the functor uniquely through $D(\mathcal{A})^{\mathrm{op}}$. The factorization is $R\mathrm{Hom}(-, B)$. Its value on $Q(f)$ is $Q(f^*)$, and its value on $Q(s)^{-1}$, for a quasi-isomorphism s, is $Q(s^*)^{-1}$.

Step 3: both variables. Put $R\mathrm{Hom}(A, \beta) := Q\big(\mathrm{Hom}^\bullet(A, \tilde{\beta})\big)$, a functor of β by Step 1 and lemma 57.4.3(2). For $\alpha\colon A' \to A$ in $D(\mathcal{A})$ and $\beta\colon B \to B'$ consider the square

$$\begin{array}{ccc} R\mathrm{Hom}(A, B) & \xrightarrow{R\mathrm{Hom}(A,\beta)} & R\mathrm{Hom}(A, B') \\ {\scriptstyle R\mathrm{Hom}(\alpha,B)}\downarrow & & \downarrow{\scriptstyle R\mathrm{Hom}(\alpha,B')} \\ R\mathrm{Hom}(A', B) & \xrightarrow[R\mathrm{Hom}(A',\beta)]{} & R\mathrm{Hom}(A', B') \end{array}$$

If $\alpha = Q(f)$ for a chain map f, both composites are $Q\big(\mathrm{Hom}^\bullet(f, \tilde{\beta})\big)$, because f^* and $\tilde{\beta}_*$ commute (lemma 57.4.3(2)). If $\alpha = Q(s)^{-1}$ for a quasi-isomorphism $s\colon A \to A'$, the square is the square for $Q(s)$ with its two vertical isomorphisms inverted, so it commutes. Squares of this shape paste along composites in α, and every morphism of $D(\mathcal{A})$ is $Q(f)Q(s)^{-1}$ by theorem 57.2.4, so the square commutes for every α. Setting $R\mathrm{Hom}(\alpha, \beta) := R\mathrm{Hom}(\alpha, B') \circ R\mathrm{Hom}(A, \beta)$, the commutativity of these squares is exactly what makes $R\mathrm{Hom}$ preserve composites in the pair (α, β). This is (2).

Step 4: independence of the resolutions. As in Step 1, lemma 57.4.4(2) gives unique $c_B\colon I_B \to I'_B$ and $c'_B\colon I'_B \to I_B$ in $\mathrm{K}(\mathcal{A})$ with $Q(c_B)Q(\iota_B) = Q(\iota'_B)$ and $Q(c'_B)Q(\iota'_B) = Q(\iota_B)$. Both $c'_B c_B$ and id_{I_B} satisfy the condition defining $\widetilde{\mathrm{id}_B}$, so $c'_B c_B = \mathrm{id}_{I_B}$, and symmetrically $c_B c'_B = \mathrm{id}_{I'_B}$. So c_B is an isomorphism of $\mathrm{K}(\mathcal{A})$ and $\mathrm{Hom}^\bullet(A, c_B)$ one of $\mathrm{K}(\mathbf{Ab})$. Writing $\tilde{\beta}'$ for the morphism of Step 1 built from the primed resolutions, $c_{B'}\tilde{\beta}$ and $\tilde{\beta}' c_B$ both satisfy $Q(-)\,Q(\iota_B) = Q(\iota'_{B'})\,\beta$, so they are equal by the same uniqueness. With lemma 57.4.3(2), and Step 3 for the passage from chain maps to all morphisms of $D(\mathcal{A})$, the isomorphisms $\mathrm{Hom}^\bullet(A, c_B)$ are natural in both variables. This is (3).

Step 5: bounds. Suppose $A^i = 0$ for $i > a$ and $I_B^j = 0$ for $j < b$. A factor $\mathrm{Hom}(A^i, I_B^{i+n})$ of $\mathrm{Hom}^n(A, I_B)$ is nonzero only if $i \le a$ and $i + n \ge b$, which forces $n \ge b - a$. So $\mathrm{Hom}^n(A, I_B) = 0$ for $n < b - a$, completing the proof.

Dually, when $\mathcal{A}$ has enough projectives, let $\pi_A\colon P_A \to A$ be a *projective resolution* of a bounded-above complex A, that is, a quasi-isomorphism from a bounded-above complex of projectives. Then $\mathrm{Hom}^\bullet(P_A, B)$ defines a bifunctor $D^-(\mathcal{A})^{\mathrm{op}} \times D(\mathcal{A}) \to D(\mathbf{Ab})$ (Weibel [101] Theorem 10.7.4). When both kinds of resolution exist, the two constructions agree, which is Weibel's Exercise 10.7.1.

Proposition 57.4.9: $R\mathrm{Hom}$ May Be Computed by Resolving Either Variable

Let $\mathcal{A}$ have enough injectives and enough projectives, let A be a bounded-above complex with a projective resolution $\pi_A\colon P_A \to A$, and let B be a bounded-below complex. Then both chain maps in

$$R\mathrm{Hom}(A,B) = \mathrm{Hom}^\bullet(A, I_B) \xrightarrow{\pi_A^*} \mathrm{Hom}^\bullet(P_A, I_B) \xleftarrow{(\iota_B)_*} \mathrm{Hom}^\bullet(P_A, B)$$

are quasi-isomorphisms. In particular $R\mathrm{Hom}(A,B) \cong \mathrm{Hom}^\bullet(P_A, B)$ in $D(\mathbf{Ab})$.

***Proof*:**
The map π_A^* is a quasi-isomorphism by corollary 57.4.5(1), with $I = I_B$ and $s = \pi_A$. The map $(\iota_B)_*$ is one by corollary 57.4.5(2), with $P = P_A$ and $t = \iota_B$. Projective resolutions exist by theorem 56.2.17, completing the proof.

In example 57.4.7, the projective resolution $\mathbb{Z} \xrightarrow{n} \mathbb{Z}$ of $\mathbb{Z}/n$ in degrees -1 and 0 gives $\mathrm{Hom}^\bullet(P,\mathbb{Z}) = \left(\mathbb{Z} \xrightarrow{-n} \mathbb{Z}\right)$ in degrees 0 and 1, the sign being the $-(-1)^0\varphi d_P$ of definition 57.4.1. Its cohomology is again $\mathbb{Z}/n$ in degree 1 and 0 elsewhere.

Theorem 57.4.10: Ext as Morphisms in the Derived Category

Let $\mathcal{A}$ have enough injectives.

1. For every complex A, every bounded-below complex B and every $n \in \mathbb{Z}$ there is an isomorphism
$$\mathrm{Hom}_{D(\mathcal{A})}\big(A, B[n]\big) \cong H^n R\mathrm{Hom}(A,B)$$
natural in A and B.

2. For objects A and B of $\mathcal{A}$, regarded as complexes in degree 0, and every $n \in \mathbb{Z}$, there are isomorphisms natural in A and B
$$\mathrm{Ext}^n_{\mathcal{A}}(A,B) \cong \mathrm{Hom}_{D(\mathcal{A})}\big(A, B[n]\big) \cong H^n R\mathrm{Hom}(A,B)$$
where $\mathrm{Ext}^n_{\mathcal{A}}(A,-) = R^n\mathrm{Hom}_{\mathcal{A}}(A,-)$ is the right derived functor of section 56.3, as in example 56.3.6(2). In particular $\mathrm{Hom}_{D(\mathcal{A})}(A, B[n]) = 0$ for $n < 0$, and $Q\colon \mathrm{Hom}_{\mathcal{A}}(A,B) \to \mathrm{Hom}_{D(\mathcal{A})}(A,B)$ is bijective.

***Proof*:**
Step 1: (1). The shift of $Q(\iota_B)$ is an isomorphism $B[n] \to I_B[n]$ of $D(\mathcal{A})$, and composing with it gives $\mathrm{Hom}_{D(\mathcal{A})}(A, B[n]) \cong \mathrm{Hom}_{D(\mathcal{A})}(A, I_B[n])$. Since $I_B[n]$ is a bounded-below complex of injectives, lemma 57.4.4(2) identifies this with $\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(A, I_B[n])$, and lemma 57.4.3(1) identifies that with $H^n\mathrm{Hom}^\bullet(A, I_B) = H^n R\mathrm{Hom}(A,B)$. Each identification is natural in chain maps of A, by lemma 57.4.3(3) and because Q is a functor, hence in all morphisms of $D(\mathcal{A})$, each being $Q(f)Q(s)^{-1}$. Each is natural in B because $Q(\tilde{\beta}[n])\,Q(\iota_B[n]) = Q(\iota_{B'}[n])\,\beta[n]$ by theorem 57.4.8(1).

Step 2: (2). By theorem 57.4.8(3) the choice of ι_B does not matter, so take ι_B to be an injective resolution of B in the sense of definition 56.2.11, with $I_B^n = 0$ for $n < 0$. As observed after definition 57.4.6, $R\mathrm{Hom}(A, B)$ is then the complex $\mathrm{Hom}_{\mathcal{A}}(A, I_B)$, whose nth cohomology is $R^n\mathrm{Hom}_{\mathcal{A}}(A, -)(B) = \mathrm{Ext}^n_{\mathcal{A}}(A, B)$ by the definition of right derived functors in section 56.3. Together with (1) this gives the displayed isomorphisms, natural in A because a morphism $A' \to A$ acts on both sides by precomposition. For naturality in B, let $b\colon B \to B'$ be a morphism of $\mathcal{A}$. The map $\mathrm{Ext}^n_{\mathcal{A}}(A, b)$ of section 56.3 is induced by a comparison lift $\hat{b}\colon I_B \to I_{B'}$ with $\hat{b}\,\iota_B$ homotopic to $\iota_{B'} b$ (the injective case of proposition 56.2.15). Then $Q(\hat{b})\,Q(\iota_B) = Q(\iota_{B'})\,Q(b)$, so $\hat{b} = \tilde{b}$ in $\mathrm{K}(\mathcal{A})$ by the uniqueness in theorem 57.4.8(1), with $\tilde{b}$ the morphism there for $Q(b)$. Hence $\mathrm{Ext}^n_{\mathcal{A}}(A, b) = H^n\mathrm{Hom}_{\mathcal{A}}(A, \hat{b})$ is $H^n R\mathrm{Hom}(A, Q(b))$, and with (1) the displayed isomorphisms are natural in B. For $n < 0$ the group $\mathrm{Hom}_{\mathcal{A}}(A, I_B^n)$ is zero.

Step 3: $n = 0$. The sequence $0 \to B \xrightarrow{\iota_B} I_B^0 \to I_B^1$ is exact, and $\mathrm{Hom}_{\mathcal{A}}(A, -)$ is left exact, so $H^0\mathrm{Hom}_{\mathcal{A}}(A, I_B) = \ker\big(\mathrm{Hom}(A, I_B^0) \to \mathrm{Hom}(A, I_B^1)\big)$ consists of the maps $\iota_B\varphi$ for $\varphi \in \mathrm{Hom}_{\mathcal{A}}(A, B)$. Follow φ through Step 1: $Q(\varphi)$ goes to $Q(\iota_B)Q(\varphi) = Q(\iota_B\varphi)$, then to the homotopy class of the chain map $\iota_B\varphi\colon A \to I_B$, then to the cocycle $\iota_B\varphi \in \mathrm{Hom}(A, I_B^0)$. So the composite of Q with the bijection $\mathrm{Hom}_{D(\mathcal{A})}(A, B) \to H^0\mathrm{Hom}_{\mathcal{A}}(A, I_B) \cong \mathrm{Hom}_{\mathcal{A}}(A, B)$ is the identity of $\mathrm{Hom}_{\mathcal{A}}(A, B)$, and Q is bijective, completing the proof.

Part (2) is Weibel [101] Theorem 10.7.4 and Corollary 10.7.5, and Gelfand-Manin [53] III.6.14. Gelfand-Manin take $\mathrm{Hom}_{D(\mathcal{A})}(A, B[n])$ as the definition of $\mathrm{Ext}^n_{\mathcal{A}}(A, B)$ (III.5.3), which needs no injectives and no projectives, and prove that Q is fully faithful on objects of $\mathcal{A}$ with no hypothesis on $\mathcal{A}$ (III.5.2). When $\mathcal{A}$ also has enough projectives, proposition 57.4.9 computes the same groups from a projective resolution of A.

Example 57.4.11: The Extension $\mathbb{Z}/4$ as a Morphism of $D(\mathbf{Ab})$

Let $u\colon \mathbb{Z}/2 \to \mathbb{Z}/4$ be multiplication by 2 and $v\colon \mathbb{Z}/4 \to \mathbb{Z}/2$ reduction modulo 2. Theorem 57.2.10 completes $0 \to \mathbb{Z}/2 \xrightarrow{u} \mathbb{Z}/4 \xrightarrow{v} \mathbb{Z}/2 \to 0$ to a distinguished triangle (u, v, w) of $D(\mathbf{Ab})$ with $w\colon \mathbb{Z}/2 \to \mathbb{Z}/2[1]$, and example 57.2.11 shows that no morphism of $\mathrm{K}(\mathbf{Ab})$ completes it to a distinguished triangle there.

By theorem 57.4.10(2) and example 56.4.10, $\mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/2[1]) \cong \mathrm{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2) \cong \mathbb{Z}/2$, and w is its nonzero element. To see that $w \neq 0$, rotate the triangle to $(v, w, -u[1])$ and apply $\mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, -)$, which is cohomological by proposition 57.1.8, $D(\mathbf{Ab})$ being triangulated by theorem 57.2.7. Exactness of

$$\mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/4) \xrightarrow{v_*} \mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/2) \xrightarrow{w_*} \mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/2[1])$$

shows that $w = 0$ would make v_* surjective. By the last clause of theorem 57.4.10(2) the first two groups are $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/4)$ and $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2)$, with v_* composition with v. The two homomorphisms $\mathbb{Z}/2 \to \mathbb{Z}/4$ send 1 to 0 and to 2, and $v(2) = 0$, so v_* is zero and misses $\mathrm{id}_{\mathbb{Z}/2}$. Hence $w \neq 0$.

So the short exact sequence determines, through its triangle, the nonzero element of $\mathrm{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/2, \mathbb{Z}/2)$. Through the resolution P of example 57.4.2, $\mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/2[1]) \cong \mathrm{Hom}_{D(\mathbf{Ab})}(P, P[1]) \cong \mathrm{Hom}_{\mathrm{K}(\mathbf{Ab})}(P, P[1])$ by lemma 57.4.4(1), and w corresponds to the chain map φ with $\varphi(e) = f$. No chain map $\mathbb{Z}/2 \to \mathbb{Z}/2[1]$ represents w, the two complexes being concentrated in the different

degrees 0 and -1, so that $\mathrm{Hom}_{\mathrm{K}(\mathbf{Ab})}(\mathbb{Z}/2, \mathbb{Z}/2[1]) = 0$.

The tensor product is derived in the same way, by resolving with projective or flat modules. For a ring R, write Mod-R and R-Mod for the categories of right and left R-modules. Both have enough projectives, free modules being projective (example 56.2.2(4)).

Definition 57.4.12: Total Tensor Complex

Let X be a complex of right R-modules and Y a complex of left R-modules. The *total tensor complex* $\mathrm{Tot}(X \otimes_R Y)$ is the complex of abelian groups with

$$\mathrm{Tot}(X \otimes_R Y)^n := \bigoplus_{i+j=n} X^i \otimes_R Y^j, \qquad d(x \otimes y) := d_X x \otimes y + (-1)^i x \otimes d_Y y$$

for $x \in X^i$ and $y \in Y^j$, the sum being a direct sum in $\mathbf{Ab}$. For chain maps $f\colon X \to X'$ and $g\colon Y \to Y'$, the chain map $\mathrm{Tot}(f \otimes g)$ is $x \otimes y \mapsto f(x) \otimes g(y)$.

The differential is defined on the whole direct sum, since it carries the summand $X^i \otimes_R Y^j$ into the two summands $X^{i+1} \otimes_R Y^j$ and $X^i \otimes_R Y^{j+1}$. This is the direct-sum total complex $\mathrm{Tot}^{\oplus}$ of proposition 56.5.2. When X and Y are bounded above each sum is finite: if $X^i = 0$ for $i > a$ and $Y^j = 0$ for $j > b$, then $i + j = n$ forces $n - b \le i \le a$, and $\mathrm{Tot}(X \otimes_R Y)^n = 0$ for $n > a + b$. The sign is the twist $(-1)^p$ of section 56.5, which makes the squares of the grid $X^i \otimes_R Y^j$ anticommute, and

$$d\big(d(x \otimes y)\big) = d_X d_X x \otimes y + (-1)^{i+1} d_X x \otimes d_Y y + (-1)^i d_X x \otimes d_Y y + x \otimes d_Y d_Y y = 0$$

The map $\mathrm{Tot}(f \otimes g)$ commutes with d because f and g commute with the differentials and preserve degrees.

Example 57.4.13: Two Total Tensor Complexes for $\mathbb{Z}/2$

Let $R = \mathbb{Z}$ and let P be the resolution $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ of example 57.4.2, with $de = 2f$. For $Y = \mathbb{Z}/2$ in degree 0, $\mathrm{Tot}(P \otimes \mathbb{Z}/2)$ is $\mathbb{Z}/2 \xrightarrow{0} \mathbb{Z}/2$ in degrees -1 and 0, with cohomology $\mathbb{Z}/2$ in both degrees. For $Y = P$, the complex $\mathrm{Tot}(P \otimes P)$ has bases $\{e \otimes e\}$, $\{e \otimes f,\ f \otimes e\}$ and $\{f \otimes f\}$ in degrees -2, -1 and 0, and

$$d(e \otimes e) = 2f \otimes e - 2e \otimes f, \qquad d(e \otimes f) = d(f \otimes e) = 2f \otimes f$$

the minus sign being $(-1)^{-1}$. The kernel of d in degree -1 is spanned by $e \otimes f - f \otimes e$, and the image of d in that degree is spanned by twice it, so the cohomology is 0 in degree -2, $\mathbb{Z}/2$ in degree -1 and $\mathbb{Z}/2$ in degree 0, the same as for $\mathrm{Tot}(P \otimes \mathbb{Z}/2)$. Without the sign, $d(e \otimes e)$ would be $2f \otimes e + 2e \otimes f$, and $d \circ d$ would send $e \otimes e$ to $8f \otimes f \neq 0$.

Lemma 57.4.14: Tensoring with a Bounded-Above Flat Complex Preserves Quasi-Isomorphisms

Let R be a ring. All complexes below are bounded above, of right R-modules on the left of $\otimes_R$ and of left R-modules on the right.

1. If f and f' are homotopic, so are $\mathrm{Tot}(f \otimes g)$ and $\mathrm{Tot}(f' \otimes g)$, and likewise in the second variable. Hence $\mathrm{Tot}(- \otimes_R -)$ is a functor on the product of the homotopy categories, with values in $\mathrm{K}^-(\mathbf{Ab})$.
2. If X is exact and every Y^j is flat, or Y is exact and every X^i is flat, then $\mathrm{Tot}(X \otimes_R Y)$ is exact.
3. If every Y^j is flat and $s\colon X \to X'$ is a quasi-isomorphism, then $\mathrm{Tot}(s \otimes Y)$ is a quasi-isomorphism. If every X^i is flat and $t\colon Y \to Y'$ is a quasi-isomorphism, then $\mathrm{Tot}(X \otimes t)$ is a quasi-isomorphism.

***Proof*:**

Step 1: homotopies. Here $\mathrm{Tot}(f \otimes g)$ is bilinear in (f, g). If $f - f' = dh + hd$, then $H(x \otimes y) := h(x) \otimes g(y)$ satisfies, for $x \in X^i$,

$$(dH + Hd)(x \otimes y) = dhx \otimes gy + (-1)^{i-1} hx \otimes dgy + hdx \otimes gy + (-1)^i hx \otimes gdy = (dh + hd)x \otimes gy$$

using $gd = dg$, so $\mathrm{Tot}\big((f - f') \otimes g\big) = dH + Hd$. If $g - g' = dk + kd$, then $H(x \otimes y) := (-1)^i f(x) \otimes k(y)$ satisfies

$$(dH + Hd)(x \otimes y) = (-1)^i dfx \otimes ky + fx \otimes dky + (-1)^{i+1} fdx \otimes ky + fx \otimes kdy = fx \otimes (dk + kd)y$$

using $fd = df$. This is (1), the degree bound having been checked after definition 57.4.12.

Step 2: exactness. The groups $X^i \otimes_R Y^j$ with the maps $d_X \otimes 1$ and $(-1)^i(1 \otimes d_Y)$ form a double complex with anticommuting squares whose total complex is $\mathrm{Tot}(X \otimes_R Y)$. Suppose X exact and every Y^j flat. For fixed j, the row $X \otimes_R Y^j$ with differential $d_X \otimes 1$ is the image of X under $- \otimes_R Y^j$, which is exact by definition 17.5.4. An exact functor preserves kernels and images, so it carries the exact complex X to an exact complex, and every row is exact. In the other case $X^i \otimes_R -$ is exact for every i, and every column $X^i \otimes_R Y$, with differential $(-1)^i(1 \otimes d_Y)$, is exact. If $X^i = 0$ for $i > a$ and $Y^j = 0$ for $j > b$, re-indexing by $p = i - a$ and $q = j - b$ places the double complex in the bidegrees $p, q \leq 0$ without changing any object or map. The sign $(-1)^i$ differs from the twist $(-1)^p = (-1)^{i-a}$ of section 56.5 by the constant $(-1)^a$, and $x \otimes y \mapsto (-1)^{aj} x \otimes y$, for $y \in Y^j$, is an isomorphism between the two total complexes. So proposition 56.5.4 makes the total complex exact.

Step 3: the first variable of (3). Let every Y^j be flat and $s\colon X \to X'$ a quasi-isomorphism. As graded groups,

$$\begin{aligned} MC\big(\mathrm{Tot}(s \otimes Y)\big)^n &= \mathrm{Tot}(X \otimes_R Y)^{n+1} \oplus \mathrm{Tot}(X' \otimes_R Y)^n \\ &= \bigoplus_{i+j=n} \big(X^{i+1} \oplus X'^i\big) \otimes_R Y^j = \mathrm{Tot}\big(MC(s) \otimes_R Y\big)^n \end{aligned}$$

and the differentials agree. For $x \in X^{i+1}$, $x' \in X'^{i}$ and $y \in Y^{j}$, the differential of $\mathrm{Tot}(MC(s) \otimes_R Y)$ sends $(x, x') \otimes y$ to

$$\big(-dx,\ sx + dx'\big) \otimes y + (-1)^i (x, x') \otimes dy$$

since (x, x') has degree i in $MC(s)$. By definition 56.1.21, the differential of the cone sends $(x \otimes y,\ x' \otimes y)$ to

$$\big(-d(x \otimes y),\ sx \otimes y + d(x' \otimes y)\big) = \big(-dx \otimes y + (-1)^i x \otimes dy,\ sx \otimes y + dx' \otimes y + (-1)^i x' \otimes dy\big)$$

the sign $(-1)^{i+1}$ of $x \in X^{i+1}$ in $d(x \otimes y)$ being negated. These are the same element. The cone $MC(s)$ is exact by proposition 56.1.24 and bounded above, so Step 2 makes $\mathrm{Tot}(MC(s) \otimes_R Y) = MC(\mathrm{Tot}(s \otimes Y))$ exact, and proposition 56.1.24 makes $\mathrm{Tot}(s \otimes Y)$ a quasi-isomorphism.

Step 4: the second variable of (3). Here the identification needs a sign. Define $\theta \colon \mathrm{Tot}\big(X \otimes_R MC(t)\big) \to MC\big(\mathrm{Tot}(X \otimes t)\big)$ by $\theta\big(x \otimes (y, y')\big) := \big((-1)^i x \otimes y,\ x \otimes y'\big)$ for $x \in X^i$, $y \in Y^{j+1}$ and $y' \in Y'^{j}$, a bijection in each degree. Applying θ to $d\big(x \otimes (y, y')\big) = dx \otimes (y, y') + (-1)^i x \otimes (-dy,\ ty + dy')$ gives

$$\big((-1)^{i+1} dx \otimes y - x \otimes dy,\ dx \otimes y' + (-1)^i x \otimes ty + (-1)^i x \otimes dy'\big)$$

and the cone differential applied to $\theta\big(x \otimes (y, y')\big)$ gives $\big(-(-1)^i d(x \otimes y),\ (-1)^i x \otimes ty + d(x \otimes y')\big)$, the same element. So θ is an isomorphism of complexes. With every X^i flat and $MC(t)$ exact, Step 2 and proposition 56.1.24 finish as in Step 3, completing the proof.

Definition 57.4.15: Derived Tensor Product

Let R be a ring. For every bounded-above complex B of left R-modules fix a projective resolution $\pi_B \colon P_B \to B$. For a bounded-above complex A of right R-modules, the *derived tensor product* of A and B is

$$A \otimes_R^L B := \mathrm{Tot}(A \otimes_R P_B)$$

regarded as an object of $D^-(\mathbf{Ab})$.

Projective resolutions exist by theorem 56.2.17. For a fixed right module M, $B \mapsto M \otimes_R^L B$ is the complex $M \otimes_R P_B$, the right exact functor $M \otimes_R -$ applied term by term, which is the total left derived functor $L(M \otimes_R -)$ of definition 57.3.5 with the projectives, adapted by example 57.3.3(2).

Example 57.4.16: $\mathbb{Z}/m \otimes^L \mathbb{Z}/n$

Let $R = \mathbb{Z}$, let $m, n \geq 1$ and let $d = \gcd(m, n)$. The complex $\mathbb{Z} \xrightarrow{n} \mathbb{Z}$ in degrees -1 and 0 is a projective resolution of $\mathbb{Z}/n$, so $\mathbb{Z}/m \otimes_{\mathbb{Z}}^L \mathbb{Z}/n$ is

$$\mathbb{Z}/m \xrightarrow{n} \mathbb{Z}/m$$

in degrees -1 and 0. Its cohomology is $\{x \in \mathbb{Z}/m : nx = 0\} \cong \mathbb{Z}/d$ in degree -1, $\mathbb{Z}/(m\mathbb{Z} + n\mathbb{Z}) = \mathbb{Z}/d$ in degree 0, and 0 elsewhere. For $m = n = 2$ it is the complex $\mathrm{Tot}(P \otimes \mathbb{Z}/2)$ of example 57.4.13 with the two factors exchanged.

Theorem 57.4.17: The Derived Tensor Product Is a Balanced Bifunctor

Let R be a ring.

1. $\otimes_R^L$ is a bifunctor $D^-(\text{Mod-}R) \times D^-(R\text{-Mod}) \to D^-(\mathbf{Ab})$, and another choice of projective resolutions changes it by a natural isomorphism, as in theorem 57.4.8(3).
2. If $\varphi\colon F \to A$ is a quasi-isomorphism from a bounded-above complex of flat right modules, then both chain maps in
$$A \otimes_R^L B = \operatorname{Tot}(A \otimes_R P_B) \xleftarrow{\varphi\otimes 1} \operatorname{Tot}(F \otimes_R P_B) \xrightarrow{1\otimes \pi_B} \operatorname{Tot}(F \otimes_R B)$$
are quasi-isomorphisms, so $A \otimes_R^L B \cong \operatorname{Tot}(F \otimes_R B)$ in $D(\mathbf{Ab})$. When $F = P_A$ is a projective resolution of A, this isomorphism is natural in chain maps of A and of B.
3. If $\psi\colon G \to B$ is a quasi-isomorphism from a bounded-above complex of flat left modules, then $A \otimes_R^L B \cong \operatorname{Tot}(A \otimes_R G)$ in $D(\mathbf{Ab})$.

***Proof*:**

Step 1: the first variable. Fix B. Every P_B^j is projective, hence flat by corollary 17.5.5. By lemma 57.4.14(1), $A \mapsto \operatorname{Tot}(A \otimes_R P_B)$ is a functor $\mathrm{K}^-(\text{Mod-}R) \to \mathrm{K}^-(\mathbf{Ab})$, and by lemma 57.4.14(3) it carries quasi-isomorphisms to quasi-isomorphisms. Followed by Q, it inverts the quasi-isomorphisms of $\mathrm{K}^-(\text{Mod-}R)$, so it factors uniquely through the localization of $\mathrm{K}^-(\text{Mod-}R)$ at them. By box 57.2.5 the canonical functor from that localization to $D^-(\text{Mod-}R)$ is an equivalence, so it is fully faithful. With the objects of $D^-(\text{Mod-}R)$ taken to be the bounded-above complexes it is also bijective on objects, hence an isomorphism of categories, and the factorization is a functor on $D^-(\text{Mod-}R)$.

Step 2: the second variable. By lemma 57.4.4(1), with the bounded-above complex of projectives P_B, each morphism $\beta\colon B \to B'$ of $D^-(R\text{-Mod})$ determines a unique $\tilde{\beta}\colon P_B \to P_{B'}$ in $\mathrm{K}(R\text{-Mod})$ with $Q(\pi_{B'})\,Q(\tilde{\beta}) = \beta\,Q(\pi_B)$. The uniqueness argument of Step 1 of the proof of theorem 57.4.8 makes $\beta \mapsto \tilde{\beta}$ a functor. Set $A \otimes_R^L \beta := Q\big(\operatorname{Tot}(A \otimes \tilde{\beta})\big)$.

Step 3: (1). Steps 3 and 4 of the proof of theorem 57.4.8 apply with $\operatorname{Tot}(-\otimes_R -)$ in place of $\mathrm{Hom}^\bullet$, lemma 57.4.14(1) in place of lemma 57.4.3(2), and lemma 57.4.4(1) in place of lemma 57.4.4(2), with one change. Those steps pass from chain maps to all morphisms by writing a morphism as a roof $Q(f)Q(s)^{-1}$ (theorem 57.2.4), and the apex of a roof between bounded-above complexes need not be bounded above, so it lies outside $\mathrm{K}^-(\text{Mod-}R)$, the domain of the functor of Step 1, and lemma 57.4.14 is proved only for bounded-above complexes. In place of roofs, use that every morphism of the localization of $\mathrm{K}^-(\text{Mod-}R)$, which is $D^-(\text{Mod-}R)$ by Step 1, is a composite of morphisms $Q(f)$ and $Q(s)^{-1}$ with f and s chain maps of bounded-above complexes and s a quasi-isomorphism. The construction in the proof of theorem 55.2.2 exhibits every morphism in this form, and any two localizations are identified by an isomorphism commuting with Q. The interchange square in Step 3 of the proof of theorem 57.4.8 commutes for each factor $Q(f)$ and $Q(s)^{-1}$ by the argument given there, hence for every morphism, and the same factorization gives the naturality in Step 4 of that proof. The values are bounded above by the degree bound after definition 57.4.12.

Step 4: (2). The map $\varphi \otimes 1$ is a quasi-isomorphism by the first half of lemma 57.4.14(3), every P_B^j being flat, and $1 \otimes \pi_B$ is one by the second half, every F^i being flat. For naturality when $F = P_A$, let $a\colon A \to A'$ and $b\colon B \to B'$ be chain maps, let $\tilde{a}\colon P_A \to P_{A'}$ be a lift with $\pi_{A'}\tilde{a}$ homotopic to $a\pi_A$ (theorem 56.2.17), and let $\tilde{b}$ be the morphism of Step 2 for $Q(b)$, so that $\pi_{B'}\tilde{b}$ and $b\pi_B$ are homotopic by the injectivity in lemma 57.4.4(1). Then

$$(\pi_{A'} \otimes 1)(\tilde{a} \otimes \tilde{b}) = \pi_{A'}\tilde{a} \otimes \tilde{b}, \qquad (1 \otimes \pi_{B'})(\tilde{a} \otimes \tilde{b}) = \tilde{a} \otimes \pi_{B'}\tilde{b}$$

are homotopic to $(a \otimes \tilde{b})(\pi_A \otimes 1)$ and $(\tilde{a} \otimes b)(1 \otimes \pi_B)$ by lemma 57.4.14(1), so both squares commute in $\mathrm{K}(\mathbf{Ab})$.

Step 5: (3). Let $\pi_A\colon P_A \to A$ be a projective resolution. By (2), $A \otimes^L_R B \cong \mathrm{Tot}(P_A \otimes_R B)$. By lemma 57.4.14(3), the maps $1 \otimes \psi\colon \mathrm{Tot}(P_A \otimes_R G) \to \mathrm{Tot}(P_A \otimes_R B)$, every P_A^i being flat, and $\pi_A \otimes 1\colon \mathrm{Tot}(P_A \otimes_R G) \to \mathrm{Tot}(A \otimes_R G)$, every G^j being flat, are quasi-isomorphisms. So $\mathrm{Tot}(P_A \otimes_R B) \cong \mathrm{Tot}(A \otimes_R G)$ in $D(\mathbf{Ab})$, completing the proof.

Weibel [101] Definition 10.6.1 and Theorem 10.6.3 construct $\otimes^L_R$ by resolving the second variable, as here, and (2) is Weibel's Exercise 10.6.1. By (2), for a fixed left module N the functor $A \mapsto A \otimes^L_R N \cong P_A \otimes_R N$ is the total left derived functor $L(- \otimes_R N)$ of definition 57.3.5.

Theorem 57.4.18: Tor as the Cohomology of the Derived Tensor Product

Let R be a ring, A a right R-module and B a left R-module, regarded as complexes in degree 0. For every $n \in \mathbb{Z}$ there is an isomorphism natural in A and B

$$\mathrm{Tor}^R_n(A, B) \cong H^{-n}\big(A \otimes^L_R B\big)$$

where $\mathrm{Tor}^R_n(-, B) = L_n(- \otimes_R B)$ is the left derived functor of definition 56.3.5, as in example 56.3.6(1). In particular $H^{-n}(A \otimes^L_R B) = 0$ for $n < 0$, $H^0(A \otimes^L_R B) \cong A \otimes_R B$, and $\mathrm{Tor}^R_n(A, B) \cong H^{-n}(A \otimes_R P_B)$ for a projective resolution P_B of B.

***Proof*:**
Let $\pi_A\colon P_A \to A$ be a projective resolution in the sense of definition 56.2.11, with $P_A^n = 0$ for $n > 0$. By theorem 57.4.17(2) there is an isomorphism $A \otimes^L_R B \cong \mathrm{Tot}(P_A \otimes_R B)$ natural in A and B, and since B sits in degree 0 this is the complex $P_A \otimes_R B$ with differential $d \otimes 1$. Its $(-n)$th cohomology is $L_n(- \otimes_R B)(A) = \mathrm{Tor}^R_n(A, B)$ by definition 56.3.5, whose construction, stated in example 56.3.6(1) for a commutative ring, uses no commutativity. For $n < 0$ the term P_A^{-n} is zero. In degree 0, the sequence $P_A^{-1} \to P_A^0 \to A \to 0$ is exact and $- \otimes_R B$ is right exact, so $H^0(P_A \otimes_R B) = \mathrm{coker}\big(P_A^{-1} \otimes_R B \to P_A^0 \otimes_R B\big) \cong A \otimes_R B$. The last statement is definition 57.4.15 itself, $\mathrm{Tot}(A \otimes_R P_B)$ being $A \otimes_R P_B$ when A sits in degree 0, completing the proof.

The theorem is Weibel [101] Theorem 10.6.3 and Corollary 10.6.4, and Gelfand-Manin [53] III.6.15. Its last statement is the balance of Tor, here over an arbitrary ring.

Over a commutative ring R a module is both a left and a right module, and each $X^i \otimes_R Y^j$ and each $\mathrm{Hom}_R(X^i, Y^j)$ is an R-module. Then $\mathrm{Tot}(X \otimes_R Y)$ and the Hom complex $\mathrm{Hom}^\bullet_R(X, Y)$ of definition 57.4.1, formed in R-Mod, are complexes of R-modules. A chain map of complexes of

R-modules is a quasi-isomorphism exactly when it is one of complexes of abelian groups, cohomology being computed on the underlying groups, so the constructions and proofs above run inside R-Mod. Writing $D(R)$ for $D(R\text{-Mod})$, they give

$$\otimes_R^L \colon D^-(R) \times D^-(R) \to D^-(R), \qquad R\mathrm{Hom}_R \colon D(R)^{\mathrm{op}} \times D^+(R) \to D(R)$$

with $R\mathrm{Hom}_R(B,C) = \mathrm{Hom}_R^\bullet(B, I_C)$. The forgetful functor R-Mod $\to$ **Ab** is exact, so it induces a functor $D(R) \to D(\mathbf{Ab})$, which carries these two bifunctors to those of theorem 57.4.17 and theorem 57.4.8.

Theorem 57.4.19: Adjunction Between $\otimes^L$ and RHom

Let R be a commutative ring, let $A, B \in D^-(R)$ and let $C \in D^+(R)$. There is an isomorphism

$$\mathrm{Hom}_{D(R)}\big(A \otimes_R^L B,\ C\big) \cong \mathrm{Hom}_{D(R)}\big(A,\ R\mathrm{Hom}_R(B,C)\big)$$

natural in A and C.

***Proof*:**

Step 1: the adjunction for complexes. Let X and Y be bounded-above complexes and Z any complex of R-modules, and define

$$\Phi \colon \mathrm{Hom}_R^\bullet\big(\mathrm{Tot}(X \otimes_R Y), Z\big) \to \mathrm{Hom}_R^\bullet\big(X, \mathrm{Hom}_R^\bullet(Y,Z)\big), \qquad \Phi(\varphi)(x)(y) := \varphi(x \otimes y)$$

In degree n the source is the product over pairs (i,j) of $\mathrm{Hom}_R(X^i \otimes_R Y^j, Z^{i+j+n})$, a homomorphism out of a finite direct sum being a family of homomorphisms, and the target is the product over the same pairs of $\mathrm{Hom}_R\big(X^i, \mathrm{Hom}_R(Y^j, Z^{i+j+n})\big)$, a homomorphism into a product being a family. On each factor Φ is the bijection of theorem 15.3.9, with both rings equal to R. For the differentials, let φ have degree n, $x \in X^i$ and $y \in Y^j$. By definition 57.4.1 and definition 57.4.12,

$$(D\varphi)(x \otimes y) = d_Z\varphi(x \otimes y) - (-1)^n \varphi(dx \otimes y) - (-1)^{n+i}\varphi(x \otimes dy)$$

On the other side $\Phi(\varphi)(x)$ has degree $i+n$ in $\mathrm{Hom}_R^\bullet(Y,Z)$, where D is $d_Z \circ - - (-1)^{i+n}(-) \circ d_Y$, so

$$\begin{aligned}\big(D\Phi(\varphi)\big)(x)(y) &= \big(D(\Phi(\varphi)(x))\big)(y) - (-1)^n \Phi(\varphi)(dx)(y) \\ &= d_Z\varphi(x \otimes y) - (-1)^{i+n}\varphi(x \otimes dy) - (-1)^n \varphi(dx \otimes y)\end{aligned}$$

The two agree, so Φ is an isomorphism of complexes.

Step 2: resolutions. Let $\pi_A \colon P_A \to A$ and $\pi_B \colon P_B \to B$ be the projective resolutions and $\iota_C \colon C \to I_C$ the injective resolution. By theorem 57.4.17(2) with $F = P_A$, the chain map $\pi_A \otimes 1 \colon T := \mathrm{Tot}(P_A \otimes_R P_B) \to \mathrm{Tot}(A \otimes_R P_B) = A \otimes_R^L B$ is a quasi-isomorphism. By corollary 57.4.5(1), $\pi_B^* \colon \mathrm{Hom}_R^\bullet(B, I_C) \to \mathrm{Hom}_R^\bullet(P_B, I_C) =: H$ is one, so $R\mathrm{Hom}_R(B,C) \cong H$ in $D(R)$.

Step 3: the chain of isomorphisms. Using Step 2 and $Q(\iota_C)$, then lemma 57.4.4(2), lemma 57.4.3(1),

Step 1, lemma 57.4.3(1), lemma 57.4.4(1), and finally Step 2 with $Q(\pi_A)$,

$$\begin{aligned}\mathrm{Hom}_{D(R)}(A \otimes^L_R B, C) &\cong \mathrm{Hom}_{D(R)}(T, I_C) \cong \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(T, I_C) = H^0\mathrm{Hom}^\bullet_R(T, I_C)\\ &\cong H^0\mathrm{Hom}^\bullet_R(P_A, H) = \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P_A, H) \cong \mathrm{Hom}_{D(R)}(P_A, H)\\ &\cong \mathrm{Hom}_{D(R)}\big(A, R\mathrm{Hom}_R(B, C)\big)\end{aligned}$$

Step 4: naturality. By lemma 57.4.4(1), a morphism $\alpha\colon A \to A'$ of $D^-(R)$ determines a unique $\tilde{\alpha}\colon P_A \to P_{A'}$ in $\mathrm{K}(R\text{-Mod})$ with $Q(\pi_{A'})\,Q(\tilde{\alpha}) = \alpha\, Q(\pi_A)$, and under the isomorphisms of Step 2 it acts as $Q(\mathrm{Tot}(\tilde{\alpha} \otimes 1))$ on T, by the factorization in Step 1 of the proof of theorem 57.4.17, and as $Q(\tilde{\alpha})$ on P_A. By theorem 57.4.8(1), a morphism $\gamma\colon C \to C'$ acts on I_C as $Q(\tilde{\gamma})$. Each isomorphism of Step 3 commutes with precomposition by these and postcomposition by $\tilde{\gamma}$: the two uses of lemma 57.4.3(1) by its part (3), the two uses of lemma 57.4.4 because Q is a functor, and Φ because $\Phi\big(\varphi \circ \mathrm{Tot}(\tilde{\alpha} \otimes 1)\big) = \Phi(\varphi) \circ \tilde{\alpha}$ and $\Phi(\tilde{\gamma} \circ \varphi) = \tilde{\gamma}_* \circ \Phi(\varphi)$ by the formula for Φ. So the composite isomorphism is natural in A and C, completing the proof.

This is Weibel [101] Theorem 10.8.7, which states it as an adjunction between $- \otimes^L_R B\colon D^-(R) \to D^-(R)$ and $R\mathrm{Hom}_R(B, -)\colon D^+(R) \to D^+(R)$, for fixed $B \in D^-(R)$. The two functors have different domains, so the precise content is the bijection of the theorem, natural in $A \in D^-(R)$ and $C \in D^+(R)$. That $R\mathrm{Hom}_R(B, C)$ lies in $D^+(R)$ is theorem 57.4.8(4).

57.4.20 Note: Where the Bounds Enter The bounds enter at two places. Lemma 57.4.4 needs P bounded above and I bounded below, through proposition 56.2.8, and lemma 57.4.14(2) needs the flat factor bounded above, through the acyclic assembly lemma proposition 56.5.4. The bound on the other factor only makes the sums in definition 57.4.12 finite. With the direct sums of that definition, the exactness in (2) needs only the bound on the flat factor, by the remark after proposition 56.5.4. The first bound cannot be dropped: example 59.1.7 gives an exact complex of injective $\mathbb{Z}/4$-modules, unbounded in both directions, for which the conclusion of lemma 57.4.4(2) fails, and exercise 57.4.1 (1) asks for a second one. Defining $R\mathrm{Hom}$ and $\otimes^L$ on unbounded complexes, with the adjunction of theorem 57.4.19, requires K-injective and K-flat resolutions, which chapter 59 constructs.

Exercise 57.4.1

1. Let k be a field, $\Lambda = k[x]/(x^2)$, and I the complex of Λ-modules with $I^n = \Lambda$ for every $n \in \mathbb{Z}$ and every differential multiplication by x. Show that Λ is an injective Λ-module, that I is exact, and that id_I is not null-homotopic. Conclude that $\mathrm{Hom}_{\mathrm{K}(\Lambda\text{-Mod})}(I, I) \neq 0 = \mathrm{Hom}_{D(\Lambda\text{-Mod})}(I, I)$, so that the bound in lemma 57.4.4(2) cannot be dropped. (For the null-homotopy, use lemma 56.1.26.)

2. Let $a, b \geq 1$ and $d = \gcd(a, b)$. Compute $H^n R\mathrm{Hom}(\mathbb{Z}/a, \mathbb{Z}/b)$ for every n twice: from the injective resolution $\mathbb{Z}/b \to \mathbb{Q}/\mathbb{Z} \xrightarrow{b} \mathbb{Q}/\mathbb{Z}$, whose first map sends 1 to the class of $1/b$, and, through proposition 57.4.9, from the projective resolution $\mathbb{Z} \xrightarrow{a} \mathbb{Z}$ of $\mathbb{Z}/a$. Check that both give $\mathbb{Z}/d$ for $n = 0, 1$ and 0 otherwise, in agreement with example 56.4.10.

3. Let $\mathcal{A}$ have enough injectives, let A be an object and let $0 \to B' \xrightarrow{u} B \xrightarrow{v} B'' \to 0$ be a short exact sequence in $\mathcal{A}$. Using theorem 57.2.10, proposition 57.1.8 and theorem 57.4.10, derive a

long exact sequence

$$0 \to \mathrm{Hom}(A, B') \to \mathrm{Hom}(A, B) \to \mathrm{Hom}(A, B'') \to \mathrm{Ext}^1(A, B') \to \cdots$$
$$\cdots \to \mathrm{Ext}^n(A, B) \to \mathrm{Ext}^n(A, B'') \to \mathrm{Ext}^{n+1}(A, B') \to \cdots$$

in which $\mathrm{Ext}^n(A, B') \to \mathrm{Ext}^n(A, B)$ is $\mathrm{Ext}^n(A, u)$. State and derive the corresponding sequence in the first variable for a short exact sequence $0 \to A' \to A \to A'' \to 0$.

4. Let A be the complex of abelian groups with $A^k = \mathbb{Z}$ for $k \geq 0$, $A^k = 0$ for $k < 0$, and every differential zero. Show that $H^{-k}R\mathrm{Hom}(A, \mathbb{Z}) \cong \mathbb{Z}$ for every $k \geq 0$, so that $R\mathrm{Hom}(A, \mathbb{Z})$ does not lie in $D^+(\mathbf{Ab})$ and the hypothesis of theorem 57.4.8(4) cannot be dropped. (Use the resolution $I_{\mathbb{Z}}$ of example 57.4.7 and lemma 56.1.11.)

5. Let $s\colon P \to \mathbb{Z}/2$ be the projective resolution of example 57.4.2. Show that $\mathrm{Tot}(s \otimes \mathbb{Z}/2)$ is not a quasi-isomorphism. Which hypothesis of lemma 57.4.14(3) fails, and which complex in Step 2 of its proof fails to be exact? Compare example 57.3.1, which tests the same quasi-isomorphism against $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/2, -)$.

6. Let R be a commutative ring. Show that $R \otimes^L_R B \cong B$ in $D(R)$ for every $B \in D^-(R)$, and that $\mathrm{Hom}_{D(R)}(R, X) \cong H^0(X)$ for every complex X of R-modules. Combine these with theorem 57.4.19 for $A = R$ to obtain $\mathrm{Hom}_{D(R)}(B, C) \cong H^0R\mathrm{Hom}_R(B, C)$ for $B \in D^-(R)$ and $C \in D^+(R)$, and compare with theorem 57.4.10(1).

7. Let R be a commutative ring and X, Y bounded-above complexes of R-modules. Show that $\mathrm{sw}(x \otimes y) := (-1)^{ij}\, y \otimes x$, for $x \in X^i$ and $y \in Y^j$, is an isomorphism of complexes $\mathrm{Tot}(X \otimes_R Y) \to \mathrm{Tot}(Y \otimes_R X)$, and that the same formula without the sign is not a chain map when $X = Y = P$ is the complex of example 57.4.13. Deduce that $A \otimes^L_R B \cong B \otimes^L_R A$ in $D(R)$ for $A, B \in D^-(R)$, and that $\mathrm{Tor}^R_n(A, B) \cong \mathrm{Tor}^R_n(B, A)$ for R-modules A and B.

58

Applications of (co)Homology

With cohomology theory more securely under our belt, it is time to use it! All the work in this chapter can be learnt without the need for any algebraic topology background, as it is the goal of the book to minimize the need for external material. However, the proceeding ideas are abstractions of ideas in algebraic topology, and ignoring the source of inspiration for these ideas is itself a disservice to the pedagogy of the material. Therefore, the section will be written in such a way that a background in homology/cohomology will be advantageous. Namely, it is best if the reader is familiar with simplicial and singular homology, how cohomology is derived from $\mathrm{Hom}(C_\bullet(X), G) = C^\bullet(X; G)$ and the relation of homology to cohomology (ex. the universal coefficient theorem for cohomology). The reader may choose to consult [76] or [59] for the details.

This chapter does *not* present an in-depth coverage of any of the material, in particular these subjects are a large source of modern development in mathematics (as of the early 21st century). The material presented is to demonstrate to the reader the power of cohomological theories so that the reader has an easier time when reading the more dense books containing this information. For a book in the EYNTKA series covering group and galois cohomology, see [26], and for K-theory see [81].

In this chapter we:

1. Shall use the above theory to find cohomological invariants of groups
2. Shall show some ways of interpreting Ext and Tor
3. Shall show that the notion of dimension from the geometric setting can be brought over to the algebraic!
4. Some K-theory will certainly interest the reader

We shall not do sheaf cohomology, as (naturally) it required sheaf theory that was not covered, and it is an exploration for EYNTKA Algebraic Geometry [13].

58.1 Group Cohomology

We start with no link to algebraic topology, and shall include the relation to singular cohomology before the examples.

Given a (not necessarily abelian) group G, what would it mean to extract cohomological information from it? A (co)chain would have to naturally be formed, and a functor must be found to derive. Groups themselves do not form an abelian category, but it was shown that representations, that is $k[G]$-modules, do form them. This is perhaps a first place in which we may think we can study groups, however this category is too nice (think of (co)homology with $\mathbb{Z}$ vs. $\mathbb{R}/\mathbb{C}$ coefficients). What is more useful is it's generalization:

Definition 58.1.1: G-Modules

Let G be an arbitrary group, and M an abelian group. Then M is a *G-module* if there exists a [left] group-action on M. Equivalently, if there exists a $\mathbb{Z}[G]$-module structure on M.

The reader is free to parse through the technicalities of the group action. All $k[G]$-modules presented in chapter 53 are $\mathbb{Z}[G]$-modules with the action restricted. An example of a G-module that is not a representation is the action of the group $\mathrm{Gal}_K(L)$ on the module L/K (a galois extension of L over K). All finite groups G have a non-trivial G-module given by the action of G on the group-ring $k[G]$ (note the addition is abelian). From a geometric perspective, modules represent sheaves (or in special cases vector bundles) over some schemes,

As we have seen many times at this point, the object acts on an abelian group can give lots of information on the object acting on it and the object being acted on. Given a G-module M, we can define the following:

Definition 58.1.2: G-Invariant subgroup

Let M be a G-module. Then the *G-invariant* set of M is the set:

$$M^G := \{m \in M \mid g \cdot m = m,\ \forall g \in G\}$$

which is the largest trivial G-submodule of M.

It is easy to see that $(-)^G$ is a functor. The following will help in computing cohomology

Corollary 58.1.3: Hom Representation of G-invariant

$$M^G \cong \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}, M^G) \cong \mathrm{Hom}_G(\mathbb{Z}, M)$$

***Proof*:**
Give $\mathbb{Z}$ the trivial G-action, which is the action the statement requires.

For any abelian group N, evaluation at 1 is an isomorphism $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}, N) \to N$, with inverse sending x to the map $m \mapsto mx$. Taking $N = M^G$ gives the first isomorphism.

For the second, let $\varphi\colon \mathbb{Z} \to M$ be $\mathbb{Z}[G]$-linear and put $m = \varphi(1)$. Equivariance gives $\varphi(g \cdot 1) = g\varphi(1)$, and $g \cdot 1 = 1$ because the action on $\mathbb{Z}$ is trivial, so $m = gm$ for every $g \in G$, that is $m \in M^G$. Conversely, any $m \in M^G$ defines a $\mathbb{Z}[G]$-linear map $\mathbb{Z} \to M$, $k \mapsto km$, since $g(km) = k(gm) = km$. These assignments are mutually inverse and additive, so $\mathrm{Hom}_G(\mathbb{Z}, M) \cong M^G$, completing the proof.

Similarly, we can define:

Definition 58.1.4: G-Coinvariant subgroup

Let M be a G-module. Then the *G-coinvariant* of M is the set:

$$M_G := \frac{M}{\langle (gm - m) \mid g \in G, m \in M \rangle}$$

and is the maximal invariant quotient module with the trivial action.

Just like $(-)^G$, $(-)_G$ is also a functor. The reader should further verify that

Proposition 58.1.5: Tensor Representation of Coinvariant Module

$$M_G \cong_G \mathbb{Z} \otimes_{\mathbb{Z}[G]} M$$

Proposition 58.1.6: Invariants Is Left-exact

The functor $(-)^G$ is left-exact, the functor $(-)_G$ is right exact.

***Proof*:**
First, prove that $(-)^G$ is right-adjoint to the trivial-action functor.

$$\mathrm{Hom}(T(M), N) \cong \mathrm{Hom}(M, N^G)$$

And similarly for $(-)_G$; it is left-adjoint to the trivial-action functor. As $T(-)$ is an exact functor, $(-)^G$ and $(-)_G$ are left-exact and right-exact respectively, completing the proof.

Both of these functors are not exact:

Example 58.1.7: Lack Of Exactness's
Let $G = C_2$ be the cyclic group of order 2 and:

$$0 \to I_G \to \mathbb{Z}[G] \xrightarrow{\epsilon} \mathbb{Z} \to 0$$

where $\epsilon(1 \cdot a + \sigma \cdot b) = a + b$ and I_G is the kernel. This sequence is exact. Take $(-)^G$:

$$0 \to (I_G)^G \to (\mathbb{Z}[G])^G \xrightarrow{\epsilon^G} (\mathbb{Z})^G \to 0$$

i.e.:

$$0 \to 0 \to \Delta \xrightarrow{\epsilon^G} \mathbb{Z} \to 0$$

where $\Delta = \{(a,a) \mid a \in \mathbb{Z}\}$. Then ϵ^G is no longer surjective as $\epsilon^G(a,a) = 2a$. The above example can also be used to show $(-)_G$ is not left-exact. More generally, if $0 \to M_2^G \to M_2 \to M_3 \to 0$ is exact, taking $(-)^G$ does not change $M - 2^G$, but now we get an isomorphism between the 1st and second terms, so it cannot be surjective.

More generally, let G act trivially on a coset $[m]$ of a quotient M/L. Can this action always be lifted so that G acts trivially on a representative m?

Thus, it is fruitful to take the ith right-derived functor of $(-)^G$ (similarly the left-derived functors of $(-)_G$):

$$\mathbf{R}^i(-)^G := H^i(G,-)$$

which would give us the long exact sequence of abelian groups:

$$0 \to L^G \to M^G \to N^G \to H^1(G,L) \to H^1(G,M) \to \cdots$$

Since $M^G = \text{Hom}_G(\mathbb{Z}, M)$ by taking an injective resolution of M, or a projective resolution of $\mathbb{Z}$, we can write:

$$H^i(G,M) = \text{Ext}^i_{\mathbb{Z}[G]}(\mathbb{Z}, M)$$

Note that $H^0(G,M) = M^G$, hence the higher order cohomology groups represent some failure for points to be fixed. Let us compute some examples to show the power of the machinery developed in chapter 56 before concretely demonstrating how the cohomology groups represent the obstruction of points being fixed.

Example 58.1.8: Group Cohomologies – Homological Algebra Computations

1. The trivial group has trivial cohomology
2. (Integers) Let $G = \mathbb{Z}$. Then $\mathbb{Z}[G] \cong \mathbb{Z}[x, x^{-1}]$. Then since $\mathbb{Z}[x,x^{-1}]/(1-x) \cong_G \mathbb{Z}$ with the trivial action, define the following free (hence projective) resolution:

   $$\cdots \to 0 \to \mathbb{Z}[x,x^{-1}] \xrightarrow{\cdot(1-x)} \mathbb{Z}[x,x^{-1}] \to 0 \to \cdots$$

   Applying the (contravariant) $\text{Hom}_{\mathbb{Z}[x,x^{-1}]}(-,M)$, we can compute the cohomology of

   $$\cdots \to 0 \to M \xrightarrow{\cdot(1-x)} M \to 0 \to \cdots$$

   Then we can conclude by direct computation:

   $$H^0(\mathbb{Z},M) \cong \ker(M \xrightarrow{\cdot(1-x)} M) = M^{\mathbb{Z}}$$

   and:

   $$H^1(\mathbb{Z},M) = \frac{M}{(1-x)M}$$

   and furthermore $H^i(\mathbb{Z},M) = 0$ for $i \notin \{0,1\}$
3. Let $G = C_n$ be a finite cyclic group of over n with generator σ. Let us form a free resolution of $\mathbb{Z}[G]$ by taking advantage of the fact that $\sigma - 1$ and $N = \sum_{i=0}^{n-1} \sigma^i$ are zero divisors:

   $$N \cdot (\sigma - 1) = (1 + \sigma + \cdots + \sigma^{n-1})(\sigma - 1) = \sigma^n - 1 = 1 - 1 = 0$$

This gives a resolution:

$$\cdots \xrightarrow{\sigma-1} \mathbb{Z}[G] \xrightarrow{N} \mathbb{Z}[G] \xrightarrow{\sigma-1} \mathbb{Z}[G] \xrightarrow{\epsilon} \mathbb{Z} \to 0$$

where

$$\epsilon\left(\sum_g a_g g\right) = \sum_g a_g$$

is the usual augmentation map. Then:

$$H^k(C_n, M) = \begin{cases} \frac{M^G}{NM} & k \text{ even}, k \geq 2 \\ \frac{{}_N M}{(\sigma-1)M} & k \text{ odd}, k \geq 1 \end{cases} \qquad \text{where} \qquad {}_N M = \{m \in M \mid N \cdot m = 0\}$$

For example, if $M = \mathbb{Z}$, then:

$$H^k(C_n, \mathbb{Z}) = \begin{cases} \mathbb{Z}/m\mathbb{Z} & k \text{ even}, k \geq 2 \\ 0 & \text{otherwise} \end{cases}$$

4. Let $G = *_{s\in S}\mathbb{Z}$ be the free product of S copies of $\mathbb{Z}$. This has a simple free resolution, namely take:
$$\epsilon : \mathbb{Z}[G] \to \mathbb{Z}$$
where the kernel is:
$$I_S = \sum_{s\in S} \mathbb{Z}[G] \cdot (s-1)$$
It should be verified that I_S is a free G-module, hence we have a free-resoluion:
$$0 \to I_S \to \mathbb{Z}[G] \xrightarrow{\epsilon} \mathbb{Z} \to 0$$
and cohomology:
$$H^k(*_{s\in S}\mathbb{Z}, \mathbb{Z}^G) = \begin{cases} \mathbb{Z} & k = 0 \\ \bigoplus_{s\in S} \mathbb{Z} & k = 1 \\ 0 & k \geq 2 \end{cases}$$

5. (If you know some algebraic geometry) *Galois Cohomology*: Take the category of varieties W over k such that when extending scalars to $\overline{k}$ we have $V/\overline{k} \cong W/\overline{k}$. Let's label it $\mathbf{Var}_{k\to\overline{k}}$, and say that the objects are:
$$\text{Obj}(\mathbf{Var}_{k\to\overline{k}}) = \left\{W/k \;\middle|\; V/\overline{k} \cong W/\overline{k}\right\}$$
and the morphism are regular morphisms. Then I claim that:
$$\mathbf{Var}_{k\to\overline{k}} \cong H^1(\text{Gal}_k(\overline{k}), \text{Aut}(V/\overline{k}))$$
To see this, first note that an element $\sigma \in \text{Gal}_k(\overline{k})$ acts on a $\overline{k}$-variety $W/\overline{k} = W_k \times_{\text{Spec}\,(k)} \text{Spec}\,(\overline{k})$ via:
$$\text{id}_{W_k} \times \text{Spec}\,(\sigma^{-1}) : W/\overline{k} \to W/\overline{k}$$
Or, for those less comfortable with fibered produced from algebraic geometry, they can think of this map as the "equivalent":
$$\text{id}_{W_k} \otimes_k \sigma^{-1} : k[W] \otimes_k \overline{k}$$

With the action defined, let us look at the correspondence. Take $W_k \in \mathbf{Var}_{k\to\overline{k}}$ so that $\varphi : W_{\overline{k}} \xrightarrow{\sim} V_{\overline{k}}$ is an isomorphism. Then notice that this isomorphism induces a map $\varphi\circ\sigma^{-1}\circ\varphi^{-1}$, which is an automorphism on $W_{\overline{k}}$. The collection of all these maps as σ varies can uniquely define W_k (k is the fixed subfield over all σ). This is true up to a choice of $\mathrm{Aut}_k(V)$, and so we quotient out by it. Then we can see this creates the correspondence between these two categories, and shows how far away the category $\mathbf{Var}_{k\to\overline{k}}$ is from being invariant to the group-action of the galois group.

6. (if you know elliptic curves) An excellent example of where galois cohomology is immediately useful is in the theory of elliptic curves. On a high level, it is relatively easy to find the solution of an elliptic curve over $\mathbb{C}$, but it becomes much more difficult to solve it over finite extensions of $\mathbb{Q}$, or $\mathbb{Q}$ itself. If the reader has read (or is reading) [25], then the have encountered the short exact sequence of $\mathrm{Gal}_K(\overline{K})$-modules:

$$0 \to E[m] \to E(\overline{K}) \xrightarrow{[m]} E(\overline{K}) \to 0$$

where $E[m]$ are the m-torsion points of an elliptic curve ($m \geq 2$), K is a number field, $E(\overline{K})$ are the points of the elliptic curve over $\overline{K}$. Let $G = \mathrm{Gal}_K(\overline{K})$. Then when considering solutions over K, the short exact sequence sequence becomes a long exact sequences:

$$\begin{aligned} 0 \to E(K)[m] \to E(K) \xrightarrow{[m]} E(K) \xrightarrow{\delta} H^1(G, E[m]) \\ \to H^1(G, E(\overline{K})) \xrightarrow{[m]} H^1(G, E(\overline{K}) \to \cdots \end{aligned}$$

This is the foundation on which the torsion-free points of E/K will be computed!

7. If the reader knows about the classifying space BG, then:

$$H^n(BG, \mathbb{Z}) \cong H^n(G, \mathbb{Z})$$

where he left hand side is singular cohomology and the right hand side is group cohomology.

What obstruction information does this capture? Since there is a failure in surjectivity $\varphi : M \twoheadrightarrow N$ when applying $(-)^G$, this means that a fixed element $n \in N^G$ does *not* necessarily come form a fixed element $m \in M^G$. Thus, even though $\varphi(m) = n$ exists, it need not be the case that there exists an $m' \in M^G$ such that $\varphi^G(m') = n$. To measure this failure, take the short exact sequence

$$0 \to L \xrightarrow{\iota} M \xrightarrow{\varphi} N \to 0$$

and let $n \in N^G$. As $N^G \subseteq N$, there exists an $m \in M$ such that $\varphi(m) = n$. Consider any $g \in G$ and take $g \cdot m - m$. Then applying the G-homomorphism:

$$\varphi(g \cdot m - m) = g \cdot \varphi(m) - \varphi(m) = g \cdot n - n \overset{!}{=} n - n = 0$$

where $\overset{!}{=}$ comes from $n \in N^G$. By exactness $\ker\varphi = \mathrm{im}\iota$, so there must exist an element $\lambda_m(g) \in L$ such that

$$\iota(\lambda_m(g)) = g \cdot m - m$$

Now, $n \in N^G$ can be lifted if and only if $g \cdot m - m = 0$ for all $g \in G$, since then $m \in M^G$. In terms of elements of L:

$$\forall g \in G,\ \iota(\lambda_m(g)) = 0$$

by injectivity, it must be that $\lambda_m(g) = 0$ for all $g \in G$. Thus, the function $\lambda_m : G \to L$ is non-trivial if the lift does not exist. Let us explore the properties of λ_m. First, if $g_1, g_2 \in G$ then:

$$\begin{aligned}
\iota(\lambda_m(g_1 g_2)) &= g_1 g_2 \cdot m - m \\
&= g_1 g_2 \cdot m - g_1 \cdot m + g_1 \cdot m - m \\
&= g_1 \cdot (g_2 \cdot m - m) + (g_1 \cdot m - m) \\
&= g_1 \iota(\lambda_m(g_2)) + \iota(\lambda_m(g_1)) \\
&= \iota(g_1 \lambda_m(g_2)) + \iota(\lambda_m(g_1)) \\
&= \iota(g_1 \lambda_m(g_2) + \lambda_m(g_1))
\end{aligned}$$

Thus, as f is injective (more specifically a monomorphism) we get:

$$\lambda_m(g_1 g_2) = \lambda_m(g_1) + g_1 \lambda_m(g_2)$$

A function with this property is given a name:

Definition 58.1.9: 1-Cocycle

A function $f : G \to M$ is a called a *1-cocycle*, *1-derivation*, or *crossed homomorphism* if:

$$f(gh) = f(g) + gf(h)$$

The set of all derivations is denoted $Z^1(G, M)$. If it is clear from context, the "1-" is dropped.

Now, the above λ_m was dependent on a choice of m. But $M \hookrightarrow N$ is surjective, and hence there may be another m' such that $\varphi(m') = n$. As φ is a G-homomorphism

$$\varphi(m - m') = c - c = 0$$

and so $m - m' \in \ker \varphi = \text{im}\iota$. Thus, there is an $\ell \in L$ such that

$$m - m' = \iota(\ell) \qquad \text{or} \qquad m' = m + \iota(\ell)$$

Thus, let us relate $\lambda_{m'}$ to λ_m:

$$\begin{aligned}
\iota(\lambda_{m'}(g)) &= g \cdot m' - m' \\
&= g \cdot (m + \iota(\ell)) - m - \iota(\ell) \\
&= g \cdot m + g \cdot \iota(\ell)) - m - \iota(\ell) \\
&= (g \cdot m - m) + g \cdot \iota(\ell) - \iota(\ell) \\
&= \iota(\lambda_m(g)) + \iota(g \cdot \ell) - \iota(\ell) \\
&= \iota(\lambda_m(g) + g \cdot \ell - \iota(\ell))
\end{aligned}$$

Thus, as ι is a monomorphism:

$$\lambda_{m'}(g) = \lambda_m(g) + g \cdot \ell - \ell$$

Thus, the term $g \cdot \ell - \ell$ can be seen as the "trivial" part of the obstruction, as it does not change the difficulty in finding an obstruction. This is given a name:

Definition 58.1.10: 1-Coboundary

A function $f_m : G \to M$ is a called a *1-coboundary* or *principal derivation* if:

$$f_m(g) = g \cdot m - m$$

The set of all boundary maps is denoted $B^1(G, M)$.If it is clear from context, the "1-" is dropped.

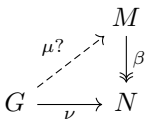
Note that a coboundary is a cocycle:

$$f_m(gh) = gh \cdot m - m = gh \cdot m - h \cdot m + h \cdot m - m = f_m(g) + gf_m(h)$$

Hence $B^1(G, M) \subseteq Z^1(G, M)$. It shall be shown in a moment that:

$$H^1(G, M) \cong \frac{Z^1(G, M)}{B^1(G, M)}$$

First, let us show there is a map $L^G \to H^1(G, M)$. Indeed there is a well-defined G-module homomorphism:



$$\ell \mapsto [g \mapsto g \cdot m - m]$$

where m is in the fiber of ℓ.

Let us next motivate the 2nd order cohomology group. Let us assume the cocycle-representation and the derived functor representation are isomorphic for the next part. Let us start with the long exact sequence we know is given:

$$0 \to L^G \xrightarrow{\alpha} M^G \xrightarrow{\beta} N^G \xrightarrow{\delta^0} H^1(G, L) \xrightarrow{\alpha_*} H^1(G, M) \xrightarrow{\beta_*} H^1(G, N) \xrightarrow{\delta^1} H^2(G, L) \cdots$$

Consider $[\nu] \in H^1(G, N)$; let us call it a 1-obstruction. Then can it be lifted some $[\mu] \in H^1(G, M)$, namely does there exist $[\mu]$ such that $\beta_*([\mu]) = [\nu]$. To find out, first take some representative cocycle $\nu : G \to N$ (notice we are now working with a map, not an element). As $M \hookrightarrow N$ is surjective, we have a diagram:

We can certainly lift each point *locally*, namely given a point $\nu(g) = n \in N$ there is a point (or points) m such that $\beta(m) = n$[1]. But this lifting can fail *globally*, namely such a lift is not guaranteed to be a 1-cocycle. This mirrors the general pattern in cohomology where having local data of a function does not imply the existence of a global function that restricts to all the local data. Let us measure this failure of lifting. If the lifted μ is a cocycle, it would satisfy:

$$\mu(g_1 g_2) - \mu(g_1) - g_1 \mu(g_2) = 0$$

Thus, define the function:

$$\psi : G \times G \to M, \qquad \psi(g_1, g_2) = \mu(g_1 g_2) - \mu(g_1) - g_1 \mu(g_2)$$

[1]Technically, the axiom of choice is invoked here for making a potentially uncountable number of choices

Let us show that for any $(g_1, g_2) \in G \times G$, $\psi(g_1, g_2) \in \ker \beta$. Indeed:

$$\begin{aligned}
\beta(\psi(g_1, g_2)) &= \beta(\mu(g_1 g_2) - \mu(g_1) - g_1\mu(g_2) \\
&= \beta(\mu(g_1 g_2)) - \beta(\mu(g_1)) - \beta(g_1\mu(g_2)) \\
&\overset{!}{=} \nu(g_1 g_2)) - \nu(g_1) - g_1\nu(g_2)) \\
&= 0 && \nu \text{ is a cocycle}
\end{aligned}$$

where $\overset{!}{=}$ comes from μ being defined as a lift of ν and hence $\beta \circ \mu = \nu$. Thus, by exactness $\ker \beta = \text{im}\alpha$ and so for each pair $(g_1, g_2) \in G \times G$, there exists a unique element in L that maps to $\psi(g_1, g_2)$, namely there exists a function $\Omega : G \times G \to L$ such that

$$\alpha(\Omega(g_1, g_2)) = \psi(g_1, g_2)$$

This Ω would now be our new 2-cocycle and are denoted $Z^2(G, M)$. Doing a similar but longer computations such as the one for the 1-cycle, we can find that:

$$g_1\Omega(g_2, g_3) - \Omega(g_1 g_2, g_3) + \Omega(g_1, g_2 g_3) - \Omega(g_1, g_2) = 0$$

Similarly, an explicit computation would fine that 2-boundaries (given a 1-chain ψ) are of the form

$$\Omega(g_1, g_2) = g_1 \cdot \psi(g_2) - \psi(g_1 g_2) + \psi(g_1)$$

These are label $B^2(G, M)$ and:

$$H^2(G, M) \cong \frac{Z^2(G, M)}{B^2(G, M)}$$

The same process continues for higher order cohomology. For the reader who knows some algebraic topology, the following informal discussion grounds the higher order group-cohomology as the singular (or simplicial) cohomology of BG, the classifying space of G with the property that $\pi_1(BG) = G$ and $\pi_n(BG) = \{0\}$ for all $n > 1$ (see [76, Existence of the Universal Bundle, Cohomology of BG is Group Cohomology]). In particular:

$$H^n_{\text{Sing}}(BG, M) \cong H^n(G, M)$$

Note that if M has a non-trivial G-module action, it corresponds to cohomology with local coefficients, but the geometric picture remains the same (the details are left for [26]). Using the nerve or bar construction on BG and considering the usual covering $EG \to BG$ we get the following correspondence:

Geometric Object in EG	Correspondence in BG	Algebraic equivalent
0-Simplices (Vertices)	A single 0-simplex, base point $*$.	elements of G
1-Simplices (Edges)	Directed edge for each element $g \in G$. An arrow from $*$ to $*$ labeled by g.	Functions on G
2-Simplices (Triangles)	Oriented triangle for each pair $(g_1, g_2) \in G \times G$. Edges are the 1-simplices for g_1, g_2, and the product $g_1 g_2$.	Functions on $G \times G$

3-Simplices (Tetrahedral)	Oriented tetrahedron for each triple $(g_1, g_2, g_3) \in G \times G \times G$. Faces are the triangles for (g_2, g_3), $(g_1, g_2 g_3)$, etc.	Functions on $G \times G \times G$
n-Simplices	n-tuple $(g_1, \dots, g_n) \in G^n$.	Functions on G^n

Where "functions" here means set-function (to take into account the "failed" lifting), and the transition maps d_i captures the G-module homomorphism information. Geometrically, the G-module homomorphisms correspond to G-equivariant maps $f : G^n \to M$.

Using this intuition, we can construct a standard way of defining a projective resolution of $\mathbb{Z}$ by G-modules. First, let $\mathbb{Z}[G^n]$ be a G-module with the diagonal action given by multiplying on the left, or more specifically:

$$g \cdot (g_1, ..., g_n) = (gg_1, ..., gg_n)$$

Note that this diagonal map corresponds to the natural action of left multiplication by g on EG. These modules are free G-modules; clearly $\mathbb{Z}[G]$ is a $\mathbb{Z}$-module with basis given by the elements G. Then for $n \geq 0$:

$$\mathbb{Z}[G^{n+1}] \cong \bigoplus_{(g_1,\dots,g_n) \in G^n} \mathbb{Z}[G] \cdot (1, g_1, ..., g_n)$$

which shows that these are free. From this, we can consider the following projective (even free) resolution:

Definition 58.1.11: Standard Resolution

Let G be a group. Then the *standard resolution* of $\mathbb{Z}$ by G-modules is the exact sequence of G-module homomorphism:

$$\cdots \to \mathbb{Z}[G^{n+1}] \xrightarrow{d_n} \mathbb{Z}[G^n] \xrightarrow{d_{n-1}} \cdots \xrightarrow{d_1} \mathbb{Z}[G] \xrightarrow{\epsilon} \mathbb{Z} \to 0$$

where $\mathbb{Z}[G^{n+1}]$ carries the diagonal G-action and, on the basis G^{n+1},

$$d_n(g_0, ..., g_n) = \sum_{i=0}^{n} (-1)^i (g_0, ..., \hat{g}_i, ..., g_n)$$

the term $\hat{g}_i$ being omitted from the tuple, while $\epsilon(g) = 1$ for every $g \in G$. The map ϵ is also called the *augmentation map*.

Note that each $\mathbb{Z}[G^{n+1}]$ is a free $\mathbb{Z}[G]$-module, the diagonal action permuting a basis freely. We claimed this is an exact sequence, however this ought to be verified.

Lemma 58.1.12: Standard Resolution is Exact

The standard resolution of $\mathbb{Z}$ by G-modules is exact

This shows that the nomenclature of cocycles and coboundaries above is used correctly.

***Proof*:**
Exactness is a statement about the underlying abelian groups, so it is enough to produce a contracting homotopy by $\mathbb{Z}$-linear maps; these need not be G-equivariant, and indeed the ones below are not.

Step 1: The maps. Write $e \in G$ for the identity element and define

$$s_{-1}\colon \mathbb{Z} \to \mathbb{Z}[G], \quad 1 \mapsto (e), \qquad s_n\colon \mathbb{Z}[G^{n+1}] \to \mathbb{Z}[G^{n+2}], \quad (g_0, \dots, g_n) \mapsto (e, g_0, \dots, g_n)$$

extended $\mathbb{Z}$-linearly.

Step 2: The contracting identity in positive degrees. Fix $n \geq 1$ and compute $d_{n+1}s_n(g_0, \dots, g_n) = d_{n+1}(e, g_0, \dots, g_n)$. Omitting the entry in position 0 gives $(g_0, \dots, g_n)$ with sign $+1$; omitting the entry in position $j \geq 1$, which is g_{j-1}, gives $(e, g_0, \dots, \hat{g}_{j-1}, \dots, g_n)$ with sign $(-1)^j$. Reindexing by $i = j - 1$ and using $(-1)^{i+1} = -(-1)^i$,

$$d_{n+1}s_n(g_0, \dots, g_n) = (g_0, \dots, g_n) - \sum_{i=0}^{n}(-1)^i(e, g_0, \dots, \hat{g}_i, \dots, g_n)$$

The subtracted sum is exactly $s_{n-1}d_n(g_0, \dots, g_n)$, since s_{n-1} prepends e to each term of $d_n(g_0, \dots, g_n) = \sum_i (-1)^i(g_0, \dots, \hat{g}_i, \dots, g_n)$. Hence

$$d_{n+1}s_n + s_{n-1}d_n = \mathrm{id}$$

Step 3: The bottom of the complex. At the augmentation, $\epsilon s_{-1}(1) = \epsilon(e) = 1$, so $\epsilon s_{-1} = \mathrm{id}_{\mathbb{Z}}$. In degree zero,

$$d_1 s_0(g_0) = d_1(e, g_0) = (g_0) - (e), \qquad s_{-1}\epsilon(g_0) = s_{-1}(1) = (e)$$

so $d_1 s_0 + s_{-1}\epsilon = \mathrm{id}$ as well.

Step 4: Conclusion. The augmented complex therefore has its identity morphism null-homotopic as a complex of abelian groups. By Step 1 of the proof of lemma 56.1.26, a complex whose identity is null-homotopic is exact. Hence the standard resolution is exact, completing the proof.

Hence, after taking the contravariant functor $\mathrm{Hom}_{\mathbb{Z}[G]}(-, M)$, we get the cochain complex:

$$0 \to \mathrm{Hom}_{\mathbb{Z}[G]}(\mathbb{Z}[G], M) \to \cdots \to \mathrm{Hom}_{\mathbb{Z}[G^n]}(-, M) \xrightarrow{d_n^*} \mathrm{Hom}_{\mathbb{Z}[G^{n+1}]}(-, M) \to \cdots$$

where d_n^* maps $\varphi \mapsto \varphi \circ d_n$. Similarly, we can take the covariant functor

$$\cdots \to \mathbb{Z}[G^3] \otimes_{\mathbb{Z}[G]} A \xrightarrow{d_{2*}} \mathbb{Z}[G^2] \otimes_{\mathbb{Z}[G]} A \xrightarrow{d_{1*}} \mathbb{Z}[G] \otimes_{\mathbb{Z}[G]} A \to 0$$

where d_{n*} is given by $(g_0, ..., g_n) \otimes a \mapsto d_n(g_0, ..., g_n) \otimes a$, the map ϵ is the augmentation map given by $\sum a_g g \mapsto \sum a_g$, and we view the modules as *right* $\mathbb{Z}[G]$-modules with the action

$$(g_1, ..., g_n) \cdot g = (g_1 g, ..., g_n g)$$

Let us now better understand these hom-sets and relate to the above discussion. Let

Definition 58.1.13: coChain

Let

$$C^n(G,M) = (\mathrm{Hom}_{\mathbf{Set}}(G^n, M), +)$$

with group operation defined on the maps given by point-wise addition. This group is called the *n-cochain group*.

From this, we can define a boundary map:

$$\begin{aligned} d^n &: C^n(G,M) \to C^{n+1}(G,M) \\ d^n(f)(g_0,...,g_n) &= g_0 f(g_1,...,g_n) - f(g_0g_1, g_2, ..., g_n) \\ &\quad + f(g_0, g_1g_2, ..., g_n) - \cdots + (-1)^n f(g_0,...,g_{n-2}, g_{n-1}g_n) + (-1)^{n+1} f(g_0,...,g_{n-1}) \end{aligned}$$

Then $d^{n+1} \circ d^n = 0$, giving us a cochain complex. We can then have:

Definition 58.1.14: Cohomology Group – using Cocycles and Coboundaries

$$H^n(G,M) = \frac{\ker d^n}{\mathrm{im} d^{n-1}} = \frac{Z^n(G,M)}{B^n(G,M)}$$

We sum up many of the results that we have shown before using the new notation:

1. $C^0(G,M) = M$, and $H^0(G,M) \cong M^G$
2. $d^0 : C^0(G,M) \to C^1(G,M)$ is given by $d^0(a)(g) = ga - a$
3. $H^0(G,M) \cong \ker d^0 = M^G$
4. $\mathrm{im} d^0 = \{f : G \to M \mid \exists a \in M \text{ such that } f(g) = ga - a, \ \forall g \in G\}$ (principal crossed homomorphism)
5. $d^1 : C^1(G,M) \to C^2(G,M)$ given by $d^1(f)(g,h) = gf(h) - f(gh) + f(g)$
6. $\ker d^1 = \{f : G \to M \mid f(gh) = f(g) + gf(h)\}$ (crossed homomorphisms)
7. If $0 \to A \to B \to C \to 0$ is exact, we get an exact sequence of cochains for every n:

$$0 \to C^n(G,A) \to C^n(G,B) \to C^n(G,C) \to 0$$

We shall show that the collection of complexes given by the above is isomorphic to those given by the standard resolution

Proposition 58.1.15: Characterizing Hom of Resolution

Let M be a G-module. Then for every $n \geq 0$ there is an isomorphism:

$$\Phi^n : \mathrm{Hom}_{\mathbb{Z}[G]}(\mathbb{Z}[G^{n+1}], M) \xrightarrow{\cong} C^n(G, M)$$

where the map $\varphi : \mathbb{Z}[G^{n+1}] \to M$ goes to $f : G^n \to M$ given by:

$$f(g_1, ..., g_n) = \varphi(1, g_1, g_1g_2, g_1g_2g_3, ..., g_1g_2g_3 \cdots g_n)$$

The isomorphism Φ^n commutes with boundary maps, that is

$$\Phi^{n+1} \circ d^*_{n+1} = d^n \circ \Phi^n$$

Hence the two cochain complexes agree: the one built from the standard resolution and the one built from cocycles and coboundaries are isomorphic, so the two descriptions of $H^n(G, M)$ coincide.

***Proof*:**

Step 1: Φ^n is a bijection. The group G acts diagonally on the basis G^{n+1} of $\mathbb{Z}[G^{n+1}]$, and this action is free, since $g \cdot (h_0, \dots, h_n) = (h_0, \dots, h_n)$ forces $gh_0 = h_0$ and hence $g = e$. Each orbit contains exactly one tuple whose first entry is e, namely $h_0^{-1} \cdot (h_0, \dots, h_n)$. A $\mathbb{Z}[G]$-linear map out of $\mathbb{Z}[G^{n+1}]$ is therefore determined freely and without constraint by its values on the tuples $(e, k_1, \dots, k_n)$, so restriction to those tuples is a bijection onto $\mathrm{Hom}_{\mathbf{Set}}(G^n, M) = C^n(G, M)$.

The substitution in the statement is the reparametrization $k_i = g_1g_2 \cdots g_i$ of that indexing. It is a bijection $G^n \to G^n$, with inverse $g_1 = k_1$ and $g_i = k_{i-1}^{-1}k_i$ for $i \geq 2$. Composing the two bijections gives Φ^n, and it is additive because both steps are, so Φ^n is an isomorphism of abelian groups.

Step 2: Compatibility with the differentials. Let $\varphi \in \mathrm{Hom}_{\mathbb{Z}[G]}(\mathbb{Z}[G^{n+1}], M)$ and set $f = \Phi^n(\varphi)$. Write $h_i = g_1 \cdots g_i$, so that $f(g_1, \dots, g_n) = \varphi(e, h_1, \dots, h_n)$. Applying Φ^{n+1} to $d^*_{n+1}\varphi = \varphi \circ d_{n+1}$ and evaluating at $(g_0, \dots, g_n)$ gives $\varphi\big(d_{n+1}(e, k_1, \dots, k_{n+1})\big)$ where $k_i = g_0g_1 \cdots g_{i-1}$.

Expand d_{n+1} by definition 58.1.11. The term omitting position 0 is $(k_1, \dots, k_{n+1})$; pulling out the common left factor $k_1 = g_0$ by equivariance of φ turns it into $g_0 \cdot \varphi(e, g_0^{-1}k_2, \dots) = g_0 f(g_1, \dots, g_n)$. The term omitting position j for $1 \leq j \leq n$ merges g_{j-1} and g_j, contributing $(-1)^j f(g_0, \dots, g_{j-1}g_j, \dots, g_n)$, and the term omitting the last position drops g_n, contributing $(-1)^{n+1} f(g_0, \dots, g_{n-1})$. Summing,

$$\Phi^{n+1}(d^*_{n+1}\varphi)(g_0, \dots, g_n) = g_0 f(g_1, \dots, g_n) + \sum_{j=1}^{n} (-1)^j f(g_0, \dots, g_{j-1}g_j, \dots, g_n) + (-1)^{n+1} f(g_0, \dots, g_{n-1})$$

which is precisely $d^n(f)(g_0, \dots, g_n)$ as defined above. Hence $\Phi^{n+1} \circ d^*_{n+1} = d^n \circ \Phi^n$.

The maps $\Phi^\bullet$ are therefore isomorphisms commuting with the differentials, that is an isomorphism

of cochain complexes, completing the proof.

Due to the relevance of the standard representation, we have the following definition:

Definition 58.1.16: Induced and Coinduced G-module

Let G be a group and A an abelian group. Then:

$$\mathrm{CoInd}^G(A) = \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}[G], A)$$

with the G-action defined as $(g\varphi)(z) = \varphi(zg)$ is called the *coinduced G-module* associated to A. Similarly

$$\mathrm{Ind}^G(A) = \mathbb{Z}[G] \otimes_{\mathbb{Z}} A$$

with G-action defined by $g(z \otimes a) = (gz) \otimes a$ is the is the induced G-module associated to A.

A result that is common in many Cohomologies theories is some version of the following:

Lemma 58.1.17: Induced and Coinduced Equivalence

Let G be a finite group and A an abelian group. Then

$$\mathrm{Ind}^G(A) \cong \mathrm{CoInd}^G(A)$$

As a consequence, if $B = \mathrm{Ind}^G(A)$ or $B = \mathrm{CoInd}^G(A)$, then

$$H_0(G, B) \cong H^0(G, B) \cong A$$

and they are both zero for $n \geq 1$.

***Proof*:**

Define the map: $\alpha : \mathrm{CoInd}^G(A) \to \mathrm{Ind}^G(A)$ given by:

$$\varphi \mapsto \sum_{g \in G} g^{-1} \otimes \varphi(g)$$

$$(g^{-1} \mapsto a) \leftarrow\!\shortmid\, g \otimes a$$

with $(g^{-1} \mapsto a)(h) = 0$ for $h \in G \setminus \{g^{-1}\}$. These are certainly inverses, and easily verifiable to be G-module homomorphisms, a technique also used in the proof of Maschke's Theorem (see theorem 53.1.9).

For the last part, write $B = \mathrm{CoInd}^G(A) = \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}[G], A)$, which the first part identifies with $\mathrm{Ind}^G(A)$. Let $P_\bullet \to \mathbb{Z}$ be a resolution by free $\mathbb{Z}[G]$-modules; each P_i is then also free as an abelian group. The adjunction

$$\mathrm{Hom}_{\mathbb{Z}[G]}\big(M, \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}[G], A)\big) \cong \mathrm{Hom}_{\mathbb{Z}}(M, A)$$

of theorem 15.3.9, natural in M, turns the complex computing $H^\bullet(G, B)$ into $\mathrm{Hom}_{\mathbb{Z}}(P_\bullet, A)$. Its cohomology is $\mathrm{Ext}^\bullet_{\mathbb{Z}}(\mathbb{Z}, A)$, which is A in degree 0 and vanishes in positive degrees because $\mathbb{Z}$ is projective over $\mathbb{Z}$. Dually $P_\bullet \otimes_{\mathbb{Z}[G]} (\mathbb{Z}[G] \otimes_{\mathbb{Z}} A) \cong P_\bullet \otimes_{\mathbb{Z}} A$ computes $\mathrm{Tor}^{\mathbb{Z}}_\bullet(\mathbb{Z}, A)$, which is A in degree 0 and zero above. So $H^0(G, B) \cong H_0(G, B) \cong A$ and both vanish for $n \geq 1$, as we sought to show.

Proposition 58.1.18: Torsion of H^1

If G has order n and is finite, then every element of $H^1(G,M)$ has order dividing n.

***Proof*:**
By proposition 58.1.15, $H^1(G,M) = Z^1(G,M)/B^1(G,M)$. Let $\delta \in Z^1(G,M)$, so that $\delta(gh) = \delta(g) + g\delta(h)$ for all $g,h \in G$, and put $S = \sum_{h\in G} \delta(h)$. Fix g and sum the cocycle identity over $h \in G$. As $h \mapsto gh$ permutes G, the left side sums to S, so

$$S = n\,\delta(g) + gS$$

that is, $n\,\delta(g) = g(-S) - (-S)$ for every $g \in G$. So $n\delta$ is the coboundary f_{-S} of definition 58.1.10, and n kills the class of δ in $H^1(G,M)$. Hence the order of every class divides n, as claimed.

Proposition 58.1.19: M finitely generated, then H1 finite

Let M be a finitely generated G-module and G finite. Then $H^1(G,M)$ is finite.

***Proof*:**
Let $m_1,\dots,m_r$ generate M as a G-module. Since G is finite, the finitely many elements gm_i generate M as an abelian group, so the group $C^1(G,M)$ of all functions $G \to M$, which is the product of $|G|$ copies of M, is a finitely generated abelian group, a quotient of some $\mathbb{Z}^k$. The preimage in $\mathbb{Z}^k$ of the subgroup $Z^1(G,M)$ is free of finite rank by theorem 14.1.5, as $\mathbb{Z}$ is a PID, so $Z^1(G,M)$ is finitely generated, and so is its quotient $H^1(G,M) = Z^1(G,M)/B^1(G,M)$ (proposition 58.1.15). If s elements generate $H^1(G,M)$, each has order dividing $|G|$ by proposition 58.1.18, so $H^1(G,M)$ has at most $|G|^s$ elements, completing the proof.

Finally, let us prove the foreshadowing in box 20.4.5. Let L/K be a cyclic extension so that $G = \mathrm{Gal}_K(L) \cong \mathbb{Z}/m\mathbb{Z}$. The G acts on $L^\times$ in the natural way, and hence we find it's group cohomology. First:

Lemma 58.1.20: Cocycles using Norm and Trace

Let L/K be a cyclic extension $G = \mathrm{Gal}_K(L) \cong \mathbb{Z}/m\mathbb{Z}$ with generator σ, and $Z^1(G,L^\times)$ the 1-cocycles. Let $U_{L/K} = \left\{ l \in L \;\middle|\; \mathrm{Nm}_{L/K}(l) = 1 \right\}$ (sometimes this is denoted L^1). Then as groups:

$$Z^1(G,L^\times) \cong U_{L/K}$$
$$c \mapsto c(\sigma)$$

Similarly:

$$Z^1(G,L) \cong T_{L/K}$$

where $T_{L/K}$ is the traceless elements[a]

[a] There is less common notation, sometimes it is denoted L^0

***Proof*:**
Let M be $L^\times$ or L, with its group law written additively as in definition 58.1.9, so that the cocycle condition reads $c(gh) = c(g) + g(c(h))$ and the neutral element 0_M is 1 when $M = L^\times$ and 0 when $M = L$. For $\beta \in M$ and $k \geq 0$ put

$$s_k(\beta) = \sum_{i=0}^{k-1} \sigma^i(\beta)$$

with $s_0(\beta) = 0_M$. For $M = L^\times$ and $k \geq 1$, $s_k(\beta)$ is the product $\beta\,\sigma(\beta)\cdots\sigma^{k-1}(\beta)$. Splitting the sum at $i = j$ gives, for all $j, k \geq 0$,

$$s_{j+k}(\beta) = s_j(\beta) + \sigma^j\big(s_k(\beta)\big)$$

The extension L/K is Galois with group $G = \{\sigma^i : 0 \leq i < m\}$, so the norm and the trace are the product and the sum of the conjugates $\sigma^i(\beta)$ [83, Chapter I, Proposition 2.6]: $s_m(\beta)$ is $\mathrm{Nm}_{L/K}(\beta)$ for $M = L^\times$ and $\mathrm{tr}_{L/K}(\beta)$ for $M = L$. As $\mathrm{Nm}_{L/K}(0) = 0$, the set $U_{L/K}$ lies in $L^\times$, so in both cases the claimed target is $\{\beta \in M : s_m(\beta) = 0_M\}$.

Step 1: $c \mapsto c(\sigma)$ is a homomorphism into the target. The group law of $Z^1(G, M)$ is pointwise, so the map is a homomorphism. Let $c \in Z^1(G, M)$ and $\beta = c(\sigma)$. The cocycle condition at $g = h = e$ gives $c(e) = c(e) + c(e)$, so $c(e) = 0_M$. At $g = \sigma$ and $h = \sigma^k$ it gives $c(\sigma^{k+1}) = \beta + \sigma(c(\sigma^k))$, so by induction on k, using the splitting formula with $j = 1$, $c(\sigma^k) = s_k(\beta)$ for every $k \geq 0$. For $k = m$ this reads $s_m(\beta) = c(\sigma^m) = c(e) = 0_M$, so β lies in the target.

Step 2: injectivity. By Step 1, $c(\sigma^k) = s_k(c(\sigma))$ for all k, so c is determined by $c(\sigma)$.

Step 3: surjectivity. Let $\beta \in M$ with $s_m(\beta) = 0_M$. The splitting formula with $k = m$ gives $s_{j+m}(\beta) = s_j(\beta) + \sigma^j(0_M) = s_j(\beta)$, so $s_k(\beta)$ depends only on the class of k modulo m, and $c(\sigma^k) = s_k(\beta)$ defines a function $c\colon G \to M$. For $g = \sigma^j$ and $h = \sigma^k$ with $j, k \geq 0$ the splitting formula reads $c(gh) = c(g) + g(c(h))$, so $c \in Z^1(G, M)$, and $c(\sigma) = s_1(\beta) = \beta$. Hence $c \mapsto c(\sigma)$ is an isomorphism from $Z^1(G, L^\times)$ onto $U_{L/K}$ and from $Z^1(G, L)$ onto $T_{L/K}$, as claimed.

Theorem 58.1.21: Hilbert's 90th Theorem: Cohomology Upgrade

Using the above lemma's notation:

$$H^1(G, L^\times) \cong \{1\}$$

***Proof*:**
By proposition 58.1.15, $H^1(G, L^\times) = Z^1(G, L^\times)/B^1(G, L^\times)$, so it suffices to show that every cocycle c is a coboundary. Written multiplicatively, the coboundaries of definition 58.1.10 are the functions $g \mapsto g(\gamma)/\gamma$ with $\gamma \in L^\times$. By lemma 58.1.20, $\beta = c(\sigma)$ satisfies $\mathrm{Nm}_{L/K}(\beta) = 1$, and a cocycle is determined by its value at σ, so it suffices to find $\gamma \in L^\times$ with $\beta = \sigma(\gamma)/\gamma$.

Put $s_0 = 1$ and $s_k = \beta\,\sigma(\beta)\cdots\sigma^{k-1}(\beta)$ for $k \geq 1$, so that $s_{k+1} = \beta\,\sigma(s_k)$ and, as in the proof of

lemma 58.1.20, $s_m = \mathrm{Nm}_{L/K}(\beta) = 1$. The automorphisms $\sigma^0, \dots, \sigma^{m-1}$ of L are distinct, hence linearly independent over L (corollary 20.1.40), and the coefficients $s_0, \dots, s_{m-1}$ are nonzero, so some $\theta \in L$ gives

$$\alpha = \sum_{k=0}^{m-1} s_k \, \sigma^k(\theta) \neq 0$$

Applying σ and multiplying by β,

$$\beta \, \sigma(\alpha) = \sum_{k=0}^{m-1} \beta \, \sigma(s_k) \, \sigma^{k+1}(\theta) = \sum_{k=1}^{m} s_k \, \sigma^k(\theta) = \alpha - \theta + s_m \, \sigma^m(\theta) = \alpha$$

because $s_m = 1$ and $\sigma^m = \mathrm{id}$. So $\beta = \alpha/\sigma(\alpha) = \sigma(\gamma)/\gamma$ with $\gamma = \alpha^{-1}$, and c is the coboundary of γ, completing the proof.

Note this theorem generalizes to arbitrary finite Galois extensions; see [26]. This result should now make intuitive sense: the elements of K are *exactly* the $\mathrm{Gal}_K(L)$-invariant element. Note that if there were more complicated groups instead of $L^\times$, there can be more interesting cohomology groups, see [26] for more details.

Exercise 58.1.1

1. Let A, B be any G-modules. Show that $H^n(G, A \oplus B) \cong H^n(G, A) \oplus H^n(G, B)$
2. Show that $H^0(G, \mathrm{CoInd}^G(A)) \cong A$ and $H^n(G, \mathrm{CoInd}^G(A)) \cong 0$ for all $n \geq 1$ (hint: consider $\zeta : \mathrm{Hom}_{\mathbb{Z}[G]}(\mathbb{Z}[G^n], \mathrm{CoInd}^G(A)) \to \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}[G^n], A)$ given by $\varphi \mapsto (z \mapsto \varphi(z)(1))$. What is the inverse of this map?)
3. Show that $H_0(G, \mathrm{Ind}^G(A)) \cong A$ and $H_n(G, \mathrm{Ind}^G(A)) \cong 0$ for all $n \geq 1$.

58.2 Homological Dimension

We now turn to measuring the "complexity" of modules and rings using the length of their resolutions. Before defining these measures rigorously, it is worth stepping back to 1890 to understand why mathematicians began counting the length of resolutions in the first place.

Historical Motivation: Invariant Theory

In the late 19th century, algebra was dominated by *Invariant Theory*. Imagine a group G acting on a polynomial ring $S = \mathbb{C}[x_1, \dots, x_n]$ (for example, by linear substitutions of variables). Mathematicians were looking for *invariant ring* S^G:

$$S^G = \{f \in S \big| g \cdot f = f \text{ for all } g \in G\}$$

The central question was if S^G finitely generated? Can we find a finite set of basic invariant polynomials $f_1, \dots, f_m$ such that every other invariant is just a polynomial combination of these?

Hilbert showed we can map a polynomial ring onto the invariants:

$$\varphi : \mathbb{C}[y_1, \dots, y_m] \twoheadrightarrow S^G \qquad y_i \mapsto f_i$$

and then the kernel $I = \ker(\varphi)$ represents the *relations* between the invariants. Hence, the study of invariants reduced to the study of the kernel. To find these invariants, 19th-century computationalists (like Paul Gordan) asked tried computing them and found the following problem:

1. **First Syzygies:** The ideal I describes the relations. By the Basis Theorem, I is finitely generated.
2. **Second Syzygies:** Are these relations independent? Or are there "relations between the relations"? If we have a relation $Ar_1 + Br_2 = 0$, that is a second syzygy.
3. **Higher Syzygies:** We can keep going. We can form a module of second syzygies and ask for its generators, then ask for the relations between *those* generators.

Mathematicians feared this chain of relations might continue forever, becoming infinitely complex. Hilbert's *Syzygy Theorem* proved that if you are working with a polynomial ring in n variables, this process *must stop*. Specifically, after at most n steps, the module of relations becomes free—there are no more "hidden" relations.

This was part of David Hilbert's seminal paper laying the foundation of commutative geometry. In particular, he proved three theorems: The *Basis Theorem*, the *Nullstellensatz*, and the *Syzygy Theorem*.

58.2.1 Etymology The word *Syzygy* comes from the Greek *syzygia*, meaning "yoked together". In astronomy, it refers to the alignment of three celestial bodies (like the Sun, Earth, and Moon). In algebra, it refers to a relation that "yokes" generators together to zero.

58.2.1 Projective and Global Dimension

We can now formalize Hilbert's discovery using the language of resolutions.

Definition 58.2.2: Projective Dimension

Let M be an R-module. The *projective dimension* of M, denoted $\mathrm{pd}_R(M)$, is the minimal length n of a projective resolution of M:

$$0 \to P_n \to \cdots \to P_1 \to P_0 \to M \to 0$$

If no finite resolution exists, we say $\mathrm{pd}_R(M) = \infty$.

Definition 58.2.3: Global Dimension

The *global dimension* of a ring R, denoted $\mathrm{gldim}(R)$, is the supremum of the projective dimensions of all R-modules:

$$\mathrm{gldim}(R) = \sup\{\mathrm{pd}_R(M) \,|\, M \in R\text{-}\mathbf{Mod}\}$$

Lemma 58.2.4: Detecting Projective Dimension with Ext

Let R be a ring, M an R-module and $m \geq 0$ an integer. The following are equivalent:

1. $\mathrm{pd}_R(M) \leq m$
2. $\mathrm{Ext}^i_R(M, N) = 0$ for all R-modules N and all $i > m$.
3. $\mathrm{Ext}^{m+1}_R(M, N) = 0$ for all R-modules N.

***Proof*:**

For a projective resolution $\cdots \to P_1 \to P_0 \to M \to 0$, theorem 56.5.8 computes $\mathrm{Ext}^i_R(M, N)$ as $H^i(\mathrm{Hom}_R(P_\bullet, N))$, where the cochain complex $\mathrm{Hom}_R(P_\bullet, N)$ has $\mathrm{Hom}_R(P_i, N)$ in degree i.

Step 1: (1) implies (2), and (2) implies (3). If $\mathrm{pd}_R(M) \leq m$, then definition 58.2.2 gives a projective resolution of M with $P_i = 0$ for every $i > m$. For $i > m$ the group $\mathrm{Hom}_R(P_i, N)$ is zero, and so is its cohomology $\mathrm{Ext}^i_R(M, N)$. Condition (3) is the case $i = m + 1$ of (2).

Step 2: Dimension shifting. Fix a projective resolution

$$\cdots \to P_2 \xrightarrow{d_2} P_1 \xrightarrow{d_1} P_0 \xrightarrow{d_0} M \to 0$$

of M, which exists by example 56.2.2(4). Put $K_j = \mathrm{im}(d_j)$ for $j \geq 0$. Then $K_0 = M$, and $K_j = \ker(d_{j-1})$ for $j \geq 1$ by exactness. Let $\pi\colon P_m \to K_m$ be the map d_m with codomain K_m. The complex

$$\cdots \to P_{m+2} \xrightarrow{d_{m+2}} P_{m+1} \xrightarrow{d_{m+1}} P_m \xrightarrow{\pi} K_m \to 0$$

is exact: π is onto, $\ker(\pi) = \ker(d_m) = \mathrm{im}(d_{m+1})$, and exactness at the remaining terms is that of the resolution of M. So $Q_j = P_{m+j}$ is a projective resolution of K_m. For $j \geq 1$ the cohomology of $\mathrm{Hom}_R(Q_\bullet, N)$ in degree j is computed from

$$\mathrm{Hom}_R(P_{m+j-1}, N) \xrightarrow{d^*_{m+j}} \mathrm{Hom}_R(P_{m+j}, N) \xrightarrow{d^*_{m+j+1}} \mathrm{Hom}_R(P_{m+j+1}, N)$$

and the same two maps compute the cohomology of $\mathrm{Hom}_R(P_\bullet, N)$ in degree $m + j$. By theorem 56.5.8, applied to both resolutions,

$$\mathrm{Ext}^j_R(K_m, N) \cong \mathrm{Ext}^{m+j}_R(M, N) \qquad (j \geq 1)$$

Step 3: A module K with $\mathrm{Ext}^1_R(K, N) = 0$ for every R-module N is projective. By example 56.2.2(4), K has a resolution

$$\cdots \to F_2 \xrightarrow{e_2} F_1 \xrightarrow{e_1} F_0 \xrightarrow{e_0} K \to 0$$

by free modules, and free modules are projective (corollary 17.2.6). Let $L = \ker(e_0)$, with inclusion $\iota\colon L \to F_0$, and let $q\colon F_1 \to L$ be the map e_1 with codomain $\mathrm{im}(e_1) = L$, so that $e_1 = \iota \circ q$ and q is onto. Since $\iota \circ q \circ e_2 = e_1 \circ e_2 = 0$ and ι is injective, $q \circ e_2 = 0$, so q is a cocycle of degree 1 in $\mathrm{Hom}_R(F_\bullet, L)$. The cohomology of that complex in degree 1 is $\mathrm{Ext}^1_R(K, L) = 0$ (theorem 56.5.8), so q is a coboundary: $q = g \circ e_1$ for some $g\colon F_0 \to L$. Then $(g \circ \iota) \circ q = g \circ e_1 = q$, and as q is onto, $g \circ \iota = \mathrm{id}_L$.

Every $p \in F_0$ equals $\iota(g(p)) + \big(p - \iota(g(p))\big)$, and the second summand lies in $\ker(g)$. Also

$\iota(L) \cap \ker(g) = 0$, because $g \circ \iota = \mathrm{id}_L$. So $F_0 = \iota(L) \oplus \ker(g)$. The restriction of e_0 to $\ker(g)$ is injective, since $\ker(e_0) \cap \ker(g) = \iota(L) \cap \ker(g) = 0$, and it is onto K, since e_0 is onto and vanishes on $\iota(L)$. Hence $K \cong \ker(g)$ is isomorphic to a direct summand of the free module F_0, and K is projective by theorem 17.2.4.

Step 4: (3) implies (1). Take the resolution and the modules K_j of Step 2. By (3) and Step 2, $\mathrm{Ext}^1_R(K_m, N) \cong \mathrm{Ext}^{m+1}_R(M, N) = 0$ for every R-module N, so K_m is projective by Step 3. If $m = 0$, then $M = K_0$ is projective, and $0 \to M \xrightarrow{\mathrm{id}} M \to 0$ is a projective resolution of length 0. If $m \geq 1$, then $K_m = \ker(d_{m-1})$, and

$$0 \to K_m \to P_{m-1} \to \cdots \to P_1 \to P_0 \to M \to 0$$

is exact, a projective resolution of length m. In both cases $\mathrm{pd}_R(M) \leq m$ by definition 58.2.2, completing the proof.

Theorem 58.2.5: Global Dimension of Polynomial Rings

Let R be a nonzero commutative ring. Then

$$\mathrm{gldim}(R[x]) = \mathrm{gldim}(R) + 1$$

***Proof*:**
Step 1: The characteristic exact sequence. Let M be any $R[x]$-module. Restricting scalars makes M an R-module, and $R[x] \otimes_R M$ is an $R[x]$-module.

Define a sequence of $R[x]$-modules:

$$0 \to R[x] \otimes_R M \xrightarrow{\alpha} R[x] \otimes_R M \xrightarrow{\beta} M \to 0$$

where the maps are defined by:

- $\alpha(f(x) \otimes m) = xf(x) \otimes m - f(x) \otimes xm$
- $\beta(f(x) \otimes m) = f(x)m$

Both formulas are R-bilinear in $(f(x), m)$, because x acts R-linearly on M, so they define maps on $R[x] \otimes_R M$, and both maps are $R[x]$-linear.

- *Surjectivity of β:* For any $m \in M$, $\beta(1 \otimes m) = m$, so β is surjective.
- *Exactness at the middle:* The elements $1 \otimes m$ generate $R[x] \otimes_R M$ as an $R[x]$-module and $\beta \circ \alpha$ is $R[x]$-linear, so the computation $\beta(\alpha(1 \otimes m)) = \beta(x \otimes m - 1 \otimes xm) = xm - xm = 0$ gives $\mathrm{im}(\alpha) \subseteq \ker(\beta)$. Conversely, any element in $R[x] \otimes_R M$ can be written as $\sum_{i=0}^{d} x^i \otimes m_i$. If it lies in $\ker(\beta)$, then $\sum_{i=0}^{d} x^i m_i = 0$. We can rewrite our original element as:

  $$\sum_{i=0}^{d} x^i \otimes m_i = \sum_{i=0}^{d} (x^i \otimes m_i - 1 \otimes x^i m_i)$$

  Since $x^i \otimes m - 1 \otimes x^i m = \alpha\left(\sum_{j=0}^{i-1} x^{i-1-j} \otimes x^j m\right)$ for every $m \in M$, the element is in the image of α.

- *Injectivity of α:* Suppose $\sum_{i=0}^{d} x^i \otimes m_i \in \ker(\alpha)$. Then:

$$\sum_{i=0}^{d} x^{i+1} \otimes m_i - \sum_{i=0}^{d} x^i \otimes x m_i = 0$$

  Because $R[x]$ is free over R, we can compare the coefficients of $x^k \otimes -$ degree by degree. For degree 0, we have $-1 \otimes x m_0 = 0 \implies x m_0 = 0$. For degree $k > 0$, we have $m_{k-1} - x m_k = 0 \implies m_{k-1} = x m_k$. For degree $d+1$, we have $m_d = 0$. Working backward from $m_d = 0$, we get $m_{d-1} = x m_d = 0$, and by induction, $m_i = 0$ for all i. Hence, α is injective.

Step 2: Extending scalars along $R \to R[x]$. Let M be an R-module and $P_\bullet \to M$ a projective resolution over R. Because $R[x]$ is free over R, it is flat (corollary 17.5.5), so tensoring the resolution with $R[x]$ preserves exactness. Each $R[x] \otimes_R P_i$ is a projective $R[x]$-module by theorem 17.2.4: if $P_i \oplus Q \cong R^{(I)}$ for an R-module Q and a set I, then $(R[x] \otimes_R P_i) \oplus (R[x] \otimes_R Q) \cong R[x]^{(I)}$, because $R[x] \otimes_R -$ commutes with direct sums (theorem 15.2.4) and carries $R^{(I)}$ to $R[x]^{(I)}$ (example 15.3.3). Therefore $R[x] \otimes_R P_\bullet$ is a projective resolution of $R[x] \otimes_R M$ over $R[x]$. Taking $P_\bullet$ of length $\mathrm{pd}_R(M)$ when that is finite gives

$$\mathrm{pd}_{R[x]}(R[x] \otimes_R M) \leq \mathrm{pd}_R(M)$$

Let N be an $R[x]$-module. Regard $\mathrm{Hom}_{R[x]}(-, N)$ as a functor on the opposite category of $R[x]$-modules. Its right derived functors, computed from projective resolutions as in example 56.3.6, are the functors $\mathrm{Ext}^i_{R[x]}(-, N)$ by theorem 56.5.8, and the opposite category has enough injectives, because $R[x]$-modules have projective resolutions (example 56.2.2(4)). For an $R[x]$-module M, corollary 56.3.12 therefore turns the sequence of Step 1, regarded as a short exact sequence in the opposite category, into the long exact sequence

$$\cdots \to \mathrm{Ext}^i_{R[x]}(R[x] \otimes_R M, N) \xrightarrow{\alpha^*} \mathrm{Ext}^i_{R[x]}(R[x] \otimes_R M, N) \to \mathrm{Ext}^{i+1}_{R[x]}(M, N)$$
$$\to \mathrm{Ext}^{i+1}_{R[x]}(R[x] \otimes_R M, N) \xrightarrow{\alpha^*} \mathrm{Ext}^{i+1}_{R[x]}(R[x] \otimes_R M, N) \to \cdots$$

in which α^* is the map induced by α.

Step 3: The upper bound $\mathrm{gldim}(R[x]) \leq \mathrm{gldim}(R) + 1$. If $\mathrm{gldim}(R) = \infty$, the right-hand side is infinite. Otherwise put $n = \mathrm{gldim}(R)$, and let M be an $R[x]$-module. As an R-module, M has $\mathrm{pd}_R(M) \leq n$ by definition 58.2.3, so $\mathrm{pd}_{R[x]}(R[x] \otimes_R M) \leq n$ by Step 2, and by lemma 58.2.4 the groups $\mathrm{Ext}^i_{R[x]}(R[x] \otimes_R M, N)$ vanish for every $R[x]$-module N and every $i \geq n+1$. In the long exact sequence of Step 2 with $i = n+1$, the terms on either side of $\mathrm{Ext}^{n+2}_{R[x]}(M, N)$ are therefore zero, and exactness reads

$$0 \to \mathrm{Ext}^{n+2}_{R[x]}(M, N) \to 0$$

So $\mathrm{Ext}^{n+2}_{R[x]}(M, N) = 0$ for every $R[x]$-module N, and lemma 58.2.4 gives $\mathrm{pd}_{R[x]}(M) \leq n+1$. Because this holds for all $R[x]$-modules, $\mathrm{gldim}(R[x]) \leq n+1$.

Step 4: Let M and K be R-modules, regarded as $R[x]$-modules on which x acts as 0. If $\mathrm{Ext}^i_R(M, K) \neq 0$ for some $i \geq 0$, then $\mathrm{Ext}^{i+1}_{R[x]}(M, K) \neq 0$. Choose a projective resolution $P_\bullet \to M$ over R. By Step 2, $R[x] \otimes_R P_\bullet$ is a projective resolution of $R[x] \otimes_R M$ over $R[x]$. Restriction along $p \mapsto 1 \otimes p$ gives isomorphisms

$$\mathrm{Hom}_{R[x]}(R[x] \otimes_R P_j, K) \cong \mathrm{Hom}_R(P_j, K)$$

by corollary 15.3.5, and they commute with the differentials, since $(1 \otimes d)(1 \otimes p) = 1 \otimes d(p)$. Taking cohomology, theorem 56.5.8 on both sides gives

$$\mathrm{Ext}^i_{R[x]}(R[x] \otimes_R M, K) \cong \mathrm{Ext}^i_R(M, K) \quad \text{for all } i \geq 0$$

Since $xM = 0$, the map α of Step 1 is $\alpha(f(x) \otimes m) = xf(x) \otimes m$, which is multiplication by x on $R[x] \otimes_R M$. Write μ for multiplication by x on each $R[x] \otimes_R P_j$. It commutes with the $R[x]$-linear differentials and augmentation, so it is a morphism of resolutions lifting α. By proposition 56.2.15 every lift of α is homotopic to μ, and homotopic morphisms induce the same map after applying $\mathrm{Hom}_{R[x]}(-, K)$ and taking cohomology (lemma 56.1.32, proposition 56.1.29). So α^* on $\mathrm{Ext}^i_{R[x]}(R[x] \otimes_R M, K)$ is induced by the cochain map $\psi \mapsto \psi \circ \mu$ on $\mathrm{Hom}_{R[x]}(R[x] \otimes_R P_\bullet, K)$. That cochain map is zero: $(\psi \circ \mu)(z) = \psi(xz) = x\psi(z) = 0$ for every z, because ψ is $R[x]$-linear and $xK = 0$. Hence $\alpha^* = 0$ in every degree.

The long exact sequence of Step 2 with $N = K$ therefore breaks into short exact sequences, one for each $i \geq 0$, which read

$$0 \to \mathrm{Ext}^i_R(M, K) \to \mathrm{Ext}^{i+1}_{R[x]}(M, K) \to \mathrm{Ext}^{i+1}_R(M, K) \to 0$$

after the isomorphism above. The injection on the left gives the claim.

Step 5: The lower bound gldim$(R[x]) \geq$ gldim$(R)+1$. Let $m \geq 0$ be an integer with $m \leq \mathrm{gldim}(R)$. Some R-modules M and K satisfy $\mathrm{Ext}^m_R(M, K) \neq 0$. For $m = 0$ take $M = K = R$: computing with the projective resolution $0 \to R \xrightarrow{\mathrm{id}} R \to 0$, theorem 56.5.8 gives $\mathrm{Ext}^0_R(R, R) \cong \mathrm{Hom}_R(R, R)$, which contains $\mathrm{id}_R \neq 0$ because $R \neq 0$. For $m \geq 1$, $\mathrm{gldim}(R) > m - 1$, so by definition 58.2.3 some R-module M has $\mathrm{pd}_R(M) > m - 1$, and lemma 58.2.4, applied with $m - 1$ in place of m, gives an R-module K with $\mathrm{Ext}^m_R(M, K) \neq 0$.

Regard M and K as $R[x]$-modules on which x acts as 0. By Step 4, $\mathrm{Ext}^{m+1}_{R[x]}(M, K) \neq 0$, so $\mathrm{pd}_{R[x]}(M) > m$ by lemma 58.2.4, and $\mathrm{gldim}(R[x]) \geq m + 1$. If $\mathrm{gldim}(R) = n$ is finite, the case $m = n$ gives $\mathrm{gldim}(R[x]) \geq n + 1$. If $\mathrm{gldim}(R) = \infty$, every $m \geq 0$ is allowed, and $\mathrm{gldim}(R[x]) = \infty$.

Combining the upper and lower bounds gives $\mathrm{gldim}(R[x]) = \mathrm{gldim}(R) + 1$, completing the proof.

Hilbert's theorem is effectively the calculation of the global dimension of polynomial rings.

Theorem 58.2.6: Hilbert's Syzygy Theorem

Let k be a field and $R = k[x_1, \ldots, x_n]$ be the polynomial ring in n variables. Then every finitely generated R-module has finite projective dimension, and:

$$\mathrm{gldim}(R) = n$$

***Proof*:**
For $n = 0$, $R = k$ is a field, over which every module is free, so $\mathrm{gldim}(k) = 0$. For $n \geq 1$, write $R = S[x_n]$ with $S = k[x_1, \ldots, x_{n-1}]$. By induction on n, $\mathrm{gldim}(S) = n - 1$, and theorem 58.2.5, applied to the nonzero ring S, gives $\mathrm{gldim}(R) = \mathrm{gldim}(S) + 1 = n$. By definition 58.2.3, every R-module, finitely generated or not, therefore has projective dimension at most n.

The residue field $k \cong R/(x_1, \dots, x_n)$ attains this bound. Let V be a k-vector space of dimension n with basis $e_1, \dots, e_n$. The *Koszul complex* of $x_1, \dots, x_n$ is $\bigwedge^\bullet V \otimes_k R$, augmented to k:

$$0 \to \bigwedge^n V \otimes R \xrightarrow{d_n} \dots \xrightarrow{d_2} \bigwedge^1 V \otimes R \xrightarrow{d_1} R \xrightarrow{\epsilon} k \to 0$$

where d_i sends $e_{j_1} \wedge \cdots \wedge e_{j_i} \otimes 1$ to $\sum_{s=1}^{i} (-1)^{s+1} x_{j_s}\, e_{j_1} \wedge \cdots \wedge \widehat{e_{j_s}} \wedge \cdots \wedge e_{j_i} \otimes 1$, so that $d_1(e_i \otimes 1) = x_i$. Because the variables $x_1, \dots, x_n$ form a regular sequence, this complex is exact (example 16.5.6), so it is a free resolution of k of length n and $\mathrm{pd}_R(k) \leq n$. For the reverse inequality, compute $\mathrm{Tor}_n^R(k,k)$ with this resolution. Every d_i has its matrix entries in $(x_1, \dots, x_n)$, so after applying $- \otimes_R k$ every differential vanishes, and $\mathrm{Tor}_n^R(k,k) \cong \bigwedge^n V \cong k \neq 0$. A projective resolution of k of length at most $n-1$ would compute $\mathrm{Tor}_n^R(k,k) = 0$, so $\mathrm{pd}_R(k) = n$, completing the proof.

This theorem has implications beyond just counting relations:

1. *Degree of the Hilbert Polynomial:* Hilbert originally used this theorem to prove that the Hilbert Function $H_M(t) = \dim_k(M_t)$ of a graded module eventually becomes a polynomial. The finite resolution allows us to calculate $H_M(t)$ as an alternating sum of the Hilbert functions of free modules, which are essentially binomial coefficients $\binom{t+k}{k}$.
2. *Structure of Projective Modules:* A celebrated problem posed by Serre (related to this theorem) asked if every projective module over $k[x_1, \dots, x_n]$ is free. This is the algebraic analogue of "vector bundles over affine space are trivial". This was solved affirmatively in 1976 (the *Quillen-Suslin Theorem*). This implies that over polynomial rings, "projective resolution" and "free resolution" are synonymous.

58.2.2 Dimension of Local Rings

Computing the global dimension for general rings seems daunting, as one must check *every* module. However, we can simplify this task using derived functors.

Proposition 58.2.7: Detecting Projective Dimension with Tor

Let R be a ring, M a right R-module and $n \geq 0$ an integer, and consider the conditions

1. $\mathrm{pd}_R(M) \leq n$
2. $\mathrm{Tor}_i^R(M, N) = 0$ for all left R-modules N and all $i > n$.
3. $\mathrm{Tor}_{n+1}^R(M, N) = 0$ for all left R-modules N.

Then (1) implies (2), and (2) implies (3). If R is commutative and Noetherian and M is finitely generated, then (3) implies (1), so the three conditions are equivalent.

***Proof*:**

For a projective resolution $\cdots \to P_1 \to P_0 \to M \to 0$, theorem 56.5.8 computes $\mathrm{Tor}_i^R(M, N)$ as $H_i(P_\bullet \otimes_R N)$, the homology at the term $P_i \otimes_R N$.

Step 1: (1) implies (2), and (2) implies (3). If $\operatorname{pd}_R(M) \leq n$, then definition 58.2.2 gives a projective resolution of M with $P_i = 0$ for every $i > n$. For $i > n$ the module $P_i \otimes_R N$ is zero, and so is $\operatorname{Tor}_i^R(M, N)$. Condition (3) is the case $i = n + 1$ of (2).

Step 2: A resolution by finitely generated free modules. From here on R is commutative and Noetherian, M is finitely generated, and (3) holds. Then M has a projective resolution

$$\cdots \to P_2 \xrightarrow{d_2} P_1 \xrightarrow{d_1} P_0 \xrightarrow{d_0} M \to 0$$

in which every P_j is a finitely generated free module. To build it, write M as a quotient of a finitely generated free module P_0. Every submodule of a finitely generated module over the Noetherian ring R is finitely generated [7, Props. 6.2 and 6.5], so $\ker(d_0)$ is a quotient of a finitely generated free module P_1. The same argument applied to $\ker(d_j)$ produces P_{j+1} and d_{j+1} for every $j \geq 1$.

Step 3: Dimension shifting. Put $K_n = \operatorname{im}(d_n)$, and let $\pi \colon P_n \to K_n$ be the map d_n with codomain K_n. The complex

$$\cdots \to P_{n+2} \xrightarrow{d_{n+2}} P_{n+1} \xrightarrow{d_{n+1}} P_n \xrightarrow{\pi} K_n \to 0$$

is exact: π is onto, $\ker(\pi) = \ker(d_n) = \operatorname{im}(d_{n+1})$, and exactness at the remaining terms is that of the resolution of M. So $Q_j = P_{n+j}$ is a projective resolution of K_n. For $j \geq 1$ the homology of $Q_\bullet \otimes_R N$ at $Q_j \otimes_R N$ is computed from

$$P_{n+j+1} \otimes_R N \xrightarrow{d_{n+j+1} \otimes 1} P_{n+j} \otimes_R N \xrightarrow{d_{n+j} \otimes 1} P_{n+j-1} \otimes_R N$$

and the same two maps compute the homology of $P_\bullet \otimes_R N$ at $P_{n+j} \otimes_R N$. By theorem 56.5.8, applied to both resolutions, and by (3),

$$\operatorname{Tor}_1^R(K_n, N) \cong \operatorname{Tor}_{n+1}^R(M, N) = 0$$

for every R-module N.

Step 4: K_n is flat. Let $\psi \colon N' \to N$ be an injective homomorphism of R-modules with cokernel N'', and put $T = K_n \otimes_R -$. Since R-modules have projective resolutions (example 56.2.2(4)), theorem 56.3.11 applies to T and to the short exact sequence $0 \to N' \to N \to N'' \to 0$, and gives an exact sequence

$$L_1T(N'') \to L_0T(N') \xrightarrow{L_0T(\psi)} L_0T(N)$$

By definition 56.3.5, $L_1T(N'')$ is $H_1(K_n \otimes_R P''_\bullet)$ for a projective resolution $P''_\bullet$ of N'', which is $\operatorname{Tor}_1^R(K_n, N'') = 0$ by theorem 56.5.8 and Step 3. So $L_0T(\psi)$ is injective. The functor T is right exact (theorem 17.5.1), so L_0T is naturally isomorphic to T by proposition 56.3.13, and $T(\psi) = 1 \otimes \psi$ is injective as well. As ψ was an arbitrary injection, K_n is flat (proposition 17.5.3).

Step 5: (3) implies (1). The exact sequence $P_{n+1} \to P_n \to K_n \to 0$ of Step 3, with P_{n+1} and P_n finitely generated free, shows that K_n is finitely presented. A finitely presented flat module is projective [101, Thm. 3.2.7], so K_n is projective by Step 4. If $n = 0$, then $M = K_0$ is projective and $\operatorname{pd}_R(M) = 0$. If $n \geq 1$, then $K_n = \ker(d_{n-1})$, and

$$0 \to K_n \to P_{n-1} \to \cdots \to P_1 \to P_0 \to M \to 0$$

is a projective resolution of length n. In both cases $\operatorname{pd}_R(M) \leq n$ by definition 58.2.2, completing the proof.

Without the hypotheses on R and M, (3) does not imply (1). The $\mathbb{Z}$-module $\mathbb{Q}$ is torsion-free, hence flat (theorem 17.5.7), so the exact functor $\mathbb{Q}\otimes_{\mathbb{Z}} -$ keeps a projective resolution $P_\bullet \to N$ of any abelian group N exact, and $\operatorname{Tor}_1^{\mathbb{Z}}(\mathbb{Q}, N) \cong H_1(\mathbb{Q}\otimes_{\mathbb{Z}} P_\bullet) = 0$ by theorem 56.5.8. This is (3) for $n = 0$. Yet $\mathbb{Q}$ is not projective: over the principal ideal domain $\mathbb{Z}$ projective modules are free (proposition 17.2.11), every element of $\mathbb{Q}$ is twice an element of $\mathbb{Q}$, and a basis element e of a nonzero free abelian group is not twice any element, since the coefficient of e in $2v$ is even. The ring $\mathbb{Z}$ is Noetherian, so finite generation of M is the hypothesis that fails.

It is more common that we consider rings that already have certain properties and verify how these conditions affect the global dimension. For example, given a local ring, the work is significantly reduced. In the local case, we can verify condition (3) by checking a *single* module: the residue field.

Lemma 58.2.8: Projective Dimension over Local Rings

Let $(R, \mathfrak{m}, k)$ be a local Noetherian ring and M a finitely generated R-module. Then:

$$\operatorname{pd}_R(M) \le n \iff \operatorname{Tor}_{n+1}^R(M, k) = 0$$

Consequently, $\operatorname{pd}_R(M)$ is the smallest n such that $\operatorname{Tor}_i^R(M, k) = 0$ for all $i > n$.

***Proof*:**
The forward direction is immediate from proposition 58.2.7. For the converse, let $\cdots \to P_1 \to P_0 \to M \to 0$ be a *minimal* free resolution, meaning that every P_i is free of finite rank β_i and the matrices of the maps $P_{i+1} \to P_i$ have entries in $\mathfrak{m}$.

Such a resolution exists. Choose $m_1, \dots, m_\beta \in M$ whose images form a k-basis of $M/\mathfrak{m}M$. They generate M by lemma 23.4.29, so $e_i \mapsto m_i$ defines a surjection $R^\beta \to M$. Its kernel lies in $\mathfrak{m}R^\beta$, since a relation $\sum_i a_i m_i = 0$ reduces modulo $\mathfrak{m}$ to a relation among the basis vectors of $M/\mathfrak{m}M$, which forces every a_i into $\mathfrak{m}$. As a submodule of a finitely generated module over the Noetherian ring R, the kernel is finitely generated [7, Props. 6.2 and 6.5], so the same construction applies to it in place of M. Continuing in this way produces a free resolution in which the image of each map $P_{i+1} \to P_i$ is the kernel of $P_i \to P_{i-1}$ (of $P_0 \to M$ when $i = 0$), which lies in $\mathfrak{m}P_i$. So every matrix entry lies in $\mathfrak{m}$.

The differentials in the complex $P_\bullet \otimes_R k$ are therefore all zero maps, and by theorem 56.5.8

$$\operatorname{Tor}_i^R(M, k) \cong H_i(P_\bullet \otimes k) \cong P_i \otimes k \cong k^{\beta_i}$$

If $\operatorname{Tor}_{n+1}^R(M, k) = 0$, then $k^{\beta_{n+1}} = 0$, so $\beta_{n+1} = 0$ and $P_{n+1} = 0$. The map $P_n \to P_{n-1}$ (the map $P_0 \to M$ when $n = 0$) then has kernel equal to the image of $P_{n+1} = 0$, so $0 \to P_n \to \cdots \to P_0 \to M \to 0$ is a projective resolution of length n, and $\operatorname{pd}_R(M) \le n$ by definition 58.2.2. For the consequence, the forward direction applied with $i - 1$ in place of n gives $\operatorname{Tor}_i^R(M, k) = 0$ for every $i > \operatorname{pd}_R(M)$, and if $\operatorname{Tor}_i^R(M, k) = 0$ for all $i > n$, then the converse, applied to $\operatorname{Tor}_{n+1}^R(M, k) = 0$, gives $\operatorname{pd}_R(M) \le n$.

This leads to the fundamental equality attributed to Auslander, Buchsbaum, and Serre, which connects the homological algebra back to the geometry of the ring.

Theorem 58.2.9: Auslander-Buchsbaum-Serre Theorem

Let $(R, \mathfrak{m}, k)$ be a local Noetherian ring. Then the global dimension is determined by the residue field:

$$\operatorname{gldim}(R) = \operatorname{pd}_R(k)$$

Furthermore, $\operatorname{gldim}(R)$ is finite if and only if R is a *regular local ring*, that is, if and only if $\mathfrak{m}$ can be generated by $\dim R$ elements ([20, Regular Local Ring]).

This theorem is the bridge between algebra and geometry. Regularity is a condition on the number of generators of $\mathfrak{m}$, equivalently on the associated graded ring ([20, Characterizations of a Regular Local Ring]), while global dimension is a homological condition on resolutions. Geometrically the regular local rings are the local rings at the nonsingular points of a variety, which is the reading [42] develops.

***Proof*:**
By definition 58.2.3, $\operatorname{gldim}(R) \geq \operatorname{pd}_R(k)$, which settles the case $\operatorname{pd}_R(k) = \infty$. Otherwise let $n = \operatorname{pd}_R(k)$, and let M be any finitely generated R-module. By lemma 58.2.8, $\operatorname{pd}_R(M) \leq n$ holds once $\operatorname{Tor}^R_{n+1}(M, k) = 0$. Since $\operatorname{pd}_R(k) = n$, definition 58.2.2 gives a projective resolution $Q_\bullet$ of k with $Q_i = 0$ for every $i > n$. Computing with this resolution of the second variable, theorem 56.5.8 gives

$$\operatorname{Tor}^R_{n+1}(M, k) \cong H_{n+1}(M \otimes_R Q_\bullet) = 0$$

because the term $M \otimes_R Q_{n+1}$ is zero. Hence $\operatorname{pd}_R(M) \leq n$. This holds for every finitely generated M, in particular for every cyclic module R/I. By the Global Dimension Theorem [101, Thm. 4.1.2], $\operatorname{gldim}(R)$ is the supremum of $\operatorname{pd}_R(R/I)$ over the ideals I of R, so $\operatorname{gldim}(R) \leq n$, and hence $\operatorname{gldim}(R) = n$.

For the second statement, a regular local ring has $\operatorname{gldim}(R) = \dim R$, finite, by corollary 58.2.17, whose proof draws on this theorem only for its first statement. The converse, that finite global dimension forces R to be regular, is Serre's theorem [101, Main Thm. 4.4.16].

Definition 58.2.10: Regular Ring

A Noetherian ring A is *regular* if $A_\mathfrak{p}$ is a regular local ring for every prime ideal $\mathfrak{p}$ of A.

Lemma 58.2.11: Localization Does Not Raise Global Dimension

Let A be a commutative ring and $S \subseteq A$ a multiplicative set. Every $S^{-1}A$-module M, regarded as an A-module through $A \to S^{-1}A$, satisfies $\operatorname{pd}_{S^{-1}A}(M) \leq \operatorname{pd}_A(M)$. Consequently

$$\operatorname{gldim}(S^{-1}A) \leq \operatorname{gldim}(A)$$

***Proof*:**
Let M be an $S^{-1}A$-module. If $\operatorname{pd}_A(M) = \infty$ there is nothing to prove. Otherwise put $n = \operatorname{pd}_A(M)$ and choose, by definition 58.2.2, a projective resolution

$$0 \to P_n \to \cdots \to P_1 \to P_0 \to M \to 0$$

over A. Localization at S preserves short exact sequences (proposition 23.4.9), hence every exact sequence, since an exact sequence is spliced from short exact sequences through its images. So

$$0 \to S^{-1}P_n \to \cdots \to S^{-1}P_1 \to S^{-1}P_0 \to S^{-1}M \to 0$$

is an exact sequence of $S^{-1}A$-modules. Each $S^{-1}P_i$ is projective over $S^{-1}A$: if $P_i \oplus Q \cong A^{(I)}$ for an A-module Q and a set I, then $S^{-1}P_i \oplus S^{-1}Q \cong (S^{-1}A)^{(I)}$, because localization commutes with direct sums.

The localized sequence ends in $S^{-1}M$, and the map $\varphi\colon M \to S^{-1}M$, $\varphi(m) = m/1$, is an isomorphism of $S^{-1}A$-modules. An element $s \in S$ acts on M as the unit $s/1$ of $S^{-1}A$. For $a \in A$ and $s \in S$, the element $m' = (a/s)m$ of M satisfies $sm' = am$, so

$$\frac{a}{s} \cdot \varphi(m) = \frac{am}{s} = \frac{sm'}{s} = \frac{m'}{1} = \varphi\Big(\frac{a}{s}\, m\Big)$$

and φ is $S^{-1}A$-linear. It is injective, since $m/1 = 0$ means $um = 0$ for some $u \in S$, and u acts on M invertibly. It is surjective, since the display with $a = 1$ reads $m/s = \varphi\big((1/s)m\big)$. Composing the augmentation with φ^{-1} turns the localized sequence into a projective resolution of M over $S^{-1}A$ of length n, so $\operatorname{pd}_{S^{-1}A}(M) \le n$.

By definition 58.2.3, $\operatorname{gldim}(S^{-1}A)$ is the supremum of $\operatorname{pd}_{S^{-1}A}(M)$ over all $S^{-1}A$-modules M, and each of these is at most $\operatorname{pd}_A(M) \le \operatorname{gldim}(A)$, completing the proof.

Combined with theorem 58.2.9, the lemma shows that a Noetherian ring A of finite global dimension is regular, since each $A_\mathfrak{p}$ is then a Noetherian local ring of global dimension at most $\operatorname{gldim}(A)$.

Corollary 58.2.12: Polynomial Rings over Regular Rings Are Regular

Let A be a regular ring. Then the polynomial ring $A[t_1, \dots, t_n]$ is a regular ring for every $n \ge 0$.

***Proof*:**
Since $A[t_1, \dots, t_n] = A[t_1, \dots, t_{n-1}][t_n]$, induction on n reduces the claim to $n = 1$. Write t for the variable. The ring $A[t]$ is Noetherian by Hilbert's Basis Theorem (theorem 23.2.1).

Let P be a prime ideal of $A[t]$ and $\mathfrak{p} = P \cap A$, a prime ideal of A. The multiplicative set $A \setminus \mathfrak{p}$ is contained in $A[t] \setminus P$, and inverting it coefficientwise gives $(A \setminus \mathfrak{p})^{-1}A[t] = A_\mathfrak{p}[t]$. Let T be the image of $A[t] \setminus P$ in $A_\mathfrak{p}[t]$. By the universal property of localization (theorem 23.4.1), both $T^{-1}(A_\mathfrak{p}[t])$ and $A[t]_P$ are initial among $A[t]$-algebras in which every element of $A[t] \setminus P$ becomes a unit. Hence $A[t]_P \cong T^{-1}(A_\mathfrak{p}[t])$ is a localization of $A_\mathfrak{p}[t]$.

The ring $A_\mathfrak{p}$ is a regular local ring by definition 58.2.10, in particular Noetherian and local, so the implication from regularity to finite global dimension in theorem 58.2.9 gives $\operatorname{gldim}(A_\mathfrak{p}) < \infty$. Then lemma 58.2.11 and theorem 58.2.5 give

$$\operatorname{gldim}(A[t]_P) \le \operatorname{gldim}(A_\mathfrak{p}[t]) = \operatorname{gldim}(A_\mathfrak{p}) + 1 < \infty$$

The ring $A[t]_P$ is local, and it is Noetherian as a localization of the Noetherian ring $A[t]$ (proposition 23.4.5). The implication from finite global dimension to regularity in theorem 58.2.9 therefore makes $A[t]_P$ a regular local ring. As P was an arbitrary prime of $A[t]$, the Noetherian ring $A[t]$ is regular.

Geometrically, $\operatorname{Spec} A[t_1, \dots, t_n] = \operatorname{Spec} A \times_{\operatorname{Spec} \mathbb{Z}} \mathbb{A}^n_{\mathbb{Z}}$, so the product of a regular affine scheme with affine n-space is regular.

58.2.3 Beyond Regularity: The Hierarchy of Singularities

The Auslander-Buchsbaum-Serre theorem (theorem 58.2.9) presents a stark dichotomy: a local ring either has finite global dimension (and is geometrically smooth), or its global dimension is completely infinite.

For decades, algebraists sought to understand the "infinite" case. If a ring is singular, just *how* singular is it? How chaotic do the infinite free resolutions become? This inquiry led to a classification of local Noetherian rings, a hierarchy that measures the severity of singularities based on homological behavior.

To properly measure the complexity of rings that fail to be regular, we need to formalize the notion of a regular sequence:

Definition 58.2.13: Regular Sequence

Let R be a ring and M an R-module. A sequence of elements $x_1, \dots, x_n \in R$ is called an *M-regular sequence* if:

1. $(x_1, \dots, x_n)M \neq M$
2. For $i = 1, \dots, n$, the element x_i is not a zero-divisor on the quotient module $M/(x_1, \dots, x_{i-1})M$.

Intuitively, a regular sequence is a sequence of elements that "cut down" the dimension of the module as cleanly and efficiently as possible, without creating any hidden nilpotent. This allows us to define a new homological invariant.

Definition 58.2.14: Depth

Let $(R, \mathfrak{m})$ be a local Noetherian ring and M a finitely generated R-module. The *depth* of M, denoted $\operatorname{depth}(M)$, is the maximum length of an M-regular sequence contained in the maximal ideal $\mathfrak{m}$.

Depth is always bounded above by the Krull dimension ($\operatorname{depth}(R) \leq \operatorname{kdim}(R)$). The gap between a ring's depth and its dimension is one of the primary ways we measure how "bad" a singularity is.

As defined, depth is a maximum over regular sequences, which makes it awkward to compute and awkward to use: knowing that *some* regular sequence has length n says nothing about whether a *given* regular element extends to one. Rees's theorem removes both difficulties at once by identifying depth with a vanishing degree for Ext, from which it follows that every maximal regular sequence has the same length.

Theorem 58.2.15: Depth via Ext (Rees)

Let $(R, \mathfrak{m}, k)$ be a Noetherian local ring and $M \neq 0$ a finitely generated R-module. If $x_1, \dots, x_n \in \mathfrak{m}$ is an M-regular sequence, then

$$\operatorname{Ext}^i_R(k, M) = 0 \text{ for } i < n, \qquad \operatorname{Ext}^n_R(k, M) \cong \operatorname{Hom}_R\big(k,\, M/(x_1, \dots, x_n)M\big)$$

Consequently every maximal M-regular sequence in $\mathfrak{m}$ has length $\min\big\{i \mid \operatorname{Ext}^i_R(k, M) \neq 0\big\}$, and in particular they all have the same length, namely $\operatorname{depth}(M)$.

***Proof*:**

Step 1: $\mathfrak{m}$ acts as zero on $\operatorname{Ext}^i_R(k, M)$. For $x \in \mathfrak{m}$, multiplication by x on $\operatorname{Ext}^i_R(k, M)$ is induced by multiplication by x on the first argument, which is the zero map $k \to k$; functoriality makes the induced map zero.

Step 2: the displayed formulas, by induction on n. For $n = 0$ there is nothing to prove, $\operatorname{Ext}^0_R(k, M) \cong \operatorname{Hom}_R(k, M)$ by proposition 56.3.13. Let $n \geq 1$ and put $M' = M/x_1M$, which is nonzero by Nakayama's lemma. As x_1 is a non-zero divisor on M, there is a short exact sequence

$$0 \to M \xrightarrow{x_1} M \to M' \to 0$$

and corollary 56.3.12, applied to $\operatorname{Hom}_R(k, -)$, gives a long exact sequence in which every map induced by x_1 vanishes by Step 1. It therefore breaks into short exact sequences

$$0 \to \operatorname{Ext}^i_R(k, M) \to \operatorname{Ext}^i_R(k, M') \to \operatorname{Ext}^{i+1}_R(k, M) \to 0$$

for every i. Now $x_2, \dots, x_n$ is an M'-regular sequence of length $n-1$, so by induction $\operatorname{Ext}^i_R(k, M') = 0$ for $i < n-1$ and $\operatorname{Ext}^{n-1}_R(k, M') \cong \operatorname{Hom}_R(k, M/(x_1, \dots, x_n)M)$. Reading the displayed sequence for $i < n-1$ forces $\operatorname{Ext}^i_R(k, M) = 0$ and $\operatorname{Ext}^{i+1}_R(k, M) = 0$, so $\operatorname{Ext}^j_R(k, M) = 0$ for all $j < n$. Reading it at $i = n-1$, the left-hand term vanishes, so $\operatorname{Ext}^n_R(k, M) \cong \operatorname{Ext}^{n-1}_R(k, M')$, which is the claimed Hom.

Step 3: maximality. A regular sequence $x_1, \dots, x_n$ is maximal exactly when no element of $\mathfrak{m}$ is a non-zero divisor on $N = M/(x_1, \dots, x_n)M$, that is when $\mathfrak{m}$ consists of zero-divisors on N. The zero-divisors on N are the union of its associated primes ([20, The Zero-Divisors Are the Union of the Associated Primes]), of which there are finitely many ([20, Finiteness of Associated Primes]), so prime avoidance ([20, Prime Avoidance]) makes this equivalent to $\mathfrak{m} \in \operatorname{Ass}(N)$, that is to $\operatorname{Hom}_R(k, N) \neq 0$. By Step 2 that says $\operatorname{Ext}^n_R(k, M) \neq 0$, while $\operatorname{Ext}^i_R(k, M) = 0$ for $i < n$. So n is the least degree in which $\operatorname{Ext}^\bullet_R(k, M)$ is nonzero, a quantity independent of the sequence chosen, completing the proof.

Two consequences are immediate and are used throughout what follows: a given M-regular sequence in $\mathfrak{m}$ extends to one of length $\operatorname{depth}(M)$, since any maximal extension of it has that length; and $\operatorname{depth}(M) = 0$ exactly when $\mathfrak{m} \in \operatorname{Ass}(M)$.

Using this, we can make the Auslander-Buchsbaum-Serre theorem more refined by looking at modules over R:

Theorem 58.2.16: Auslander-Buchsbaum Formula

Let $(R, \mathfrak{m}, k)$ be a local Noetherian ring, and let M be a non-zero finitely generated R-module with finite projective dimension. Then:

$$\mathrm{pd}_R(M) + \mathrm{depth}(M) = \mathrm{depth}(R)$$

***Proof Key ideas*:**
The proof is an induction on $\mathrm{depth}(M)$ whose steps are standard commutative algebra rather than homological algebra; it is given in full in *An Introduction to Homological Algebra* [101, Thm. 4.4.15].

The base case is $\mathrm{depth}(M) = 0$, where $\mathfrak{m}$ is an associated prime of M and one shows $\mathrm{pd}_R(M) = \mathrm{depth}(R)$ directly from a minimal free resolution: the length of that resolution is detected by $\mathrm{Tor}_i^R(M, k)$ against the residue field (lemma 58.2.8), and the depth of R bounds where those groups can survive.

The inductive step reduces the depth of M by one. If $\mathrm{depth}(M) > 0$ and $\mathrm{depth}(R) > 0$, prime avoidance applied to $\mathrm{Ass}(R) \cup \mathrm{Ass}(M)$ produces an $x \in \mathfrak{m}$ regular on both M and R; passing to M/xM over $R/(x)$ drops both $\mathrm{depth}(M)$ and $\mathrm{depth}(R)$ by one while leaving pd unchanged, so the formula for the quotient gives the formula for M. The remaining case is $\mathrm{depth}(R) = 0$, handled separately: there finite projective dimension forces M to be free, so both sides of the formula vanish.

The two theorems combine into the numerical statement that the applications actually use: for a regular local ring the global dimension is not merely finite, it is the Krull dimension.

Corollary 58.2.17: Global Dimension of a Regular Local Ring

Let $(R, \mathfrak{m}, k)$ be a Noetherian regular local ring of dimension m. Then

$$\mathrm{gldim}(R) \;=\; \mathrm{depth}(R) \;=\; \dim R \;=\; m$$

In particular every finitely generated R-module has projective dimension at most $\dim R$.

***Proof*:**
Step 1: $\mathfrak{m}$ is generated by a regular sequence of length m. Choose $x_1, \dots, x_m$ generating $\mathfrak{m}$, possible by regularity, and induct on m. For $m = 0$ the sequence is empty. For $m > 0$, a regular local ring is a domain ([20, A Regular Local Ring Is a Domain]), and $x_1 \neq 0$: regularity makes $\dim_k \mathfrak{m}/\mathfrak{m}^2 = m$, so an m-element generating set of $\mathfrak{m}$ is minimal and none of its members can vanish. Hence x_1 is a nonzerodivisor; hence $\dim R/(x_1) = m - 1$ by [20, One Equation Cuts Dimension by One], applicable because R is local. The maximal ideal of $R/(x_1)$ is generated by the $m - 1$ images of $x_2, \dots, x_m$, so $R/(x_1)$ is regular local of dimension $m - 1$, and by induction those images form a regular sequence. Prefixing x_1 gives the claim.

Step 2: $\mathrm{depth}(R) = m$. That regular sequence lies in $\mathfrak{m}$ and has length m, so $\mathrm{depth}(R) \geq m$; and $\mathrm{depth}(R) \leq \dim R = m$ by corollary 58.2.21.

Step 3: $\mathrm{pd}_R(k)$ is finite and at most m. By Step 1 and [21, Exactness of the Koszul Complex], the Koszul complex on $x_1, \ldots, x_m$ is a finite free resolution of $R/\mathfrak{m} = k$ of length m. So $\mathrm{pd}_R(k) \leq m$.

Step 4: assembly. Theorem 58.2.9 gives $\mathrm{gldim}(R) = \mathrm{pd}_R(k)$, finite by Step 3, so the Auslander-Buchsbaum formula (theorem 58.2.16) applies to $M = k$. Every element of $\mathfrak{m}$ annihilates the nonzero module k and is therefore a zerodivisor on it, so no element of $\mathfrak{m}$ is k-regular and $\mathrm{depth}(k) = 0$. The formula reads $\mathrm{gldim}(R) = \mathrm{depth}(R)$, which is m by Step 2.

Using depth and other structural properties, local rings can be classified into a strict chain of implications:

$$\text{Regular} \implies \text{Complete Intersection} \implies \text{Gorenstein} \implies \text{Cohen-Macaulay}$$

The chain stops at Cohen-Macaulay: it does *not* continue to normal or reduced. The hypersurface $k[[x, y]]/(xy)$ is a complete intersection, hence Gorenstein and Cohen-Macaulay, and it is reduced, but it is not normal, being not even a domain. By Serre's criterion (theorem 58.3.2) normality is the conjunction of R_1 and S_2; Cohen-Macaulay gives S_2 and says nothing about R_1, which is where the implication fails. The correct companion chain runs

$$\text{Regular} \implies \text{Normal} \implies \text{Reduced}$$

While these definitions are strictly for *local* rings, we say a Noetherian ring has one of these properties if its localization at every prime ideal has it (for regularity this is definition 58.2.10).

Complete Intersections: These are the "nicest" singularities. Geometrically, they are spaces cut out by exactly the correct number of equations (e.g., a 1D curve in $\mathbb{C}^3$ defined by exactly two equations). Algebraically, R is the quotient of a regular local ring by a regular sequence. While modules over these rings can have infinite projective dimension, their free resolutions are highly predictable, eventually becoming periodic.

Gorenstein Rings: These rings represent spaces with "symmetric" singularities. They are exactly the spaces where a generalized form of Poincaré Duality still holds. Algebraically, a local ring is Gorenstein if it has finite injective dimension over itself. The free resolutions over Gorenstein rings exhibit a mirror symmetry when the functor $\mathrm{Hom}_R(-, R)$ is applied.

Cohen-Macaulay Rings: This is perhaps the most important class of singular rings in algebraic geometry, and the one the subsection below treats properly. A local ring is Cohen-Macaulay if its depth equals its Krull dimension (definition 58.2.18). Geometrically, these spaces are "equidimensional" and lack hidden, embedded fuzzy components. Here, the Auslander-Buchsbaum formula perfectly aligns with the geometric dimension.

Normal Rings: A ring is normal if it is integrally closed in its total ring of fractions. Geometrically, this means the space is "smooth in codimension 1". For example, a 2D normal surface can have an isolated singular point (like the tip of a cone), but it cannot have a singular crease or folded line running through it.

Reduced Rings: A ring is reduced if it contains no non-zero nilpotents ($x^n = 0 \implies x = 0$). Geometrically, this simply means the space has no "thickness" or "fuzz"; it is a classical geometric space uniquely determined by the values of functions at its points.

58.2.4 Cohen-Macaulay Rings

Of the classes just listed, Cohen-Macaulay is the one downstream geometry actually uses, and it deserves more than a description. Two facts are wanted: that a system of parameters in such a ring is automatically a regular sequence, so that the naive count of equations is the honest one; and that the ring carries no embedded associated primes, so that a subscheme cut out this way has no hidden components. Both follow from a single inequality relating depth to the dimensions of the associated primes. Associated primes, prime avoidance, and the identification of the zero-divisors with the union of the associated primes are those of [20, Associated Prime, Prime Avoidance, Zero-Divisors and Annihilators].

Definition 58.2.18: Cohen-Macaulay Ring

A Noetherian local ring $(R, \mathfrak{m})$ is *Cohen-Macaulay* if $\operatorname{depth}(R) = \operatorname{kdim}(R)$. A Noetherian ring is Cohen-Macaulay if its localization at every prime is. More generally a finitely generated module $M \neq 0$ over a Noetherian local ring is *Cohen-Macaulay* if $\operatorname{depth}(M) = \operatorname{kdim}(M)$, the dimension of $R/\operatorname{Ann}(M)$.

Lemma 58.2.19: Depth Drops by One Modulo a Non-Zero Divisor

Let $(R, \mathfrak{m})$ be Noetherian local, $M \neq 0$ finitely generated, and $x \in \mathfrak{m}$ a non-zero divisor on M. Then $\operatorname{depth}(M/xM) = \operatorname{depth}(M) - 1$.

***Proof*:**
Prepending x to any M/xM-regular sequence in $\mathfrak{m}$ yields an M-regular sequence, so $\operatorname{depth}(M) \geq \operatorname{depth}(M/xM) + 1$ directly from definition 58.2.14.

For the reverse, extend x to a maximal M-regular sequence $x, y_1, \ldots, y_m$ in $\mathfrak{m}$; this is possible, and the result has length $\operatorname{depth}(M)$, by theorem 58.2.15. Then $y_1, \ldots, y_m$ is an M/xM-regular sequence, so $\operatorname{depth}(M/xM) \geq m = \operatorname{depth}(M) - 1$. Combining the two, both are equalities, as we sought to show.

Proposition 58.2.20: Depth Is Bounded by the Dimension of Every Associated Prime

Let $(R, \mathfrak{m})$ be Noetherian local, $M \neq 0$ finitely generated, and $\mathfrak{p} \in \operatorname{Ass}(M)$. Then

$$\operatorname{depth}(M) \;\leq\; \operatorname{kdim}(R/\mathfrak{p})$$

***Proof*:**
Induct on $n = \operatorname{depth}(M)$. For $n = 0$ there is nothing to prove. Let $n > 0$ and let $x \in \mathfrak{m}$ be a non-zero divisor on M, which exists because the depth is positive. Since $\mathfrak{p}$ consists of zero-divisors on M, [20, The Zero-Divisors Are the Union of the Associated Primes] gives $x \notin \mathfrak{p}$.

Write $\mathfrak{p} = \operatorname{Ann}(m)$ with $m \neq 0$. We first arrange $m \notin xM$. If $m = xm_1$ then $\operatorname{Ann}(m_1) = \mathfrak{p}$: an r killing m_1 kills m, and conversely $rm = 0$ gives $rxm_1 = 0$, whence $rm_1 = 0$ as x is a non-zero divisor. Iterating produces $m = x^k m_k$ with $\operatorname{Ann}(m_k) = \mathfrak{p}$ for each k, and the submodules $Rm \subseteq Rm_1 \subseteq Rm_2 \subseteq \cdots$ ascend. As M is Noetherian the chain stabilizes, say $Rm_k = Rm_{k+1}$,

so $m_{k+1} = rm_k = rx\, m_{k+1}$ for some r; then $(1 - rx)m_{k+1} = 0$, and $1 - rx$ is a unit because $x \in \mathfrak{m}$, forcing $m_{k+1} = 0$ and hence $m = 0$. That contradiction means the iteration halts, so we may take $m \notin xM$.

Let $N = Rm$ and let $\overline{N}$ be its image in M/xM, nonzero by the previous paragraph. Every element of $\mathfrak{p}$ kills N, hence $\overline{N}$; and x kills $\overline{N}$ too, since $xN \subseteq xM$. So $\operatorname{Ann}(\overline{N}) \supseteq \mathfrak{p} + (x)$. Choose $\mathfrak{q} \in \operatorname{Ass}(\overline{N}) \subseteq \operatorname{Ass}(M/xM)$, nonempty by [20, Zero-Divisors and Annihilators]. Then $\mathfrak{q} \supseteq \mathfrak{p} + (x)$, and $\mathfrak{q} \neq \mathfrak{p}$ because $x \notin \mathfrak{p}$, so $\mathfrak{q} \supsetneq \mathfrak{p}$ and $\operatorname{kdim}(R/\mathfrak{q}) \leq \operatorname{kdim}(R/\mathfrak{p}) - 1$. By lemma 58.2.19 and the inductive hypothesis applied to M/xM and $\mathfrak{q}$,

$$n - 1 \;=\; \operatorname{depth}(M/xM) \;\leq\; \operatorname{kdim}(R/\mathfrak{q}) \;\leq\; \operatorname{kdim}(R/\mathfrak{p}) - 1$$

which is the assertion.

Corollary 58.2.21: Depth Is at Most the Dimension

For $M \neq 0$ finitely generated over a Noetherian local ring, $\operatorname{depth}(M) \leq \operatorname{kdim}(M)$. In particular $\operatorname{depth}(R) \leq \operatorname{kdim}(R)$, so Cohen-Macaulay is the extremal case.

***Proof*:**
$\operatorname{Ass}(M)$ is nonempty ([20, Zero-Divisors and Annihilators]); pick $\mathfrak{p}$ in it. Then $\mathfrak{p} \supseteq \operatorname{Ann}(M)$, so $\operatorname{kdim}(R/\mathfrak{p}) \leq \operatorname{kdim}(R/\operatorname{Ann}(M)) = \operatorname{kdim}(M)$, and proposition 58.2.20 bounds the depth by the left-hand side.

This is the inequality asserted informally above, and a Cohen-Macaulay ring is one in which it is an equality (definition 58.2.18).

Corollary 58.2.22: A Cohen-Macaulay Ring Has No Embedded Associated Primes

Let $(R, \mathfrak{m})$ be a Cohen-Macaulay local ring of dimension d. Then every $\mathfrak{p} \in \operatorname{Ass}(R)$ satisfies $\operatorname{kdim}(R/\mathfrak{p}) = d$, and every such $\mathfrak{p}$ is a minimal prime of R. In particular R has no embedded associated primes, and R is equidimensional.

***Proof*:**
For $\mathfrak{p} \in \operatorname{Ass}(R)$, proposition 58.2.20 gives $d = \operatorname{depth}(R) \leq \operatorname{kdim}(R/\mathfrak{p}) \leq d$, so $\operatorname{kdim}(R/\mathfrak{p}) = d$. If $\mathfrak{p}$ were not minimal it would strictly contain a prime $\mathfrak{p}_0$, and then $\operatorname{kdim}(R/\mathfrak{p}) < \operatorname{kdim}(R/\mathfrak{p}_0) \leq d$, a contradiction. An associated prime that is minimal is by definition not embedded.

Theorem 58.2.23: A System of Parameters in a Cohen-Macaulay Local Ring Is a Regular Sequence

Let $(R, \mathfrak{m})$ be a Cohen-Macaulay local ring of dimension d and let $x_1, \ldots, x_d \in \mathfrak{m}$ be a system of parameters, that is d elements generating an $\mathfrak{m}$-primary ideal. Then $x_1, \ldots, x_d$ is a regular sequence, and $R/(x_1, \ldots, x_d)$ is Cohen-Macaulay of dimension zero.

***Proof*:**
Induct on d, the case $d = 0$ being the empty sequence. Let $d > 0$. Since $x_1, \dots, x_d$ generate an $\mathfrak{m}$-primary ideal, the images of $x_2, \dots, x_d$ generate an $\mathfrak{m}$-primary ideal of $R/(x_1)$, so $\operatorname{kdim} R/(x_1) \leq d-1$ by the dimension theorem of [20, Dimension Theorem]; and $\operatorname{kdim} R/(x_1) \geq d-1$ by Krull's height theorem there. So $\operatorname{kdim} R/(x_1) = d-1$.

Now x_1 is a non-zero divisor. Suppose $x_1 \in \mathfrak{p}$ for some $\mathfrak{p} \in \operatorname{Ass}(R)$. By corollary 58.2.22, $\operatorname{kdim}(R/\mathfrak{p}) = d$; but $\mathfrak{p} \supseteq (x_1)$ gives a surjection $R/(x_1) \twoheadrightarrow R/\mathfrak{p}$ and hence $\operatorname{kdim} R/(x_1) \geq d$, contradicting the previous paragraph. So x_1 lies outside every associated prime and is a non-zero divisor by [20, The Zero-Divisors Are the Union of the Associated Primes].

By lemma 58.2.19, $\operatorname{depth} R/(x_1) = d - 1 = \operatorname{kdim} R/(x_1)$, so $R/(x_1)$ is Cohen-Macaulay of dimension $d-1$, and the images of $x_2, \dots, x_d$ are a system of parameters for it. The inductive hypothesis makes them a regular sequence there, which is exactly the statement that $x_1, \dots, x_d$ is a regular sequence on R and that the final quotient is Cohen-Macaulay of dimension zero.

The form geometry reaches for is slightly more general: the elements need not be a full system of parameters, only as many as the height of the ideal they generate.

Corollary 58.2.24: Height-Many Elements in a Cohen-Macaulay Ring Form a Regular Sequence

Let R be a Cohen-Macaulay local ring and let $x_1, \dots, x_h \in R$ generate an ideal $I = (x_1, \dots, x_h)$ of height h. Then $x_1, \dots, x_h$ is a regular sequence.

***Proof*:**
Let $\mathfrak{p}$ be a prime minimal over I with $\operatorname{ht} \mathfrak{p} = h$, which exists because the height of I is the minimum of $\operatorname{ht} \mathfrak{q}$ over primes $\mathfrak{q}$ minimal over I. Localizing, $R_{\mathfrak{p}}$ is Cohen-Macaulay of dimension h (localization of a Cohen-Macaulay local ring at a prime is Cohen-Macaulay, and $\dim R_{\mathfrak{p}} = \operatorname{ht} \mathfrak{p} = h$), and the images of $x_1, \dots, x_h$ generate an ideal primary to the maximal ideal of $R_{\mathfrak{p}}$, since $\mathfrak{p}$ is minimal over I. They are therefore a system of parameters of $R_{\mathfrak{p}}$, hence a regular sequence there by theorem 58.2.23.

To descend, induct on i: suppose $x_1, \dots, x_{i-1}$ is a regular sequence on R and that x_i is a zero divisor on $M = R/(x_1, \dots, x_{i-1})$. Then x_i lies in an associated prime $\mathfrak{q}$ of M ([20, Zero-Divisors and Annihilators]), and M is Cohen-Macaulay of dimension $\dim R - i + 1$ by theorem 58.2.23 applied step by step, so $\mathfrak{q}$ has no embedded components by corollary 58.2.22 and $\dim R/\mathfrak{q} = \dim R - i + 1$. But $\mathfrak{q} \supseteq (x_1, \dots, x_i)$ forces $\operatorname{ht} \mathfrak{q} \geq$ the height of that ideal, and comparing with the localized statement above bounds $\dim R/\mathfrak{q}$ strictly below $\dim R - i + 1$, a contradiction. So each x_i is a non-zero divisor on the preceding quotient, as we sought to show.

58.3 Serre's Criterion for Normality

Depth and regularity are conditions on a local ring; imposing them at every prime, with a strength that grows with the height, produces the two families of conditions Serre introduced. Their point is the theorem below: normality, which is a statement about integral closure and has no homological content on its face, is exactly the conjunction of a regularity condition in codimension one and a

depth condition everywhere.

Definition 58.3.1: Serre's Conditions

Let R be a Noetherian ring and $k \geq 0$ an integer. Then R satisfies

- (R_k) if $R_{\mathfrak{p}}$ is a regular local ring for every prime $\mathfrak{p}$ with $\operatorname{ht}\mathfrak{p} \leq k$;
- (S_k) if $\operatorname{depth}(R_{\mathfrak{p}}) \geq \min\left(k,\ \operatorname{ht}\mathfrak{p}\right)$ for every prime $\mathfrak{p}$.

Both conditions weaken as attention moves to primes of large height: (R_k) says nothing about primes of height above k, and (S_k) asks only for depth k once the height reaches k. A regular ring satisfies (R_k) for every k, and a Cohen-Macaulay ring satisfies (S_k) for every k, since there $\operatorname{depth} R_{\mathfrak{p}} = \operatorname{kdim} R_{\mathfrak{p}} = \operatorname{ht}\mathfrak{p}$.

Theorem 58.3.2: Serre's Criterion for Normality

Let R be a Noetherian domain. Then R is integrally closed in its fraction field if and only if it satisfies (R_1) and (S_2).

***Proof*:**

Necessity. Suppose R is normal. For (R_1), a prime of height zero is (0) and $R_{(0)}$ is a field, which is regular; and for $\operatorname{ht}\mathfrak{p} = 1$ the ring $R_{\mathfrak{p}}$ is a discrete valuation ring by [20, A Normal Domain Is the Intersection of Its Height-One Localizations], hence regular.

For (S_2) let $\mathfrak{p}$ be a prime. If $\operatorname{ht}\mathfrak{p} = 0$ there is nothing to prove. If $\operatorname{ht}\mathfrak{p} = 1$ then $R_{\mathfrak{p}}$ is a discrete valuation ring, whose maximal ideal is generated by a non-zero divisor, so its depth is at least $1 = \min(2, 1)$. Suppose $\operatorname{ht}\mathfrak{p} \geq 2$, so that $\min(2, \operatorname{ht}\mathfrak{p}) = 2$. The ring $R_{\mathfrak{p}}$ is a Noetherian normal domain, so any nonzero $b \in \mathfrak{p}R_{\mathfrak{p}}$ is a non-zero divisor and $\operatorname{depth}(R_{\mathfrak{p}}) \geq 1$. By [20, Associated Primes of a Principal Ideal Have Height One], every associated prime of $bR_{\mathfrak{p}}$ has height one, so $\mathfrak{p}R_{\mathfrak{p}}$, of height at least two, is not one of them; hence $\operatorname{depth}(R_{\mathfrak{p}}/bR_{\mathfrak{p}}) \neq 0$ by the second consequence of theorem 58.2.15. Then lemma 58.2.19 gives $\operatorname{depth}(R_{\mathfrak{p}}) = \operatorname{depth}(R_{\mathfrak{p}}/bR_{\mathfrak{p}}) + 1 \geq 2$.

Sufficiency. Suppose R satisfies (R_1) and (S_2), and write K for its fraction field. Every prime of height one has $R_{\mathfrak{p}}$ regular local of dimension one by (R_1), hence a discrete valuation ring, hence integrally closed. An intersection of integrally closed subrings of K each with fraction field K is integrally closed, so it suffices to prove

$$R = \bigcap_{\operatorname{ht}\mathfrak{p}=1} R_{\mathfrak{p}}$$

One inclusion is immediate. For the other, let x lie in every such $R_{\mathfrak{p}}$, write $x = a/b$ with $b \neq 0$, and suppose $a \notin (b)$. Then $\operatorname{Ann}(\overline{a}) = (b : a)$ is a proper ideal consisting of zero-divisors on $R/(b)$, so as in [20, The Zero-Divisors Are the Union of the Associated Primes] together with prime avoidance it lies in a single $\mathfrak{q} \in \operatorname{Ass}(R/(b))$.

The height of $\mathfrak{q}$ is one. It is at least one because R is a domain and $b \neq 0$. If it were at least two, then (S_2) would give $\operatorname{depth}(R_{\mathfrak{q}}) \geq 2$, and b is a non-zero divisor in $\mathfrak{q}R_{\mathfrak{q}}$, so lemma 58.2.19 would give $\operatorname{depth}(R_{\mathfrak{q}}/bR_{\mathfrak{q}}) \geq 1$, whence $\mathfrak{q}R_{\mathfrak{q}} \notin \operatorname{Ass}(R_{\mathfrak{q}}/bR_{\mathfrak{q}})$ by theorem 58.2.15. But associated primes localize, so $\mathfrak{q} \in \operatorname{Ass}(R/(b))$ makes $\mathfrak{q}R_{\mathfrak{q}}$ associated to $R_{\mathfrak{q}}/bR_{\mathfrak{q}}$, a contradiction.

So $\operatorname{ht}\mathfrak{q} = 1$ and $x \in R_{\mathfrak{q}}$ by hypothesis; that produces $s \notin \mathfrak{q}$ with $sa \in bR$, so $s \in (b : a) \subseteq \mathfrak{q}$, a contradiction. Hence $a \in (b)$ and $x \in R$, completing the proof.

Geometrically, (R_1) says a normal variety is smooth away from a closed set of codimension at least two, and (S_2) says a function defined outside such a set extends across it. That reading, and the divisor theory it supports, is [42].

58.4 The Local Criterion for Flatness

One of the most powerful applications of Nakayama's Lemma and homological algebra is the Local Criterion for Flatness. Checking whether a module is flat directly from the definition (that tensoring preserves exactness) can be extremely difficult. The local criterion reduces this to checking exactness against a single module (the residue field), or checking that regular sequences map to regular sequences.

Theorem 58.4.1: Local Criterion for Flatness

Let $\varphi : (R, \mathfrak{m}) \to (S, \mathfrak{n})$ be a local homomorphism of Noetherian local rings, and let M be a finitely generated S-module. Then the following are equivalent:

1. M is flat over R.
2. $\operatorname{Tor}_1^R(M, R/\mathfrak{m}) = 0$.
3. The natural multiplication map $\mathfrak{m} \otimes_R M \to \mathfrak{m}M$ is an isomorphism.

***Proof*:**

The implication (1) $\Rightarrow$ (2) is trivial since M is flat implies $\operatorname{Tor}_i^R(M, -) = 0$ for all $i > 0$. The equivalence (2) $\iff$ (3) follows from applying $- \otimes_R M$ to the short exact sequence $0 \to \mathfrak{m} \to R \to R/\mathfrak{m} \to 0$, which gives the long exact sequence in Tor:

$$0 = \operatorname{Tor}_1^R(R, M) \to \operatorname{Tor}_1^R(R/\mathfrak{m}, M) \to \mathfrak{m} \otimes_R M \to R \otimes_R M \to R/\mathfrak{m} \otimes_R M \to 0$$

Since $R \otimes_R M \cong M$, the kernel of $M \to M/\mathfrak{m}M$ is precisely $\mathfrak{m}M$. Thus $\operatorname{Tor}_1^R(R/\mathfrak{m}, M) = 0$ if and only if $\mathfrak{m} \otimes_R M \to \mathfrak{m}M$ is injective (and it is always surjective).

For (2) $\Rightarrow$ (1), we must show that $\operatorname{Tor}_1^R(M, N) = 0$ for all finitely generated R-modules N. We proceed by induction on the length of N. By Nakayama's Lemma (lemma 23.4.27), if $N \neq 0$, we can find a non-zero quotient $N \to R/\mathfrak{m}$. Let K be the kernel, so we have $0 \to K \to N \to R/\mathfrak{m} \to 0$. The long exact sequence in Tor gives:

$$\operatorname{Tor}_1^R(K, M) \to \operatorname{Tor}_1^R(N, M) \to \operatorname{Tor}_1^R(R/\mathfrak{m}, M) = 0$$

Thus, $\operatorname{Tor}_1^R(K, M)$ surjects onto $\operatorname{Tor}_1^R(N, M)$. By iterating this process (using the Artin-Rees lemma and the $\mathfrak{m}$-adic filtration on N; theorem 25.4.1), one can show that $\operatorname{Tor}_1^R(N, M) \subseteq \mathfrak{m}\operatorname{Tor}_1^R(N, M)$. Since M is a finitely generated S-module and S is Noetherian, $\operatorname{Tor}_1^R(N, M)$ is a finitely generated S-module. By Nakayama's Lemma (applied over S, since $\mathfrak{m}S \subseteq \mathfrak{n}$), we conclude $\operatorname{Tor}_1^R(N, M) = 0$.

In algebraic geometry, we often deal with regular local rings and regular sequences. The Local Criterion gives us an incredibly useful corollary for checking flatness in terms of regular sequences. This is the algebraic engine behind an infamous result known as the "Miracle Flatness" theorem, an important "shortcut" for proving flatness in [13].

Corollary 58.4.2: Regular Sequence Criterion for Flatness

Let $\varphi : (R, \mathfrak{m}) \to (S, \mathfrak{n})$ be a local homomorphism of Noetherian local rings, and M a finitely generated S-module. Let $x \in \mathfrak{m}$ be a non-zero divisor on R. Then M is flat over R if and only if both of the following hold if and only if:

1. x is a non-zero divisor on M, and
2. M/xM is flat over $R/(x)$.

By induction, if $x_1, \ldots, x_d \in \mathfrak{m}$ is a regular sequence in R, then M is flat over R if and only if $x_1, \ldots, x_d$ forms a regular sequence on M and $M/(x_1, \ldots, x_d)M$ is flat over $R/(x_1, \ldots, x_d)$.

***Proof*:**

($\Rightarrow$): If M is flat over R, applying $- \otimes_R M$ to the exact sequence $0 \to R \xrightarrow{\cdot x} R \to R/(x) \to 0$ yields the exact sequence $0 \to M \xrightarrow{\cdot x} M \to M/xM \to 0$. Thus x is a non-zero divisor on M. Furthermore, base change preserves flatness, so $M/xM \cong M \otimes_R R/(x)$ is flat over $R/(x)$.

($\Leftarrow$): Assume x is regular on M and M/xM is flat over $R/(x)$. We want to show M is flat. Since M/xM is flat over $R/(x)$, $\operatorname{Tor}_1^{R/(x)}(R/\mathfrak{m}, M/xM) = 0$. Combined with the fact that x is regular on M, this gives $\operatorname{Tor}_1^{R}(R/\mathfrak{m}, M) = 0$: taking a free resolution $F_\bullet \to M$ over R, regularity of x on both R and M makes $F_\bullet \otimes_R R/(x)$ a free resolution of M/xM over $R/(x)$, so $\operatorname{Tor}_i^{R/(x)}(N, M/xM) \cong \operatorname{Tor}_i^{R}(N, M)$ for every $R/(x)$-module N, and $N = R/\mathfrak{m}$ is one. By the Local Criterion for Flatness (theorem 58.4.1), M is flat over R.

The variant that geometry actually asks for reverses the roles: rather than a regular sequence downstairs, one is handed an element that is a nonzerodivisor *on the fibre*, and wants to conclude that it was a nonzerodivisor upstairs all along. This is how flatness of a family cut out by equations gets verified one equation at a time.

Corollary 58.4.3: Fibrewise Nonzerodivisor Criterion for Flatness

Let $\varphi : (R, \mathfrak{m}) \to (S, \mathfrak{n})$ be a local homomorphism of Noetherian local rings with $\kappa = R/\mathfrak{m}$, let M be a finitely generated S-module that is flat over R, and let $u \in \mathfrak{n}$. If u is a non-zero divisor on $M/\mathfrak{m}M = M \otimes_R \kappa$, then u is a non-zero divisor on M, and M/uM is flat over R.

***Proof*:**

Write $K = \ker(u : M \to M)$ and $M' = M/K$, so that multiplication by u factors as a surjection $M \twoheadrightarrow M'$ followed by an injection $M' \hookrightarrow M$, and $N := M/uM$ is the cokernel of the latter. Both sequences

$$0 \to K \to M \to M' \to 0, \qquad 0 \to M' \xrightarrow{u} M \to N \to 0$$

are exact by construction.

Step 1: N is flat. Apply $-\otimes_R \kappa$ to the second sequence. Flatness of M gives $\operatorname{Tor}_1^R(\kappa, M) = 0$, so the long exact sequence begins

$$0 \to \operatorname{Tor}_1^R(\kappa, N) \to M' \otimes_R \kappa \to M \otimes_R \kappa \to N \otimes_R \kappa \to 0$$

Now right-exactness applied to the first sequence makes $M \otimes_R \kappa \to M' \otimes_R \kappa$ surjective, and composing it with $M' \otimes_R \kappa \to M \otimes_R \kappa$ recovers multiplication by u on $M \otimes_R \kappa$, which is injective by hypothesis. A surjection whose composite with a further map is injective is itself injective, so $M \otimes_R \kappa \to M' \otimes_R \kappa$ is an isomorphism, and therefore $M' \otimes_R \kappa \to M \otimes_R \kappa$ is injective as well. Hence $\operatorname{Tor}_1^R(\kappa, N) = 0$, and N is flat over R by theorem 58.4.1.

Step 2: $K = 0$. Since M and N are both flat over R, the second sequence forces M' to be flat too: for any R-module T the long exact sequence reads $0 = \operatorname{Tor}_2^R(T, N) \to \operatorname{Tor}_1^R(T, M') \to \operatorname{Tor}_1^R(T, M) = 0$. In particular $\operatorname{Tor}_1^R(\kappa, M') = 0$, so applying $-\otimes_R \kappa$ to the first sequence leaves $K \otimes_R \kappa \to M \otimes_R \kappa$ injective. But Step 1 showed $M \otimes_R \kappa \to M' \otimes_R \kappa$ is an isomorphism, so exactness at $M \otimes_R \kappa$ makes the image of $K \otimes_R \kappa$ zero. An injective map with zero image is zero, so $K/\mathfrak{m}K = 0$. As K is a submodule of the finitely generated module M over the Noetherian ring S, it is finitely generated, and $\mathfrak{m}S \subseteq \mathfrak{n}$, so Nakayama gives $K = 0$.

A third consequence is the one deformation arguments in geometry lean on: a resolution of a flat object stays a resolution after restriction to a fibre. Without it a resolution built on a total space says nothing about the special fibres it was built to compare.

Proposition 58.4.4: Restriction of a Resolution to a Fibre

Let R be a ring, A an R-algebra, and M an A-module that is flat over R. Let

$$0 \to G_n \to G_{n-1} \to \cdots \to G_0 \to M \to 0$$

be an exact sequence of A-modules with every G_i flat over R. Then for every R-algebra $R \to k$, applying $-\otimes_R k$ leaves the sequence exact:

$$0 \to G_n \otimes_R k \to \cdots \to G_0 \otimes_R k \to M \otimes_R k \to 0$$

In particular, if $X \to S$ is a morphism of schemes, $\mathscr{F}$ a quasi-coherent sheaf on X flat over S, and $G_\bullet \to \mathscr{F}$ a resolution by quasi-coherent sheaves flat over S, then the restriction of $G_\bullet \to \mathscr{F}$ to any fibre X_s is a resolution of $\mathscr{F}|_{X_s}$.

***Proof*:**
Break the sequence into short exact pieces $0 \to Z_{i+1} \to G_i \to Z_i \to 0$ with $Z_0 = M$ and $Z_{n+1} = 0$. We show by induction on i that every Z_i is flat over R, the base case $Z_0 = M$ being the hypothesis. Given that Z_i is R-flat, the sequence $0 \to Z_{i+1} \to G_i \to Z_i \to 0$ has flat right-hand and middle terms, so the long exact sequence of $\operatorname{Tor}^R(-, N)$ gives $0 = \operatorname{Tor}_2^R(Z_i, N) \to \operatorname{Tor}_1^R(Z_{i+1}, N) \to \operatorname{Tor}_1^R(G_i, N) = 0$ for every N, whence Z_{i+1} is flat. The induction therefore gives flatness of every syzygy.

Now tensor each short exact piece with k over R. Flatness of Z_i makes $\operatorname{Tor}_1^R(Z_i, k) = 0$, so $0 \to Z_{i+1} \otimes_R k \to G_i \otimes_R k \to Z_i \otimes_R k \to 0$ is exact. Splicing the pieces back together reassembles the long sequence, still exact. The sheaf statement is this one applied on affine opens, flatness and exactness both being local, as we sought to show.

Exercise 58.4.1

1. Let $R = k[x, y]$. Find a free resolution for the module $M = R/(x^2, xy, y^2)$. What is the length of this resolution?
2. Show that over $R = \mathbb{Z}$, the module $M = \mathbb{Q}$ has projective dimension 1, but does not have a finite *free* resolution if we require finitely generated free modules (which is impossible since $\mathbb{Q}$ is not finitely generated).
3. Why does the Syzygy theorem fail for $R = k[x_1, x_2, \dots]$ (infinite variables)? Find a module with infinite projective dimension.

58.5 The Limit of a Tower and Its First Derived Functor

The functors derived so far in this chapter have been Hom and $\otimes$, and the objects they were applied to were modules over a ring. The functor of this section is neither, and its source category is not a category of modules: it is the limit, applied to a sequence of abelian groups indexed by $\mathbb{N}$ with maps running backwards. The limit of such a sequence is left exact and not exact, so it has derived functors like any other left-exact functor. What is special is how few of them there are. Exactly one is nonzero, it admits a description with no resolutions in it at all, and it vanishes under a hypothesis satisfied in most of the situations where the limit is taken.

That last point is why the section exists. A cohomology theory evaluated on an infinite complex, the cohomology of an infinite-dimensional classifying space, the completion of a ring: each is computed as a limit over a sequence of finite approximations, and in each the answer is the naive limit *provided* a single obstruction group vanishes. Naming that group is what allows the provision to be checked rather than assumed.[2]

Definition 58.5.1: Tower of Abelian Groups

A *tower* of abelian groups is a sequence $A_\bullet = (A_n)_{n \geq 0}$ of abelian groups together with homomorphisms

$$A_0 \xleftarrow{f_1} A_1 \xleftarrow{f_2} A_2 \xleftarrow{f_3} \cdots$$

called the *transition maps*. For $m \geq n$ write $f_{n,m} \colon A_m \to A_n$ for the composite $f_{n+1} \circ \cdots \circ f_m$, with $f_{n,n} = \mathrm{id}_{A_n}$.
A *morphism of towers* $u \colon A_\bullet \to B_\bullet$ is a family of homomorphisms $u_n \colon A_n \to B_n$ with $u_n \circ f_{n+1} = g_{n+1} \circ u_{n+1}$ for every n, where $g_\bullet$ denotes the transition maps of $B_\bullet$. Towers and their morphisms form an abelian category, in which kernels, cokernels, images and exactness are all computed degreewise.

That the category is abelian with everything computed degreewise is what makes the section possible: a sequence of towers is exact exactly when each of its levels is exact, so the hypotheses of every result below can be checked one group at a time. The limit itself is the group of coherent families, and the observation that turns it into something derivable is that this group is the kernel of a single explicit

[2] The older literature writes this group $\varprojlim^1$ and calls it the first derived functor of the inverse limit. This series says *limit* and names the shape of the diagram separately, so the notation here is $\varprojlim^1$ and the phrase is "the limit of a tower".

map.

Definition 58.5.2: The Limit and $\varprojlim^1$ of a Tower

Let $A_\bullet$ be a tower of abelian groups. Define

$$d^A\colon \prod_{n\geq 0} A_n \to \prod_{n\geq 0} A_n, \qquad d^A\big((a_n)_n\big) = \big(a_n - f_{n+1}(a_{n+1})\big)_n$$

The *limit* of the tower is $\varprojlim A_\bullet := \ker d^A$, and the *first derived functor of the limit* is

$$\varprojlim{}^1 A_\bullet := \operatorname{coker} d^A$$

Both are functors from towers to abelian groups: a morphism $u\colon A_\bullet \to B_\bullet$ induces $\prod u_n$ on products, and $d^B \circ \prod u_n = \prod u_n \circ d^A$ because $u_n f_{n+1} = g_{n+1} u_{n+1}$, so $\prod u_n$ carries $\ker d^A$ into $\ker d^B$ and descends to cokernels.

The kernel is the usual object under a different description. An element $(a_n) \in \prod A_n$ lies in $\ker d^A$ precisely when $a_n = f_{n+1}(a_{n+1})$ for every n, which is the condition that the family be compatible with the transition maps; so $\ker d^A$ is the group of coherent sequences, with the projections $\varprojlim A_\bullet \to A_n$ obtained by restricting the product projections. The cokernel measures how far d^A is from being surjective, and the content of the next theorem is that this single group is the entire obstruction to the limit being exact.

Theorem 58.5.3: The Six-Term Sequence of the Limit

Let $0 \to A_\bullet \to B_\bullet \to C_\bullet \to 0$ be a short exact sequence of towers of abelian groups. Then there is an exact sequence

$$0 \to \varprojlim A_\bullet \to \varprojlim B_\bullet \to \varprojlim C_\bullet \xrightarrow{\partial} \varprojlim{}^1 A_\bullet \to \varprojlim{}^1 B_\bullet \to \varprojlim{}^1 C_\bullet \to 0$$

natural in the short exact sequence.

The sequence says two things worth separating. Reading the left half, the limit is left exact but its failure to preserve surjections is entirely accounted for by the connecting map ∂ into $\varprojlim^1 A_\bullet$: if that group vanishes, $\varprojlim B_\bullet \to \varprojlim C_\bullet$ is onto. Reading the right half, the sequence *stops*. There is no seven-term continuation, and proposition 58.5.4 explains why: the higher derived functors are zero, so no further obstruction can appear.

***Proof*:**
Write $P(A) = \prod_{n\geq 0} A_n$ and likewise for B and C, and let $u\colon A_\bullet \to B_\bullet$, $v\colon B_\bullet \to C_\bullet$ be the given morphisms.

Step 1: The two rows are short exact. By definition 58.5.1 exactness of a sequence of towers is checked degreewise, so $0 \to A_n \to B_n \to C_n \to 0$ is exact for every n. A product of short exact sequences of abelian groups is short exact, since kernels, images and surjectivity of a family of maps into a product are all tested coordinatewise (this is the exactness of arbitrary products in

R-Mod recorded in lemma 56.1.11). Hence

$$0 \to P(A) \xrightarrow{\prod u_n} P(B) \xrightarrow{\prod v_n} P(C) \to 0$$

is exact, and the same sequence serves as both rows of the diagram below.

Step 2: The squares commute. Take the vertical maps to be d^A, d^B, d^C:

$$\begin{array}{ccccccccc} 0 & \longrightarrow & P(A) & \xrightarrow{\prod u_n} & P(B) & \xrightarrow{\prod v_n} & P(C) & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle d^A} & & \downarrow{\scriptstyle d^B} & & \downarrow{\scriptstyle d^C} & & \\ 0 & \longrightarrow & P(A) & \xrightarrow{\prod u_n} & P(B) & \xrightarrow{\prod v_n} & P(C) & \longrightarrow & 0 \end{array}$$

Commutativity of the left square is the computation already made in definition 58.5.2: for $(a_n) \in P(A)$,

$$d^B\big((u_n(a_n))_n\big) = \big(u_n(a_n) - g_{n+1}(u_{n+1}(a_{n+1}))\big)_n = \big(u_n(a_n) - u_n(f_{n+1}(a_{n+1}))\big)_n$$

using $g_{n+1}u_{n+1} = u_n f_{n+1}$, and the right-hand side is $\prod u_n$ applied to $d^A((a_n))$. The right square is the same computation for v.

Step 3: Apply the snake lemma and identify the terms. Read each of the three vertical maps as a complex concentrated in degrees 0 and 1, so that the diagram of Step 2 is a short exact sequence of two-term complexes. This is exactly the reading carried out in example 56.1.19(1): for a two-term complex $H^0 = \ker$ and $H^1 = \operatorname{coker}$, and $H^n = 0$ otherwise, so the long exact sequence of theorem 56.1.18 has only six nonzero terms,

$$0 \to \ker d^A \to \ker d^B \to \ker d^C \xrightarrow{\partial} \operatorname{coker} d^A \to \operatorname{coker} d^B \to \operatorname{coker} d^C \to 0$$

The connecting map is the one built in the proof of theorem 56.1.18, by the recipe: given $c \in \ker d^C$, choose $b \in P(B)$ with $\prod v_n(b) = c$, note that $d^B(b)$ has zero image in $P(C)$ and so equals $\prod u_n(a)$ for a unique $a \in P(A)$, and set $\partial(c) := [a] \in \operatorname{coker} d^A$. By definition 58.5.2 the three kernels are $\varprojlim A_\bullet$, $\varprojlim B_\bullet$, $\varprojlim C_\bullet$ and the three cokernels are $\varprojlim{}^1 A_\bullet$, $\varprojlim{}^1 B_\bullet$, $\varprojlim{}^1 C_\bullet$, which is the displayed sequence.

Step 4: Naturality. Let (s,t,r) be a morphism from $0 \to A_\bullet \to B_\bullet \to C_\bullet \to 0$ to a second short exact sequence $0 \to \tilde{A}_\bullet \to \tilde{B}_\bullet \to \tilde{C}_\bullet \to 0$, so $s\colon A_\bullet \to \tilde{A}_\bullet$ and so on, with both squares commuting. Each of s,t,r induces a map on products commuting with the relevant d, by the computation of Step 2, so the four maps other than ∂ are natural for the reason that they are restrictions and quotients of $\prod s_n$, $\prod t_n$, $\prod r_n$.

For ∂, take $c \in \varprojlim C_\bullet$ and run the recipe of Step 3, producing b and a with $\partial(c) = [a]$. Applying s gives $\big[\prod s_n(a)\big]$. Running the recipe instead on $\prod r_n(c)$, one *may* take $\prod t_n(b)$ as the required lift, since $\prod \tilde{v}_n(\prod t_n(b)) = \prod r_n(\prod v_n(b)) = \prod r_n(c)$; and then

$$d^{\tilde{B}}\Big(\prod t_n(b)\Big) = \prod t_n\big(d^B(b)\big) = \prod t_n\Big(\prod u_n(a)\Big) = \prod \tilde{u}_n\Big(\prod s_n(a)\Big)$$

so the unique preimage is $\prod s_n(a)$ and $\tilde{\partial}(\prod r_n(c)) = \big[\prod s_n(a)\big]$ as well. The two agree, and the value does not depend on the lift chosen, that being the well-definedness already established for $\tilde{\partial}$ in the target sequence. Hence the square through ∂ commutes, completing the proof.

The name given to $\operatorname{coker} d^A$ in definition 58.5.2 has so far been unearned: nothing above identifies it with a derived functor in the sense of definition 56.3.5 and the right-derived construction recorded alongside it. The identification is genuine, and it is what permits both the notation and the assertion made after theorem 58.5.3 that the sequence terminates.

Proposition 58.5.4: $\varprojlim^1$ Is the First Derived Functor of the Limit

The category of towers of abelian groups has enough injectives, and the functor $\varprojlim$ is left exact. Writing $R^n \varprojlim$ for its right derived functors,

$$R^0 \varprojlim \cong \varprojlim, \qquad R^1 \varprojlim \cong \varprojlim{}^1, \qquad R^n \varprojlim = 0 \text{ for } n \geq 2$$

***Proof Key ideas*:**
Two ingredients are used here and not proved: that the category of towers has enough injectives, and that the right derived functors of $\varprojlim$ are computed by the two-term complex

$$P(A) \xrightarrow{d^A} P(A)$$

placed in degrees 0 and 1. Both are established in [101, §3.5]. The deferral is deliberate rather than incidental: constructing the injectives is long, and nothing in this book or in the books citing this section uses more than the two-term description, which definition 58.5.2 and theorem 58.5.3 give on their own.

Granting the two ingredients, the rest is a reading-off. Left exactness of $\varprojlim$ is the left half of theorem 58.5.3, proved above without any of this. The displayed complex has $H^0 = \ker d^A = \varprojlim A_\bullet$ and $H^1 = \operatorname{coker} d^A = \varprojlim{}^1 A_\bullet$ by definition 58.5.2, and it is concentrated in degrees 0 and 1, so $H^n = 0$ for $n \geq 2$. These three groups are the values of $R^0 \varprojlim$, $R^1 \varprojlim$ and $R^n \varprojlim$ for $n \geq 2$, which is the statement.

With the sequence in hand the practical question is when the obstruction vanishes. The condition is not that the transition maps be surjective, which would be too strong to be useful, but that the images they produce inside any fixed level eventually stop shrinking.

Definition 58.5.5: Mittag-Leffler Condition

A tower $A_\bullet$ satisfies the *Mittag-Leffler condition* if for every n the decreasing chain of subgroups

$$A_n = \operatorname{im} f_{n,n} \supseteq \operatorname{im} f_{n,n+1} \supseteq \operatorname{im} f_{n,n+2} \supseteq \cdots$$

is eventually constant: there is an $m_0 \geq n$ with $\operatorname{im} f_{n,m} = \operatorname{im} f_{n,m_0}$ for all $m \geq m_0$. The common value $A'_n := \bigcap_{m \geq n} \operatorname{im} f_{n,m}$ is the *stable image* in level n.

The condition is deliberately weak. It permits the transition maps to be far from surjective, and it permits the stable image to be a proper subgroup of A_n; it forbids only an infinite strictly decreasing chain of images inside a single level. A tower whose transition maps are all surjective satisfies it with $A'_n = A_n$, and a tower whose transition maps are eventually zero in each level satisfies it with $A'_n = 0$.

Theorem 58.5.6: Mittag-Leffler Vanishing

If a tower $A_\bullet$ of abelian groups satisfies the Mittag-Leffler condition, then $\varprojlim^1 A_\bullet = 0$.

***Proof*:**

The claim is that d^A is surjective. Two special cases are treated first, and the general case reduces to them.

Step 1: Surjective transition maps. Suppose every f_{n+1} is surjective, and let $(b_n) \in P(A)$ be given. Set $a_0 := 0$, and having chosen a_n, use surjectivity of f_{n+1} to choose $a_{n+1} \in A_{n+1}$ with $f_{n+1}(a_{n+1}) = a_n - b_n$. Then

$$a_n - f_{n+1}(a_{n+1}) = a_n - (a_n - b_n) = b_n$$

for every n, so $d^A((a_n)) = (b_n)$ and d^A is surjective.

Step 2: Transition maps eventually zero in each level. Suppose instead that for each n there is an $m_1 \geq n$ with $f_{n,m} = 0$ for all $m \geq m_1$. Given $(b_n) \in P(A)$, the sum

$$a_n := \sum_{k \geq n} f_{n,k}(b_k)$$

has only finitely many nonzero terms and so defines an element of A_n. Since $f_{n+1} \circ f_{n+1,k} = f_{n,k}$ for $k \geq n+1$,

$$f_{n+1}(a_{n+1}) = \sum_{k \geq n+1} f_{n,k}(b_k) = a_n - f_{n,n}(b_n) = a_n - b_n$$

so again $a_n - f_{n+1}(a_{n+1}) = b_n$ and d^A is surjective.

Step 3: The general Mittag-Leffler case. Let A'_n be the stable image of definition 58.5.5, and let $m_0(n)$ be an index with $\mathrm{im} f_{n,m} = A'_n$ for all $m \geq m_0(n)$. The subgroups A'_n form a subtower: for $m \geq n+1$ one has $f_{n+1}(\mathrm{im} f_{n+1,m}) = \mathrm{im} f_{n,m}$, so $f_{n+1}(A'_{n+1}) \subseteq \bigcap_{m \geq n+1} \mathrm{im} f_{n,m} = A'_n$.

That subtower has surjective transition maps. Let $x \in A'_n$ and choose $m \geq \max\{m_0(n), m_0(n+1)\}$. Since $x \in \mathrm{im} f_{n,m}$ there is $z \in A_m$ with $f_{n,m}(z) = x$; put $y := f_{n+1,m}(z)$. Then $y \in \mathrm{im} f_{n+1,m} = A'_{n+1}$ because $m \geq m_0(n+1)$, and $f_{n+1}(y) = f_{n+1}(f_{n+1,m}(z)) = f_{n,m}(z) = x$. So $f_{n+1} \colon A'_{n+1} \to A'_n$ is onto, and Step 1 gives $\varprojlim^1 A'_\bullet = 0$.

The quotient tower $(A_n/A'_n)_n$ has transition maps that are eventually zero in each level: for $m \geq m_0(n)$ the image of $A_m/A'_m \to A_n/A'_n$ is $(\mathrm{im} f_{n,m} + A'_n)/A'_n = A'_n/A'_n = 0$. So Step 2 gives $\varprojlim^1 (A_\bullet/A'_\bullet) = 0$.

Now apply theorem 58.5.3 to the short exact sequence of towers $0 \to A'_\bullet \to A_\bullet \to A_\bullet/A'_\bullet \to 0$, which is exact degreewise by construction. Its last three terms read

$$\varprojlim{}^1 A'_\bullet \to \varprojlim{}^1 A_\bullet \to \varprojlim{}^1 (A_\bullet/A'_\bullet) \to 0$$

with the two outer groups zero, so $\varprojlim^1 A_\bullet = 0$, completing the proof.

Corollary 58.5.7: Surjective Towers Have Vanishing $\varprojlim^1$

If every transition map of a tower $A_\bullet$ is surjective, then $\varprojlim^1 A_\bullet = 0$. Consequently, for a short exact sequence of towers $0 \to A_\bullet \to B_\bullet \to C_\bullet \to 0$ in which $A_\bullet$ has surjective transition maps, the sequence of limits

$$0 \to \varprojlim A_\bullet \to \varprojlim B_\bullet \to \varprojlim C_\bullet \to 0$$

is exact.

***Proof*:**
A surjective tower satisfies the Mittag-Leffler condition with $A'_n = A_n$, so theorem 58.5.6 applies; equivalently this is Step 1 of that proof on its own. Substituting $\varprojlim^1 A_\bullet = 0$ into theorem 58.5.3 makes the connecting map ∂ land in the zero group, so the first four terms of the six-term sequence give the displayed short exact sequence, as we sought to show.

The corollary is the form in which the result is usually met, and it is the statement proved directly, without the surrounding theory, in proposition 25.1.3, where it is what makes completion along a surjective system an exact operation. The theory developed here names the group that appears once the surjectivity hypothesis is dropped: the cokernels left unlabelled in that argument are the $\varprojlim^1$ terms.

Example 58.5.8: The Tower of Residue Rings $\mathbb{Z}/p^n\mathbb{Z}$
Fix a prime p and let $T_\bullet$ be the tower $T_n = \mathbb{Z}/p^n\mathbb{Z}$ with transition maps the natural reductions $\mathbb{Z}/p^{n+1}\mathbb{Z} \twoheadrightarrow \mathbb{Z}/p^n\mathbb{Z}$ (so $T_0 = 0$). A coherent family is a sequence of residues agreeing under reduction, which is precisely a p-adic integer, so

$$\varprojlim T_\bullet = \mathbb{Z}_p$$

Every transition map is surjective, so corollary 58.5.7 gives $\varprojlim^1 T_\bullet = 0$. This is the typical situation: the obstruction is absent and the limit behaves as expected.

The next example shows that the obstruction is not always absent, and that it can be large. It is worth working through, because a reader who meets only towers with surjective transition maps will reasonably conclude that $\varprojlim^1$ is a formality.

Example 58.5.9: A Tower With Nonvanishing $\varprojlim^1$
Keep p fixed and let $S_\bullet$ be the tower of subgroups $S_n = p^n\mathbb{Z} \subseteq \mathbb{Z}$, with transition maps the inclusions $p^{n+1}\mathbb{Z} \hookrightarrow p^n\mathbb{Z}$. Rescaling by $p^n\mathbb{Z} \cong \mathbb{Z}$ identifies $S_\bullet$ with the tower

$$\mathbb{Z} \xleftarrow{p} \mathbb{Z} \xleftarrow{p} \mathbb{Z} \xleftarrow{p} \cdots$$

Mittag-Leffler fails: inside $S_n = p^n\mathbb{Z}$ the image $\operatorname{im} f_{n,m}$ is $p^m\mathbb{Z}$, and these subgroups shrink strictly as m grows, so the chain in definition 58.5.5 is never constant. The limit vanishes, since $\varprojlim S_\bullet \subseteq \bigcap_{n\geq 0} p^n\mathbb{Z} = 0$.

To compute $\varprojlim^1 S_\bullet$, let $\underline{\mathbb{Z}}$ denote the constant tower with $\underline{\mathbb{Z}}_n = \mathbb{Z}$ and all transition maps the identity, and let $T_\bullet$ be the tower of example 58.5.8. The quotient maps $\mathbb{Z} \to \mathbb{Z}/p^n\mathbb{Z}$ assemble into

a short exact sequence of towers

$$0 \to S_\bullet \to \underline{\mathbb{Z}} \to T_\bullet \to 0$$

exact in each level because $p^n\mathbb{Z}$ is the kernel of $\mathbb{Z} \to \mathbb{Z}/p^n\mathbb{Z}$, and compatible with the transition maps by construction. The identity transition maps of $\underline{\mathbb{Z}}$ are surjective, so $\varprojlim \underline{\mathbb{Z}} = \mathbb{Z}$ and $\varprojlim^1 \underline{\mathbb{Z}} = 0$ by corollary 58.5.7; and $\varprojlim T_\bullet = \mathbb{Z}_p$ with $\varprojlim^1 T_\bullet = 0$ by example 58.5.8. Feeding all of this into theorem 58.5.3 leaves

$$0 \to 0 \to \mathbb{Z} \to \mathbb{Z}_p \xrightarrow{\partial} \varprojlim{}^1 S_\bullet \to 0 \to 0 \to 0$$

where the map $\mathbb{Z} \to \mathbb{Z}_p$ is the canonical inclusion. Exactness identifies ∂ as a surjection whose kernel is the image of $\mathbb{Z}$, so

$$\varprojlim{}^1 S_\bullet \cong \mathbb{Z}_p/\mathbb{Z}$$

This is nonzero, and not by a small margin: $\mathbb{Z}_p$ is uncountable while $\mathbb{Z}$ is countable, so the quotient is uncountable. The failure of $\varprojlim$ to be exact on this sequence is exactly the failure of the inclusion $\mathbb{Z} \hookrightarrow \mathbb{Z}_p$ to be onto.

Exercise 58.5.1

1. Let A be an abelian group and $\underline{A}$ the constant tower with every level A and every transition map the identity. Compute $\varprojlim \underline{A}$ and $\varprojlim^1 \underline{A}$ directly from definition 58.5.2, without invoking corollary 58.5.7, by exhibiting a solution of $d^{\underline{A}}((a_n)) = (b_n)$ for an arbitrary (b_n).

2. Show that a tower in which every A_n is a finite group satisfies the Mittag-Leffler condition, and conclude that $\varprojlim^1 A_\bullet = 0$. Where does the argument fail for a tower of finitely generated abelian groups?

3. Give a morphism of towers $u\colon B_\bullet \to C_\bullet$ that is surjective in every level but for which $\varprojlim B_\bullet \to \varprojlim C_\bullet$ is not surjective. Name the group in theorem 58.5.3 that receives the resulting obstruction, and say which tower it is computed from.

4. Let $A_\bullet$ be a tower and let $A^{(2)}_\bullet$ be the tower $A_0 \leftarrow A_2 \leftarrow A_4 \leftarrow \cdots$ obtained by keeping the even levels and composing transition maps in pairs. Show that $\varprojlim A_\bullet \cong \varprojlim A^{(2)}_\bullet$ and that $A_\bullet$ satisfies the Mittag-Leffler condition if and only if $A^{(2)}_\bullet$ does.

5. Let $A_\bullet$ be the tower of subgroups $A_n = (n!)\mathbb{Z} \subseteq \mathbb{Z}$ with the inclusions as transition maps, so that rescaling identifies it with $\mathbb{Z} \xleftarrow{1} \mathbb{Z} \xleftarrow{2} \mathbb{Z} \xleftarrow{3} \cdots$, the n-th transition map being multiplication by n. Show that Mittag-Leffler fails and that $\varprojlim A_\bullet = 0$, then run the argument of example 58.5.9 with $\mathbb{Z}/(n!)\mathbb{Z}$ in place of $\mathbb{Z}/p^n\mathbb{Z}$ to compute $\varprojlim^1 A_\bullet$. The limit of the quotient tower is the profinite completion $\widehat{\mathbb{Z}}$ rather than $\mathbb{Z}_p$; say which property of the sequence $(n!)$ is responsible, and give $\varprojlim^1 A_\bullet$ itself.

6. In the situation of example 58.5.9, make the connecting map $\partial\colon \mathbb{Z}_p \to \varprojlim^1 S_\bullet$ explicit by running the construction of ∂ from theorem 58.5.3: given a p-adic integer presented as a coherent family of residues, produce a representative in $\prod_n S_n$ of the class it maps to, and check that the class does not depend on the lifts chosen.

59

Unbounded Derived Categories and t-Structures

The derived functors of chapter 57 are defined on complexes bounded on one side, bounded below for RF and for the second variable of $R\mathrm{Hom}$ and bounded above for LF and $\otimes^L$, because the injective and projective resolutions that compute them are bounded on that side. For a bounded-below complex I of injectives the map $Q\colon \mathrm{Hom}_{\mathrm{K}}(X, I) \to \mathrm{Hom}_D(X, I)$ is bijective for every complex X (lemma 57.4.4(2)), and without the bound this fails. The complex of $\mathbb{Z}/4$-modules with $\mathbb{Z}/4$ in every degree and every differential multiplication by 2 consists of injectives and is exact, yet its identity is not null-homotopic (example 59.1.7). The K-injective and K-flat complexes of Spaltenstein [95] are resolutions that need no bound. With them the right derived functor of an additive functor out of a Grothendieck abelian category, and $R\mathrm{Hom}$ and $\otimes^L$ over a commutative ring, extend to unbounded complexes, and the tensor-Hom adjunction of theorem 57.4.19 holds for the extended functors.

The second half answers the question of box 57.2.13, what in $D(\mathcal{A})$ recovers $\mathcal{A}$. The canonical truncations of definition 56.1.12 descend to $D(\mathcal{A})$. There they cut out the full subcategories of complexes with cohomology in degrees at most 0 and at least 0, and every complex sits in a distinguished triangle whose first vertex lies in the first subcategory and whose third vertex has cohomology in degrees at least 1. The complexes in both subcategories, those with cohomology concentrated in degree 0, form a full subcategory equivalent to $\mathcal{A}$. The axioms satisfied by the two halves define the t-structures of Beilinson, Bernstein and Deligne [8], and the heart of every t-structure is an abelian category.

59.1 Grothendieck Abelian Categories and K-Injective Resolutions

A bounded-below complex of injectives I computes the morphisms into it in the derived category: by lemma 57.4.4(2) the map $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X, I) \to \mathrm{Hom}_{D(\mathcal{A})}(X, I)$ is bijective for every complex X. Without the bound this fails already for a complex of injective $\mathbb{Z}/4$-modules (example 59.1.7), and the same terms $\mathbb{Z}/4$ carry a second complex for which it holds (example 59.1.10). The replacement for the bound is therefore a condition on the complex as a whole, K-injectivity [95]. Over a Grothendieck abelian category, such as the category of modules over a ring or of sheaves of modules on a ringed site, every complex has a K-injective resolution. With these resolutions the Hom-classes of $D(\mathcal{A})$ are sets, and every additive functor has a right derived functor on all of $D(\mathcal{A})$, which for a left exact functor agrees on bounded-below complexes with the total derived functor of section 57.3.

Grothendieck's construction of injective objects, and its extension to K-injective complexes, produce them as colimits of transfinite sequences of monomorphisms, and both arguments need colimits over directed index sets to preserve exactness ([98, Tag 079H], [98, Tag 079P]).

Definition 59.1.1: Directed System and Its Colimit

A *directed poset* is a nonempty partially ordered set I in which any two elements have a common upper bound. Let $\mathcal{C}$ be a category. A *directed system* over I in $\mathcal{C}$ is a family of objects $(A_i)_{i\in I}$ with morphisms $\varphi_{ij}\colon A_i \to A_j$ for $i \le j$, such that $\varphi_{ii} = \mathrm{id}$ and $\varphi_{jk}\varphi_{ij} = \varphi_{ik}$ whenever $i \le j \le k$. A *morphism* $f\colon (A_i, \varphi_{ij}) \to (B_i, \psi_{ij})$ of directed systems over I is a family of morphisms $f_i\colon A_i \to B_i$ with $f_j\varphi_{ij} = \psi_{ij}f_i$ for $i \le j$.

A *colimit* of (A_i, φ_{ij}) is an object $\varinjlim_i A_i$ with morphisms $\lambda_i\colon A_i \to \varinjlim_i A_i$ satisfying $\lambda_j\varphi_{ij} = \lambda_i$, such that for every object T and every family $t_i\colon A_i \to T$ with $t_j\varphi_{ij} = t_i$ there is a unique $t\colon \varinjlim_i A_i \to T$ with $t\lambda_i = t_i$ for all i.

The simplest directed systems are increasing unions, and for them the colimit is the union.

Example 59.1.2: An Increasing Union of Submodules

Let M be an R-module and $(M_i)_{i\in I}$ a family of submodules indexed by a directed poset, with $M_i \subseteq M_j$ for $i \le j$ and $\bigcup_i M_i = M$. With the inclusions as φ_{ij} this is a directed system, and M with the inclusions $\lambda_i\colon M_i \to M$ is its colimit. Given a compatible family $t_i\colon M_i \to T$, define $t(x) := t_i(x)$ for any i with $x \in M_i$. This does not depend on i: if $x \in M_i \cap M_j$, choose $k \ge i, j$, and compatibility gives $t_i(x) = t_k(x) = t_j(x)$. Two elements x, y lie in a common M_k, so $t(rx + y) = t_k(rx + y) = rt(x) + t(y)$ and t is a homomorphism, with $t\lambda_i = t_i$. It is the only one, since every element of M lies in some M_i.

For instance $\mathbb{Q} = \bigcup_{n\ge 0} \frac{1}{n!}\mathbb{Z}$, an increasing union since $\frac{1}{n!}\mathbb{Z} \subseteq \frac{1}{(n+1)!}\mathbb{Z}$, and every p/q with $q \ge 1$ equals $p(q-1)!/q!$. Multiplication by $n!$ identifies $\frac{1}{n!}\mathbb{Z}$ with $\mathbb{Z}$, and under these identifications the inclusion $\frac{1}{n!}\mathbb{Z} \subseteq \frac{1}{(n+1)!}\mathbb{Z}$ becomes multiplication by $n+1$ on $\mathbb{Z}$. So $\mathbb{Q}$ is the colimit of $\mathbb{Z} \xrightarrow{1} \mathbb{Z} \xrightarrow{2} \mathbb{Z} \xrightarrow{3} \cdots$, with $\lambda_n(a) = a/n!$.

A morphism f of directed systems induces $\varinjlim f\colon \varinjlim_i A_i \to \varinjlim_i B_i$, the unique morphism with

$(\varinjlim f)\lambda_i^A = \lambda_i^B f_i$. It exists because the family $\lambda_i^B f_i$ is compatible: $\lambda_j^B f_j \varphi_{ij} = \lambda_j^B \psi_{ij} f_i = \lambda_i^B f_i$. In an abelian category with all set-indexed direct sums every directed system has a colimit, the cokernel of the morphism

$$\bigoplus_{i \le j} A_i \longrightarrow \bigoplus_{i \in I} A_i$$

whose restriction to the summand indexed by the pair (i,j) is $e_i - e_j\varphi_{ij}$, where e_i is the inclusion of the summand A_i. A morphism $t\colon \bigoplus_i A_i \to T$ vanishes on this morphism exactly when $te_i = te_j\varphi_{ij}$ for all $i \le j$, that is, when $(te_i)_i$ is a compatible family. So the universal properties of the direct sum and of the cokernel combine into that of the colimit, with λ_i the composite of e_i and the projection onto the cokernel.

Proposition 59.1.3: Directed Colimits of Modules Are Exact

Let R be a ring, I a directed poset and (M_i, φ_{ij}) a directed system of R-modules over I.

1. The colimit $\varinjlim_i M_i$ exists. Every element of it is $\lambda_i(x)$ for some $i \in I$ and $x \in M_i$, and $\lambda_i(x) = 0$ if and only if $\varphi_{ik}(x) = 0$ for some $k \ge i$.

2. Let $0 \to A \xrightarrow{f} B \xrightarrow{g} C \to 0$ be morphisms of directed systems of R-modules over I such that $0 \to A_i \to B_i \to C_i \to 0$ is exact for every i. Then the sequence

$$0 \to \varinjlim_i A_i \xrightarrow{\varinjlim f} \varinjlim_i B_i \xrightarrow{\varinjlim g} \varinjlim_i C_i \to 0$$

is exact.

***Proof*:**

1. The category of R-modules has direct sums, so the colimit is the quotient $(\bigoplus_i M_i)/N$, where N is the submodule generated by the elements $e_i(x) - e_j(\varphi_{ij}x)$ for $i \le j$ and $x \in M_i$. An element of the quotient is a finite sum $\sum_{r=1}^{s} \lambda_{i_r}(x_r)$. As I is directed, induction on s gives $k \in I$ with $k \ge i_1, \dots, i_s$, and then $\lambda_{i_r}(x_r) = \lambda_k\varphi_{i_r k}(x_r)$, so the sum is $\lambda_k\big(\sum_r \varphi_{i_r k}(x_r)\big)$. If $\varphi_{ik}(x) = 0$ then $\lambda_i(x) = \lambda_k\varphi_{ik}(x) = 0$.

   Conversely let $\lambda_i(x) = 0$, that is, $e_i(x) \in N$. The generators are closed under multiplication by scalars, since $r\big(e_a(y) - e_b(\varphi_{ab}y)\big) = e_a(ry) - e_b(\varphi_{ab}(ry))$, so

$$e_i(x) = \sum_{r=1}^{s} \big(e_{a_r}(y_r) - e_{b_r}(\varphi_{a_r b_r} y_r)\big)$$

   with $a_r \le b_r$. Let J be the finite set $\{i, a_1, b_1, \dots, a_s, b_s\}$ and choose an upper bound k of J. Both sides of the equation lie in the summand $\bigoplus_{j\in J} M_j$, on which $\psi(e_j(z)) := \varphi_{jk}(z)$ defines a homomorphism ψ to M_k. For $a \le b$ in J, $\psi\big(e_a(y) - e_b(\varphi_{ab}y)\big) = \varphi_{ak}(y) - \varphi_{bk}\varphi_{ab}(y) = 0$, so applying ψ to the equation gives $\varphi_{ik}(x) = 0$.

2. Write φ, ψ, χ for the transition maps of A, B, C, and use (1) to write every element of a colimit as $\lambda_i(x)$ for some i and x. If $(\varinjlim f)(\lambda_i a) = \lambda_i(f_i a) = 0$, then (1) gives $k \ge i$ with $0 = \psi_{ik}f_i(a) = f_k\varphi_{ik}(a)$. As f_k is injective, $\varphi_{ik}(a) = 0$ and $\lambda_i(a) = 0$, so $\varinjlim f$ is injective.

Every $\lambda_i(c)$ is $\lambda_i(g_i b) = (\varinjlim g)(\lambda_i b)$ for some $b \in B_i$, so $\varinjlim g$ is surjective. The composite $(\varinjlim g)(\varinjlim f)$ satisfies $(\varinjlim g)(\varinjlim f)\lambda_i = \lambda_i g_i f_i = 0$ for every i, so it is 0 by the uniqueness in the universal property. Finally let $(\varinjlim g)(\lambda_i b) = \lambda_i(g_i b) = 0$. By (1) there is $k \geq i$ with $0 = \chi_{ik} g_i(b) = g_k \psi_{ik}(b)$, so $\psi_{ik}(b) = f_k(a)$ for some $a \in A_k$, by exactness at B_k. Then $\lambda_i(b) = \lambda_k \psi_{ik}(b) = \lambda_k f_k(a) = (\varinjlim f)(\lambda_k a)$, which is exactness at $\varinjlim_i B_i$ and completes the proof.

Directedness enters (2) through (1): a common upper bound k places two elements of a colimit in a single M_k, where they can be compared. The three properties of R-Mod that Grothendieck's axioms abstract are arbitrary direct sums, the exactness of proposition 59.1.3(2), and an object detecting nonzero morphisms. For the last, a homomorphism $f\colon M \to N$ is nonzero exactly when $f(m) \neq 0$ for some m, that is, when $f \circ u \neq 0$ for the map $u\colon R \to M$, $r \mapsto rm$.

Definition 59.1.4: Grothendieck Abelian Category

An abelian category $\mathcal{A}$ is a *Grothendieck abelian category* if it satisfies the following.

(AB3) Every family $(A_t)_{t \in T}$ of objects indexed by a set has a direct sum $\bigoplus_t A_t$.

(AB5) Colimits over directed posets are exact: for every directed poset I and all morphisms of directed systems $0 \to A \to B \to C \to 0$ over I such that $0 \to A_i \to B_i \to C_i \to 0$ is exact for every i, the sequence $0 \to \varinjlim_i A_i \to \varinjlim_i B_i \to \varinjlim_i C_i \to 0$ is exact.

(G) There is a *generator*: an object U such that for every nonzero morphism $f\colon X \to Y$ there is a morphism $u\colon U \to X$ with $fu \neq 0$.

The colimits in (AB5) exist by (AB3), as the cokernel of the morphism $\bigoplus_{i \leq j} A_i \to \bigoplus_{i \in I} A_i$ with components $e_i - e_j \varphi_{ij}$. This is the definition of [98, Tag 079B], whose discussion of (AB5) states the exactness condition for systems over a directed set, as here. The generator there is required to satisfy the following: for every subobject $N \subseteq M$ with $N \neq M$ some morphism $U \to M$ does not factor through N. The two forms agree. Given such N, apply (G) to the nonzero quotient $f\colon M \to M/N$, and note that $u\colon U \to M$ factors through $N = \ker f$ exactly when $fu = 0$. Given a nonzero $f\colon X \to Y$, apply the subobject form to $\ker f \neq X$.

Example 59.1.5: Module and Sheaf Categories

1. For a ring R the category R-Mod is a Grothendieck abelian category. Direct sums give (AB3), proposition 59.1.3(2) is (AB5), and R is a generator: if $f\colon M \to N$ is nonzero, choose m with $f(m) \neq 0$ and let $u\colon R \to M$ be $r \mapsto rm$. Then $fu(1) = f(m) \neq 0$.
2. For a ringed site $(\mathcal{C}, \mathcal{O})$, the category of $\mathcal{O}$-modules is a Grothendieck abelian category [98, Tag 07A5]. For the constant sheaf of rings $\mathbb{Z}$ its objects are the sheaves of abelian groups on $\mathcal{C}$, and for $\mathcal{C}$ the open sets of a topological space they are the sheaves of abelian groups on the space.

The axioms of definition 59.1.4 are Grothendieck's, from the paper in which he proved that injective objects exist in this generality [98, Tag 079A]. In the proof the generator plays the role that the ring plays in Baer's criterion (theorem 17.3.5), and its subobjects the role of the ideals.

Theorem 59.1.6: Grothendieck Abelian Categories Have Enough Injectives

Let $\mathcal{A}$ be a Grothendieck abelian category. There are a functor $E\colon \mathcal{A} \to \mathcal{A}$ and a natural transformation $\upsilon\colon \mathrm{id} \to E$ such that for every object M the morphism $\upsilon_M\colon M \to E(M)$ is a monomorphism and $E(M)$ is injective. In particular $\mathcal{A}$ has enough injectives (definition 56.2.3).

The proof is a transfinite construction that uses nothing from homological algebra beyond (AB5) and the generator, and it is deferred to [98, Tag 079H].

***Proof Key ideas*:**
Fix a generator U. The replacement for Baer's criterion is [98, Tag 079G]: an object is injective if every morphism into it from a subobject $N \subseteq U$ extends to U. For an object M, form the pushout $\mathbf{M}(M)$ of $M \leftarrow \bigoplus N \to \bigoplus U$, the sums running over all pairs of a subobject $N \subseteq U$ and a morphism $\varphi\colon N \to M$. Then every such φ extends to $U \to \mathbf{M}(M)$, and $M \to \mathbf{M}(M)$ is a monomorphism. Iterate transfinitely, taking colimits at limit ordinals, up to an ordinal whose cofinality exceeds the cardinality of the set of subobjects of U. A morphism from a subobject of U into the final stage then factors through an earlier stage, by (AB5) and that cardinality bound [98, Tag 079F], and so extends to U. The criterion makes the final stage injective, and every step is functorial in M, which gives E and υ as claimed.

For R-Mod, through example 59.1.5(1), the theorem gives enough injectives over an arbitrary ring, together with injective embeddings compatible with homomorphisms.

When the category is fixed, $\mathrm{Hom}_{\mathrm{K}}$ and Hom_D abbreviate $\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}$ and $\mathrm{Hom}_{D(\mathcal{A})}$. Recall from lemma 56.1.17 that a complex is acyclic, meaning that its cohomology vanishes, exactly when it is exact.

Example 59.1.7: An Exact Complex of Injectives That Is Not Contractible
Let I be the complex of $\mathbb{Z}/4$-modules with $I^n = \mathbb{Z}/4$ for every $n \in \mathbb{Z}$ and every differential multiplication by 2.

1. $\mathbb{Z}/4$ is an injective $\mathbb{Z}/4$-module. By theorem 17.3.5(1) it suffices to extend homomorphisms from the ideals 0, $2\mathbb{Z}/4$ and $\mathbb{Z}/4$ to $\mathbb{Z}/4$, and only $2\mathbb{Z}/4 = \{0, 2\}$ needs an argument. A homomorphism $g\colon 2\mathbb{Z}/4 \to \mathbb{Z}/4$ satisfies $2g(2) = g(4) = g(0) = 0$, so $g(2) \in \{0, 2\}$. If $g(2) = 0$ then g extends by 0, and if $g(2) = 2$ it extends by the identity of $\mathbb{Z}/4$.
2. I is exact: the kernel and the image of multiplication by 2 on $\mathbb{Z}/4$ are both $\{0, 2\}$.
3. id_I is not null-homotopic. Every $\mathbb{Z}/4$-linear endomorphism of $\mathbb{Z}/4$ is multiplication by its value at 1, so a family $s^n\colon I^n \to I^{n-1}$ consists of multiplications by elements $a_n \in \mathbb{Z}/4$. Then $d^{n-1}s^n + s^{n+1}d^n$ is multiplication by $2a_n + 2a_{n+1}$, which sends 1 into $\{0, 2\}$ and so is never the identity.

So id_I is a nonzero element of $\mathrm{Hom}_{\mathrm{K}(\mathbb{Z}/4\text{-Mod})}(I, I)$. But I is exact, hence isomorphic to 0 in $D(\mathbb{Z}/4\text{-Mod})$ by proposition 57.2.12(1), and $\mathrm{Hom}_{D(\mathbb{Z}/4\text{-Mod})}(I, I) = 0$. The map $Q\colon \mathrm{Hom}_{\mathrm{K}}(I, I) \to \mathrm{Hom}_D(I, I)$ is not injective, and the conclusion of lemma 57.4.4(2) fails for this complex of injectives.

The defect in the example is a nonzero homotopy class of maps from an acyclic complex into I,

namely id_I.

Definition 59.1.8: K-Injective Complex

Let $\mathcal{A}$ be an abelian category. A complex $I \in \mathrm{Ch}(\mathcal{A})$ is *K-injective* if $\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X, I) = 0$ for every acyclic complex X. A *K-injective resolution* of a complex X is a quasi-isomorphism $X \to I$ with I K-injective.

This is [98, Tag 070H]. The complex of example 59.1.7 is not K-injective, since id_I is a nonzero element of $\mathrm{Hom}_{\mathrm{K}}(I, I)$ with I acyclic.

Lemma 59.1.9: Shifts of K-Injective Complexes

Let $\mathcal{A}$ be an abelian category and $I \in \mathrm{Ch}(\mathcal{A})$ a K-injective complex. Then $I[n]$ is K-injective for every $n \in \mathbb{Z}$.

***Proof*:**
Let X be an acyclic complex. By (57.1) the shift $[-n]$ is an automorphism of $\mathrm{K}(\mathcal{A})$ inverse to $[n]$, so $f \mapsto f[-n]$ is a bijection from $\mathrm{Hom}_{\mathrm{K}}(X, I[n])$ to $\mathrm{Hom}_{\mathrm{K}}(X[-n], I)$. The complex $X[-n]$ is acyclic, since $H^i(X[-n]) = H^{i-n}(X) = 0$ by (57.1), and I is K-injective, so $\mathrm{Hom}_{\mathrm{K}}(X[-n], I) = 0$. Hence $\mathrm{Hom}_{\mathrm{K}}(X, I[n]) = 0$, as we sought to show.

By lemma 57.4.3(1), $H^n\mathrm{Hom}^\bullet(X, I) = \mathrm{Hom}_{\mathrm{K}}(X, I[n])$, so with the lemma I is K-injective exactly when the Hom complex $\mathrm{Hom}^\bullet(X, I)$ is acyclic for every acyclic X. This is the definition of [95, p. 1.1], which credits it to J. Bernstein.

Example 59.1.10: Complexes of Injectives With Zero Differential

Let $(E_n)_{n\in\mathbb{Z}}$ be injective objects of $\mathcal{A}$ and E the complex with $E^n = E_n$ and every differential zero. For every complex X,

$$\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(X, E) \cong \prod_{n\in\mathbb{Z}} \mathrm{Hom}_{\mathcal{A}}\big(H^n(X), E_n\big)$$

and in particular E is K-injective.

Write $Z^n = \ker d_X^n$ and $B^n = \mathrm{im} d_X^{n-1}$. A chain map $f\colon X \to E$ is a family $f^n\colon X^n \to E_n$ with $f^{n+1}d_X^n = 0 \circ f^n = 0$, so each f^n vanishes on B^n, and the chain maps are $\prod_n \mathrm{Hom}(X^n/B^n, E_n)$. A null-homotopy s has $f^n = 0 \circ s^n + s^{n+1}d_X^n = s^{n+1}d_X^n$ with $s^{n+1}\colon X^{n+1} \to E_n$. The differential d_X^n factors as $X^n \to X^n/Z^n \cong B^{n+1} \hookrightarrow X^{n+1}$, and since E_n is injective, $\mathrm{Hom}(X^{n+1}, E_n) \to \mathrm{Hom}(B^{n+1}, E_n)$ is surjective (definition 56.2.1). So the maps of the form $s^{n+1}d_X^n$ are exactly those factoring through $X^n \to X^n/Z^n$, that is, $\mathrm{Hom}(X^n/Z^n, E_n)$. Applying the exact functor $\mathrm{Hom}(-, E_n)$ to

$$0 \to H^n(X) = Z^n/B^n \to X^n/B^n \to X^n/Z^n \to 0$$

identifies $\mathrm{Hom}(X^n/B^n, E_n)/\mathrm{Hom}(X^n/Z^n, E_n)$ with $\mathrm{Hom}(H^n(X), E_n)$, by restriction. Over $\mathbb{Z}/4$ with every $E_n = \mathbb{Z}/4$, injective by example 59.1.7(1), this complex is K-injective, while the complex of example 59.1.7 has the same terms and differential 2 and is not.

Proposition 59.1.11: K-Injective Complexes Compute Morphisms in $D(\mathcal{A})$

Let $\mathcal{A}$ be an abelian category and $I \in \mathrm{Ch}(\mathcal{A})$. The following are equivalent.

1. I is K-injective.
2. For every quasi-isomorphism $s\colon X' \to X$ the map $s^*\colon \mathrm{Hom}_{\mathrm{K}}(X, I) \to \mathrm{Hom}_{\mathrm{K}}(X', I)$, $f \mapsto fs$, is bijective.
3. For every complex X the map $Q\colon \mathrm{Hom}_{\mathrm{K}}(X, I) \to \mathrm{Hom}_{D}(X, I)$ is bijective.

***Proof*:**

(1) implies (2). By theorem 57.1.12 the mapping cone triangle $X' \xrightarrow{s} X \xrightarrow{v} MC(s) \xrightarrow{w} X'[1]$ is distinguished in $\mathrm{K}(\mathcal{A})$, and by (TR2) so is $\big(-w[-1], s, v\big)$ on $(MC(s)[-1], X', X)$. The complex $MC(s)$ is acyclic by proposition 56.1.24, and so is $MC(s)[-1]$. The functor $\mathrm{Hom}_{\mathrm{K}}(-, I)$ is cohomological by proposition 57.1.8, and applied to the two triangles it gives sequences

$$\mathrm{Hom}_{\mathrm{K}}(MC(s), I) \xrightarrow{v^*} \mathrm{Hom}_{\mathrm{K}}(X, I) \xrightarrow{s^*} \mathrm{Hom}_{\mathrm{K}}(X', I) \xrightarrow{(-w[-1])^*} \mathrm{Hom}_{\mathrm{K}}(MC(s)[-1], I)$$

exact at $\mathrm{Hom}_{\mathrm{K}}(X, I)$ and at $\mathrm{Hom}_{\mathrm{K}}(X', I)$. The two outer groups vanish because I is K-injective, so s^* is injective and surjective.

(2) implies (3). By theorem 57.2.4 a morphism $X \to I$ of $D(\mathcal{A})$ is $Q(f)Q(s)^{-1}$ for a roof (X', s, f), with $s\colon X' \to X$ a quasi-isomorphism. By (2), $f = gs$ in $\mathrm{K}(\mathcal{A})$ for some $g\colon X \to I$, and then $Q(f)Q(s)^{-1} = Q(g)$, so Q is surjective. The functor Q is additive by theorem 57.2.7. If $Q(h) = 0$, then proposition 57.2.12(2) gives a quasi-isomorphism $t\colon X'' \to X$ with ht null-homotopic, that is, $t^*(h) = 0$, and the injectivity of t^* gives $h = 0$ in $\mathrm{K}(\mathcal{A})$.

(3) implies (1). An acyclic X is isomorphic to 0 in $D(\mathcal{A})$ by proposition 57.2.12(1), so $\mathrm{Hom}_{D}(X, I) = 0$, and the bijection of (3) gives $\mathrm{Hom}_{\mathrm{K}}(X, I) = 0$, completing the proof.

The equivalence is [98, Tag 070I]. Condition (3) says that the morphisms into a K-injective complex are the same in $D(\mathcal{A})$ as in $\mathrm{K}(\mathcal{A})$, so they need no roofs. For a bounded-below complex of injectives, condition (3) is lemma 57.4.4(2).

Corollary 59.1.12: Bounded-Below Complexes of Injectives Are K-Injective

Let $\mathcal{A}$ be an abelian category. Every bounded-below complex of injective objects of $\mathcal{A}$ is K-injective.

***Proof*:**

For such a complex I, lemma 57.4.4(2) is condition (3) of proposition 59.1.11, as required.

So the injective resolutions of bounded-below complexes used in chapter 57, for instance the resolutions ι_B of definition 57.4.6, are K-injective resolutions. A quasi-isomorphism between bounded-below complexes of injectives is a homotopy equivalence by theorem 56.2.9, and the same holds with the bound replaced by K-injectivity.

Corollary 59.1.13: Quasi-Isomorphisms Between K-Injective Complexes

Let $\mathcal{A}$ be an abelian category.

1. A quasi-isomorphism $s\colon I \to J$ between K-injective complexes is a homotopy equivalence.
2. If $a\colon X \to I$ and $a'\colon X \to I'$ are K-injective resolutions, there is a homotopy equivalence $c\colon I \to I'$ with $ca = a'$ in $\mathrm{K}(\mathcal{A})$, and c is unique up to homotopy with this property.

***Proof*:**

1. By proposition 59.1.11(2) for I, the map $s^*\colon \mathrm{Hom}_{\mathrm{K}}(J, I) \to \mathrm{Hom}_{\mathrm{K}}(I, I)$ is bijective, so there is $t\colon J \to I$ with $ts = \mathrm{id}_I$ in $\mathrm{K}(\mathcal{A})$. Then $(st)s = s = \mathrm{id}_J s$, and $s^*\colon \mathrm{Hom}_{\mathrm{K}}(J, J) \to \mathrm{Hom}_{\mathrm{K}}(I, J)$ is injective by the same proposition for J, so $st = \mathrm{id}_J$ in $\mathrm{K}(\mathcal{A})$ and s is a homotopy equivalence.
2. By proposition 59.1.11(2) for I' and the quasi-isomorphism a, there is a unique class $c \in \mathrm{Hom}_{\mathrm{K}}(I, I')$ with $ca = a'$. Then $H^n(c)H^n(a) = H^n(a')$ with $H^n(a)$ and $H^n(a')$ isomorphisms, so c is a quasi-isomorphism and, by (1), a homotopy equivalence, as claimed.

For a bounded-below complex of injectives I, every quasi-isomorphism $s\colon X \to X'$ induces a quasi-isomorphism $s^*\colon \mathrm{Hom}^\bullet(X', I) \to \mathrm{Hom}^\bullet(X, I)$ of Hom complexes by corollary 57.4.5(1).

Corollary 59.1.14: Hom into a K-Injective Complex Preserves Quasi-Isomorphisms

Let $\mathcal{A}$ be an abelian category, $I \in \mathrm{Ch}(\mathcal{A})$ a K-injective complex and $s\colon X \to X'$ a quasi-isomorphism. Then $s^*\colon \mathrm{Hom}^\bullet(X', I) \to \mathrm{Hom}^\bullet(X, I)$ is a quasi-isomorphism.

***Proof*:**
Fix $n \in \mathbb{Z}$. By lemma 57.4.3(1) and (3), $H^n(s^*)$ is the map $\mathrm{Hom}_{\mathrm{K}}(X', I[n]) \to \mathrm{Hom}_{\mathrm{K}}(X, I[n])$, $\psi \mapsto \psi s$. The complex $I[n]$ is K-injective by lemma 59.1.9, so this map is bijective by proposition 59.1.11(2), as we sought to show.

The existence of K-injective resolutions for modules is Spaltenstein's theorem [95, Proposition 3.11], and its proof runs through the limit of a tower and its first derived functor from section 58.5. A complex X is the limit of the tower of its truncations $\tau^{\geq -n}X$ (example 59.1.16). Each truncation is bounded below and so has a bounded-below injective resolution, and the resolutions can be chosen to form a tower with split surjective transition maps. The limit of that tower is a K-injective resolution of X.

For a tower $A_\bullet$ of R-modules the map d^A of definition 58.5.2 is R-linear, so $\varprojlim A_\bullet$ and $\varprojlim{}^1 A_\bullet$ are R-modules. A homomorphism $M \to \varprojlim A_\bullet$ is the same as a family of homomorphisms $M \to A_n$ compatible with the transition maps, since $\varprojlim A_\bullet = \ker d^A$ is the module of coherent sequences.

Definition 59.1.15: Tower of Complexes and Its Limit

Let R be a ring. A *tower of complexes* of R-modules $C_\bullet = (C_n)_{n\geq 0}$ is a family of complexes C_n with chain maps $q_{n+1}\colon C_{n+1} \to C_n$. For each i the differentials $d^i\colon C_n^i \to C_n^{i+1}$ form a morphism of towers, the q_{n+1} being chain maps, so they induce $\varprojlim_n C_n^i \to \varprojlim_n C_n^{i+1}$ by definition 58.5.2, with square zero. The *limit* $\varprojlim C_\bullet$ is the resulting complex, with $(\varprojlim C_\bullet)^i = \varprojlim_n C_n^i$.

Example 59.1.16: The Tower of Truncations of a Complex

Let X be a complex of R-modules and put $X_n := \tau^{\geq -n}X$ for $n \geq 0$ (definition 56.1.12). Let $r_{n+1}\colon X_{n+1} \to X_n$ be zero in degrees below $-n$, the quotient $X^{-n} \to X^{-n}/B^{-n}$ in degree $-n$, and the identity in degrees above $-n$. It is a chain map: in degree $-n-1$ the differential of X_{n+1} lands in B^{-n}, which the quotient kills, and in degree $-n$ the induced differential of X_n composed with the quotient is d^{-n}. So $X_\bullet$ is a tower of complexes. Comparing degree by degree, the quotient maps $p_{-n}\colon X \to X_n$ satisfy $r_{n+1}p_{-n-1} = p_{-n}$, so they induce a chain map $X \to \varprojlim X_\bullet$. In degree i the maps p^i_{-n} and r^i_{n+1} are identities once $n > -i$, and a coherent sequence in a tower whose transition maps are identities from some index N on is determined by its term of index N. So $X \to \varprojlim X_\bullet$ is an isomorphism in every degree, and X is the limit of its truncations.

The projections $\varprojlim C_\bullet \to C_n$ are chain maps. For each m the groups $H^m(C_n)$ with the maps $H^m(q_{n+1})$ form a tower $H^m(C_\bullet)$.

Lemma 59.1.17: The Cohomology of a Limit of Complexes

Let R be a ring and $(C_n)_{n\geq 0}$ a tower of complexes of R-modules whose transition maps $q^i_{n+1}\colon C^i_{n+1} \to C^i_n$ are surjective for every i and n. Then for every $m \in \mathbb{Z}$ there is an exact sequence

$$0 \to \varprojlim{}^1 H^{m-1}(C_\bullet) \to H^m\big(\varprojlim C_\bullet\big) \to \varprojlim H^m(C_\bullet) \to 0$$

in which the second map is induced by the projections $\varprojlim C_\bullet \to C_n$.

***Proof*:**

Let $P := \prod_n C_n$, the product taken degreewise with the product differential, and let $\delta\colon P \to P$ be $(c_n)_n \mapsto \big(c_n - q_{n+1}(c_{n+1})\big)_n$, the map d^A of definition 58.5.2 for the tower $A_\bullet = C^i_\bullet$ in each degree i. It is a chain map, since the q_{n+1} are, and by definition $\varprojlim C_\bullet = \ker\delta$. The cokernel of δ in degree i is $\varprojlim{}^1 C^i_\bullet$, which vanishes by corollary 58.5.7. So

$$0 \to \varprojlim C_\bullet \to P \xrightarrow{\delta} P \to 0$$

is a short exact sequence of complexes, and theorem 56.1.18 gives the exact sequence

$$H^{m-1}(P) \xrightarrow{H^{m-1}(\delta)} H^{m-1}(P) \xrightarrow{\partial} H^m\big(\varprojlim C_\bullet\big) \to H^m(P) \xrightarrow{H^m(\delta)} H^m(P)$$

Products are exact in R-Mod, so $H^m(P) = \prod_n H^m(C_n)$ by lemma 56.1.11, and under this identification $H^m(\delta)$ is

$$([c_n])_n \longmapsto \big([c_n] - H^m(q_{n+1})[c_{n+1}]\big)_n$$

That is the map d^A of definition 58.5.2 for the tower $H^m(C_\bullet)$, so $\ker H^m(\delta) = \varprojlim H^m(C_\bullet)$, and likewise $\operatorname{coker} H^{m-1}(\delta) = \varprojlim{}^1 H^{m-1}(C_\bullet)$. Exactness at the three middle terms makes ∂ induce an injection of $\operatorname{coker} H^{m-1}(\delta)$ onto the kernel of $H^m(\varprojlim C_\bullet) \to H^m(P)$, and makes the image of that map $\ker H^m(\delta)$. The components of $H^m(\varprojlim C_\bullet) \to \prod_n H^m(C_n)$ are induced by the projections, as claimed.

This is Weibel [101] 3.5.8, in its form for cochain complexes, where it is proved under the Mittag-Leffler condition. Exercise 59.1.1 (8) recovers example 58.5.9 from it.

Lemma 59.1.18: A Limit of K-Injective Complexes Along Split Surjections Is K-Injective

Let R be a ring and $(I_n)_{n\geq 0}$ a tower of complexes of R-modules, with transition maps $q_{n+1}\colon I_{n+1} \to I_n$, such that every I_n is K-injective and every q^i_{n+1} is a split surjection. Then $\varprojlim I_\bullet$ is K-injective.

***Proof*:**
Let M be an acyclic complex of R-modules and write $I = \varprojlim I_\bullet$. In degree k,

$$\operatorname{Hom}^k(M, I) = \prod_i \operatorname{Hom}\big(M^i, \varprojlim_n I_n^{i+k}\big) = \prod_i \varprojlim_n \operatorname{Hom}\big(M^i, I_n^{i+k}\big) = \varprojlim_n \operatorname{Hom}^k(M, I_n)$$

by the description of homomorphisms into a limit, and because a product of limits is the limit of the products, the maps d^A being formed coordinatewise. The differential of definition 57.4.1 is formed by composing with differentials, so this is an isomorphism of complexes $\operatorname{Hom}^\bullet(M, I) \cong \varprojlim_n \operatorname{Hom}^\bullet(M, I_n)$, the transition maps being the chain maps $(q_{n+1})_*$ of lemma 57.4.3(2). These are surjective in each degree: if σ is a section of q^{i+k}_{n+1}, then $\sigma\psi$ is a preimage of $\psi\colon M^i \to I_n^{i+k}$. Each $\operatorname{Hom}^\bullet(M, I_n)$ is acyclic, since by lemma 57.4.3(1)

$$H^j \operatorname{Hom}^\bullet(M, I_n) = \operatorname{Hom}_{\mathrm{K}}(M, I_n[j]) = 0$$

with M acyclic and $I_n[j]$ K-injective by lemma 59.1.9. Lemma 59.1.17 for the tower $\operatorname{Hom}^\bullet(M, I_\bullet)$ of complexes of abelian groups places $H^0\operatorname{Hom}^\bullet(M, I)$ between $\varprojlim{}^1$ and $\varprojlim$ of towers of zero groups, so $\operatorname{Hom}_{\mathrm{K}}(M, I) = H^0\operatorname{Hom}^\bullet(M, I) = 0$, as we sought to show.

The lemma is [98, Tag 070L].

Theorem 59.1.19: K-Injective Resolutions Exist

Let $\mathcal{A}$ be a Grothendieck abelian category and $X \in \mathrm{Ch}(\mathcal{A})$. There is a quasi-isomorphism $\iota_X\colon X \to I_X$ such that I_X is K-injective, every I_X^n is an injective object and every ι_X^n is a monomorphism. Moreover the choice can be made functorial: there are a functor $\mathbf{I}\colon \mathrm{Ch}(\mathcal{A}) \to \mathrm{Ch}(\mathcal{A})$ and a natural transformation $\iota\colon \mathrm{id} \to \mathbf{I}$ such that $I_X = \mathbf{I}(X)$ and ι_X have these properties for every X.

For $\mathcal{A} = R$-Mod the first statement is proved below by Spaltenstein's argument. The same strategy works in every abelian category with enough injectives and exact countable products [98, Tag 090Y]. For a general Grothendieck abelian category, and for the functorial form, the proof is a transfinite

construction in the style of the proof of theorem 59.1.6, built from its functorial injective embeddings and from a set of representatives of the bounded-above acyclic complexes of bounded size. It is due to Serpé, generalizing Spaltenstein, and it is long and set-theoretic, so it is deferred to [98, Tag 079P], with the attribution at [98, Tag 079I].

***Proof*:**
Let $\mathcal{A} = R$-Mod. By theorem 59.1.6 and example 59.1.5(1) it has enough injectives.

Step 1: the tower of truncations. Let $X_\bullet$ be the tower of truncations of example 59.1.16, with $X_n = \tau^{\geq -n}X$, transition maps r_{n+1} and quotient maps $p_{-n}\colon X \to X_n$ satisfying $r_{n+1}p_{-n-1} = p_{-n}$. By proposition 56.1.14, $H^i(p_{-n})$ is an isomorphism for $i \geq -n$ and $H^i(X_n) = 0$ for $i < -n$.

Step 2: a tower of resolutions. We construct bounded-below complexes of injectives I_n, quasi-isomorphisms $\alpha_n\colon X_n \to I_n$ and chain maps $q_{n+1}\colon I_{n+1} \to I_n$, each q^i_{n+1} split surjective, with

$$q_{n+1}\alpha_{n+1} = \alpha_n r_{n+1}$$

as chain maps. Bounded-below complexes have injective resolutions by theorem 56.2.17 applied to the opposite category, as after definition 57.4.6, and this gives $\alpha_0\colon X_0 \to I_0$. Given α_n, choose likewise a quasi-isomorphism $\beta\colon X_{n+1} \to J$ with J a bounded-below complex of injectives. The complex I_n is K-injective by corollary 59.1.12, so proposition 59.1.11(2) for β gives a chain map $g\colon J \to I_n$ and a homotopy h, with $h^i\colon X^i_{n+1} \to I^{i-1}_n$, such that

$$u := \alpha_n r_{n+1} - g\beta = dh + hd$$

Let P be the complex with $P^i := I^i_n \oplus I^{i-1}_n$ and $d(a,b) := (da, -a - db)$. Then $d(da, -a - db) = (0, -da + da + ddb) = 0$, so P is a complex, and it is acyclic: if $d(a,b) = 0$ then $a = -db$, and $(a,b) = d(-b, 0)$. Its terms are injective and it is bounded below. The projection $\pi(a,b) := a$ is a chain map $P \to I_n$, split surjective in each degree with section $a \mapsto (a, 0)$. Define

$$I_{n+1} := J \oplus P, \qquad q_{n+1} := (g, \pi), \qquad \alpha_{n+1}(x) := \big(\beta x, (ux, -hx)\big)$$

The map $k(x) := (ux, -hx)$ is a chain map $X_{n+1} \to P$: the first coordinates of $dk(x)$ and $k(dx)$ are dux and udx, equal because u is a chain map, and the second ones are $-ux + dhx$ and $-hdx$, equal because $u = dh + hd$. So $\alpha_{n+1} = (\beta, k)$ is a chain map, and $q_{n+1}\alpha_{n+1} = g\beta + \pi k = g\beta + u = \alpha_n r_{n+1}$. As $H^i(P) = 0$, the map $H^i(\alpha_{n+1})$ is $H^i(\beta)$ followed by the inclusion of $H^i(J)$ as $H^i(J \oplus P) = H^i(J) \oplus 0$, so α_{n+1} is a quasi-isomorphism. Finally q_{n+1} is split surjective in each degree, with section $a \mapsto (0, (a, 0))$.

Step 3: the limit. Let $I := \varprojlim I_\bullet$. It is K-injective by lemma 59.1.18, since each I_n is K-injective by corollary 59.1.12. Its terms are injective. Choosing sections of the q^i_{n+1}, each I^i_{n+1} decomposes as $I^i_n \oplus \ker q^i_{n+1}$ with q^i_{n+1} the projection, so by induction $I^i_n \cong I^i_0 \oplus K_1 \oplus \cdots \oplus K_n$ with $K_m := \ker q^i_m$ and transition maps forgetting the last summand. Hence $I^i \cong I^i_0 \times \prod_{m \geq 1} K_m$. Each K_m is injective as a direct summand of an injective module, and a product of injective modules is injective, since $\mathrm{Hom}(-, \prod_t E_t) = \prod_t \mathrm{Hom}(-, E_t)$ and products of exact sequences of abelian groups are exact. The chain maps $\alpha_n p_{-n}\colon X \to I_n$ are compatible, as $q_{n+1}\alpha_{n+1}p_{-n-1} = \alpha_n r_{n+1}p_{-n-1} = \alpha_n p_{-n}$, so they define a chain map $\alpha\colon X \to I$.

Step 4: α is a quasi-isomorphism. Fix m. For $n \geq -m$ the map $H^m(\alpha_n p_{-n})\colon H^m(X) \to H^m(I_n)$

is an isomorphism by Step 1, α_n being a quasi-isomorphism. For $n \geq -m$, the relation $H^m(q_{n+1})H^m(\alpha_{n+1}p_{-n-1}) = H^m(\alpha_n p_{-n})$ then makes $H^m(q_{n+1})$ an isomorphism, and for $n < -m$ its target $H^m(I_n) \cong H^m(X_n)$ is 0. So every transition map of the tower $H^m(I_\bullet)$ is surjective, for every m, and $\varprojlim{}^1 H^{m-1}(I_\bullet) = 0$ by corollary 58.5.7. By lemma 59.1.17, $H^m(I) \to \varprojlim H^m(I_\bullet)$ is an isomorphism. Let $N := \max(0, -m)$. A coherent sequence in a tower whose transition maps are isomorphisms from N on is determined by its term of index N, so the projection $\varprojlim H^m(I_\bullet) \to H^m(I_N)$ is an isomorphism. The composite $H^m(X) \to H^m(I) \to \varprojlim H^m(I_\bullet) \to H^m(I_N)$ is $H^m(\alpha_N p_{-N})$, an isomorphism, so $H^m(\alpha)$ is an isomorphism.

Step 5: a monomorphic resolution. Choose monomorphisms $e^i \colon X^i \to E^i$ into injective modules. Let P' be the complex with $P'^i := E^i \oplus E^{i+1}$ and $d(a,b) := (b,0)$, so that $d^2 = 0$. The maps $s(a,b) := (0,a)$, from P'^i to $P'^{i-1} = E^{i-1} \oplus E^i$, satisfy $ds + sd = \mathrm{id}$, since $(ds+sd)(a,b) = (a,0) + (0,b)$. So $\mathrm{id}_{P'}$ is null-homotopic, P' is acyclic by proposition 56.1.27, and every chain map f into P' is null-homotopic, being homotopic to $0 \circ f$. Thus P' is K-injective. The map $x \mapsto (e^i x, e^{i+1} dx)$ is a chain map $X \to P'$, as both d of it and its value on dx are $(e^{i+1}dx, 0)$, and it is a monomorphism in each degree because e^i is. Put $I_X := I \oplus P'$ and

$$\iota_X := \big(\alpha, x \mapsto (e^i x, e^{i+1} dx)\big) \colon X \longrightarrow I_X$$

a monomorphism in each degree. It is a quasi-isomorphism, since $H^i(I_X) = H^i(I) \oplus 0$ with $H^i(\iota_X)$ equal to $H^i(\alpha)$. The complex I_X has injective terms, and it is K-injective: for acyclic M, $\mathrm{Hom}_{\mathrm{K}}(M, I_X) \cong \mathrm{Hom}_{\mathrm{K}}(M, I) \oplus \mathrm{Hom}_{\mathrm{K}}(M, P') = 0$, since $\mathrm{K}(R\text{-Mod})$ is additive (lemma 56.1.37). This completes the proof for modules.

In Step 4 the towers $H^m(I_\bullet)$ are eventually constant, so their $\varprojlim{}^1$ vanishes and the limit has the cohomology of X. Without that, lemma 59.1.17 would leave a $\varprojlim{}^1$ term in $H^m(I)$. The auxiliary complex P of Step 2 turns commutativity up to homotopy into strict commutativity. The maps produced by proposition 59.1.11(2) commute only up to homotopy, while a map into a limit needs a strictly compatible family, and a chain map into P is a chain map into I_n together with a null-homotopy of it.

Example 59.1.20: A K-Injective Resolution of the Complex $\mathbb{Z}$ in Every Degree
Let X be the complex of abelian groups with $X^n = \mathbb{Z}$ for every n and every differential zero. For each n let J_n be the complex $\mathbb{Q} \to \mathbb{Q}/\mathbb{Z}$, the quotient map, in degrees n and $n+1$. The groups $\mathbb{Q}$ and $\mathbb{Q}/\mathbb{Z}$ are injective (example 57.4.7). Let I be the complex with $I^n = \mathbb{Q} \oplus \mathbb{Q}/\mathbb{Z}$, the factor $\mathbb{Q}$ coming from J_n and the factor $\mathbb{Q}/\mathbb{Z}$ from J_{n-1}, and differential $d(x,t) = (0,[x])$, where $[x] \in \mathbb{Q}/\mathbb{Z}$ lies in I^{n+1}. Then $d^2 = 0$, and I is the degreewise product $\prod_n J_n$, each degree having only two nonzero factors.

The map $\nu \colon X \to I$, $a \mapsto (a,0)$, is a chain map, since $d\nu(a) = (0,[a]) = 0$ for $a \in \mathbb{Z}$. It is a quasi-isomorphism: the cocycles of I^n are $\mathbb{Z} \oplus \mathbb{Q}/\mathbb{Z}$, the coboundaries are $0 \oplus \mathbb{Q}/\mathbb{Z}$, and $H^n(I) \cong \mathbb{Z}$ is generated by $(1,0) = \nu(1)$. And I is K-injective. A chain map $M \to \prod_n J_n$ is a family of chain maps $M \to J_n$, and the same holds for null-homotopies, so $\mathrm{Hom}_{\mathrm{K}}(M, I) = \prod_n \mathrm{Hom}_{\mathrm{K}}(M, J_n)$. For acyclic M every factor vanishes by corollary 59.1.12. So ν is a K-injective resolution of a complex unbounded in both directions, and ν is a monomorphism in each degree.

Theorem 57.2.4 describes the morphisms of $D(\mathcal{A})$ by roofs, which range over all quasi-isomorphisms into a complex, and it guarantees that the classes of roofs form sets only when the quasi-isomorphisms

into each complex admit a cofinal set. K-injective resolutions give a set-theoretic bound with no such hypothesis.

Corollary 59.1.21: The Derived Category Has Small Hom-Sets

Let $\mathcal{A}$ be a Grothendieck abelian category, $X, Y \in \mathrm{Ch}(\mathcal{A})$, and $\iota_Y \colon Y \to I_Y$ a K-injective resolution. Then

$$\mathrm{Hom}_{\mathrm{K}}(X, I_Y) \longrightarrow \mathrm{Hom}_{D}(X, Y), \qquad f \longmapsto Q(\iota_Y)^{-1} Q(f)$$

is bijective. In particular $\mathrm{Hom}_{D(\mathcal{A})}(X, Y)$ is a set.

***Proof*:**
The map is the composite of the bijection $Q \colon \mathrm{Hom}_{\mathrm{K}}(X, I_Y) \to \mathrm{Hom}_{D}(X, I_Y)$ of proposition 59.1.11(3) and of composition with the isomorphism $Q(\iota_Y)^{-1}$. The resolution exists by theorem 59.1.19. The source is a quotient of the set of chain maps $X \to I_Y$, which is a subset of the set $\prod_n \mathrm{Hom}_{\mathcal{A}}(X^n, I_Y^n)$, completing the proof.

The corollary gives the conclusion that theorem 57.2.4 states under its cofinality hypothesis, without that hypothesis, for every Grothendieck abelian category, R-Mod included. In definition 57.3.5 the total derived functor of a left exact F was obtained by applying F term by term to a resolution in an adapted class, with bounded-below complexes throughout. K-injective resolutions do the same with no bound and with no exactness assumption on F. For an additive $F \colon \mathcal{A} \to \mathcal{B}$, applying F term by term carries null-homotopies to null-homotopies (lemma 56.1.32), so it defines a functor $\mathrm{K}(F) \colon \mathrm{K}(\mathcal{A}) \to \mathrm{K}(\mathcal{B})$. Write $Q_{\mathcal{A}}$ and $Q_{\mathcal{B}}$ for the localization functors, and $R^{+}F$ for the total derived functor of definition 57.3.5, with its transformation ε_F of theorem 57.3.6.

Corollary 59.1.22: Right Derived Functors on Unbounded Complexes

Let $\mathcal{A}$ be a Grothendieck abelian category, $\mathcal{B}$ an abelian category and $F \colon \mathcal{A} \to \mathcal{B}$ an additive functor. For every complex X fix a K-injective resolution $\iota_X \colon X \to I_X$ (theorem 59.1.19).

1. For every morphism $\varphi \colon X \to Y$ of $D(\mathcal{A})$ there is a unique $I_\varphi \in \mathrm{Hom}_{\mathrm{K}}(I_X, I_Y)$ with $Q_{\mathcal{A}}(I_\varphi)\, Q_{\mathcal{A}}(\iota_X) = Q_{\mathcal{A}}(\iota_Y)\, \varphi$, and $X \mapsto I_X$, $\varphi \mapsto I_\varphi$ is a functor $I_{(-)} \colon D(\mathcal{A}) \to \mathrm{K}(\mathcal{A})$.

2. Put $RF := Q_{\mathcal{B}} \circ \mathrm{K}(F) \circ I_{(-)}$ and $\varepsilon_X := Q_{\mathcal{B}}\big(F(\iota_X)\big) \colon F(X) \to RF(X)$. Then $\varepsilon \colon Q_{\mathcal{B}} \circ \mathrm{K}(F) \to RF \circ Q_{\mathcal{A}}$ is natural, and (RF, ε) is initial: for every functor $G \colon D(\mathcal{A}) \to D(\mathcal{B})$ and every natural transformation $\eta \colon Q_{\mathcal{B}} \circ \mathrm{K}(F) \to G \circ Q_{\mathcal{A}}$ there is a unique natural transformation $\theta \colon RF \to G$ with $\eta = (\theta * Q_{\mathcal{A}}) \circ \varepsilon$. Hence RF does not depend on the chosen resolutions, up to a unique natural isomorphism compatible with ε.

3. RF is a triangulated functor.

4. If F is left exact, then for every bounded-below complex X there is an isomorphism $\theta_X \colon RF(X) \to R^{+}F(X)$ in $D(\mathcal{B})$, natural in X for the morphisms of $D^{+}(\mathcal{A})$, with $\theta_X \varepsilon_X = \varepsilon_F(X)$. In particular $H^n\big(RF(A)\big) \cong R^nF(A)$ for every object A of $\mathcal{A}$, natural in A.

***Proof*:**
Write Q for $Q_{\mathcal{A}}$ where no confusion arises. Since I_Y is K-injective, $Q\colon \mathrm{Hom}_{\mathrm{K}}(Z, I_Y) \to \mathrm{Hom}_D(Z, I_Y)$ is bijective for every Z (proposition 59.1.11(3)), and $Q(\iota_X)$ is invertible.

(1). The morphism $Q(\iota_Y)\varphi Q(\iota_X)^{-1}$ of $\mathrm{Hom}_D(I_X, I_Y)$ has a unique preimage under Q, which is I_φ. Uniqueness gives $I_{\mathrm{id}} = \mathrm{id}$, $I_{\varphi'\varphi} = I_{\varphi'} I_\varphi$ and $I_{\varphi+\varphi'} = I_\varphi + I_{\varphi'}$, since the right-hand sides satisfy the defining equations. For a chain map $f\colon X \to Y$, the classes $I_{Qf}\,\iota_X$ and $\iota_Y f$ in $\mathrm{Hom}_{\mathrm{K}}(X, I_Y)$ have the same image under Q, so $I_{Qf}\,\iota_X = \iota_Y f$ in $\mathrm{K}(\mathcal{A})$.

(2). Naturality of ε: for a chain map $f\colon X \to Y$,

$$RF(Qf)\,\varepsilon_X = Q_{\mathcal{B}}F\big(I_{Qf}\,\iota_X\big) = Q_{\mathcal{B}}F(\iota_Y f) = \varepsilon_Y\, Q_{\mathcal{B}}F(f)$$

by (1). If W is K-injective, then $\iota_W\colon W \to I_W$ is a quasi-isomorphism between K-injective complexes, hence a homotopy equivalence (corollary 59.1.13(1)), so $F(\iota_W)$ is a homotopy equivalence by lemma 56.1.32 and ε_W is an isomorphism. Given (G, η), put $\mu_W := \eta_W \varepsilon_W^{-1}\colon RF(W) \to G(W)$ for K-injective W. For a morphism $\psi\colon W \to W'$ of $\mathrm{K}(\mathcal{A})$ between K-injective complexes, naturality of ε and η along ψ gives $\mu_{W'} RF(Q\psi) = \eta_{W'} Q_{\mathcal{B}}F(\psi)\varepsilon_W^{-1} = G(Q\psi)\mu_W$.

If θ satisfies $\theta_X \varepsilon_X = \eta_X$ for every X, then $\theta_W = \mu_W$ for K-injective W, and naturality along $Q(\iota_X)$ forces

$$\theta_X = G(Q\iota_X)^{-1}\,\mu_{I_X}\,RF(Q\iota_X)$$

so θ is unique. Conversely define θ_X by this formula. Naturality of ε along ι_X and of η along ι_X give

$$\theta_X\varepsilon_X = G(Q\iota_X)^{-1}\,\eta_{I_X}\,\varepsilon_{I_X}^{-1}\,\varepsilon_{I_X}\,Q_{\mathcal{B}}F(\iota_X) = G(Q\iota_X)^{-1}\,G(Q\iota_X)\,\eta_X = \eta_X$$

For $\varphi\colon X \to Y$ in $D(\mathcal{A})$ put $\psi := I_\varphi$, so that $Q(\iota_Y)\varphi = Q(\psi)Q(\iota_X)$. Applying RF and G to this equation gives $RF(Q\iota_Y)RF(\varphi) = RF(Q\psi)RF(Q\iota_X)$ and $G(Q\iota_Y)^{-1}G(Q\psi) = G(\varphi)G(Q\iota_X)^{-1}$, so, with the naturality of μ along ψ,

$$\theta_Y RF(\varphi) = G(Q\iota_Y)^{-1}\mu_{I_Y} RF(Q\psi)RF(Q\iota_X) = G(Q\iota_Y)^{-1}G(Q\psi)\mu_{I_X} RF(Q\iota_X) = G(\varphi)\,\theta_X$$

So θ is natural. Two choices of resolutions give two initial pairs, and the comparison transformations between them compose to identities by the uniqueness proved above.

(3). RF is additive, as $I_{(-)}$, $\mathrm{K}(F)$ and $Q_{\mathcal{B}}$ are. *Shift.* The complex $I_X[1]$ is K-injective by lemma 59.1.9, and $\iota_X[1]$ is a quasi-isomorphism since $H^n(\iota_X[1]) = H^{n+1}(\iota_X)$. As in (1) there is a unique $\omega_X \in \mathrm{Hom}_{\mathrm{K}}(I_{X[1]}, I_X[1])$ with $Q(\omega_X)Q(\iota_{X[1]}) = Q(\iota_X[1])$. Applying the functor H^n on $D(\mathcal{A})$ (proposition 57.2.8) gives $H^n(\omega_X)H^n(\iota_{X[1]}) = H^n(\iota_X[1])$ with both $H^n(\iota_{X[1]})$ and $H^n(\iota_X[1])$ isomorphisms, so ω_X is a quasi-isomorphism between K-injective complexes and hence an isomorphism of $\mathrm{K}(\mathcal{A})$ by corollary 59.1.13(1). For $\varphi\colon X \to Y$ the classes $\omega_Y I_{\varphi[1]}$ and $I_\varphi[1]\omega_X$ both satisfy the equation $Q(-)Q(\iota_{X[1]}) = Q(\iota_Y[1])\varphi[1]$, so they are equal and ω is natural. Since F is additive, $F(Z[1]) = F(Z)[1]$ for every complex Z, the differential $-d$ going to $-F(d)$. So $\zeta_X := Q_{\mathcal{B}}F(\omega_X)\colon RF(X[1]) \to RF(X)[1]$ is a natural isomorphism.

Triangles. Let $u\colon X \to Y$ be a chain map with mapping cone triangle $X \xrightarrow{u} Y \xrightarrow{v} MC(u) \xrightarrow{w} X[1]$, and put $\tilde{u} := I_{Qu}$, so that $\tilde{u}\,\iota_X = \iota_Y u$ in $\mathrm{K}(\mathcal{A})$ by (1). Let $I_Y \xrightarrow{\tilde{v}} MC(\tilde{u}) \xrightarrow{\tilde{w}} I_X[1]$ complete

the cone triangle of $\tilde{u}$. The cone $MC(\tilde{u})$ is K-injective: for acyclic M, the functor $\mathrm{Hom}_{\mathrm{K}}(M,-)$ is cohomological (proposition 57.1.8), and on the rotation $(\tilde{v},\tilde{w},-\tilde{u}[1])$ of the cone triangle it gives an exact sequence $\mathrm{Hom}_{\mathrm{K}}(M,I_Y)\to\mathrm{Hom}_{\mathrm{K}}(M,MC(\tilde{u}))\to\mathrm{Hom}_{\mathrm{K}}(M,I_X[1])$ with vanishing outer terms. By (TR3) in $\mathrm{K}(\mathcal{A})$ there is $c\colon MC(u)\to MC(\tilde{u})$ making (ι_X,ι_Y,c) a morphism of triangles, so $cv=\tilde{v}\,\iota_Y$ and $\tilde{w}c=\iota_X[1]\,w$. Its image under Q is a morphism of distinguished triangles of $D(\mathcal{A})$ (theorem 57.2.7) whose first two components are isomorphisms, so $Q(c)$ is an isomorphism by corollary 57.1.9, and c is a quasi-isomorphism. Let $\kappa\in\mathrm{Hom}_{\mathrm{K}}(I_{MC(u)},MC(\tilde{u}))$ be the unique class with $Q(\kappa)Q(\iota_{MC(u)})=Q(c)$, an isomorphism of $\mathrm{K}(\mathcal{A})$ by the argument used for ω_X.

We claim that $(\mathrm{id},\mathrm{id},\kappa)$ is an isomorphism of triangles from $\big(\tilde{u},I_{Qv},\omega_X I_{Qw}\big)$ to $(\tilde{u},\tilde{v},\tilde{w})$. The targets $MC(\tilde{u})$ and $I_X[1]$ of the remaining two squares are K-injective, so it suffices to compare their two sides after applying Q and composing with the isomorphisms $Q(\iota_Y)$ and $Q(\iota_{MC(u)})$ respectively. Using (1),

$$Q\big(\kappa\, I_{Qv}\big)Q(\iota_Y)=Q(\kappa)Q(\iota_{MC(u)})Q(v)=Q(cv)=Q(\tilde{v})Q(\iota_Y)$$
$$Q(\tilde{w}\kappa)Q(\iota_{MC(u)})=Q(\tilde{w}c)=Q(\iota_X[1])Q(w)=Q(\omega_X)Q(\iota_{X[1]})Q(w)=Q\big(\omega_X I_{Qw}\big)Q(\iota_{MC(u)})$$

Cancelling the isomorphisms $Q(\iota_Y)$ and $Q(\iota_{MC(u)})$ and using proposition 59.1.11(3) for the targets gives $\kappa\, I_{Qv}=\tilde{v}$ and $\tilde{w}\kappa=\omega_X I_{Qw}$ in $\mathrm{K}(\mathcal{A})$, which proves the claim. So the triangle $\big(\tilde{u},I_{Qv},\omega_X I_{Qw}\big)$ is distinguished in $\mathrm{K}(\mathcal{A})$, by (TR1). By definition 56.1.21, $F(MC(\tilde{u}))$ is $MC(F(\tilde{u}))$ term by term, with F applied to the inclusion and the projection, so $\mathrm{K}(F)$ carries cone triangles, and with (TR1) all distinguished triangles, to distinguished triangles of $\mathrm{K}(\mathcal{B})$, and $Q_{\mathcal{B}}$ carries those to distinguished triangles of $D(\mathcal{B})$. The image of our triangle is $\big(RF(Qu),RF(Qv),\zeta_X RF(Qw)\big)$, which is therefore distinguished. Every distinguished triangle of $D(\mathcal{A})$ is isomorphic to the image under Q of a mapping cone triangle (theorem 57.2.7 and theorem 57.1.12). The functor RF, with the natural ζ, carries isomorphic triangles to isomorphic triangles, and the distinguished triangles of $D(\mathcal{B})$ are closed under isomorphism, which proves (3).

(4). By the last assertion of (2), a second choice of resolutions changes RF and ε by a natural isomorphism compatible with ε, and composing with it carries an isomorphism θ as in (4) for one choice to one for the other. So we may take ι_X to be a quasi-isomorphism into a bounded-below complex of injectives whenever X is bounded below, as in Step 2 of the proof of theorem 59.1.19. Such ι_X is a K-injective resolution by corollary 59.1.12, and then I_φ is a morphism of $\mathrm{K}^+(\mathcal{A})$ for every morphism φ of $D^+(\mathcal{A})$ between bounded-below complexes. By theorem 57.3.6(3) we may compute R^+F with the class of injectives, adapted to F by example 57.3.3(1), $\mathcal{A}$ having enough injectives by theorem 59.1.6. Write $\mathcal{R}$ for this class, $\Psi\colon \mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]\to D^+(\mathcal{A})$ for the equivalence of theorem 57.3.4, Φ for the inverse of Ψ from which R^+F is built, $\beta\colon \mathrm{id}\to\Psi\Phi$ for the natural isomorphism exhibiting Φ as an inverse of Ψ, and $\bar{F}\colon \mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]\to D^+(\mathcal{B})$ for the functor induced by F term by term, so that $R^+F=\bar{F}\Phi$. Let W be a bounded-below complex of injectives. It lies in $\mathrm{K}^+(\mathcal{R})$, so the quasi-isomorphism $s\colon W\to Z$ in the definition of $\varepsilon_F(W)$ in theorem 57.3.6 may be taken to be id_W, the result not depending on s by part (1) of that theorem. That definition then reads $\varepsilon_F(W)=\bar{F}(\gamma)^{-1}Q_{\mathcal{B}}\big(F(\mathrm{id}_W)\big)=\bar{F}(\gamma)^{-1}$, where $\gamma\colon \Phi(Q_{\mathcal{A}}W)\to W$ is the morphism of $\mathrm{K}^+(\mathcal{R})[S_{\mathcal{R}}^{-1}]$ with $\Psi(\gamma)=Q_{\mathcal{A}}(\mathrm{id}_W)\beta_W^{-1}=\beta_W^{-1}$. As Ψ is an equivalence and β_W^{-1} is an isomorphism, γ is an isomorphism, hence so is $\bar{F}(\gamma)$, and $\varepsilon_F(W)$ is

an isomorphism. Set

$$\theta_X := R^+F(Q\iota_X)^{-1}\,\varepsilon_F(I_X)\colon RF(X) = Q_{\mathcal{B}}F(I_X) \longrightarrow R^+F(X)$$

an isomorphism. Naturality of ε_F along ι_X gives $\theta_X\varepsilon_X = R^+F(Q\iota_X)^{-1}\,\varepsilon_F(I_X)\,Q_{\mathcal{B}}F(\iota_X) = \varepsilon_F(X)$. For a morphism $\varphi\colon X \to Y$ of $D^+(\mathcal{A})$ between bounded-below complexes, naturality of ε_F along I_φ and the relation $Q(\iota_Y)^{-1}Q(I_\varphi) = \varphi\,Q(\iota_X)^{-1}$ give

$$\theta_Y RF(\varphi) = R^+F(Q\iota_Y)^{-1}R^+F\big(Q(I_\varphi)\big)\varepsilon_F(I_X) = R^+F(\varphi)\,R^+F(Q\iota_X)^{-1}\varepsilon_F(I_X) = R^+F(\varphi)\,\theta_X$$

For an object A of $\mathcal{A}$, applying H^n to θ_A and using theorem 57.3.7 gives $H^n(RF(A)) \cong R^nF(A)$, natural in A, completing the proof.

Part (2) is a stronger universal property than the one in theorem 57.3.6(2), since it quantifies over all functors G and not only triangulated ones, and by (3) the pair (RF, ε) belongs to the triangulated class. As in the bounded case, $RF(X)$ is F applied term by term to a resolution of X, now a K-injective one, and for X itself K-injective, ε_X identifies $RF(X)$ with $F(X)$. Applied term by term to a complex of injectives that is not K-injective, F need not carry quasi-isomorphisms to quasi-isomorphisms, as in example 57.3.1, where the complex was a projective resolution.

Example 59.1.23: Applying a Functor Term by Term to a Complex of Injectives
Let I be the complex of example 59.1.7 and $F := \mathrm{Hom}_{\mathbb{Z}/4}(\mathbb{Z}/2, -)\colon \mathbb{Z}/4\text{-Mod} \to \mathbf{Ab}$, where $\mathbb{Z}/2 = \mathbb{Z}/4/(2)$. A homomorphism $\varphi\colon \mathbb{Z}/2 \to \mathbb{Z}/4$ is determined by $\varphi(1)$, subject to $2\varphi(1) = \varphi(2) = 0$, so $F(\mathbb{Z}/4) \cong \{0, 2\} \cong \mathbb{Z}/2$. The differential of I induces $\varphi \mapsto 2\varphi$, which is zero since $2 \cdot 2 = 0$ in $\mathbb{Z}/4$. So $F(I)$ is the complex with $\mathbb{Z}/2$ in every degree and zero differential, and $H^n(F(I)) \cong \mathbb{Z}/2$ for every n. On the other hand I is acyclic, so $I \to 0$ is a quasi-isomorphism into the K-injective complex 0, a K-injective resolution. By the last assertion of corollary 59.1.22(2), $RF(I)$ may be computed with this resolution, so $RF(I) \cong F(0) = 0$, while term-by-term application of F to the injective terms of I has nonzero cohomology in every degree. In particular the term-by-term functor does not carry the quasi-isomorphism $I \to 0$ to a quasi-isomorphism.

Exercise 59.1.1

1. Let R be a ring and $(C_i)_{i\in I}$ a directed system of complexes of R-modules, that is, a directed system in $\mathrm{Ch}(R\text{-Mod})$, and let C be the complex with $C^n = \varinjlim_i C_i^n$ and the differential induced by those of the C_i. Using proposition 59.1.3, show that the maps $H^n(C_i) \to H^n(C)$ induce an isomorphism $\varinjlim_i H^n(C_i) \cong H^n(C)$ for every n.

2. Let $\mathcal{A}$ be an abelian category satisfying (AB3) with a generator U in the sense of (G). Show that every object X is a quotient of the direct sum $\bigoplus_{u\in\mathrm{Hom}(U,X)} U$, by applying (G) to the cokernel of the morphism $\bigoplus_u U \to X$ that restricts to u on the summand indexed by u.

3. Show that the category of finitely generated abelian groups is abelian and is not a Grothendieck abelian category. (If a countable family of copies of $\mathbb{Z}$ had a direct sum S in this category, then $\mathrm{Hom}(S, \mathbb{Z}/2)$ would be in bijection with $\prod_{n\in\mathbb{N}} \mathrm{Hom}(\mathbb{Z}, \mathbb{Z}/2)$. Compare cardinalities.)

4. Let $\mathcal{A}$ be abelian. Show that $I \oplus J$ is K-injective if and only if I and J are, and more generally that if J is a retract of a K-injective complex I in $\mathrm{K}(\mathcal{A})$, meaning that there are $a\colon J \to I$ and $b\colon I \to J$ with $ba = \mathrm{id}_J$ in $\mathrm{K}(\mathcal{A})$, then J is K-injective.

5. Show that a complex I is acyclic and K-injective if and only if id_I is null-homotopic. Deduce that if X is acyclic and $\iota_X\colon X \to I_X$ is a K-injective resolution, then id_{I_X} is null-homotopic.

6. Let I be the complex of example 59.1.7 and regard $\mathbb{Z}/2 = \mathbb{Z}/4/(2)$ and $\mathbb{Z}/4$ as complexes concentrated in degree 0. Show that $\mathrm{Hom}_{\mathrm{K}(\mathbb{Z}/4\text{-Mod})}(\mathbb{Z}/4, I) = 0$ and $\mathrm{Hom}_{\mathrm{K}(\mathbb{Z}/4\text{-Mod})}(\mathbb{Z}/2, I) \cong \mathbb{Z}/2$. Conclude that $Q\colon \mathrm{Hom}_{\mathrm{K}}(\mathbb{Z}/2, I) \to \mathrm{Hom}_D(\mathbb{Z}/2, I)$ is not injective, so that condition (3) of proposition 59.1.11 fails for I already at a complex concentrated in one degree.

7. Let $\mathcal{A}$ be abelian and let $A \xrightarrow{u} B \xrightarrow{v} C \xrightarrow{w} A[1]$ be a distinguished triangle of $\mathrm{K}(\mathcal{A})$. Show that if two of A, B, C are K-injective, then so is the third. (For an acyclic M, apply $\mathrm{Hom}_{\mathrm{K}}(M, -)$ to the triangle and to its two rotations in (TR2).)

8. Fix a prime p. For $n \geq 0$ let C_n be the complex $\mathbb{Z} \to \mathbb{Z}/p^n\mathbb{Z}$, the reduction map, in degrees 0 and 1, and let $C_{n+1} \to C_n$ be the identity in degree 0 and the reduction in degree 1. Compute $H^0(C_n)$, $H^1(C_n)$ and $\varprojlim C_\bullet$, and use lemma 59.1.17 with example 58.5.8 to show that $\varprojlim^1$ of the tower $(p^n\mathbb{Z})_n$, with the inclusions as transition maps, is isomorphic to $\mathbb{Z}_p/\mathbb{Z}$, recovering example 58.5.9.

59.2 K-Flat Complexes and the Unbounded Tensor-Hom Adjunction

Section 59.1 resolves every complex of a Grothendieck abelian category on the right by a K-injective complex, and corollary 59.1.22 uses these resolutions to derive additive functors on unbounded complexes. The tensor product is derived by resolving on the left, and box 57.4.20 records where the left resolutions of section 57.4 needed a bound: lemma 57.4.4(1) needs a bounded-above complex of projectives, and lemma 57.4.14(2) a bounded-above complex of flat modules. This section replaces both by conditions on a complex as a whole, K-projectivity and K-flatness, in the form given by Spaltenstein [95], and constructs a resolution of both kinds for every complex of modules. The derived tensor product and $R\mathrm{Hom}$ then become bifunctors on all of $D(R)$, adjoint to one another as in theorem 57.4.19, and they agree with the constructions of section 57.4 on bounded complexes. Over a principal ideal domain every complex of torsion-free modules is K-flat, so that $F \otimes^L_{\mathbb{Z}} \mathbb{Z}/n$ is F/nF for every complex F of torsion-free abelian groups.

Throughout, R is a commutative ring and $D(R) = D(R\text{-Mod})$. As explained before theorem 57.4.19, the total tensor complex $\mathrm{Tot}(X \otimes_R Y)$ of definition 57.4.12 and the Hom complex $\mathrm{Hom}^\bullet(X, Y)$ of definition 57.4.1, formed in R-Mod, are then complexes of R-modules. Neither definition requires a bound on X or Y: Tot is formed with direct sums and $\mathrm{Hom}^\bullet$ with products.

Conditions on the individual terms do not control an unbounded complex. Example 59.2.2(3) and example 59.2.6 below give an acyclic complex of free $\mathbb{Z}/4$-modules for which the conclusions of lemma 57.4.4(1) and lemma 57.4.14(3) fail. The conditions that replace the bounds are tested against every acyclic complex at once.

Definition 59.2.1: K-Projective and K-Flat Complexes

Let X be a complex of R-modules.

1. X is *K-projective* if $\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(X, A) = 0$ for every acyclic complex A of R-modules.
2. X is *K-flat* if $\mathrm{Tot}(X \otimes_R A)$ is acyclic for every acyclic complex A of R-modules.

A *K-projective resolution* of a complex Y is a quasi-isomorphism $P \to Y$ with P K-projective, and a *K-flat resolution* is a quasi-isomorphism $F \to Y$ with F K-flat.

If A is acyclic, so is every shift $A[n]$, and $H^n\mathrm{Hom}^\bullet(X, A) = \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(X, A[n])$ by lemma 57.4.3(1). So X is K-projective exactly when $\mathrm{Hom}^\bullet(X, A)$ is acyclic for every acyclic complex A, which is the definition of [95, p. 1.1], where it is attributed to J. Bernstein. K-flatness is [95, p. 5.1], stated there for complexes of sheaves of modules on a commutative ringed space, of which complexes of R-modules are the case of a one-point space with structure ring R. Both conditions say that a functor of complexes built from X carries acyclic complexes to acyclic complexes: $\mathrm{Hom}^\bullet(X, -)$ in the first case, $\mathrm{Tot}(X \otimes_R -)$ in the second.

Example 59.2.2: Bounded-Above Projective Complexes, Single Modules, and a Free Complex over $\mathbb{Z}/4$

1. Let P be a bounded-above complex of projective R-modules and A an acyclic complex. By proposition 57.2.12(1), $A \cong 0$ in $D(R)$, so $\mathrm{Hom}_{D(R)}(P, A) = 0$, and lemma 57.4.4(1) identifies $\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P, A)$ with this group. So P is K-projective.
2. Let M be an R-module, regarded as a complex in degree 0. Then $\mathrm{Tot}(M \otimes_R A)^n = M \otimes_R A^n$ with differential $1 \otimes d_A$, and $\mathrm{Hom}^n(M, A) = \mathrm{Hom}_R(M, A^n)$ with differential $\varphi \mapsto d_A\varphi$. If M is flat, the exact functor $M \otimes_R -$ of definition 17.5.4 preserves kernels and images, so it carries acyclic complexes to acyclic ones and M is K-flat. If M is projective, it is K-projective by (1). Conversely, let $0 \to N' \to N \to N'' \to 0$ be a short exact sequence, placed in degrees -1, 0, 1 as an acyclic complex A. If M is K-flat, then $M \otimes_R A$ is acyclic, which says that $M \otimes_R -$ is exact on this sequence, so M is flat. If M is K-projective, then $\mathrm{Hom}^\bullet(M, A)$ is acyclic, and its vanishing cohomology in degree 1 says that $\mathrm{Hom}_R(M, N) \to \mathrm{Hom}_R(M, N'')$ is surjective. Every surjection $N \to N''$ arises this way, so M is projective by theorem 17.2.4(2).
3. Let I be the complex of example 59.1.7, with $I^n = \mathbb{Z}/4$ for every $n \in \mathbb{Z}$ and every differential multiplication by 2. Its terms are free $\mathbb{Z}/4$-modules. By example 59.1.7(2) and (3), I is acyclic and id_I is a nonzero element of $\mathrm{Hom}_{\mathrm{K}(\mathbb{Z}/4\text{-Mod})}(I, I)$, so I is not K-projective. The same example shows that $Q\colon \mathrm{Hom}_{\mathrm{K}}(I, I) \to \mathrm{Hom}_D(I, I)$ is not injective, so the conclusion of lemma 57.4.4(1) fails for this complex of projective modules.

Together with (1), item (3) shows that a complex of projective modules is K-projective when it is bounded above and need not be otherwise. Item (2) shows that both notions extend the module-level ones.

Write $\mathcal{A} = R\text{-Mod}$. Reindexing $X^n \mapsto X^{-n}$ identifies $\mathrm{Ch}(\mathcal{A}^{\mathrm{op}})$ with $\mathrm{Ch}(\mathcal{A})^{\mathrm{op}}$, and by Step 3 of the proof of lemma 57.4.4 it carries quasi-isomorphisms to quasi-isomorphisms and null-homotopies to null-homotopies, identifies $\mathrm{K}(\mathcal{A}^{\mathrm{op}})$ with $\mathrm{K}(\mathcal{A})^{\mathrm{op}}$, and identifies $D(\mathcal{A}^{\mathrm{op}})$ with $D(\mathcal{A})^{\mathrm{op}}$ compatibly with Q. Write X° for the complex of $\mathcal{A}^{\mathrm{op}}$ corresponding to a complex X of R-modules. By lemma 56.1.17,

X is acyclic exactly when $0 \to X$ is a quasi-isomorphism, and this chain map corresponds to $X^\circ \to 0$, so X is acyclic exactly when X° is. As $\mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(P, A) = \mathrm{Hom}_{\mathrm{K}(\mathcal{A}^{\mathrm{op}})}(A^\circ, P^\circ)$ for all complexes P and A, a complex P of R-modules is K-projective exactly when P° is a K-injective complex of the abelian category $\mathcal{A}^{\mathrm{op}}$.

Lemma 59.2.3: K-Projective Complexes Compute Morphisms in $D(R)$

Let P be a K-projective complex of R-modules.

1. For every quasi-isomorphism $t\colon Y \to Y'$, the chain map $t_* := \mathrm{Hom}^\bullet(P, t)\colon \mathrm{Hom}^\bullet(P, Y) \to \mathrm{Hom}^\bullet(P, Y')$ is a quasi-isomorphism.
2. For every complex X, the map $Q\colon \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P, X) \to \mathrm{Hom}_{D(R)}(P, X)$ is bijective.
3. A quasi-isomorphism $u\colon P' \to P$ whose source P' is also K-projective is a homotopy equivalence.

***Proof*:**
(2) and (3). Under the correspondence $X \mapsto X^\circ$ above, P° is a K-injective complex of $\mathcal{A}^{\mathrm{op}}$. For a complex X, proposition 59.1.11(3) for $\mathcal{A}^{\mathrm{op}}$ makes $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A}^{\mathrm{op}})}(X^\circ, P^\circ) \to \mathrm{Hom}_{D(\mathcal{A}^{\mathrm{op}})}(X^\circ, P^\circ)$ bijective, and under the identifications of $\mathrm{K}(\mathcal{A}^{\mathrm{op}})$ with $\mathrm{K}(\mathcal{A})^{\mathrm{op}}$ and of $D(\mathcal{A}^{\mathrm{op}})$ with $D(\mathcal{A})^{\mathrm{op}}$, compatible with Q, this map is $Q\colon \mathrm{Hom}_{\mathrm{K}(\mathcal{A})}(P, X) \to \mathrm{Hom}_{D(\mathcal{A})}(P, X)$. This is (2). For (3), the chain map $u^\circ\colon P^\circ \to P'^\circ$ is a quasi-isomorphism between K-injective complexes of $\mathcal{A}^{\mathrm{op}}$, so by corollary 59.1.13(1) there is $v^\circ\colon P'^\circ \to P^\circ$ with $v^\circ u^\circ$ and $u^\circ v^\circ$ homotopic to the identities. The reindexing carries null-homotopies to null-homotopies, so the corresponding $v\colon P \to P'$ has uv and vu homotopic to the identities, and u is a homotopy equivalence.

(1). Fix n. By lemma 57.4.3(1) and (3), $H^n(t_*)$ is the map

$$\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P, Y[n]) \longrightarrow \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P, Y'[n]), \qquad \psi \longmapsto t[n] \circ \psi$$

The bijections Q of (2) carry it to $\psi \mapsto Q(t[n]) \circ \psi$ on morphisms of $D(R)$, because Q is a functor, and that map is bijective with inverse $\psi \mapsto Q(t[n])^{-1} \circ \psi$, since $t[n]$ is a quasi-isomorphism, $H^i(t[n])$ being $H^{i+n}(t)$, completing the proof.

K-flatness is defined so that $\mathrm{Tot}(X \otimes_R -)$ carries quasi-isomorphisms to quasi-isomorphisms. The identities in the proof of lemma 57.4.14 that relate cones and homotopies to total tensor complexes are identities between elementary tensors, and the bound in that lemma enters only through proposition 56.5.4 in its Step 2. Over a commutative ring the two factors can also be exchanged.

Lemma 59.2.4: The Total Tensor Complex of Unbounded Complexes

Let X and Y be complexes of R-modules.

1. The map $\mathrm{sw}_{X,Y}(x \otimes y) := (-1)^{ij}\, y \otimes x$, for $x \in X^i$ and $y \in Y^j$, is an isomorphism of complexes $\mathrm{Tot}(X \otimes_R Y) \to \mathrm{Tot}(Y \otimes_R X)$. In particular X is K-flat if and only if $\mathrm{Tot}(A \otimes_R X)$ is acyclic for every acyclic complex A.
2. If $f, f' \colon X \to X'$ are homotopic, so are $\mathrm{Tot}(f \otimes g)$ and $\mathrm{Tot}(f' \otimes g)$ for every chain map g, and likewise in the second variable. Hence $\mathrm{Tot}(- \otimes_R -)$ is a functor $\mathrm{K}(R\text{-Mod}) \times \mathrm{K}(R\text{-Mod}) \to \mathrm{K}(R\text{-Mod})$.
3. If X is K-flat and $t \colon Y \to Y'$ is a quasi-isomorphism, then $\mathrm{Tot}(X \otimes t)$ and $\mathrm{Tot}(t \otimes X)$ are quasi-isomorphisms.
4. If X is K-flat and $u \colon X \to X'$ is a homotopy equivalence, then X' is K-flat.

***Proof*:**

1. As R is commutative, $(x, y) \mapsto (-1)^{ij} y \otimes x$ is R-bilinear on $X^i \times Y^j$, so $\mathrm{sw}_{X,Y}$ is defined summand by summand, and $\mathrm{sw}_{Y,X}$ is its inverse, since $(-1)^{ij}(-1)^{ji} = 1$. For $x \in X^i$ and $y \in Y^j$, definition 57.4.12 gives
$$\mathrm{sw}\big(d(x \otimes y)\big) = \mathrm{sw}\big(dx \otimes y + (-1)^i x \otimes dy\big) = (-1)^{(i+1)j}\, y \otimes dx + (-1)^{i+i(j+1)}\, dy \otimes x$$
and
$$d\big(\mathrm{sw}(x \otimes y)\big) = (-1)^{ij}\big(dy \otimes x + (-1)^j y \otimes dx\big)$$
The exponents agree, $(i+1)j \equiv ij + j$ and $i + i(j+1) \equiv ij \pmod 2$, so $\mathrm{sw}_{X,Y}$ is a chain map. Applied with $Y = A$ it shows that $\mathrm{Tot}(X \otimes_R A)$ and $\mathrm{Tot}(A \otimes_R X)$ are isomorphic complexes.
2. Step 1 of the proof of lemma 57.4.14 writes down, for a homotopy h from f to f', a map $H(x \otimes y) = h(x) \otimes g(y)$ with $\mathrm{Tot}\big((f - f') \otimes g\big) = dH + Hd$, and the analogous map in the second variable. Both are defined and verified on elementary tensors, and an element of $\mathrm{Tot}(X \otimes_R Y)^n$ is a finite sum of elementary tensors, so the verification holds with no bound on X or Y. Composition of chain maps is preserved because $\mathrm{Tot}\big((f_1 f_2) \otimes (g_1 g_2)\big) = \mathrm{Tot}(f_1 \otimes g_1)\mathrm{Tot}(f_2 \otimes g_2)$.
3. Step 4 of the proof of lemma 57.4.14 defines an isomorphism of complexes $\theta \colon \mathrm{Tot}\big(X \otimes_R MC(t)\big) \to MC\big(\mathrm{Tot}(X \otimes t)\big)$ by a formula on elementary tensors, and the verification there uses no bound. As t is a quasi-isomorphism, $MC(t)$ is acyclic by proposition 56.1.24, so $\mathrm{Tot}(X \otimes_R MC(t))$ is acyclic because X is K-flat, and $\mathrm{Tot}(X \otimes t)$ is a quasi-isomorphism by proposition 56.1.24. Step 3 of the same proof identifies $MC\big(\mathrm{Tot}(t \otimes X)\big)$ with $\mathrm{Tot}\big(MC(t) \otimes_R X\big)$, again by a computation on elementary tensors, and this complex is acyclic by (1). So $\mathrm{Tot}(t \otimes X)$ is a quasi-isomorphism.
4. Let v be a homotopy inverse of u and A an acyclic complex. By (2), $\mathrm{Tot}(u \otimes \mathrm{id}_A)$ is a homotopy equivalence with homotopy inverse $\mathrm{Tot}(v \otimes \mathrm{id}_A)$, so it induces isomorphisms on cohomology by proposition 56.1.31. Since $\mathrm{Tot}(X \otimes_R A)$ is acyclic, so is $\mathrm{Tot}(X' \otimes_R A)$, completing the proof.

For a module M and $p \in \mathbb{Z}$, write $M[-p]$ for the complex with M in degree p and 0 elsewhere, as in (57.1).

Proposition 59.2.5: Unions and Bounded-Above Complexes of Flat Modules Are K-Flat

1. Let X be a complex of R-modules and $X_0 \subset X_1 \subset \cdots$ subcomplexes with $X = \bigcup_m X_m$. Suppose that every X_m is K-flat, and that $X_m^i \otimes_R N \to X^i \otimes_R N$ is injective for all m and i and every R-module N. Then X is K-flat.
2. Every bounded-above complex of flat R-modules is K-flat.

***Proof*:**

1. Let A be acyclic. The chain map $\mathrm{Tot}(X_m \otimes_R A) \to \mathrm{Tot}(X \otimes_R A)$ induced by the inclusion is, in each degree, a direct sum of the maps $X_m^i \otimes_R A^j \to X^i \otimes_R A^j$, which are injective by hypothesis. Identify $\mathrm{Tot}(X_m \otimes_R A)$ with its image T_m, a subcomplex. Then $T_0 \subset T_1 \subset \cdots$, and every element of $\mathrm{Tot}(X \otimes_R A)^n$ lies in some T_m: it is a finite sum of elementary tensors $x \otimes a$, and each x lies in some X_m. Let z be a cocycle of $\mathrm{Tot}(X \otimes_R A)$ of degree n, and choose m with $z \in T_m^n$. Then z is a cocycle of T_m, which is acyclic because X_m is K-flat, so $z = dw$ for some $w \in T_m^{n-1}$, and z is a coboundary of $\mathrm{Tot}(X \otimes_R A)$.
2. Let F be a bounded-above complex of flat modules and A an acyclic complex.

   Step 1: one flat module. For a flat module M in degree p, $\mathrm{Tot}(M[-p] \otimes_R A)^n = M \otimes_R A^{n-p}$, with differential $(-1)^p(1 \otimes d_A)$ by definition 57.4.12. The exact functor $M \otimes_R -$ carries the acyclic complex A to an acyclic complex, and the sign changes no kernel or image, so $\mathrm{Tot}(M[-p] \otimes_R A)$ is acyclic.

   Step 2: bounded complexes. Suppose $F^i = 0$ outside $a \le i \le b$, and induct on $b - a$, the case $b = a$ being Step 1. As $F^{b+1} = 0$, the top term $F^b[-b]$ is a subcomplex of F, and the quotient F'' has the terms F^i for $a \le i \le b-1$. In each degree $0 \to F^b[-b] \to F \to F'' \to 0$ is split, so it remains split exact after applying $- \otimes_R A^j$, and

   $$0 \to \mathrm{Tot}\big(F^b[-b] \otimes_R A\big) \to \mathrm{Tot}(F \otimes_R A) \to \mathrm{Tot}(F'' \otimes_R A) \to 0$$

   is a short exact sequence of complexes. The outer complexes are acyclic by Step 1 and by induction, so the long exact sequence of theorem 56.1.18 makes the middle one acyclic.

   Step 3: bounded-above complexes. Let $X_m \subset F$ be the subcomplex with $X_m^i = F^i$ for $i \ge -m$ and $X_m^i = 0$ for $i < -m$. It is a subcomplex because the differential raises degree, it is bounded because F is bounded above, and its terms are flat, so it is K-flat by Step 2. The X_m increase with union F, and each $X_m^i \to F^i$ is an identity or the inclusion of 0, so it stays injective after $- \otimes_R N$. Part (1) makes F K-flat, completing the proof.

Part (2) is [98, Tag 064K]. Part (1) is a special case of [98, Tag 06Y3], which shows, with no injectivity hypothesis, that every filtered colimit of K-flat complexes is K-flat, using that filtered colimits of

modules are exact and commute with tensor products. The injectivity hypothesis in (1) makes each $\mathrm{Tot}(X_m \otimes_R A)$ a subcomplex of $\mathrm{Tot}(X \otimes_R A)$, so that a cocycle can be treated inside one of them.

Example 59.2.6: An Acyclic Free Complex over $\mathbb{Z}/4$ That Is Not K-Flat

Let I be the complex of example 59.1.7, as in example 59.2.2(3), and let P be the complex

$$\cdots \xrightarrow{2} \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \to 0$$

with the last $\mathbb{Z}/4$ in degree 0, and $\pi\colon P \to \mathbb{Z}/2$ the reduction map in degree 0. The kernel of the reduction is $2\mathbb{Z}/4$, the image of the last differential, and in every negative degree the kernel and the image of multiplication by 2 are $2\mathbb{Z}/4$, so π is a quasi-isomorphism. Now P is a bounded-above complex of free, hence flat, modules (corollary 17.5.5), so it is K-flat by proposition 59.2.5(2). As I is acyclic, $\mathrm{Tot}(P \otimes I)$ is acyclic, and so is $\mathrm{Tot}(I \otimes P)$ by lemma 59.2.4(1). On the other hand $\mathrm{Tot}(I \otimes \mathbb{Z}/2)$ has $\mathbb{Z}/4 \otimes \mathbb{Z}/2 \cong \mathbb{Z}/2$ in every degree with differential multiplication by 2, which is zero on $\mathbb{Z}/2$, so its cohomology is $\mathbb{Z}/2$ in every degree. Hence $\mathrm{Tot}(I \otimes \pi)$ is not a quasi-isomorphism, and I is not K-flat by lemma 59.2.4(3).

The resolutions are built from the canonical truncations $\tau^{\leq n}X$ of definition 56.1.12. Each is bounded above, so it has a projective resolution by theorem 56.2.17, and the resolutions can be chosen so that each is a degreewise direct summand of the next. K-projectivity of their union then reduces to the acyclicity of the limit of a tower of acyclic complexes in the sense of definition 59.1.15, which lemma 59.1.17 gives.

Theorem 59.2.7: Every Complex of Modules Has a K-Projective Resolution

Let R be a commutative ring.

1. Every complex X of R-modules has a K-projective resolution $\pi\colon P \to X$ in which every P^i is projective and P is also K-flat.
2. Every K-projective complex of R-modules is K-flat.

***Proof*:**

1. *Step 1: extending a resolution along a chain map.* Let $f\colon P' \to B$ be a chain map between bounded-above complexes, with every P'^i projective. The claim is that there are a bounded-above complex S of projectives, a complex P'' with $P''^i = S^{i+1} \oplus P'^i$ containing P' as the subcomplex of elements $(0, y)$, and a quasi-isomorphism $h\colon P'' \to B$ with $h(0, y) = f(y)$. The cone $MC(f)$ is bounded above, so theorem 56.2.17 gives a quasi-isomorphism $g\colon S \to MC(f)[-1]$ with S a bounded-above complex of projectives. By definition 56.1.21 and (57.1), $MC(f)[-1]^i = P'^i \oplus B^{i-1}$ with differential $(p, b) \mapsto (dp,\ -fp - db)$. So $g = (g', g'')$ with $g'^i\colon S^i \to P'^i$ and $g''^i\colon S^i \to B^{i-1}$, and $gd = dg$ reads

$$g'd = dg', \qquad g''d + dg'' = -fg' \tag{59.1}$$

Thus $g'\colon S \to P'$ is a chain map. Let $P'' := MC(-g')$, with $P''^i = S^{i+1} \oplus P'^i$ and $d(x, y) = (-dx,\ -g'x + dy)$, and set $h(x, y) := g''x + fy$. By (59.1),

$$h\big(d(x, y)\big) = -g''dx - fg'x + fdy = dg''x + fdy = d\,h(x, y)$$

so h is a chain map, and $h(0,y) = f(y)$. The cone $MC(h)$ has terms $S^{i+2} \oplus P'^{i+1} \oplus B^i$, the same as $MC(g)[1]$, and the two differentials are

$$d_{MC(h)}(x,y,b) = \big(dx,\ g'x - dy,\ g''x + fy + db\big)$$
$$d_{MC(g)[1]}(x,y,b) = \big(dx,\ -g'x - dy,\ -g''x + fy + db\big)$$

so $(x,y,b) \mapsto (-x,y,b)$ is an isomorphism of complexes $MC(h) \to MC(g)[1]$. As g is a quasi-isomorphism, $MC(g)$ is acyclic by proposition 56.1.24, hence so are $MC(g)[1]$ and $MC(h)$, and h is a quasi-isomorphism by proposition 56.1.24.

Step 2: resolving the truncations. Write $X_n := \tau^{\leq n} X$ for $n \geq 0$, so that $X_0 \subset X_1 \subset \cdots$ are bounded-above subcomplexes of X by definition 56.1.12. Let $f_0 \colon P_0 \to X_0$ be a projective resolution, from theorem 56.2.17. Given a quasi-isomorphism $f_{n-1} \colon P_{n-1} \to X_{n-1}$ from a bounded-above complex of projectives, apply Step 1 to f_{n-1} followed by the inclusion $X_{n-1} \subset X_n$. This gives a bounded-above complex S_n of projectives, a complex P_n with $P_n^i = S_n^{i+1} \oplus P_{n-1}^i$ containing P_{n-1}, and a quasi-isomorphism $f_n \colon P_n \to X_n$ extending f_{n-1}.

Step 3: the union. Let $P := \bigcup_n P_n$, the complex with $P^i = P_0^i \oplus \bigoplus_{n \geq 1} S_n^{i+1}$ whose differential restricts to that of each P_n. A homomorphism out of a direct sum is a family of homomorphisms, and each member lifts along a surjection, so P^i is projective by theorem 17.2.4(2). The f_n are compatible, so they define a chain map $\pi \colon P \to X$. Fix i. For $n \geq i$, $H^i(P_n) \to H^i(X_n)$ is bijective, and so is $H^i(X_n) \to H^i(X)$ by proposition 56.1.14. A cocycle of P of degree i lies in some P_n with $n \geq i$, so $H^i(\pi)$ is surjective, since $H^i(P_n) \to H^i(X)$ is, and injective: if $\pi(z)$ is a coboundary, then $[z] = 0$ in $H^i(P_n)$, so z is a coboundary in $P_n \subset P$. So π is a quasi-isomorphism.

Step 4: P is K-projective. Let A be acyclic. The complexes $\mathrm{Hom}^\bullet(P_n, A)$ for $n \geq 0$, with the restriction maps $\mathrm{Hom}^\bullet(P_{n+1}, A) \to \mathrm{Hom}^\bullet(P_n, A)$, which are chain maps by lemma 57.4.3(2), form a tower of complexes of R-modules $\mathrm{Hom}^\bullet(P_\bullet, A)$ in the sense of definition 59.1.15. A homomorphism $P^i \to A^{i+k}$ is the same as a family of homomorphisms $P_n^i \to A^{i+k}$ compatible with the restrictions, since $P^i = \bigcup_n P_n^i$, and a product of limits is the limit of the products, so the restrictions $\mathrm{Hom}^\bullet(P, A) \to \mathrm{Hom}^\bullet(P_n, A)$ induce an isomorphism of complexes $\mathrm{Hom}^\bullet(P, A) \cong \varprojlim \mathrm{Hom}^\bullet(P_\bullet, A)$. Each restriction $\mathrm{Hom}^k(P_{n+1}, A) \to \mathrm{Hom}^k(P_n, A)$ is surjective, since a homomorphism on P_n^i extends by 0 on the summand S_{n+1}^{i+1} of P_{n+1}^i. Each P_n is a bounded-above complex of projectives, so it is K-projective by example 59.2.2(1), and $\mathrm{Hom}^\bullet(P_n, A)$ is acyclic. In the exact sequence of lemma 59.1.17 for this tower, the outer terms are $\varprojlim{}^1$ and $\varprojlim$ of towers of zero modules, so they vanish, and $H^m \mathrm{Hom}^\bullet(P, A) = 0$ for every m. In particular $\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P, A) = H^0 \mathrm{Hom}^\bullet(P, A) = 0$.

Step 5: P is K-flat. Each P_n is a bounded-above complex of projective, hence flat, modules (corollary 17.5.5), so it is K-flat by proposition 59.2.5(2). Each P_n^i is a direct summand of P^i, so $P_n^i \otimes_R N \to P^i \otimes_R N$ is split injective for every module N, and proposition 59.2.5(1) makes P K-flat.

2. Let P be K-projective, and let $\pi \colon P' \to P$ be the resolution of (1), with P' K-projective and

K-flat. By lemma 59.2.3(3), π is a homotopy equivalence, and P is K-flat by lemma 59.2.4(4), completing the proof.

Part (1) is the K-projective half of [95, Theorem C], and Step 1 of its proof is the inductive step in the proof of [95, Lemma 3.3], written out at the level of chain maps. [98, Tag 06XX] constructs a variant whose resolutions are also surjective in each degree. Part (2) is [95, Proposition 5.8], here for modules over a commutative ring. Two K-projective resolutions $\pi\colon P \to Y$ and $\pi'\colon P' \to Y$ are related by a unique morphism $c\colon P \to P'$ of $\mathrm{K}(R\text{-Mod})$ with $Q(\pi')Q(c) = Q(\pi)$, by lemma 59.2.3(2), and the same uniqueness in the other direction makes c an isomorphism of $\mathrm{K}(R\text{-Mod})$, that is a homotopy equivalence.

Example 59.2.8: A K-Projective Resolution of $\mathbb{Z}/2$ in Every Degree

Let $R = \mathbb{Z}$ and let V be the complex with $V^k = \mathbb{Z}/2$ for every $k \in \mathbb{Z}$ and every differential zero. For each k, let E_k be the complex $\mathbb{Z}s_k \xrightarrow{2} \mathbb{Z}t_k$ with s_k in degree $k-1$, t_k in degree k and $ds_k = 2t_k$, and let $P := \bigoplus_k E_k$. Then

$$P^i = \mathbb{Z}t_i \oplus \mathbb{Z}s_{i+1}, \qquad dt_i = 0, \qquad ds_{i+1} = 2t_{i+1}$$

Let $\pi\colon P \to V$ send t_i to 1 and s_{i+1} to 0. It is a chain map, because $\pi(ds_{i+1}) = \pi(2t_{i+1}) = 0$. The cocycles of P in degree i are $\mathbb{Z}t_i$, the coboundaries are $2\mathbb{Z}t_i$, so $H^i(P) \cong \mathbb{Z}/2$ generated by the class of t_i, which π sends to the generator of V^i. So π is a quasi-isomorphism. For an acyclic A, a family of maps out of P^i is a family of maps out of the summands, so $\mathrm{Hom}^\bullet(P, A) = \prod_k \mathrm{Hom}^\bullet(E_k, A)$ as complexes. Each E_k is K-projective by example 59.2.2(1), so each factor is acyclic, and the product is acyclic by lemma 56.1.11. So P is a K-projective resolution of V, and it is K-flat by theorem 59.2.7(2).

Definition 59.2.9: Derived Tensor Product of Unbounded Complexes

For every complex Y of R-modules fix a K-projective resolution $\pi_Y\colon P_Y \to Y$. For a complex X of R-modules, the *derived tensor product* of X and Y is

$$X \otimes^L_R Y := \mathrm{Tot}(X \otimes_R P_Y)$$

regarded as an object of $D(R)$.

The resolutions exist by theorem 59.2.7(1), and every P_Y is K-flat by theorem 59.2.7(2). The formula is that of definition 57.4.15 with the bounded-above projective resolution replaced by a K-projective one, and proposition 59.2.21 identifies the two constructions on bounded-above complexes.

Example 59.2.10: $\mathbb{Z}/2 \otimes^L V$ for $\mathbb{Z}/2$ in Every Degree

Let V and P be as in example 59.2.8, and take $P_V := P$. Then $\mathbb{Z}/2 \otimes^L_{\mathbb{Z}} V = \mathrm{Tot}(\mathbb{Z}/2 \otimes_{\mathbb{Z}} P)$ has $\mathbb{Z}/2\, t_i \oplus \mathbb{Z}/2\, s_{i+1}$ in degree i, and every differential is 0, because $2 = 0$ in $\mathbb{Z}/2$. So

$$H^i\big(\mathbb{Z}/2 \otimes^L_{\mathbb{Z}} V\big) \cong \mathbb{Z}/2 \oplus \mathbb{Z}/2 \qquad \text{for every } i \in \mathbb{Z}$$

whereas $\mathrm{Tot}(\mathbb{Z}/2 \otimes_{\mathbb{Z}} V) = V$ has $\mathbb{Z}/2$ in each degree. The class of s_{i+1} spans the cohomology in degree i of the summand $\mathbb{Z}/2 \otimes_{\mathbb{Z}} E_{i+1}$, which is $\mathrm{Tor}^{\mathbb{Z}}_1(\mathbb{Z}/2, \mathbb{Z}/2) \cong \mathbb{Z}/2$ for the summand $\mathbb{Z}/2$ of V in degree $i+1$, placed in degree i as in theorem 57.4.18.

Proposition 59.2.11: The Unbounded Derived Tensor Product Is a Balanced Bifunctor

Let R be a commutative ring.

1. $\otimes^L_R$ is a bifunctor $D(R) \times D(R) \to D(R)$, and another choice of the K-projective resolutions changes it by a natural isomorphism.

2. If $\varphi\colon F \to X$ is a quasi-isomorphism with F K-flat, then both chain maps in

$$X \otimes^L_R Y = \operatorname{Tot}(X \otimes_R P_Y) \xleftarrow{\varphi\otimes 1} \operatorname{Tot}(F \otimes_R P_Y) \xrightarrow{1\otimes \pi_Y} \operatorname{Tot}(F \otimes_R Y)$$

are quasi-isomorphisms, so $X \otimes^L_R Y \cong \operatorname{Tot}(F \otimes_R Y)$ in $D(R)$. If $\psi\colon G \to Y$ is a quasi-isomorphism with G K-flat, then $X \otimes^L_R Y \cong \operatorname{Tot}(X \otimes_R G)$ in $D(R)$. In particular $X \otimes^L_R Y \cong \operatorname{Tot}(X \otimes_R Y)$ whenever X or Y is K-flat.

***Proof*:**

1. *Step 1: the first variable.* Fix Y. By lemma 59.2.4(2), $X \mapsto \operatorname{Tot}(X \otimes_R P_Y)$ is a functor $\mathrm{K}(R\text{-Mod}) \to \mathrm{K}(R\text{-Mod})$, and by lemma 59.2.4(3), P_Y being K-flat, it carries quasi-isomorphisms to quasi-isomorphisms. Followed by Q it inverts them, and $D(R)$ is the localization of $\mathrm{K}(R\text{-Mod})$ at the quasi-isomorphisms by theorem 57.2.4, so it factors uniquely through $D(R)$ by the universal property of definition 55.2.1.

   Step 2: the second variable. Let $\beta\colon Y \to Y'$ be a morphism of $D(R)$. By lemma 59.2.3(2) for the K-projective complex P_Y, there is a unique $\tilde{\beta}\colon P_Y \to P_{Y'}$ in $\mathrm{K}(R\text{-Mod})$ with $Q(\pi_{Y'})\,Q(\tilde{\beta}) = \beta\, Q(\pi_Y)$, namely the one with $Q(\tilde{\beta}) = Q(\pi_{Y'})^{-1}\beta\, Q(\pi_Y)$. For $\beta'\colon Y' \to Y''$, both $\tilde{\beta}'\tilde{\beta}$ and $\widetilde{\beta'\beta}$ satisfy the condition defining $\widetilde{\beta'\beta}$, so they are equal, and $\widetilde{\mathrm{id}_Y} = \mathrm{id}$. Set $X \otimes^L_R \beta := Q\big(\operatorname{Tot}(X \otimes \tilde{\beta})\big)$, a functor of β by lemma 59.2.4(2).

   Step 3: both variables. For $\alpha\colon X \to X'$ in $D(R)$, the square formed by $\alpha \otimes^L_R Y$, $\alpha \otimes^L_R Y'$, $X \otimes^L_R \beta$ and $X' \otimes^L_R \beta$ commutes. For $\alpha = Q(f)$ with f a chain map, both composites are $Q\big(\operatorname{Tot}(f \otimes \tilde{\beta})\big)$. For $\alpha = Q(s)^{-1}$ with s a quasi-isomorphism, the square is that of $Q(s)$ with two parallel sides inverted. Every morphism of $D(R)$ is $Q(f)\,Q(s)^{-1}$ by theorem 57.2.4, and squares of this shape paste along composites. Setting $\alpha \otimes^L_R \beta := (\alpha \otimes^L_R Y') \circ (X \otimes^L_R \beta)$, the commuting squares make $\otimes^L_R$ preserve composites in the pair (α, β), as in Step 3 of the proof of theorem 57.4.8.

   Step 4: other resolutions. Let $\pi'_Y\colon P'_Y \to Y$ be other K-projective resolutions. By lemma 59.2.3(2) there are unique morphisms $c_Y : P_Y \to P'_Y$ and $c'_Y\colon P'_Y \to P_Y$ of $\mathrm{K}(R\text{-Mod})$ with $Q(\pi'_Y)Q(c_Y) = Q(\pi_Y)$ and $Q(\pi_Y)Q(c'_Y) = Q(\pi'_Y)$. Both $c'_Y c_Y$ and id_{P_Y} satisfy the condition defining $\widetilde{\mathrm{id}_Y}$, so they are equal, and symmetrically $c_Y c'_Y = \mathrm{id}$. So $\operatorname{Tot}(X \otimes c_Y)$ is an isomorphism of $\mathrm{K}(R\text{-Mod})$. It is natural in X because Tot is a bifunctor, and in Y because $c_{Y'}\tilde{\beta}$ and $\tilde{\beta}'c_Y$, with $\tilde{\beta}'$ built from the primed resolutions, both satisfy $Q(\pi'_{Y'})\,Q(-) = \beta\, Q(\pi_Y)$ and are therefore equal.

2. The two chain maps in the display of (2) are quasi-isomorphisms by lemma 59.2.4(3), the

first because P_Y is K-flat and the second because F is, and inverting the first in $D(R)$ gives $X \otimes^L_R Y \cong \operatorname{Tot}(F \otimes_R Y)$. For the second statement apply the first with $F = P_X$, which is K-flat by theorem 59.2.7(2), to get $X \otimes^L_R Y \cong \operatorname{Tot}(P_X \otimes_R Y)$. The chain maps

$$\operatorname{Tot}(P_X \otimes_R Y) \xleftarrow{1\otimes\psi} \operatorname{Tot}(P_X \otimes_R G) \xrightarrow{\pi_X \otimes 1} \operatorname{Tot}(X \otimes_R G)$$

are quasi-isomorphisms by lemma 59.2.4(3), because P_X and G are K-flat. The last statement is the case $F = X$, $\varphi = \mathrm{id}$, or $G = Y$, $\psi = \mathrm{id}$, completing the proof.

By (2), a K-flat resolution of either variable computes $\otimes^L_R$, so a complex known to be K-flat needs no further resolution. A complex of flat modules need not be K-flat: the complex I of example 59.2.6 has free terms.

Theorem 59.2.12: Complexes of Flat Modules Are K-Flat When Submodules of Flat Modules Are Flat

Let R be a commutative ring in which every submodule of a flat R-module is flat. Then every complex of flat R-modules is K-flat.

***Proof*:**

Step 1: the truncations. Let F be a complex of flat modules, and write Z^m and B^{m+1} for the kernel and the image of $d^m \colon F^m \to F^{m+1}$. Both are submodules of flat modules, hence flat. The canonical truncation $\tau^{\leq m}F$ of definition 56.1.12 has the terms F^i for $i < m$, Z^m in degree m, and 0 above, so it is a bounded-above complex of flat modules, and it is K-flat by proposition 59.2.5(2).

Step 2: the union. The subcomplexes $\tau^{\leq 0}F \subset \tau^{\leq 1}F \subset \cdots$ of F have union F, since F^i is the term of $\tau^{\leq m}F$ in degree i once $m > i$. Fix m, i and a module N. For $i < m$ the map $(\tau^{\leq m}F)^i \otimes_R N \to F^i \otimes_R N$ is the identity, and for $i > m$ its source is 0. For $i = m$ it is the map $Z^m \otimes_R N \to F^m \otimes_R N$ induced by the inclusion. The functor $- \otimes_R N$ is right exact by theorem 17.5.1, the tensor product being symmetric over the commutative ring R, and its first left derived functor is $\operatorname{Tor}^R_1(-, N)$ by example 56.3.6(1). By theorem 56.3.11 and proposition 56.3.13(2), the short exact sequence $0 \to Z^m \to F^m \xrightarrow{d^m} B^{m+1} \to 0$ gives an exact sequence

$$\operatorname{Tor}^R_1(B^{m+1}, N) \to Z^m \otimes_R N \to F^m \otimes_R N$$

By theorem 56.5.8, $\operatorname{Tor}^R_1(B^{m+1}, N) \cong H^{-1}(B^{m+1} \otimes_R P_N)$ for a projective resolution P_N of N. The complex P_N is exact in degree -1, and the functor $B^{m+1} \otimes_R -$ is exact because B^{m+1} is flat, so it preserves kernels and images and $H^{-1}(B^{m+1} \otimes_R P_N) = 0$. Hence $Z^m \otimes_R N \to F^m \otimes_R N$ is injective, and proposition 59.2.5(1) makes F K-flat, completing the proof.

The hypothesis on R is used once, to make the cycle modules Z^m and the boundary modules B^{m+1} of F flat. Over $\mathbb{Z}/4$ it fails at the cycle modules $Z^m = 2\mathbb{Z}/4 \cong \mathbb{Z}/2$ of the complex I of example 59.2.6, which are submodules of the free module $\mathbb{Z}/4$. The module $\mathbb{Z}/2$ is not flat over $\mathbb{Z}/4$: tensoring the injection $\mathbb{Z}/2 \to \mathbb{Z}/4$, $1 \mapsto 2$, with $\mathbb{Z}/2$ gives the map $\mathbb{Z}/2 \to \mathbb{Z}/2$ sending 1 to $2 = 0$. Correspondingly, $Z^m \otimes \mathbb{Z}/2 \to I^m \otimes \mathbb{Z}/2$ is this zero map, so the injectivity hypothesis of proposition 59.2.5(1) fails for the truncations of I.

Corollary 59.2.13: Complexes of Torsion-Free Modules over a PID Are K-Flat

Let R be a principal ideal domain. Then every complex of torsion-free R-modules is K-flat. In particular every complex of torsion-free abelian groups is K-flat.

***Proof*:**
Over a principal ideal domain a module is flat if and only if it is torsion-free, by theorem 17.5.7, and a submodule of a torsion-free module is torsion-free by proposition 12.3.23(1). So every submodule of a flat R-module is flat, a complex of torsion-free R-modules is a complex of flat R-modules, and theorem 59.2.12 makes it K-flat. Abelian groups are the modules over the principal ideal domain $\mathbb{Z}$, completing the proof.

Example 59.2.14: Reduction Modulo n of a Torsion-Free Complex
Let F be a complex of torsion-free abelian groups and $n \geq 1$. By corollary 59.2.13, F is K-flat, so proposition 59.2.11(2) gives

$$F \otimes^{L}_{\mathbb{Z}} \mathbb{Z}/n \cong \operatorname{Tot}(F \otimes_{\mathbb{Z}} \mathbb{Z}/n) \cong F/nF$$

where F/nF has the terms F^k/nF^k and the induced differentials. Each F^k is torsion-free, so multiplication by n is injective on it, and $0 \to F \xrightarrow{n} F \to F/nF \to 0$ is a short exact sequence of complexes. Its long exact sequence (theorem 56.1.18) yields the short exact sequences

$$0 \to H^k(F)/nH^k(F) \to H^k\big(F \otimes^{L}_{\mathbb{Z}} \mathbb{Z}/n\big) \to \{c \in H^{k+1}(F) : nc = 0\} \to 0$$

For a specific case, let $F^k = \mathbb{Z}$ for every k, with d^k multiplication by 2 for k odd and zero for k even. Then $d^{k+1}d^k = 0$, since one of the two factors is zero, and $H^k(F)$ is $\mathbb{Z}/2$ for k even and 0 for k odd. For $n = 2$, the complex $F/2F$ has $\mathbb{Z}/2$ in every degree and every differential zero, so $H^k(F \otimes^{L}_{\mathbb{Z}} \mathbb{Z}/2) \cong \mathbb{Z}/2$ for every k. The sequence above agrees: for k even the left term is $\mathbb{Z}/2$ and the right term is 0, and for k odd the left term is 0 and the right term is $\mathbb{Z}/2$.

The category R-Mod is a Grothendieck abelian category by example 59.1.5(1), so theorem 59.1.19 gives every complex of R-modules a K-injective resolution.

Definition 59.2.15: RHom of Unbounded Complexes

For a complex Z of R-modules let $\iota_Z \colon Z \to I_Z$ be the K-injective resolution fixed in corollary 59.1.22, with $\mathcal{A} = R$-Mod. For a complex Y of R-modules set

$$R\operatorname{Hom}_R(Y, Z) := \operatorname{Hom}^{\bullet}(Y, I_Z)$$

regarded as an object of $D(R)$.

The formula is that of definition 57.4.6 with the bounded-below injective resolution replaced by a K-injective one, and proposition 59.2.21 identifies the two constructions when the second variable is bounded below.

Example 59.2.16: RHom out of R and into a K-Injective Complex

1. Let $Y = R$ in degree 0. By definition 57.4.1, $\mathrm{Hom}^n(R, I_Z) = \mathrm{Hom}_R(R, I_Z^n)$ with differential $\varphi \mapsto d_{I_Z}\varphi$, and evaluation at 1 identifies it with I_Z^n. So $R\mathrm{Hom}_R(R, Z)$ is the complex I_Z, which $Q(\iota_Z)$ makes isomorphic to Z in $D(R)$.

2. Let J be a K-injective complex. Then $\iota_J \colon J \to I_J$ is a quasi-isomorphism between K-injective complexes, hence a homotopy equivalence by corollary 59.1.13(1). For every complex Y the chain map $\mathrm{Hom}^\bullet(Y, \iota_J)$ is then a homotopy equivalence by lemma 57.4.3(2), hence a quasi-isomorphism by proposition 56.1.31, and $R\mathrm{Hom}_R(Y, J) \cong \mathrm{Hom}^\bullet(Y, J)$ in $D(R)$. For $R = \mathbb{Z}$, J may be the complex $\mathbb{Q} \to \mathbb{Q}/\mathbb{Z}$ of example 57.4.7, in degrees 0 and 1, a bounded-below complex of injective abelian groups and so K-injective by corollary 59.1.12. Then $R\mathrm{Hom}_\mathbb{Z}(Y, J) \cong \mathrm{Hom}^\bullet(Y, J)$ for every complex Y of abelian groups, bounded or not.

Proposition 59.2.17: RHom of Unbounded Complexes Is a Bifunctor

Let R be a commutative ring.

1. $R\mathrm{Hom}_R$ is a bifunctor $D(R)^{\mathrm{op}} \times D(R) \to D(R)$, and another choice of the K-injective resolutions changes it by a natural isomorphism.

2. If $\pi \colon P \to Y$ is a K-projective resolution, then both chain maps in

$$R\mathrm{Hom}_R(Y, Z) = \mathrm{Hom}^\bullet(Y, I_Z) \xrightarrow{\pi^*} \mathrm{Hom}^\bullet(P, I_Z) \xleftarrow{(\iota_Z)_*} \mathrm{Hom}^\bullet(P, Z)$$

are quasi-isomorphisms. In particular $R\mathrm{Hom}_R(Y, Z) \cong \mathrm{Hom}^\bullet(P, Z)$ in $D(R)$.

***Proof*:**

1. *Step 1: the second variable.* For a morphism $\gamma \colon Z \to Z'$ of $D(R)$ let $I_\gamma \colon I_Z \to I_{Z'}$ be the morphism of $\mathrm{K}(R\text{-Mod})$ of corollary 59.1.22(1), the unique one with $Q(I_\gamma)\, Q(\iota_Z) = Q(\iota_{Z'})\, \gamma$, a functor of γ by that corollary. Set $R\mathrm{Hom}_R(Y, \gamma) := Q\big(\mathrm{Hom}^\bullet(Y, I_\gamma)\big)$, a functor of γ by lemma 57.4.3(2).

   Step 2: the first variable. Fix Z. By lemma 57.4.3(2), $Y \mapsto \mathrm{Hom}^\bullet(Y, I_Z)$ is a functor $\mathrm{K}(R\text{-Mod})^{\mathrm{op}} \to \mathrm{K}(R\text{-Mod})$, and by corollary 59.1.14 for the K-injective complex I_Z it carries quasi-isomorphisms to quasi-isomorphisms, so followed by Q it carries them to isomorphisms. By theorem 57.2.4, $D(R)^{\mathrm{op}}$ is the localization of $\mathrm{K}(R\text{-Mod})^{\mathrm{op}}$ at the quasi-isomorphisms, and the universal property of definition 55.2.1 factors the functor uniquely through $D(R)^{\mathrm{op}}$. The factorization is $R\mathrm{Hom}_R(-, Z)$.

   Step 3: both variables and other resolutions. Steps 3 and 4 of the proof of theorem 57.4.8 use its Steps 1 and 2, lemma 57.4.3(2), theorem 57.2.4, and the bijectivity of Q into the chosen resolutions, which there is lemma 57.4.4(2). With Steps 1 and 2 above and proposition 59.1.11(3) for that bijectivity, the same arguments show that the square formed by $R\mathrm{Hom}_R(\alpha, Z)$, $R\mathrm{Hom}_R(\alpha, Z')$, $R\mathrm{Hom}_R(Y, \gamma)$ and $R\mathrm{Hom}_R(Y', \gamma)$ commutes for all $\alpha \colon Y' \to Y$ and $\gamma \colon Z \to Z'$ in $D(R)$, so that $R\mathrm{Hom}_R$ is a bifunctor, and that another

choice $\iota'_Z\colon Z \to I'_Z$ of K-injective resolutions changes it by the natural isomorphism $\mathrm{Hom}^\bullet(Y, c_Z)$, where c_Z is the unique morphism of $\mathrm{K}(R\text{-Mod})$ with $Q(c_Z)Q(\iota_Z) = Q(\iota'_Z)$.

2. The map π^* is a quasi-isomorphism by corollary 59.1.14, applied to the quasi-isomorphism π and the K-injective complex I_Z. The map $(\iota_Z)_*$ is one by lemma 59.2.3(1), applied to the K-projective complex P and the quasi-isomorphism ι_Z, completing the proof.

Example 59.2.18: $R\mathrm{Hom}(\mathbb{Z}/2, V)$ for $\mathbb{Z}/2$ in Every Degree

Let $R = \mathbb{Z}$, let V be the complex of example 59.2.8, and let E be the complex $\mathbb{Z}s \xrightarrow{2} \mathbb{Z}t$ in degrees -1 and 0, a K-projective resolution of $\mathbb{Z}/2$ by example 59.2.2(1). By proposition 59.2.17(2), $R\mathrm{Hom}_\mathbb{Z}(\mathbb{Z}/2, V) \cong \mathrm{Hom}^\bullet(E, V)$, and

$$\mathrm{Hom}^m(E, V) = \mathrm{Hom}(\mathbb{Z}s, V^{m-1}) \times \mathrm{Hom}(\mathbb{Z}t, V^m) \cong \mathbb{Z}/2 \oplus \mathbb{Z}/2$$

For φ of degree m, the component of $D\varphi$ on s is $d_V\varphi(s) - (-1)^m\varphi(2t) = 0$, since $d_V = 0$ and $2\varphi(t) = 0$ in $\mathbb{Z}/2$, and its component on t is $d_V\varphi(t) = 0$. So every differential vanishes, and

$$H^m R\mathrm{Hom}_\mathbb{Z}(\mathbb{Z}/2, V) \cong \mathbb{Z}/2 \oplus \mathbb{Z}/2 \qquad \text{for every } m \in \mathbb{Z}$$

By lemma 59.2.3(2) and lemma 57.4.3(1) this group is also

$$\mathrm{Hom}_{D(\mathbb{Z})}(E, V[m]) \cong \mathrm{Hom}_{D(\mathbb{Z})}(\mathbb{Z}/2, V[m])$$

The complex V is bounded neither below nor above, so definition 57.4.6 does not apply to this pair.

Theorem 59.2.19: The Unbounded Tensor-Hom Adjunction

Let R be a commutative ring and let X, Y, Z be complexes of R-modules. There is an isomorphism

$$\mathrm{Hom}_{D(R)}\big(X \otimes^L_R Y,\ Z\big) \cong \mathrm{Hom}_{D(R)}\big(X,\ R\mathrm{Hom}_R(Y, Z)\big)$$

natural in X and Z.

***Proof*:**
Step 1: the adjunction for complexes. For complexes X, Y, Z, the map

$$\Phi\colon \mathrm{Hom}^\bullet\big(\mathrm{Tot}(X \otimes_R Y), Z\big) \to \mathrm{Hom}^\bullet\big(X, \mathrm{Hom}^\bullet(Y, Z)\big), \qquad \Phi(\varphi)(x)(y) := \varphi(x \otimes y)$$

is an isomorphism of complexes. By definition 57.4.1, the source in degree n is the product over all $m \in \mathbb{Z}$ of $\mathrm{Hom}_R\big(\mathrm{Tot}(X \otimes_R Y)^m, Z^{m+n}\big)$. A homomorphism out of the direct sum $\mathrm{Tot}(X \otimes_R Y)^m = \bigoplus_{i+j=m} X^i \otimes_R Y^j$ is a family of homomorphisms out of its summands, so the source is the product over all pairs (i, j) of $\mathrm{Hom}_R(X^i \otimes_R Y^j, Z^{i+j+n})$. The target in degree n is the product over all i of $\mathrm{Hom}_R\big(X^i, \mathrm{Hom}^{i+n}(Y, Z)\big)$, where $\mathrm{Hom}^{i+n}(Y, Z)$ is the product over all j of $\mathrm{Hom}_R(Y^j, Z^{i+j+n})$, and a homomorphism into a product is a family, so the target is the product over the same pairs of $\mathrm{Hom}_R\big(X^i, \mathrm{Hom}_R(Y^j, Z^{i+j+n})\big)$. On each factor Φ is the bijection of theorem 15.3.9, with both rings equal to R. The comparison of differentials in Step 1 of the proof of theorem 57.4.19 is a computation on $x \otimes y$ for $x \in X^i$ and $y \in Y^j$, and it uses no bound.

Step 2: resolutions. Let $\pi_X\colon P_X \to X$ and $\pi_Y\colon P_Y \to Y$ be the K-projective resolutions of definition 59.2.9 and $\iota_Z\colon Z \to I_Z$ the K-injective resolution of definition 59.2.15. Set $T := \mathrm{Tot}(P_X \otimes_R P_Y)$ and $H := \mathrm{Hom}^\bullet(P_Y, I_Z)$. By proposition 59.2.11(2), with $F = P_X$ and $\varphi = \pi_X$, the chain map $\pi_X \otimes 1\colon T \to \mathrm{Tot}(X \otimes_R P_Y) = X \otimes^L_R Y$ is a quasi-isomorphism, and by proposition 59.2.17(2) so is $\pi_Y^*\colon R\mathrm{Hom}_R(Y, Z) \to H$.

Step 3: T is K-projective. Let A be acyclic. By Step 1, $\mathrm{Hom}^\bullet(T, A) \cong \mathrm{Hom}^\bullet\big(P_X, \mathrm{Hom}^\bullet(P_Y, A)\big)$. The complex $\mathrm{Hom}^\bullet(P_Y, A)$ is acyclic because P_Y is K-projective, so the right side is acyclic because P_X is K-projective. Hence $\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(T, A) = H^0\mathrm{Hom}^\bullet(T, A) = 0$.

Step 4: the chain of isomorphisms. Composing with $Q(\pi_X \otimes 1)$ and $Q(\iota_Z)$, then using lemma 59.2.3(2) for T, lemma 57.4.3(1), Step 1, lemma 57.4.3(1) again, lemma 59.2.3(2) for P_X, and finally $Q(\pi_X)$ and $Q(\pi_Y^*)$,

$$\begin{aligned}\mathrm{Hom}_{D(R)}(X \otimes^L_R Y, Z) &\cong \mathrm{Hom}_{D(R)}(T, I_Z) \cong \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(T, I_Z) = H^0\mathrm{Hom}^\bullet(T, I_Z)\\ &\cong H^0\mathrm{Hom}^\bullet(P_X, H) = \mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(P_X, H) \cong \mathrm{Hom}_{D(R)}(P_X, H)\\ &\cong \mathrm{Hom}_{D(R)}\big(X, R\mathrm{Hom}_R(Y, Z)\big)\end{aligned}$$

Step 5: naturality. A morphism $\alpha\colon X \to X'$ of $D(R)$ lifts, by lemma 59.2.3(2), to a unique $\tilde\alpha\colon P_X \to P_{X'}$ in $\mathrm{K}(R\text{-Mod})$ with $Q(\pi_{X'})Q(\tilde\alpha) = \alpha\, Q(\pi_X)$. The functor of Step 1 of the proof of proposition 59.2.11 sends $Q(g)$ to $Q(\mathrm{Tot}(g \otimes 1))$ for chain maps g, so applying it to this identity shows that $\alpha \otimes^L_R Y$ acts on T as $Q\big(\mathrm{Tot}(\tilde\alpha \otimes 1)\big)$. A morphism $\gamma\colon Z \to Z'$ acts on I_Z as $Q(I_\gamma)$, with I_γ as in Step 1 of the proof of proposition 59.2.17(1), and π_Y^* commutes with $(I_\gamma)_*$. Each isomorphism of Step 4 commutes with precomposition by these and postcomposition by I_γ: the uses of lemma 57.4.3(1) by its part (3), the uses of lemma 59.2.3(2) because Q is a functor, and Φ because $\Phi\big(\varphi \circ \mathrm{Tot}(\tilde\alpha \otimes 1)\big) = \Phi(\varphi) \circ \tilde\alpha$ and $\Phi(I_\gamma \circ \varphi) = (I_\gamma)_* \circ \Phi(\varphi)$ by the formula for Φ. So the composite isomorphism is natural in X and Z, completing the proof.

For fixed Y, the theorem says that $- \otimes^L_R Y$ is left adjoint to $R\mathrm{Hom}_R(Y, -)$ as functors $D(R) \to D(R)$. In the bounded case of theorem 57.4.19 the two functors have the different domains $D^-(R)$ and $D^+(R)$, which is also the form of Weibel [101] Theorem 10.8.7.

Example 59.2.20: Morphisms out of F/nF into Shifts of $\mathbb{Z}$

Let F be a complex of torsion-free abelian groups, $n \geq 1$ and $k \in \mathbb{Z}$. The complex $C_n = (\mathbb{Z} \xrightarrow{n} \mathbb{Z})$ in degrees -1 and 0 is a K-projective resolution of $\mathbb{Z}/n$ by example 59.2.2(1), so $R\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/n, \mathbb{Z}[k]) \cong \mathrm{Hom}^\bullet(C_n, \mathbb{Z}[k])$ by proposition 59.2.17(2). As $\mathbb{Z}[k]$ is $\mathbb{Z}$ in degree $-k$, this complex is $\mathbb{Z} \to \mathbb{Z}$ in degrees $-k$ and $1-k$, with differential multiplication by $-(-1)^k n$, so its only cohomology is $\mathbb{Z}/n$ in degree $1-k$. A complex C whose only cohomology is in degree j is isomorphic in $D(\mathbb{Z})$ to $H^j(C)[-j]$, through $C \leftarrow \tau^{\leq j}C \to \tau^{\geq j}\tau^{\leq j}C$, both quasi-isomorphisms by proposition 56.1.14, the last complex being $Z^j(C)/B^j(C) = H^j(C)$ in degree j. So $R\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}/n, \mathbb{Z}[k]) \cong (\mathbb{Z}/n)[k-1]$, and with example 59.2.14 the theorem gives

$$\mathrm{Hom}_{D(\mathbb{Z})}\big(F/nF,\ \mathbb{Z}[k]\big) \cong \mathrm{Hom}_{D(\mathbb{Z})}\big(F,\ (\mathbb{Z}/n)[k-1]\big)$$

for every complex F of torsion-free abelian groups, bounded or not. For $F = \mathbb{Z}$ in degree 0 and $k = 1$, both sides are $\mathbb{Z}/n$: the left is $\mathrm{Ext}^1_{\mathbb{Z}}(\mathbb{Z}/n, \mathbb{Z}) \cong \mathbb{Z}/n$ by theorem 57.4.10(2) and

example 57.4.7, and the right is $\mathrm{Hom}_{\mathbb{Z}}(\mathbb{Z}, \mathbb{Z}/n) \cong \mathbb{Z}/n$ by the last statement of theorem 57.4.10(2).

In the commutative case, as explained before theorem 57.4.19, definition 57.4.15 gives $\otimes^{\mathbf{L}}_R$ on $D^-(R) \times D^-(R)$ and definition 57.4.6 gives $R\mathrm{Hom}_R$ on $D(R)^{\mathrm{op}} \times D^+(R)$.

Proposition 59.2.21: The Unbounded Constructions Extend the Bounded Ones

Let R be a commutative ring.

1. On $D^-(R) \times D^-(R)$, there is a natural isomorphism from the derived tensor product of definition 57.4.15 to that of definition 59.2.9.
2. On $D(R)^{\mathrm{op}} \times D^+(R)$, there is a natural isomorphism from the $R\mathrm{Hom}$ of definition 57.4.6 to that of definition 59.2.15.

***Proof*:**

1. For a bounded-above complex Y, let $\pi^-_Y \colon P^-_Y \to Y$ be the projective resolution fixed in definition 57.4.15. It is K-projective by example 59.2.2(1), so the argument of Step 4 of the proof of proposition 59.2.11(1) applies to the two K-projective resolutions P^-_Y and P_Y. It gives an isomorphism $c_Y \colon P^-_Y \to P_Y$ of $\mathrm{K}(R\text{-Mod})$ with $Q(\pi_Y)Q(c_Y) = Q(\pi^-_Y)$, and $\mathrm{Tot}(X \otimes c_Y)$ is an isomorphism from the bounded construction to the unbounded one. It is natural in X: for a chain map f the naturality square commutes because Tot is a bifunctor, and every morphism of $D^-(R)$ is a composite of morphisms $Q(f)$ and $Q(s)^{-1}$ of bounded-above complexes, as in Step 3 of the proof of theorem 57.4.17. For $\beta \colon Y \to Y'$ in $D^-(R)$, the morphism $\tilde{\beta}^- \colon P^-_Y \to P^-_{Y'}$ of Step 2 of the proof of theorem 57.4.17 satisfies $Q(\pi^-_{Y'})Q(\tilde{\beta}^-) = \beta\, Q(\pi^-_Y)$, so $c_{Y'}\tilde{\beta}^-$ and $\tilde{\beta} c_Y$ both satisfy $Q(\pi_{Y'})\, Q(-) = \beta\, Q(\pi^-_Y)$, and they are equal by the uniqueness in lemma 59.2.3(2) for the K-projective complex P^-_Y. This is naturality in Y.

2. For a bounded-below complex Z, let $\iota^+_Z \colon Z \to I^+_Z$ be the injective resolution fixed in definition 57.4.6. By proposition 59.1.11(3) for the K-injective complex I_Z there is a unique $c_Z \colon I^+_Z \to I_Z$ in $\mathrm{K}(R\text{-Mod})$ with $Q(c_Z)Q(\iota^+_Z) = Q(\iota_Z)$, and by lemma 57.4.4(2), whose source complex may be arbitrary, there is a unique $c'_Z \colon I_Z \to I^+_Z$ with $Q(c'_Z)Q(\iota_Z) = Q(\iota^+_Z)$. Both $c'_Z c_Z$ and id satisfy the condition $Q(-)Q(\iota^+_Z) = Q(\iota^+_Z)$, so they are equal by the uniqueness in lemma 57.4.4(2), and $c_Z c'_Z = \mathrm{id}$ by the uniqueness for I_Z. So $\mathrm{Hom}^\bullet(Y, c_Z)$ is an isomorphism of $\mathrm{K}(R\text{-Mod})$ from the bounded construction to the unbounded one. Naturality in Y holds for morphisms $Q(f)$, with f a chain map, because $\mathrm{Hom}^\bullet$ is a bifunctor (lemma 57.4.3(2)), and for morphisms $Q(s)^{-1}$ by inverting, every morphism of $D(R)$ being $Q(f)Q(s)^{-1}$ (theorem 57.2.4). For naturality in Z, let $\gamma \colon Z \to Z'$ be a morphism of $D^+(R)$ and $\tilde{\gamma}^+ \colon I^+_Z \to I^+_{Z'}$ its lift from theorem 57.4.8(1), with $Q(\tilde{\gamma}^+)Q(\iota^+_Z) = Q(\iota^+_{Z'})\gamma$. Then $c_{Z'}\tilde{\gamma}^+$ and $I_\gamma c_Z$, with I_γ as in Step 1 of the proof of proposition 59.2.17(1), both satisfy $Q(-)Q(\iota^+_Z) = Q(\iota_{Z'})\gamma$. They are equal, because proposition 59.1.11(3) for $I_{Z'}$ makes Q injective on $\mathrm{Hom}_{\mathrm{K}(R\text{-Mod})}(I^+_Z, I_{Z'})$ and $Q(\iota^+_Z)$ is invertible. Applying $\mathrm{Hom}^\bullet(Y, -)$ gives naturality in Z, completing the proof.

By (1) and example 57.4.16, for $m, n \geq 1$ and $d = \gcd(m, n)$, the complex $\mathbb{Z}/m \otimes^{\mathbf{L}}_{\mathbb{Z}} \mathbb{Z}/n$ of definition 59.2.9 has cohomology $\mathbb{Z}/d$ in degrees -1 and 0 and 0 elsewhere.

Exercise 59.2.1

1. Let V be the complex of abelian groups of example 59.2.8, with $V^k = \mathbb{Z}/2$ for every k and every differential zero. Let A be the acyclic complex $\mathbb{Z} \xrightarrow{2} \mathbb{Z} \to \mathbb{Z}/2$ in degrees -1, 0, 1. Compute the cohomology of $\mathrm{Tot}(V \otimes_{\mathbb{Z}} A)$ and conclude that V is not K-flat. Deduce from theorem 59.2.7(2) that V is not K-projective either.

2. Show that a direct sum of K-projective complexes is K-projective, and that a direct sum of K-flat complexes is K-flat. (Compute $\mathrm{Hom}^\bullet\big(\bigoplus_\alpha P_\alpha, A\big)$ and $\mathrm{Tot}\big((\bigoplus_\alpha X_\alpha) \otimes_R A\big)$ and use lemma 56.1.11.)

3. Let $0 \to X' \to X \to X'' \to 0$ be a short exact sequence of complexes of R-modules that is split in each degree. Show that if two of X', X, X'' are K-flat, so is the third. Show that $\mathrm{Tot}(X[1] \otimes_R A) = \mathrm{Tot}(X \otimes_R A)[1]$ as complexes, and deduce that the mapping cone of a chain map between K-flat complexes is K-flat.

4. Let k be a field, $\Lambda = k[x]/(x^2)$, and let I be the complex of Λ-modules of exercise 57.4.1 (1), with $I^m = \Lambda$ for every $m \in \mathbb{Z}$ and every differential multiplication by x. Using a bounded-above free resolution of $k = \Lambda/x\Lambda$, show that I is not K-flat, and deduce from theorem 59.2.7(2) that it is not K-projective. Show that the cycle module $x\Lambda \cong k$ of I is not a flat Λ-module, so that Λ does not satisfy the hypothesis of theorem 59.2.12.

5. Show that $R \otimes^L_R Y \cong Y$ in $D(R)$ for every complex Y, and that $\mathrm{Hom}_{D(R)}(R, W) \cong H^0(W)$ for every complex W. Applying theorem 59.2.19 with $X = R[-n]$, deduce that

$$H^n R\mathrm{Hom}_R(Y, Z) \cong \mathrm{Hom}_{D(R)}\big(Y, Z[n]\big)$$

   for all complexes Y and Z of R-modules and every $n \in \mathbb{Z}$.

6. Let F be a complex of torsion-free abelian groups and $n \geq 1$. Show that $F \otimes^L_{\mathbb{Z}} \mathbb{Z}/n \cong 0$ in $D(\mathbb{Z})$ if and only if multiplication by n is bijective on $H^k(F)$ for every $k \in \mathbb{Z}$. Check the criterion on $F = \mathbb{Q}$ in degree 0 and on $F = (\mathbb{Z} \xrightarrow{n} \mathbb{Z})$ in degrees -1 and 0.

7. With V and its resolution P as in example 59.2.8, show that for every $n \in \mathbb{Z}$

$$\mathrm{Hom}_{\mathrm{K}(\mathbb{Z}\text{-Mod})}\big(V, V[n]\big) \cong \prod_{k \in \mathbb{Z}} \mathbb{Z}/2, \qquad \mathrm{Hom}_{D(\mathbb{Z})}\big(V, V[n]\big) \cong \prod_{k \in \mathbb{Z}} \big(\mathbb{Z}/2 \oplus \mathbb{Z}/2\big)$$

   (For the second, compute $\mathrm{Hom}^\bullet(E_k, V)$ for each k.)

8. Let X and Y be K-flat complexes of R-modules. Show that $(x \otimes y) \otimes a \mapsto x \otimes (y \otimes a)$ is an isomorphism of complexes $\mathrm{Tot}\big(\mathrm{Tot}(X \otimes_R Y) \otimes_R A\big) \to \mathrm{Tot}\big(X \otimes_R \mathrm{Tot}(Y \otimes_R A)\big)$ for every complex A, with no sign, and conclude that $\mathrm{Tot}(X \otimes_R Y)$ is K-flat. Deduce that $X \otimes^L_R Y$ is represented by the K-flat complex $\mathrm{Tot}(P_X \otimes_R P_Y)$.

59.3 Truncation in the Derived Category

The canonical truncations of definition 56.1.12 cut a complex at a degree n and keep exactly its cohomology in degrees at most n, or in degrees at least n (proposition 56.1.14). In $D(\mathcal{A})$ they become functors onto the full subcategories of complexes whose cohomology vanishes above, or below, a

fixed degree. Every complex sits in a distinguished triangle between its two truncations, no nonzero morphism runs from the lower subcategory to the upper one, and each truncation is adjoint to the inclusion of its target. The complexes with cohomology only in degree 0 form a full subcategory equivalent to $\mathcal{A}$, so $\mathcal{A}$ is recovered from $D(\mathcal{A})$ together with the two subcategories cut out at degree 0, although distinct abelian categories can have equivalent derived categories (box 57.2.13).

Throughout, $\mathcal{A}$ is an arbitrary abelian category. The localization functor of corollary 55.2.6 is $Q\colon \mathrm{Ch}(\mathcal{A}) \to D(\mathcal{A})$. By theorem 57.2.4 every morphism $X \to Y$ of $D(\mathcal{A})$ is represented by a roof (N, s, f), which is the composite of (N, s, id_N), representing $Q(s)^{-1}$, with (N, id_N, f), representing $Q(f)$. Choosing chain maps in the two homotopy classes writes the morphism as $Q(f)Q(s)^{-1}$ with $f\colon N \to Y$ a chain map and $s\colon N \to X$ a quasi-isomorphism, any representative of the class s being a quasi-isomorphism because homotopic maps induce the same map on cohomology (proposition 56.1.29). An object M of $\mathcal{A}$ is regarded as a complex concentrated in degree 0, as in example 57.2.11, and $M[k]$ is then M in degree $-k$ by (57.1).

By proposition 56.1.14, $\tau^{\leq n}X$ has no cohomology above degree n and $\tau^{\geq n}X$ has none below it. The full subcategories of $D(\mathcal{A})$ cut out by these two vanishing conditions are the targets of the truncation functors.

Definition 59.3.1: The Subcategories $D^{\leq n}$ and $D^{\geq n}$

Let $\mathcal{A}$ be an abelian category and $n \in \mathbb{Z}$. Write $D^{\leq n}(\mathcal{A})$ for the full subcategory of $D(\mathcal{A})$ on the complexes X with $H^i(X) = 0$ for all $i > n$, and $D^{\geq n}(\mathcal{A})$ for the full subcategory on the complexes X with $H^i(X) = 0$ for all $i < n$. The full subcategory

$$D^{\leq 0}(\mathcal{A}) \cap D^{\geq 0}(\mathcal{A})$$

of complexes whose cohomology is concentrated in degree 0 is the *heart* of the pair $\big(D^{\leq 0}(\mathcal{A}), D^{\geq 0}(\mathcal{A})\big)$.

When $\mathcal{A}$ is fixed it is dropped from the notation. Membership depends only on the isomorphism class in $D(\mathcal{A})$, since H^i is a functor on $D(\mathcal{A})$ (proposition 57.2.8). The full subcategory $D^{+}(\mathcal{A})$ of box 57.2.5 consists of the complexes with cohomology bounded below, that is, with $H^i(X) = 0$ for all i below some n, so it is the union of the $D^{\geq n}$ over $n \in \mathbb{Z}$. Likewise $D^{-}(\mathcal{A})$, on the complexes with cohomology bounded above, is the union of the $D^{\leq n}$.

Example 59.3.2: The Complexes $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ and $\mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4$

Let X be $\mathbb{Z} \xrightarrow{2} \mathbb{Z}$ in degrees -1 and 0, as in example 56.1.13. Then $H^{-1}(X) = \ker(2) = 0$ and $H^0(X) = \mathbb{Z}/2$, so X lies in the heart $D^{\leq 0} \cap D^{\geq 0}$ although $X^{-1} \neq 0$. Example 56.1.13 computes $\tau^{\geq 0}X$ as $\mathbb{Z}/2$ in degree 0, and $p_0\colon X \to \tau^{\geq 0}X$ is a quasi-isomorphism by proposition 56.1.14, because $H^{-1}(X) = 0$. So $X \cong \mathbb{Z}/2$ in $D(\mathbf{Ab})$.

Let Y be $\mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4$ in degrees -1 and 0. Multiplication by 2 on $\mathbb{Z}/4$ has kernel $\{0, 2\}$ and image $\{0, 2\}$, so $H^{-1}(Y) \cong \mathbb{Z}/2$ and $H^0(Y) = (\mathbb{Z}/4)/\{0, 2\} \cong \mathbb{Z}/2$. Thus $Y \in D^{\leq 0} \cap D^{\geq -1}$ and $Y \notin D^{\geq 0}$.

The exact 2-periodic complex $\cdots \to \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \to \cdots$ of box 57.2.5 is nonzero in every degree, and it lies in $D^{\leq n} \cap D^{\geq m}$ for every m and n, its cohomology being zero.

The functors $\tau^{\leq n}$ and $\tau^{\geq n}$ of definition 56.1.12 are defined on $\mathrm{Ch}(\mathcal{A})$. To act on $D(\mathcal{A})$ they must carry quasi-isomorphisms to quasi-isomorphisms, and they do, because each one preserves the cohomology in its range of degrees and has zero cohomology outside it.

Lemma 59.3.3: Truncation on the Derived Category

Let $n \in \mathbb{Z}$.

1. The functors $\tau^{\leq n}, \tau^{\geq n} \colon \mathrm{Ch}(\mathcal{A}) \to \mathrm{Ch}(\mathcal{A})$ carry quasi-isomorphisms to quasi-isomorphisms. Consequently there are unique functors $\tau^{\leq n}, \tau^{\geq n} \colon D(\mathcal{A}) \to D(\mathcal{A})$, written with the same symbols, such that $\tau^{\leq n} \circ Q = Q \circ \tau^{\leq n}$ and $\tau^{\geq n} \circ Q = Q \circ \tau^{\geq n}$.
2. The morphisms $Q(i_n) \colon \tau^{\leq n} X \to X$ and $Q(p_n) \colon X \to \tau^{\geq n} X$ are natural in $X \in D(\mathcal{A})$.
3. For every X, $\tau^{\leq n} X \in D^{\leq n}$ and $\tau^{\geq n} X \in D^{\geq n}$. Moreover i_n is a quasi-isomorphism, equivalently $Q(i_n)$ is an isomorphism, if and only if $X \in D^{\leq n}$, and p_n is a quasi-isomorphism, equivalently $Q(p_n)$ is an isomorphism, if and only if $X \in D^{\geq n}$.

***Proof*:**

1. Let $f \colon X \to Y$ be a quasi-isomorphism, and write i_n^X for the map i_n of the complex X. The chain map $\tau^{\leq n} f$ is f below degree n and the restriction of f^n to $Z^n(X)$ in degree n, so $i_n^Y \circ \tau^{\leq n} f = f \circ i_n^X$. For $i \leq n$, the maps $H^i(i_n^X)$ and $H^i(i_n^Y)$ are isomorphisms by proposition 56.1.14, and so is $H^i(f)$, hence so is
$$H^i(\tau^{\leq n} f) = H^i(i_n^Y)^{-1} \circ H^i(f) \circ H^i(i_n^X)$$
For $i > n$, proposition 56.1.14 gives $H^i(\tau^{\leq n} X) = 0 = H^i(\tau^{\leq n} Y)$, and the zero map between zero objects is an isomorphism. The chain map $\tau^{\geq n} f$ is the map $X^n/B^n(X) \to Y^n/B^n(Y)$ induced by f^n in degree n and f above, so $p_n^Y \circ f = \tau^{\geq n} f \circ p_n^X$, and the same argument with the range $i \geq n$ treats $\tau^{\geq n}$. So $Q \circ \tau^{\leq n}$ carries quasi-isomorphisms to isomorphisms, and the universal property of corollary 55.2.6 gives a unique functor $\tau^{\leq n}$ on $D(\mathcal{A})$ with $\tau^{\leq n} \circ Q = Q \circ \tau^{\leq n}$. The same holds for $\tau^{\geq n}$.
2. Write a morphism $\varphi \colon X \to Y$ of $D(\mathcal{A})$ as $Q(f)Q(s)^{-1}$ with $s \colon N \to X$ a quasi-isomorphism and $f \colon N \to Y$ a chain map. Applying Q to the naturality squares of i_n in $\mathrm{Ch}(\mathcal{A})$ for f and for s, and using (1), gives
$$Q(i_n^Y) \circ \tau^{\leq n} Q(f) = Q(f) \circ Q(i_n^N), \qquad Q(i_n^X) \circ \tau^{\leq n} Q(s) = Q(s) \circ Q(i_n^N)$$
In the second equation $Q(s)$ and $\tau^{\leq n} Q(s)$ are isomorphisms. Composing with $Q(s)^{-1}$ on the left and with $(\tau^{\leq n} Q(s))^{-1} = \tau^{\leq n}(Q(s)^{-1})$ on the right gives $Q(i_n^N) \circ \tau^{\leq n}(Q(s)^{-1}) = Q(s)^{-1} \circ Q(i_n^X)$, the naturality square for $Q(s)^{-1}$. Pasting it with the square for $Q(f)$ gives $Q(i_n^Y) \circ \tau^{\leq n} \varphi = \varphi \circ Q(i_n^X)$. The argument for p_n is the same.
3. The first sentence is proposition 56.1.14. A chain map f is a quasi-isomorphism exactly when $Q(f)$ is an isomorphism: Q inverts quasi-isomorphisms, and conversely if $Q(f)$ is an isomorphism then so is $H^i(Q(f)) = H^i(f)$ for every i, since H^i is a functor on $D(\mathcal{A})$ with $H^i \circ Q = H^i$ (proposition 57.2.8). By proposition 56.1.14, $H^i(i_n)$ is an isomorphism for every $i \leq n$, and for $i > n$ its source $H^i(\tau^{\leq n} X)$ is zero, so $H^i(i_n)$ is an isomorphism exactly when $H^i(X) = 0$. Hence i_n is a quasi-isomorphism if and only if $X \in D^{\leq n}$. The statement for p_n is proved the same way with $i < n$ in place of $i > n$, completing the proof.

By lemma 59.3.3(3), an object X of $D^{\leq n}$ is isomorphic in $D(\mathcal{A})$ to $\tau^{\leq n}X$, a complex that vanishes above degree n, and an object X of $D^{\geq n}$ is isomorphic to $\tau^{\geq n}X$, which vanishes below degree n. Conversely, a complex that vanishes above degree n has no cohomology there. So $D^{\leq n}$ consists of the objects isomorphic in $D(\mathcal{A})$ to a complex that vanishes above degree n, and likewise $D^{\geq n}$ consists of those isomorphic to a complex that vanishes below degree n.

The triangle relating a complex to its two truncations comes from theorem 57.2.10. The subcomplex $\tau^{\leq n}X$ of X has a quotient complex, and that quotient is quasi-isomorphic to $\tau^{\geq n+1}X$. The vanishing of morphisms from $D^{\leq n}$ to $D^{\geq n+1}$ is proved on a roof, after truncating its apex and its target so that the two have no degree in common.

Proposition 59.3.4: Orthogonality and the Truncation Triangle

Let $\mathcal{A}$ be an abelian category and $n \in \mathbb{Z}$.

1. $D^{\leq n} \subseteq D^{\leq n+1}$ and $D^{\geq n+1} \subseteq D^{\geq n}$. For every complex X, $X \in D^{\leq 0}$ if and only if $X[-n] \in D^{\leq n}$, and $X \in D^{\geq 0}$ if and only if $X[-n] \in D^{\geq n}$.
2. $\operatorname{Hom}_{D(\mathcal{A})}(X, Y) = 0$ for all $X \in D^{\leq n}$ and $Y \in D^{\geq n+1}$.
3. For every complex X there is a morphism $w\colon \tau^{\geq n+1}X \to (\tau^{\leq n}X)[1]$ of $D(\mathcal{A})$ for which

$$\tau^{\leq n}X \xrightarrow{Q(i_n)} X \xrightarrow{Q(p_{n+1})} \tau^{\geq n+1}X \xrightarrow{w} (\tau^{\leq n}X)[1]$$

   is a distinguished triangle of $D(\mathcal{A})$.

***Proof*:**

1. A complex with $H^i(X) = 0$ for all $i > n$ has $H^i(X) = 0$ for all $i > n+1$, and one with $H^i(X) = 0$ for all $i < n+1$ has $H^i(X) = 0$ for all $i < n$. For the second sentence, $H^i(X[-n]) = H^{i-n}(X)$ by (57.1), and $i - n > 0$ exactly when $i > n$, while $i - n < 0$ exactly when $i < n$.
2. Let $\varphi\colon X \to Y$ be a morphism of $D(\mathcal{A})$, and write $\varphi = Q(f)Q(s)^{-1}$ with $s\colon N \to X$ a quasi-isomorphism and $f\colon N \to Y$ a chain map. Since s is a quasi-isomorphism, $H^i(N) \cong H^i(X) = 0$ for $i > n$, so $N \in D^{\leq n}$, and $i := i_n^N\colon \tau^{\leq n}N \to N$ is a quasi-isomorphism by lemma 59.3.3(3). Likewise $p := p_{n+1}^Y\colon Y \to \tau^{\geq n+1}Y$ is a quasi-isomorphism, Y lying in $D^{\geq n+1}$. The chain map $p \circ f \circ i\colon \tau^{\leq n}N \to \tau^{\geq n+1}Y$ is zero in every degree k: for $k > n$ its source $(\tau^{\leq n}N)^k$ is zero, and for $k \leq n$ its target $(\tau^{\geq n+1}Y)^k$ is zero. Hence

$$Q(p) \circ \varphi \circ Q(s) \circ Q(i) = Q(p) \circ Q(f) \circ Q(i) = Q(pfi) = 0$$

   and since $Q(p)$, $Q(s)$ and $Q(i)$ are isomorphisms, $\varphi = 0$.
3. The chain map $i_n\colon \tau^{\leq n}X \to X$ is a monomorphism in every degree: it is the identity below degree n, the inclusion $Z^n \to X^n$ in degree n, and the zero map out of 0 above. Let C be its cokernel, computed degreewise, so that

$$0 \to \tau^{\leq n}X \xrightarrow{i_n} X \xrightarrow{\pi} C \to 0$$

   is a short exact sequence in $\mathrm{Ch}(\mathcal{A})$. Explicitly $C^k = 0$ for $k < n$, $C^n = X^n/Z^n$ and $C^k = X^k$ for $k > n$, with $d_C^n(x + Z^n) = d^n x$, well defined because $Z^n = \ker d^n$, and

$d_C^k = d^k$ for $k > n$. By theorem 57.2.10 there is a morphism $w' \colon C \to (\tau^{\leq n} X)[1]$ of $D(\mathcal{A})$ for which $\big(Q(i_n), Q(\pi), w'\big)$ is a distinguished triangle.

Step 1: the comparison map. Define $q \colon C \to \tau^{\geq n+1} X$ by $q^k = 0$ for $k \leq n$, $q^{n+1} \colon X^{n+1} \to X^{n+1}/B^{n+1}$ the quotient map, and $q^k = \mathrm{id}$ for $k \geq n+2$. Below degree n both complexes are zero, and above degree $n+1$ every component is an identity. In the square leaving degree n, $q^{n+1}(d_C^n(x + Z^n)) = d^n x + B^{n+1} = 0$ because $d^n x \in B^{n+1}$, matching $d^n_{\tau^{\geq n+1} X} \circ q^n = 0$. The square leaving degree $n+1$ commutes because the differential of $\tau^{\geq n+1} X$ in that degree is induced by d^{n+1}. Comparing degree by degree with definition 56.1.12, $q \circ \pi = p_{n+1}$.

Step 2: q is a quasi-isomorphism. For $i < n$, $C^i = 0$. In degree n the map d_C^n is injective, since $d^n x = 0$ forces $x \in Z^n$, and nothing arrives from $C^{n-1} = 0$, so $H^n(C) = 0$. Thus $H^i(C) = 0$ for $i \leq n$, and $H^i(\tau^{\geq n+1} X) = 0$ for $i \leq n$ by proposition 56.1.14, so $H^i(q)$ is an isomorphism for $i \leq n$. For $i \geq n+1$ the map $H^i(\pi)$ is the identity: π is the identity in degrees above n, the cycles of C in degree $n+1$ are Z^{n+1}, and the boundaries there are $d_C^n(C^n) = d^n(X^n) = B^{n+1}$. Since $H^i(q) \circ H^i(\pi) = H^i(p_{n+1})$, and $H^i(p_{n+1})$ is an isomorphism for $i \geq n+1$ by proposition 56.1.14, $H^i(q)$ is an isomorphism for $i \geq n+1$ as well.

Step 3: the triangle. Set $w := w' \circ Q(q)^{-1}$. The triple $\big(\mathrm{id}, \mathrm{id}, Q(q)\big)$ is a morphism of triangles from $\big(Q(i_n), Q(\pi), w'\big)$ to $\big(Q(i_n), Q(p_{n+1}), w\big)$: the middle square is $Q(q) \circ Q(\pi) = Q(p_{n+1})$ by Step 1, and the third is $w \circ Q(q) = w'$ by the definition of w. All three of its components are isomorphisms, so it is an isomorphism of triangles, and distinguished triangles are closed under isomorphism by (TR1) of definition 57.1.3, $D(\mathcal{A})$ being triangulated by theorem 57.2.7. This completes the proof.

Properties (1), (2) and (3), together with $\tau^{\leq n} X \in D^{\leq n}$ and $\tau^{\geq n+1} X \in D^{\geq n+1}$ from lemma 59.3.3(3), are the three axioms of a t-structure in the form of Gelfand-Manin [53, Def. IV.4.2], and section 59.4 develops them on an arbitrary triangulated category, with the pair $(D^{\leq 0}, D^{\geq 0})$ as the standard example. The proposition is Gelfand-Manin [53, Prop. IV.4.3], whose proof of (2) replaces the apex K of a roof by $\tau^{\leq 0} K$ and its target Y by the quasi-isomorphic quotient complex $Y/\tau^{\leq 0} Y$.

Orthogonality already constrains morphisms between objects of $\mathcal{A}$. For $M, N \in \mathcal{A}$ and $k < 0$, the complex $N[k]$ is N in degree $-k \geq 1$, so $N[k] \in D^{\geq 1}$, while $M \in D^{\leq 0}$, and (2) gives $\mathrm{Hom}_{D(\mathcal{A})}(M, N[k]) = 0$. When $\mathcal{A}$ has enough injectives this is the vanishing of negative degrees in theorem 57.4.10(2), and here it holds with no hypothesis on $\mathcal{A}$.

Example 59.3.5: The Truncation Triangle of $\mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4$

Let Y be $\mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4$ in degrees -1 and 0, as in example 59.3.2, and take $n = -1$. The cycles in degree -1 are $\{0, 2\}$, so $\tau^{\leq -1} Y$ is $\{0, 2\} \cong \mathbb{Z}/2$ in degree -1, which is the complex $\mathbb{Z}/2[1]$. The quotient complex C of the proof of proposition 59.3.4(3) is $(\mathbb{Z}/4)/\{0, 2\} \cong \mathbb{Z}/2$ in degree -1 followed by $\mathbb{Z}/4$ in degree 0, joined by the map $1 \mapsto 2$. The truncation $\tau^{\geq 0} Y$ is $(\mathbb{Z}/4)/\{0, 2\} \cong \mathbb{Z}/2$ in degree 0, and the comparison map $q \colon C \to \tau^{\geq 0} Y$ is the reduction $\mathbb{Z}/4 \to \mathbb{Z}/2$ in degree 0. It is surjective in each degree, and its kernel is the complex $\mathbb{Z}/2 \to \{0, 2\}$, $1 \mapsto 2$, whose differential is an isomorphism, so the kernel is exact and the long exact cohomology sequence of theorem 56.1.18

shows directly that q is a quasi-isomorphism. The triangle reads

$$\mathbb{Z}/2[1] \xrightarrow{Q(i_{-1})} Y \xrightarrow{Q(p_0)} \mathbb{Z}/2 \xrightarrow{w} \mathbb{Z}/2[2]$$

By proposition 56.1.14, $H^{-1}(i_{-1})$ is an isomorphism $H^{-1}(\mathbb{Z}/2[1]) = \mathbb{Z}/2 \to H^{-1}(Y)$ and $H^0(p_0)$ is an isomorphism $H^0(Y) \to H^0(\mathbb{Z}/2) = \mathbb{Z}/2$, while $H^0(\mathbb{Z}/2[1]) = 0$ and $H^{-1}(\mathbb{Z}/2) = 0$.

Combining proposition 59.3.4(2) with the triangle of (3) shows that every morphism from an object of $D^{\leq n}$ into X factors uniquely through $Q(i_n)$, and every morphism from X into an object of $D^{\geq n}$ factors uniquely through $Q(p_n)$.

Corollary 59.3.6: Truncation Is Adjoint to Inclusion

Let $n \in \mathbb{Z}$ and $X \in D(\mathcal{A})$.

1. For every $A \in D^{\leq n}$, composition with $Q(i_n)$ is a bijection
$$\mathrm{Hom}_{D(\mathcal{A})}(A, \tau^{\leq n}X) \xrightarrow{\sim} \mathrm{Hom}_{D(\mathcal{A})}(A, X)$$
natural in A and X. That is, $\tau^{\leq n}\colon D(\mathcal{A}) \to D^{\leq n}$ is right adjoint to the inclusion $D^{\leq n} \to D(\mathcal{A})$.

2. For every $B \in D^{\geq n}$, precomposition with $Q(p_n)$ is a bijection
$$\mathrm{Hom}_{D(\mathcal{A})}(\tau^{\geq n}X, B) \xrightarrow{\sim} \mathrm{Hom}_{D(\mathcal{A})}(X, B)$$
natural in X and B. That is, $\tau^{\geq n}\colon D(\mathcal{A}) \to D^{\geq n}$ is left adjoint to the inclusion $D^{\geq n} \to D(\mathcal{A})$.

***Proof*:**

1. Write $T := \tau^{\leq n}X$ and $S := \tau^{\geq n+1}X$. Since $D(\mathcal{A})$ is triangulated (theorem 57.2.7), $\mathrm{Hom}(A, -)$ is cohomological by proposition 57.1.8. Applied to the triangle of proposition 59.3.4(3) and to its rotation $\big(-w[-1], Q(i_n), Q(p_{n+1})\big)$ on $(S[-1], T, X)$, which is distinguished by (TR2), this gives exactness of
$$\mathrm{Hom}(A, S[-1]) \to \mathrm{Hom}(A, T) \xrightarrow{Q(i_n)\circ -} \mathrm{Hom}(A, X) \to \mathrm{Hom}(A, S)$$
at the two middle terms. Here $S \in D^{\geq n+1}$ by lemma 59.3.3(3), and $S[-1] \in D^{\geq n+2} \subseteq D^{\geq n+1}$ because $H^i(S[-1]) = H^{i-1}(S)$. Since $A \in D^{\leq n}$, both outer groups vanish by proposition 59.3.4(2), so composition with $Q(i_n)$ is injective and surjective. Naturality in A holds because composing on the left commutes with composing on the right. Naturality in X is the equation $Q(i_n^{X'}) \circ \tau^{\leq n}\varphi = \varphi \circ Q(i_n^X)$ of lemma 59.3.3(2), for every $\varphi\colon X \to X'$. Finally $\tau^{\leq n}X$ lies in $D^{\leq n}$ by lemma 59.3.3(3).

2. Write $T := \tau^{\leq n-1}X$ and $S := \tau^{\geq n}X$, and use the triangle of proposition 59.3.4(3) for $n-1$, which has vertices T, X, S. The functor $\mathrm{Hom}(-, B)$ is cohomological on $D(\mathcal{A})^{\mathrm{op}}$ by proposition 57.1.8. Applied to that triangle and to its rotation $\big(Q(p_n), w, -Q(i_{n-1})[1]\big)$

on $(X, S, T[1])$, it gives exactness of

$$\mathrm{Hom}(T[1], B) \to \mathrm{Hom}(S, B) \xrightarrow{-\circ Q(p_n)} \mathrm{Hom}(X, B) \to \mathrm{Hom}(T, B)$$

at the two middle terms. Here $T \in D^{\leq n-1}$, and $T[1] \in D^{\leq n-2} \subseteq D^{\leq n-1}$ because $H^i(T[1]) = H^{i+1}(T)$. Since $B \in D^{\geq n}$, both outer groups vanish by proposition 59.3.4(2) applied with $n-1$, so precomposition with $Q(p_n)$ is a bijection. Naturality is checked as in (1), and $\tau^{\geq n}X \in D^{\geq n}$ by lemma 59.3.3(3), completing the proof.

Parts (1) and (2) characterize the pairs $\left(\tau^{\leq n}X, Q(i_n)\right)$ and $\left(\tau^{\geq n}X, Q(p_n)\right)$ by properties of $D(\mathcal{A})$ and the subcategories $D^{\leq n}$ and $D^{\geq n}$, with no reference to the formulas of definition 56.1.12. For a distinguished triangle $A' \xrightarrow{a} X \xrightarrow{b} B' \xrightarrow{c} A'[1]$ with $A' \in D^{\leq n}$ and $B' \in D^{\geq n+1}$, part (1) gives a unique $f\colon A' \to \tau^{\leq n}X$ with $Q(i_n) \circ f = a$. There is also a unique $h\colon B' \to \tau^{\geq n+1}X$ with $h \circ b = Q(p_{n+1})$, both f and h are isomorphisms, and (f, id_X, h) is an isomorphism of triangles from (a, b, c) to the triangle of proposition 59.3.4(3) (exercise 59.3.1 (2)). Truncation functors exist in this form for an arbitrary t-structure, where no complex-level formula is available.

The objects of $\mathcal{A}$ are, up to isomorphism, the complexes with cohomology concentrated in degree 0, and the morphisms between two of them in $D(\mathcal{A})$ are exactly the morphisms of $\mathcal{A}$. A morphism of $D(\mathcal{A})$ between two objects of $\mathcal{A}$ is a roof whose apex is an arbitrary complex. Truncating the apex in degree 0 reduces it to a chain map out of a complex that stops in degree 0, and such a chain map into an object of $\mathcal{A}$ is determined by its effect on H^0.

Theorem 59.3.7: The Heart of the Standard Pair Is $\mathcal{A}$

Let $\mathcal{A}$ be an abelian category, and let $j\colon \mathcal{A} \to D(\mathcal{A})$ send an object M to the complex with M in degree 0 and zero elsewhere, and a morphism f to $Q(f)$.

1. j is fully faithful, and its essential image is the heart $D^{\leq 0} \cap D^{\geq 0}$.
2. $H^0 \circ j = \mathrm{id}_{\mathcal{A}}$, and there is a natural isomorphism $\vartheta\colon \mathrm{id} \to j \circ H^0$ of functors on $D^{\leq 0} \cap D^{\geq 0}$.

In particular $H^0\colon D^{\leq 0} \cap D^{\geq 0} \to \mathcal{A}$ and j are mutually quasi-inverse equivalences, and the heart is an abelian category.

***Proof*:**

Step 1: j lands in the heart, and $H^0 \circ j = \mathrm{id}_{\mathcal{A}}$. The complex $j(M)$ has $H^i(j(M)) = 0$ for $i \neq 0$ and $H^0(j(M)) = M$. For a morphism $f\colon M \to N$, $H^0(Q(f)) = H^0(f) = f$, because $H^0 \circ Q = H^0$ (proposition 57.2.8). In particular j is faithful.

Step 2: chain maps from a truncation into $j(N)$. Let L be a complex and $N \in \mathcal{A}$, and let $u\colon \tau^{\leq 0}L \to j(N)$ be a chain map. Its only possibly nonzero component is $u^0\colon Z^0(L) \to N$. The square leaving degree -1 reads $u^0 \circ d_L^{-1} = 0$, so u^0 vanishes on $B^0(L)$ and factors as $u^0 = \bar{u} \circ \pi_L$, where $\pi_L\colon Z^0(L) \to Z^0(L)/B^0(L)$ is the quotient map. In degree 0 the complex $\tau^{\leq 0}L$ has cycles $Z^0(L)$, since nothing leaves that degree, and boundaries $d_L^{-1}(L^{-1}) = B^0(L)$, so $H^0(\tau^{\leq 0}L) = Z^0(L)/B^0(L)$ and $H^0(u) = \bar{u}$. Thus $u^0 = H^0(u) \circ \pi_L$, and two chain maps $\tau^{\leq 0}L \to j(N)$ inducing the same map on H^0 are equal.

Step 3: j is full. Let $\varphi\colon j(M) \to j(N)$ be a morphism of $D(\mathcal{A})$, and write $\varphi = Q(g)Q(s)^{-1}$ with $s\colon L \to j(M)$ a quasi-isomorphism and $g\colon L \to j(N)$ a chain map. Then $H^k(L) \cong H^k(j(M)) = 0$ for $k > 0$, so $i := i_0^L\colon \tau^{\leq 0}L \to L$ is a quasi-isomorphism by lemma 59.3.3(3). The map $H^0(s)\colon H^0(L) \to M$ is an isomorphism, and we set

$$f := H^0(g) \circ H^0(s)^{-1}\colon M \to N$$

Regard f as a chain map $j(M) \to j(N)$. The chain maps $f \circ s \circ i$ and $g \circ i$ from $\tau^{\leq 0}L$ to $j(N)$ induce $f \circ H^0(s) \circ H^0(i)$ and $H^0(g) \circ H^0(i)$ on H^0, and these agree because $f \circ H^0(s) = H^0(g)$. By Step 2, $fsi = gi$ as chain maps. Applying Q and cancelling the isomorphisms $Q(i)$ and $Q(s)$ gives $Q(f) = Q(g)Q(s)^{-1} = \varphi$, so $\varphi = j(f)$. Together with Step 1, j is fully faithful.

Step 4: every object of the heart is isomorphic to one in the image. Let X lie in the heart and put $Y := \tau^{\leq 0}X$. The map $i := i_0^X\colon Y \to X$ is a quasi-isomorphism by lemma 59.3.3(3), since $X \in D^{\leq 0}$. For $k \leq 0$, $H^k(Y) \cong H^k(X)$ by proposition 56.1.14, and this vanishes for $k < 0$, so $Y \in D^{\geq 0}$ and $p := p_0^Y : Y \to \tau^{\geq 0}Y$ is a quasi-isomorphism as well. The complex $\tau^{\geq 0}Y$ is $Y^0/B^0(Y)$ in degree 0 and zero elsewhere, and $Y^0 = Z^0(X)$ and $B^0(Y) = d^{-1}(X^{-1}) = B^0(X)$, so $\tau^{\geq 0}\tau^{\leq 0}X = j\big(H^0(X)\big)$. Set

$$\vartheta_X := Q(p) \circ Q(i)^{-1}\colon X \to j\big(H^0(X)\big)$$

an isomorphism of $D(\mathcal{A})$. Both $H^0(i)$ and $H^0(p)$ are the identity of $Z^0(X)/B^0(X)$: the first is induced by the inclusion $Z^0(X) \to X^0$ and the second by the quotient $Z^0(X) \to Z^0(X)/B^0(X)$, each restricted to the cycles $Z^0(X)$ and taken modulo $B^0(X)$. Hence $H^0(\vartheta_X) = \mathrm{id}_{H^0(X)}$.

Step 5: naturality of ϑ. Let $\varphi\colon X \to X'$ be a morphism of the heart. The morphism $\psi := \vartheta_{X'} \circ \varphi \circ \vartheta_X^{-1}$ runs from $j(H^0(X))$ to $j(H^0(X'))$, so $\psi = j(a)$ for some morphism a of $\mathcal{A}$ by Step 3. By Step 1 and Step 4,

$$a = H^0(j(a)) = H^0(\vartheta_{X'}) \circ H^0(\varphi) \circ H^0(\vartheta_X)^{-1} = H^0(\varphi)$$

so $\vartheta_{X'} \circ \varphi = j(H^0(\varphi)) \circ \vartheta_X$, which is naturality.

Step 6: conclusion. Steps 1, 3 and 4 give (1), and Steps 1, 4 and 5 give (2), so j and the restriction of H^0 are quasi-inverse equivalences. The heart contains 0 and is closed under finite direct sums in the additive category $D(\mathcal{A})$, since each H^i is additive, so it is an additive category, and j is an additive functor because Q is. The conditions of definition 55.1.6 (kernels and cokernels exist, every monomorphism is a kernel and every epimorphism is a cokernel) are stated by universal properties, and an equivalence of categories carries each of them from $\mathcal{A}$ to the heart. For instance, the kernel of a morphism $\varphi\colon X \to X'$ of the heart is $\vartheta_X^{-1} \circ j(k)$, where k is a kernel of $H^0(\varphi)$ in $\mathcal{A}$. So the heart is abelian, completing the proof.

The theorem places $\mathcal{A}$ inside $D(\mathcal{A})$ with no hypothesis on $\mathcal{A}$. When $\mathcal{A}$ has enough injectives, full faithfulness of j is also the last clause of theorem 57.4.10(2), proved there through $R\mathrm{Hom}$. Short exact sequences of $\mathcal{A}$ become distinguished triangles of $D(\mathcal{A})$ with all three vertices in the heart, by theorem 57.2.10. The kernel of a morphism φ of the heart is computed in $\mathcal{A}$, as the kernel of $H^0(\varphi)$, and transported along j. Inside $D(\mathcal{A})$ it is produced by a cone followed by a truncation.

Example 59.3.8: The Cone of a Morphism of $\mathcal{A}$

Let $f\colon M \to N$ be a morphism of $\mathcal{A}$, regarded as a chain map of complexes concentrated in degree 0. In definition 56.1.21, $MC(f)^i = M^{i+1} \oplus N^i$ with differential $(l,m) \mapsto \big(-d_M(l),\ f(l) + d_N(m)\big)$, so $MC(f)$ is M in degree -1 and N in degree 0, joined by f:

$$MC(f)\colon \qquad \cdots \to 0 \to M \xrightarrow{f} N \to 0 \to \cdots$$

Hence $H^{-1}(MC(f)) = \ker f$ and $H^0(MC(f)) = \operatorname{coker} f$, and $MC(f) \in D^{\leq 0} \cap D^{\geq -1}$. The mapping cone triangle on f is distinguished in $\mathrm{K}(\mathcal{A})$ (theorem 57.1.12), so its image is distinguished in $D(\mathcal{A})$ (theorem 57.2.7), and by proposition 57.1.10 every distinguished triangle on $Q(f)$ has third vertex isomorphic to $MC(f)$.

Truncate at $n = -1$. The cycles of $MC(f)$ in degree -1 form $\ker f$, so $\tau^{\leq -1} MC(f)$ is $\ker f$ in degree -1, the complex $(\ker f)[1]$. The quotient of N by the boundaries $f(M)$ is $\operatorname{coker} f$, so $\tau^{\geq 0} MC(f)$ is $\operatorname{coker} f$ in degree 0. The triangle of proposition 59.3.4(3) is

$$(\ker f)[1] \longrightarrow MC(f) \longrightarrow \operatorname{coker} f \longrightarrow (\ker f)[2]$$

So the kernel and the cokernel of f are recovered from $D(\mathcal{A})$ and the pair $(D^{\leq 0}, D^{\geq 0})$: complete $Q(f)$ to a distinguished triangle, truncate its third vertex, and apply H^0 to $\big(\tau^{\leq -1} MC(f)\big)[-1]$ and to $\tau^{\geq 0} MC(f)$, both of which lie in the heart. When f is a monomorphism, $H^{-1}(MC(f)) = 0$, the cone itself lies in the heart, and it is isomorphic to $\operatorname{coker} f$ by the quasi-isomorphism of lemma 57.2.9 for the short exact sequence $0 \to M \to N \to \operatorname{coker} f \to 0$.

Exercise 59.3.1

1. Let $X \in D(\mathcal{A})$ and $n \in \mathbb{Z}$, and let w be the third morphism of the triangle of proposition 59.3.4(3). Show that $H^i(w) = 0$ for every i, and deduce from proposition 57.2.8 that

   $$0 \to H^i(\tau^{\leq n} X) \to H^i(X) \to H^i(\tau^{\geq n+1} X) \to 0$$

   is exact for every i. Compare with proposition 56.1.14.

2. Let $A' \xrightarrow{a} X \xrightarrow{b} B' \xrightarrow{c} A'[1]$ be a distinguished triangle of $D(\mathcal{A})$ with $A' \in D^{\leq n}$ and $B' \in D^{\geq n+1}$. Show that there are unique morphisms $f\colon A' \to \tau^{\leq n} X$ and $h\colon B' \to \tau^{\geq n+1} X$ with $Q(i_n) \circ f = a$ and $h \circ b = Q(p_{n+1})$, and that both are isomorphisms. (Apply $\operatorname{Hom}(T, -)$ for $T \in D^{\leq n}$ and $\operatorname{Hom}(-, T)$ for $T \in D^{\geq n+1}$, then argue as in the last paragraph of the proof of corollary 57.1.9.) Show further that $w \circ h = f[1] \circ c$, where w is the third morphism of the triangle of proposition 59.3.4(3), so that (f, id_X, h) is an isomorphism of triangles from (a, b, c) to $\big(Q(i_n), Q(p_{n+1}), w\big)$. (Complete (f, id_X) to a morphism of triangles by (TR3) of definition 57.1.3, and compare its third component with h.)

3. Let $X \in \mathrm{Ch}(\mathcal{A})$ and $m \leq n$. Show that the complexes $\tau^{\geq m} \tau^{\leq n} X$ and $\tau^{\leq n} \tau^{\geq m} X$ are canonically isomorphic, and that for $m = n$ both are $H^n(X)$ in degree n, that is $H^n(X)[-n]$.

4. Let $X' \to X \to X'' \to X'[1]$ be a distinguished triangle of $D(\mathcal{A})$. Show that if X' and X'' lie in $D^{\leq 0}$ then so does X, and that the same holds for $D^{\geq 0}$. Conclude that the heart is closed under extensions in $D(\mathcal{A})$.

5. Show that $X \in D^{\leq 0}$ if and only if $\mathrm{Hom}_{D(\mathcal{A})}(X, B) = 0$ for every $B \in D^{\geq 1}$, and that $X \in D^{\geq 1}$ if and only if $\mathrm{Hom}_{D(\mathcal{A})}(A, X) = 0$ for every $A \in D^{\leq 0}$. (Test against $\tau^{\geq 1}X$ and $\tau^{\leq 0}X$, and use corollary 59.3.6.)

6. Let $k \in \mathbb{Z}$. Show that H^k restricts to an equivalence from $D^{\leq k} \cap D^{\geq k}$ to $\mathcal{A}$, with quasi-inverse $M \mapsto j(M)[-k]$.

7. Let X be the complex $\mathbb{Z} \xrightarrow{d^{-1}} \mathbb{Z}^2 \xrightarrow{d^0} \mathbb{Z}$ of abelian groups in degrees -1, 0 and 1, with $d^{-1}(x) = (2x, 0)$ and $d^0(a, b) = 3b$. Compute $H^\bullet(X)$, $\tau^{\leq 0}X$ and $\tau^{\geq 1}X$, and show that $\tau^{\leq 0}X \cong \mathbb{Z}/2$ and $\tau^{\geq 1}X = \mathbb{Z}/3[-1]$ in $D(\mathbf{Ab})$. Then show that the third morphism w of the triangle of proposition 59.3.4(3) for $n = 0$ is zero. (The Hom-sets of $D(\mathbf{Ab})$ are abelian groups and composition is bilinear, by theorem 57.2.7. Compare $3w$ and $2w$.)

59.4 t-Structures and Their Hearts

The full subcategories $D^{\leq 0}$ and $D^{\geq 0}$ of $D(\mathcal{A})$ in section 59.3, cut out by the vanishing of cohomology above and below degree 0, have three properties (proposition 59.3.4). No nonzero morphism runs from an object of $D^{\leq 0}$ to an object of $D^{\geq 1}$, the subcategories nest under shifting, and every complex sits in a distinguished triangle whose outer vertices are its two canonical truncations. Once that triangle is replaced by the existence of some distinguished triangle with first vertex in $D^{\leq 0}$ and third vertex in $D^{\geq 1}$, the three properties involve only objects, morphisms and distinguished triangles, so they make sense in any triangulated category, and this section takes them as axioms. The objects lying in both halves form the *heart*. The main results are that the heart is an abelian category (theorem 59.4.13), and that a functor H^0_t built from two truncations carries every distinguished triangle to an exact sequence in the heart (corollary 59.4.15). For the standard t-structure on $D(\mathcal{A})$ the heart is equivalent to $\mathcal{A}$ and H^0_t corresponds to ordinary cohomology. One triangulated category can carry t-structures with inequivalent hearts, and example 59.4.3 puts one with zero heart on every triangulated category.

Definition 59.4.1: t-Structure

Let $\mathcal{K}$ be a triangulated category. A *t-structure* on $\mathcal{K}$ is a pair $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ of full subcategories, each closed under isomorphism, such that, writing for $n \in \mathbb{Z}$

$$\mathcal{K}^{\leq n} := \{X \in \mathcal{K} \,|\, X[n] \in \mathcal{K}^{\leq 0}\}, \qquad \mathcal{K}^{\geq n} := \{X \in \mathcal{K} \,|\, X[n] \in \mathcal{K}^{\geq 0}\}$$

the following hold.

(T1) $\mathrm{Hom}_{\mathcal{K}}(X, Y) = 0$ for all $X \in \mathcal{K}^{\leq 0}$ and $Y \in \mathcal{K}^{\geq 1}$.

(T2) $\mathcal{K}^{\leq 0} \subseteq \mathcal{K}^{\leq 1}$ and $\mathcal{K}^{\geq 1} \subseteq \mathcal{K}^{\geq 0}$.

(T3) Every $X \in \mathcal{K}$ sits in a distinguished triangle $A \to X \to B \to A[1]$ with $A \in \mathcal{K}^{\leq 0}$ and $B \in \mathcal{K}^{\geq 1}$.

The *heart* of the t-structure is the full subcategory $\mathcal{K}^\heartsuit := \mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq 0}$.

Since [1] is an automorphism, $X \in \mathcal{K}^{\leq n}$ if and only if $X[1] \in \mathcal{K}^{\leq n-1}$, both conditions saying that

$X[n] \in \mathcal{K}^{\le 0}$, and likewise for $\mathcal{K}^{\ge n}$. This moves (T1) and (T2) to every degree: for all integers $m < n$,

$$\mathcal{K}^{\le m} \subseteq \mathcal{K}^{\le n}, \qquad \mathcal{K}^{\ge n} \subseteq \mathcal{K}^{\ge m}, \qquad \mathrm{Hom}_{\mathcal{K}}(X, Y) = 0 \ \text{ for } X \in \mathcal{K}^{\le m} \text{ and } Y \in \mathcal{K}^{\ge n} \tag{59.2}$$

For the first, $X \in \mathcal{K}^{\le m}$ gives $X[m] \in \mathcal{K}^{\le 0} \subseteq \mathcal{K}^{\le 1}$ by (T2), so $X[m+1] \in \mathcal{K}^{\le 0}$ and $X \in \mathcal{K}^{\le m+1}$, and induction reaches n. For the second, $X \in \mathcal{K}^{\ge n}$ gives $X[n-1] \in \mathcal{K}^{\ge 1} \subseteq \mathcal{K}^{\ge 0}$, so $X \in \mathcal{K}^{\ge n-1}$, and induction reaches m. For the third, $X \in \mathcal{K}^{\le n-1}$ by the first, so $X[n-1] \in \mathcal{K}^{\le 0}$ and $Y[n-1] \in \mathcal{K}^{\ge 1}$, and $\mathrm{Hom}_{\mathcal{K}}(X, Y) \cong \mathrm{Hom}_{\mathcal{K}}(X[n-1], Y[n-1])$ vanishes by (T1). In particular $X[1] \in \mathcal{K}^{\le -1} \subseteq \mathcal{K}^{\le 0}$ for $X \in \mathcal{K}^{\le 0}$, so $\mathcal{K}^{\le 0}$ is stable under $[1]$, and dually $\mathcal{K}^{\ge 0}$ is stable under $[-1]$.

The axioms say that every object is assembled, in a single distinguished triangle, from a piece in $\mathcal{K}^{\le 0}$ and a piece in $\mathcal{K}^{\ge 1}$, and that every morphism from an object of the first kind to an object of the second is zero.[1]

Example 59.4.2: The Standard t-Structure on $D(\mathcal{A})$

Let $\mathcal{A}$ be an abelian category, and take the full subcategories $D^{\le 0}$ and $D^{\ge 0}$ of $D(\mathcal{A})$ defined in definition 59.3.1. Each is closed under isomorphism, because H^i is a functor on $D(\mathcal{A})$ (proposition 57.2.8). By proposition 59.3.4(1), $X[n] \in D^{\le 0}$ exactly when $X \in D^{\le n}$, and likewise for $D^{\ge n}$, so the subcategories that definition 59.4.1 attaches to degree n are the $D^{\le n}$ and $D^{\ge n}$ of definition 59.3.1. Axiom (T2) is the case $n = 0$ of proposition 59.3.4(1), and (T1) is proposition 59.3.4(2) with $n = 0$. For (T3), proposition 59.3.4(3) with $n = 0$ gives the distinguished triangle $\tau^{\le 0}X \to X \to \tau^{\ge 1}X \to (\tau^{\le 0}X)[1]$ on the canonical truncations of definition 56.1.12, and $\tau^{\le 0}X \in D^{\le 0}$ and $\tau^{\ge 1}X \in D^{\ge 1}$ by lemma 59.3.3(3). So $(D^{\le 0}, D^{\ge 0})$ is a t-structure on $D(\mathcal{A})$, the *standard* one. Its heart is the heart of definition 59.3.1, the complexes with cohomology concentrated in degree 0, and theorem 59.3.7 shows that H^0 restricts to an equivalence from the heart to $\mathcal{A}$.

Example 59.4.3: A Degenerate t-Structure

Let $\mathcal{K}$ be any triangulated category, let $\mathcal{K}^{\le 0} = \mathcal{K}$, and let $\mathcal{K}^{\ge 0}$ be the full subcategory of zero objects. Both are closed under isomorphism, and since $[n]$ carries zero objects to zero objects, $\mathcal{K}^{\le n} = \mathcal{K}$ and $\mathcal{K}^{\ge n}$ is the subcategory of zero objects for every n. (T1) holds because every morphism into a zero object is zero, and (T2) holds with equalities. For (T3), the triangle $(\mathrm{id}_X, 0, 0)$ on $(X, X, 0)$ is distinguished by (TR1) and has $0 \in \mathcal{K}^{\ge 1}$. The heart is the subcategory of zero objects. On $\mathcal{K} = D(\mathcal{A})$ with $\mathcal{A}$ nonzero, this and the standard t-structure of example 59.4.2 are two t-structures on one triangulated category, one with heart equivalent to $\mathcal{A}$ and one with zero heart.

Exactness of Hom sequences converts the vanishing in (59.2) into statements about objects and morphisms. Let (u, v, w) be a distinguished triangle on (A, B, C). By (TR2) the rotations $(v, w, -u[1])$ on $(B, C, A[1])$, $(-w[-1], u, v)$ on $(C[-1], A, B)$ and $(-v[-1], -w[-1], u)$ on $(B[-1], C[-1], A)$ are distinguished, the last being the second rotation backwards. Applying proposition 57.1.8 to (u, v, w) and these three triangles gives, for every $T \in \mathcal{K}$, sequences

$$\begin{gathered}\mathrm{Hom}(T, B[-1]) \to \mathrm{Hom}(T, C[-1]) \to \mathrm{Hom}(T, A) \xrightarrow{u_*} \mathrm{Hom}(T, B) \xrightarrow{v_*} \mathrm{Hom}(T, C) \xrightarrow{w_*} \mathrm{Hom}(T, A[1]) \\ \mathrm{Hom}(A[1], T) \xrightarrow{w^*} \mathrm{Hom}(C, T) \xrightarrow{v^*} \mathrm{Hom}(B, T) \xrightarrow{u^*} \mathrm{Hom}(A, T) \to \mathrm{Hom}(C[-1], T)\end{gathered} \tag{59.3}$$

[1] The notion is due to Beilinson, Bernstein and Deligne [8, Def. 1.3.1], whose categories of perverse sheaves are hearts of t-structures. Gelfand and Manin [53, Def. IV.4.2] call the heart the *core*.

exact at every interior term, where the unlabelled maps are composition with $-v[-1]$, $-w[-1]$ and $-w[-1]$, in that order. A sign changes no kernel and no image, so it is dropped below whenever only exactness is used.

The axioms are stated in degree 0, and moving (T3) to another degree needs the translation to carry distinguished triangles to distinguished triangles. Rotating three times does this, up to a sign on the third edge.

Lemma 59.4.4: Translates of Distinguished Triangles

Let (u, v, w) be a distinguished triangle on (A, B, C) and let $n \in \mathbb{Z}$. There is a morphism $w_n \colon C[n] \to A[n+1]$ such that $(u[n], v[n], w_n)$ is a distinguished triangle on $(A[n], B[n], C[n])$. One may take $w_1 = -w[1]$ and $w_{-1} = -w[-1]$.

***Proof*:**
Three rotations by the first form of (TR2) give the distinguished triangles

$$(v, w, -u[1]), \qquad (w, -u[1], -v[1]), \qquad (-u[1], -v[1], -w[1])$$

on $(B, C, A[1])$, $(C, A[1], B[1])$ and $(A[1], B[1], C[1])$ respectively. From the last of these to $(u[1], v[1], -w[1])$ the triple $(\mathrm{id}_{A[1]}, -\mathrm{id}_{B[1]}, \mathrm{id}_{C[1]})$ is an isomorphism of triangles, because its three squares read

$$(-\mathrm{id})(-u[1]) = u[1]\,\mathrm{id}, \qquad \mathrm{id}\,(-v[1]) = v[1]\,(-\mathrm{id}), \qquad \mathrm{id}\,(-w[1]) = (-w[1])\,\mathrm{id}$$

by bilinearity of composition. So $(u[1], v[1], -w[1])$ is distinguished by (TR1). Three rotations by the second form of (TR2) give $(-w[-1], u, v)$ on $(C[-1], A, B)$, then $(-v[-1], -w[-1], u)$ on $(B[-1], C[-1], A)$, then $(-u[-1], -v[-1], -w[-1])$ on $(A[-1], B[-1], C[-1])$, and the same isomorphism $(\mathrm{id}, -\mathrm{id}, \mathrm{id})$ carries the last to $(u[-1], v[-1], -w[-1])$. For general n, induct on $|n|$: if $(u[n], v[n], w_n)$ is distinguished, the cases $n = \pm 1$, applied to it, give the distinguished triangles $(u[n+1], v[n+1], -w_n[1])$ and $(u[n-1], v[n-1], -w_n[-1])$, completing the proof.

Deciding whether an object lies in $\mathcal{K}^{\leq 0}$ will come down to deciding whether the first edge of a distinguished triangle is an isomorphism.

Lemma 59.4.5: A Triangle with Zero Third Vertex

Let (u, v, w) be a distinguished triangle on (A, B, C). Then u is an isomorphism if and only if $C \cong 0$.

***Proof*:**
Suppose $C \cong 0$. Then $C[-1] \cong 0$, since the automorphism $[-1]$ carries zero objects to zero objects. For every $T \in \mathcal{K}$ the first sequence of (59.3) contains

$$0 = \mathrm{Hom}(T, C[-1]) \to \mathrm{Hom}(T, A) \xrightarrow{u_*} \mathrm{Hom}(T, B) \to \mathrm{Hom}(T, C) = 0$$

exact at its two middle terms, so u_* is bijective. Taking $T = B$ gives $s \colon B \to A$ with $us = \mathrm{id}_B$. Taking $T = A$, both su and id_A are carried by u_* to u, since $u(su) = (us)u = u$, so $su = \mathrm{id}_A$ and u is an isomorphism with inverse s.

Conversely suppose u is an isomorphism. The triangle $(\mathrm{id}_A, 0, 0)$ on $(A, A, 0)$ is distinguished by (TR1), and $u \circ \mathrm{id}_A = u \circ \mathrm{id}_A$, so (TR3) gives $h\colon 0 \to C$ with (id_A, u, h) a morphism of triangles from $(\mathrm{id}_A, 0, 0)$ to (u, v, w). Its first two components are isomorphisms, so corollary 57.1.9 makes h an isomorphism and $C \cong 0$, completing the proof.

(TR3) extends a commutative square to a morphism of triangles but does not make the extension unique, so the isomorphism of cones in proposition 57.1.10 need not be unique and the axioms give no functorial cone (box 57.1.4). An extension of a morphism of middle vertices exists and is unique when two Hom groups vanish, and in a t-structure (59.2) makes them vanish.

Lemma 59.4.6: Unique Extension to a Morphism of Triangles

Let (u, v, w) on (A, B, C) and (u', v', w') on (A', B', C') be distinguished triangles and let $g\colon B \to B'$.

1. If $\mathrm{Hom}(A, C') = 0$, there are $f\colon A \to A'$ and $h\colon C \to C'$ such that (f, g, h) is a morphism of triangles.
2. If $\mathrm{Hom}(A[1], C') = 0$, there is at most one f with $u'f = gu$ and at most one h with $hv = v'g$.

***Proof*:**

1. The first sequence of (59.3) for (u', v', w') and $T = A$ is exact at the middle term of
$$\mathrm{Hom}(A, A') \xrightarrow{u'_*} \mathrm{Hom}(A, B') \xrightarrow{v'_*} \mathrm{Hom}(A, C') = 0$$
so $gu = u'f$ for some $f\colon A \to A'$. (TR3), applied to f, g and the commutative square $gu = u'f$, gives h with (f, g, h) a morphism of triangles.
2. Applying $[1]$ is a bijection $\mathrm{Hom}(A, C'[-1]) \to \mathrm{Hom}(A[1], C')$, so $\mathrm{Hom}(A, C'[-1]) = 0$. In the first sequence of (59.3) for (u', v', w') and $T = A$, the kernel of u'_* on $\mathrm{Hom}(A, A')$ is the image of $\mathrm{Hom}(A, C'[-1]) = 0$. So $u'f = u'f_1$ forces $f = f_1$. In the second sequence for (u, v, w) and $T = C'$, the kernel of v^* on $\mathrm{Hom}(C, C')$ is the image of $\mathrm{Hom}(A[1], C') = 0$. So $hv = h_1 v$ forces $h = h_1$, completing the proof.

Nothing in definition 59.4.1 singles out degree 0, and shifting the indexing gives another t-structure.

Lemma 59.4.7: Shifted t-Structures

Let $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ be a t-structure on $\mathcal{K}$ and let $m \in \mathbb{Z}$. Then $(\mathcal{K}^{\leq m}, \mathcal{K}^{\geq m})$ is a t-structure on $\mathcal{K}$, its subcategories in degree n are $\mathcal{K}^{\leq m+n}$ and $\mathcal{K}^{\geq m+n}$, and its heart $\mathcal{K}^{\leq m} \cap \mathcal{K}^{\geq m}$ consists of the objects X with $X[m] \in \mathcal{K}^{\heartsuit}$.

***Proof*:**

Both subcategories are closed under isomorphism, as $X \cong Y$ gives $X[m] \cong Y[m]$. An object X lies in the degree-n subcategory $\{X \,|\, X[n] \in \mathcal{K}^{\leq m}\}$ exactly when $X[n+m] \in \mathcal{K}^{\leq 0}$, that is when $X \in \mathcal{K}^{\leq m+n}$, and likewise for $\mathcal{K}^{\geq m+n}$. With this, (T1) and (T2) for the new pair say that

$\mathrm{Hom}(X,Y)=0$ for $X\in\mathcal{K}^{\leq m}$ and $Y\in\mathcal{K}^{\geq m+1}$, and that $\mathcal{K}^{\leq m}\subseteq\mathcal{K}^{\leq m+1}$ and $\mathcal{K}^{\geq m+1}\subseteq\mathcal{K}^{\geq m}$. All three are instances of (59.2). For (T3), let $X\in\mathcal{K}$ and take, by (T3) for the original pair, a distinguished triangle (u,v,w) on $(A,X[m],B)$ with $A\in\mathcal{K}^{\leq 0}$ and $B\in\mathcal{K}^{\geq 1}$. Lemma 59.4.4 with $n=-m$ gives a distinguished triangle $(u[-m],v[-m],w_{-m})$ on $(A[-m],X,B[-m])$. Here $A[-m]\in\mathcal{K}^{\leq m}$ since $A[-m][m]=A$, and $B[-m]\in\mathcal{K}^{\geq m+1}$ since $B[-m][m+1]=B[1]\in\mathcal{K}^{\geq 0}$. The description of the heart is the definition of $\mathcal{K}^{\leq m}$ and $\mathcal{K}^{\geq m}$, completing the proof.

Example 59.4.8: Shifts of the Standard *t*-Structure

For the standard t-structure of example 59.4.2 and $m\in\mathbb{Z}$, the heart of $(D^{\leq m},D^{\geq m})$ consists of the complexes X with $H^i(X)=0$ for $i\neq m$. The functor $X\mapsto H^0(X[m])=H^m(X)$ is an equivalence from it to $\mathcal{A}$, being the composite of the equivalence $[m]$ onto $D^{\leq 0}\cap D^{\geq 0}$ with the equivalence of theorem 59.3.7. So the shifted hearts are equivalent to one another. If $\mathcal{A}$ has a nonzero object M, they are also different subcategories of $D(\mathcal{A})$, since M, placed in degree 0, lies in the heart of $(D^{\leq m},D^{\geq m})$ only for $m=0$, while $M[-m]$ lies in it for every m.

Axiom (T3) asserts only that a triangle exists. Making it functorial in X needs a choice that is unique up to unique isomorphism, and (T1), through lemma 59.4.6, gives exactly that. The resulting functors and adjunctions extend lemma 59.3.3 and corollary 59.3.6 to an arbitrary t-structure.

Proposition 59.4.9: Truncation Functors of a *t*-Structure

Let $(\mathcal{K}^{\leq 0},\mathcal{K}^{\geq 0})$ be a t-structure on $\mathcal{K}$ and let $n\in\mathbb{Z}$.

1. There are additive functors $\tau^{\leq n}\colon\mathcal{K}\to\mathcal{K}^{\leq n}$ and $\tau^{\geq n+1}\colon\mathcal{K}\to\mathcal{K}^{\geq n+1}$ and natural transformations $\alpha^n\colon\tau^{\leq n}\to\mathrm{id}$, $\beta^n\colon\mathrm{id}\to\tau^{\geq n+1}$ and $\partial^n\colon\tau^{\geq n+1}\to\tau^{\leq n}[1]$ such that for every $X\in\mathcal{K}$ the triangle
$$\tau^{\leq n}X\xrightarrow{\alpha^n_X}X\xrightarrow{\beta^n_X}\tau^{\geq n+1}X\xrightarrow{\partial^n_X}(\tau^{\leq n}X)[1]$$
is distinguished.
2. For all $A\in\mathcal{K}^{\leq n}$, $B\in\mathcal{K}^{\geq n+1}$ and $X\in\mathcal{K}$, composition with α^n_X and with β^n_X gives bijections
$$\mathrm{Hom}(A,\tau^{\leq n}X)\xrightarrow{\sim}\mathrm{Hom}(A,X),\qquad\mathrm{Hom}(\tau^{\geq n+1}X,B)\xrightarrow{\sim}\mathrm{Hom}(X,B)$$
natural in all three variables. So $\tau^{\leq n}$ is right adjoint to the inclusion of $\mathcal{K}^{\leq n}$ in $\mathcal{K}$, and $\tau^{\geq n+1}$ is left adjoint to the inclusion of $\mathcal{K}^{\geq n+1}$.
3. If (u,v,w) is a distinguished triangle on (A,X,B) with $A\in\mathcal{K}^{\leq n}$ and $B\in\mathcal{K}^{\geq n+1}$, there is exactly one isomorphism of triangles of the form (f,id_X,h) from it to the triangle of (1). In particular ∂^n_X is the only morphism completing (α^n_X,β^n_X) to a distinguished triangle.

***Proof*:**

By lemma 59.4.7, $(\mathcal{K}^{\leq n},\mathcal{K}^{\geq n})$ is a t-structure whose subcategories in degrees 0 and 1 are $\mathcal{K}^{\leq n}$ and $\mathcal{K}^{\geq n+1}$, so the statement for n is the statement for $n=0$ applied to that t-structure. Take $n=0$, and write α, β, ∂ for α^0, β^0, ∂^0.

Step 1: The bijections for a chosen triangle. For each $X \in \mathcal{K}$ choose by (T3) a distinguished triangle $(\alpha_X, \beta_X, \partial_X)$ on $(\tau^{\leq 0}X, X, \tau^{\geq 1}X)$ with $\tau^{\leq 0}X \in \mathcal{K}^{\leq 0}$ and $\tau^{\geq 1}X \in \mathcal{K}^{\geq 1}$. For the standard t-structure on $D(\mathcal{A})$, where after the reduction $\mathcal{K}^{\leq 0}$ and $\mathcal{K}^{\geq 1}$ are the subcategories $D^{\leq n}$ and $D^{\geq n+1}$, we choose the triangle of proposition 59.3.4(3) for that n, whose outer vertices lie in them by lemma 59.3.3(3). Let $A \in \mathcal{K}^{\leq 0}$. The first sequence of (59.3) with $T = A$ contains

$$\operatorname{Hom}(A, (\tau^{\geq 1}X)[-1]) \to \operatorname{Hom}(A, \tau^{\leq 0}X) \xrightarrow{(\alpha_X)_*} \operatorname{Hom}(A, X) \to \operatorname{Hom}(A, \tau^{\geq 1}X)$$

exact at its middle terms. The last group vanishes by (T1). So does the first, since $(\tau^{\geq 1}X)[-1] \in \mathcal{K}^{\geq 2}$ and $\operatorname{Hom}(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 2}) = 0$ by (59.2). So $(\alpha_X)_*$ is bijective. For $B \in \mathcal{K}^{\geq 1}$ the second sequence of (59.3) contains

$$\operatorname{Hom}((\tau^{\leq 0}X)[1], B) \to \operatorname{Hom}(\tau^{\geq 1}X, B) \xrightarrow{\beta_X^*} \operatorname{Hom}(X, B) \to \operatorname{Hom}(\tau^{\leq 0}X, B)$$

exact at its middle terms. The last group vanishes by (T1), and the first because $(\tau^{\leq 0}X)[1] \in \mathcal{K}^{\leq -1}$. So β_X^* is bijective.

Step 2: Functoriality. Let $g\colon X \to Y$ be a morphism of $\mathcal{K}$. The groups $\operatorname{Hom}(\tau^{\leq 0}X, \tau^{\geq 1}Y)$ and $\operatorname{Hom}((\tau^{\leq 0}X)[1], \tau^{\geq 1}Y)$ vanish by (59.2), since their sources lie in $\mathcal{K}^{\leq 0}$ and $\mathcal{K}^{\leq -1}$ and their target lies in $\mathcal{K}^{\geq 1}$. Hence lemma 59.4.6 extends g to a morphism of triangles $(\tau^{\leq 0}g, g, \tau^{\geq 1}g)$ from the chosen triangle on X to the chosen triangle on Y, where $\tau^{\leq 0}g$ is the unique morphism with $\alpha_Y \circ \tau^{\leq 0}g = g \circ \alpha_X$ and $\tau^{\geq 1}g$ the unique morphism with $\tau^{\geq 1}g \circ \beta_X = \beta_Y \circ g$. Uniqueness gives functoriality: $\mathrm{id}_{\tau^{\leq 0}X}$ satisfies the condition characterizing $\tau^{\leq 0}(\mathrm{id}_X)$, and for $g'\colon Y \to W$ the composite $\tau^{\leq 0}g' \circ \tau^{\leq 0}g$ satisfies

$$\alpha_W \circ \tau^{\leq 0}g' \circ \tau^{\leq 0}g = g' \circ \alpha_Y \circ \tau^{\leq 0}g = g'g \circ \alpha_X$$

the condition characterizing $\tau^{\leq 0}(g'g)$. Additivity is the same argument, as $\alpha_Y \circ (\tau^{\leq 0}g + \tau^{\leq 0}g_1) = (g + g_1) \circ \alpha_X$ by bilinearity of composition. The argument for $\tau^{\geq 1}$ is identical with β in place of α. The three squares of the morphism of triangles $(\tau^{\leq 0}g, g, \tau^{\geq 1}g)$ are the naturality of α, β and ∂. This proves (1).

Step 3: Naturality of the bijections. The bijection $(\alpha_X)_*$ is natural in A, being composition on the other side, and natural in X because $\alpha_Y \circ \tau^{\leq 0}g \circ \varphi = g \circ \alpha_X \circ \varphi$ for every $\varphi\colon A \to \tau^{\leq 0}X$. The same argument applies to β_X^*. This proves (2).

Step 4: Uniqueness of the triangle. Let (u, v, w) be distinguished on (A, X, B) with $A \in \mathcal{K}^{\leq 0}$ and $B \in \mathcal{K}^{\geq 1}$. As in Step 2, (59.2) gives the vanishing that lemma 59.4.6 needs for $g = \mathrm{id}_X$ in both directions between (u, v, w) and $(\alpha_X, \beta_X, \partial_X)$. So there are morphisms of triangles (f, id_X, h) from (u, v, w) to $(\alpha_X, \beta_X, \partial_X)$ and (f', id_X, h') back, each the only one with middle component id_X. A composite of morphisms of triangles is one, by functoriality of [1], so $(f'f, \mathrm{id}_X, h'h)$ and the identity are two morphisms from (u, v, w) to itself with middle component id_X, and the same lemma, applied to (u, v, w) and itself, makes them equal. Likewise $(ff', \mathrm{id}_X, hh')$ is the identity. So (f, id_X, h) is an isomorphism of triangles, and it is the only one with middle component id_X. Finally, if $(\alpha_X, \beta_X, \partial')$ is distinguished, the isomorphism (f, id_X, h) from it to $(\alpha_X, \beta_X, \partial_X)$ satisfies $\alpha_X f = \alpha_X$ and $h\beta_X = \beta_X$, so f and h are identities by the injectivity of $(\alpha_X)_*$ and β_X^* in Step 1. The third square then reads $\partial' = \partial_X$, completing the proof.

Proposition 59.4.9 is [8, Prop. 1.3.3] and [53, Lemma IV.4.5]. Part (2) says that every morphism into X from an object of $\mathcal{K}^{\leq n}$ factors uniquely through α^n_X, and every morphism out of X into an object of $\mathcal{K}^{\geq n+1}$ factors uniquely through β^n_X. Part (3) says that the triangle of (T3) is unique up to unique isomorphism fixing X, the uniqueness coming from (T1) through lemma 59.4.6. For the standard t-structure, Step 1 of the proof chooses the triangle of proposition 59.3.4(3), so $\alpha^n_X = Q(i_n)$ and $\beta^n_X = Q(p_{n+1})$. On morphisms, the naturality of $Q(i_n)$ and $Q(p_{n+1})$ in lemma 59.3.3(2) is the condition that characterizes $\tau^{\leq n}g$ and $\tau^{\geq n+1}g$ in Step 2. So the functors of (1) are those of lemma 59.3.3, (2) becomes corollary 59.3.6, and one symbol τ denotes both kinds of truncation.

The truncation functors convert membership in the two halves into a vanishing condition.

Lemma 59.4.10: The Two Halves Determine Each Other

Let $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ be a t-structure on $\mathcal{K}$ and let $n \in \mathbb{Z}$.

1. For $X \in \mathcal{K}$ the following are equivalent: (a) $X \in \mathcal{K}^{\leq n}$, (b) $\mathrm{Hom}(X, B) = 0$ for every $B \in \mathcal{K}^{\geq n+1}$, (c) $\tau^{\geq n+1}X \cong 0$, (d) α^n_X is an isomorphism.
2. For $Y \in \mathcal{K}$ the following are equivalent: (a) $Y \in \mathcal{K}^{\geq n+1}$, (b) $\mathrm{Hom}(A, Y) = 0$ for every $A \in \mathcal{K}^{\leq n}$, (c) $\tau^{\leq n}Y \cong 0$, (d) β^n_Y is an isomorphism.
3. $\mathcal{K}^{\leq n}$ and $\mathcal{K}^{\geq n}$ contain the zero objects and are closed under finite direct sums and under extensions: if (u, v, w) is distinguished on (A, X, C) and A and C lie in one of the two, then so does X.
4. $\tau^{\geq n}$ carries $\mathcal{K}^{\leq n}$ into $\mathcal{K}^{\leq n} \cap \mathcal{K}^{\geq n}$, and $\tau^{\leq n}$ carries $\mathcal{K}^{\geq n}$ into $\mathcal{K}^{\leq n} \cap \mathcal{K}^{\geq n}$.

***Proof*:**

1. (a) implies (b) by (59.2). If (b) holds, then $\mathrm{Hom}(\tau^{\geq n+1}X, B) = 0$ for every $B \in \mathcal{K}^{\geq n+1}$ by proposition 59.4.9(2), and taking $B = \tau^{\geq n+1}X$ gives $\mathrm{id}_{\tau^{\geq n+1}X} = 0$, so $\tau^{\geq n+1}X$ is a zero object, which is (c). If (c) holds, lemma 59.4.5 applied to the truncation triangle of proposition 59.4.9(1) makes α^n_X an isomorphism, which is (d). If (d) holds, $X \cong \tau^{\leq n}X \in \mathcal{K}^{\leq n}$, and $\mathcal{K}^{\leq n}$ is closed under isomorphism, which is (a).

2. The argument is that of (1) with the arrows turned around. (a) implies (b) by (59.2). If (b) holds, then $\mathrm{Hom}(A, \tau^{\leq n}Y) = 0$ for every $A \in \mathcal{K}^{\leq n}$ by proposition 59.4.9(2), and $A = \tau^{\leq n}Y$ gives $\tau^{\leq n}Y \cong 0$. If (c) holds, the rotated truncation triangle $(\beta^n_Y, \partial^n_Y, -\alpha^n_Y[1])$ on $(Y, \tau^{\geq n+1}Y, (\tau^{\leq n}Y)[1])$ has third vertex $(\tau^{\leq n}Y)[1] \cong 0$, and lemma 59.4.5 makes β^n_Y an isomorphism. If (d) holds, $Y \cong \tau^{\geq n+1}Y \in \mathcal{K}^{\geq n+1}$.

3. A zero object Z has $\mathrm{Hom}(Z, B) = 0 = \mathrm{Hom}(A, Z)$ for all A and B, so it lies in $\mathcal{K}^{\leq n}$ by (1) and in $\mathcal{K}^{\geq n}$ by (2) with $n-1$ in place of n. For $X, X' \in \mathcal{K}^{\leq n}$ and $B \in \mathcal{K}^{\geq n+1}$, $\mathrm{Hom}(X \oplus X', B) \cong \mathrm{Hom}(X, B) \times \mathrm{Hom}(X', B) = 0$ by the universal property of the coproduct, so $X \oplus X' \in \mathcal{K}^{\leq n}$ by (1). The same argument with the product and (2) treats $\mathcal{K}^{\geq n}$. For extensions, let $A, C \in \mathcal{K}^{\leq n}$ and $B \in \mathcal{K}^{\geq n+1}$. The second sequence of (59.3) contains $\mathrm{Hom}(C, B) \to \mathrm{Hom}(X, B) \to \mathrm{Hom}(A, B)$, exact in the middle with both ends zero, so $\mathrm{Hom}(X, B) = 0$ and $X \in \mathcal{K}^{\leq n}$ by (1). If instead $A, C \in \mathcal{K}^{\geq n}$, then for every $T \in \mathcal{K}^{\leq n-1}$ the first sequence contains $\mathrm{Hom}(T, A) \to \mathrm{Hom}(T, X) \to \mathrm{Hom}(T, C)$ with both ends zero, so $\mathrm{Hom}(T, X) = 0$, and $X \in \mathcal{K}^{\geq n}$ by (2) with $n-1$ in place of n.

4. Let $X \in \mathcal{K}^{\leq n}$. Rotating the truncation triangle for $n-1$ gives the distinguished triangle $(\beta_X^{n-1}, \partial_X^{n-1}, -\alpha_X^{n-1}[1])$ on $(X, \tau^{\geq n}X, (\tau^{\leq n-1}X)[1])$. Its outer vertices lie in $\mathcal{K}^{\leq n}$, the second because $(\tau^{\leq n-1}X)[1] \in \mathcal{K}^{\leq n-2} \subseteq \mathcal{K}^{\leq n}$, so $\tau^{\geq n}X \in \mathcal{K}^{\leq n}$ by (3), and $\tau^{\geq n}X \in \mathcal{K}^{\geq n}$ by construction. Let $X \in \mathcal{K}^{\geq n}$. Rotating the truncation triangle for n backwards gives the distinguished triangle $(-\partial_X^n[-1], \alpha_X^n, \beta_X^n)$ on $((\tau^{\geq n+1}X)[-1], \tau^{\leq n}X, X)$. Its outer vertices lie in $\mathcal{K}^{\geq n}$, the first because $(\tau^{\geq n+1}X)[-1] \in \mathcal{K}^{\geq n+2} \subseteq \mathcal{K}^{\geq n}$, so $\tau^{\leq n}X \in \mathcal{K}^{\geq n}$ by (3), completing the proof.

By (1) and (2), each half of a t-structure determines the other: $\mathcal{K}^{\geq 1}$ consists of the objects that receive only the zero morphism from objects of $\mathcal{K}^{\leq 0}$, and $\mathcal{K}^{\leq 0}$ of the objects that admit only the zero morphism to objects of $\mathcal{K}^{\geq 1}$. By (4), truncating an object of $\mathcal{K}^{\leq 0}$ from below lands in the heart, which gives a functor into the heart.

Definition 59.4.11: Cohomology Functors of a t-Structure

Let $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ be a t-structure on $\mathcal{K}$. Its *cohomology functors* are

$$H_t^0 := \tau^{\geq 0}\tau^{\leq 0} \colon \mathcal{K} \to \mathcal{K}^\heartsuit, \qquad H_t^n(X) := H_t^0(X[n]) \quad (n \in \mathbb{Z})$$

which take values in $\mathcal{K}^\heartsuit$ by lemma 59.4.10(4) with $n = 0$.

Example 59.4.12: The Cohomology Functors of the Standard t-Structure

Take the standard t-structure on $D(\mathcal{A})$ and let $X \in D(\mathcal{A})$ and $n \in \mathbb{Z}$. Ordinary cohomology is cohomological on $D(\mathcal{A})$ (proposition 57.2.8), so applying it to the truncation triangle of proposition 59.4.9(1) and its rotations gives the long exact sequence

$$\cdots \to H^{i-1}(\tau^{\geq n+1}X) \to H^i(\tau^{\leq n}X) \xrightarrow{H^i(\alpha_X^n)} H^i(X) \xrightarrow{H^i(\beta_X^n)} H^i(\tau^{\geq n+1}X) \to H^{i+1}(\tau^{\leq n}X) \to \cdots$$

By example 59.4.2, $H^i(\tau^{\leq n}X) = 0$ for $i > n$ and $H^i(\tau^{\geq n+1}X) = 0$ for $i \leq n$. For $i \leq n$ the terms on either side of $H^i(\alpha_X^n)$ are $H^{i-1}(\tau^{\geq n+1}X) = 0$ and $H^i(\tau^{\geq n+1}X) = 0$, and for $i \geq n+1$ the terms on either side of $H^i(\beta_X^n)$ are $H^i(\tau^{\leq n}X) = 0$ and $H^{i+1}(\tau^{\leq n}X) = 0$. Hence

$$H^i(\tau^{\leq n}X) \cong \begin{cases} H^i(X) & i \leq n \\ 0 & i > n \end{cases} \qquad H^i(\tau^{\geq n+1}X) \cong \begin{cases} 0 & i \leq n \\ H^i(X) & i \geq n+1 \end{cases}$$

the abstract counterpart of proposition 56.1.14. The first formula with $n = 0$, followed by the second with $n = -1$ applied to $\tau^{\leq 0}X$, gives $H^i(H_t^0 X) = H^i(\tau^{\geq 0}\tau^{\leq 0}X) \cong H^0(X)$ for $i = 0$ and 0 for $i \neq 0$, the isomorphism in degree 0 being $H^0(\alpha_X^0) \circ H^0(\beta_{\tau^{\leq 0}X}^{-1})^{-1}$, which is natural in X. So the equivalence H^0 of theorem 59.3.7 carries the functor H_t^0 to ordinary H^0, and H_t^n to $X \mapsto H^0(X[n]) = H^n(X)$. For the complex $X = (\mathbb{Z} \xrightarrow{2} \mathbb{Z})$ in degrees -1 and 0 of example 59.3.2, $H^{-1}(X) = 0$ and $H^0(X) = \mathbb{Z}/2$, so $H_t^0(X)$ corresponds to $\mathbb{Z}/2$ and $H_t^{-1}(X) \cong 0$.

By example 59.3.8, the cone of a morphism f of $\mathcal{A}$ lies in $D^{\leq 0} \cap D^{\geq -1}$, and under H^0 the objects $\big(\tau^{\leq -1}MC(f)\big)[-1]$ and $\tau^{\geq 0}MC(f)$ of the heart correspond to $\ker f$ and $\operatorname{coker} f$. For an arbitrary t-structure the cone of a morphism of the heart still lies in $\mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq -1}$, and the same two truncations give a kernel and a cokernel in the heart.

Theorem 59.4.13: The Heart of a t-Structure Is Abelian

Let $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ be a t-structure on a triangulated category $\mathcal{K}$.

1. The heart $\mathcal{K}^\heartsuit$ is an abelian category, and it is closed under extensions in $\mathcal{K}$.
2. Let $f\colon X \to Y$ be a morphism of $\mathcal{K}^\heartsuit$ and (f, g, h) a distinguished triangle on (X, Y, Z). Then $Z \in \mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq -1}$, the composite $\beta_Z^{-1} \circ g\colon Y \to \tau^{\geq 0} Z$ is a cokernel of f in $\mathcal{K}^\heartsuit$, and the composite $h[-1] \circ \alpha_Z^{-1}[-1]\colon (\tau^{\leq -1} Z)[-1] \to X$ is a kernel of f in $\mathcal{K}^\heartsuit$.
3. A sequence $0 \to X \xrightarrow{f} Y \xrightarrow{g} Z \to 0$ of $\mathcal{K}^\heartsuit$ is exact if and only if there is a morphism $h\colon Z \to X[1]$ with (f, g, h) distinguished, and such an h is unique.

***Proof*:**

Step 1: $\mathcal{K}^\heartsuit$ is additive. By lemma 59.4.10(3) with $n = 0$, $\mathcal{K}^\heartsuit$ contains the zero objects and the direct sum of any two of its objects. A full subcategory of the additive category $\mathcal{K}$ with these two properties is additive (definition 55.1.1). It has the Hom groups of $\mathcal{K}$ with their bilinear composition, a zero object of $\mathcal{K}$ is a zero object of it, and the biproduct $X \oplus Y$ of $\mathcal{K}$, lying in it, has the universal properties of product and coproduct there because the subcategory is full. Closure under extensions is lemma 59.4.10(3) for $\mathcal{K}^{\leq 0}$ and $\mathcal{K}^{\geq 0}$ together.

Step 2: $Z \in \mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq -1}$. Rotating gives the distinguished triangle $(g, h, -f[1])$ on $(Y, Z, X[1])$. Here $Y \in \mathcal{K}^{\leq 0}$ and $X[1] \in \mathcal{K}^{\leq -1} \subseteq \mathcal{K}^{\leq 0}$, so $Z \in \mathcal{K}^{\leq 0}$ by lemma 59.4.10(3). Likewise $Y \in \mathcal{K}^{\geq 0} \subseteq \mathcal{K}^{\geq -1}$ and $X[1] \in \mathcal{K}^{\geq -1}$, so $Z \in \mathcal{K}^{\geq -1}$.

Step 3: The cokernel. Put $C := \tau^{\geq 0} Z$ and $c := \beta_Z^{-1} g$. Then $C \in \mathcal{K}^{\geq 0}$, and $C \in \mathcal{K}^{\leq 0}$ by lemma 59.4.10(4) because $Z \in \mathcal{K}^{\leq 0}$, so $C \in \mathcal{K}^\heartsuit$. Let $T \in \mathcal{K}^\heartsuit$. Precomposition with β_Z^{-1} is a bijection $\mathrm{Hom}(C, T) \to \mathrm{Hom}(Z, T)$ by proposition 59.4.9(2), as $T \in \mathcal{K}^{\geq 0}$. The second sequence of (59.3) for (f, g, h) gives the exact sequence

$$0 = \mathrm{Hom}(X[1], T) \to \mathrm{Hom}(Z, T) \xrightarrow{g^*} \mathrm{Hom}(Y, T) \xrightarrow{f^*} \mathrm{Hom}(X, T)$$

where $\mathrm{Hom}(X[1], T) = 0$ because $X[1] \in \mathcal{K}^{\leq -1}$ and $T \in \mathcal{K}^{\geq 0}$. Composing, $\varphi \mapsto \varphi c$ is a bijection from $\mathrm{Hom}(C, T)$ onto $\{\psi \in \mathrm{Hom}(Y, T) \big| \psi f = 0\}$. Taking $T = C$ and $\varphi = \mathrm{id}_C$ shows $cf = 0$, and the bijection for every $T \in \mathcal{K}^\heartsuit$ is the universal property of a cokernel of f in $\mathcal{K}^\heartsuit$.

Step 4: The kernel. Put $N := (\tau^{\leq -1} Z)[-1]$ and $k := h[-1] \circ \alpha_Z^{-1}[-1]$. Since $\tau^{\leq -1} Z \in \mathcal{K}^{\leq -1}$, and $\tau^{\leq -1} Z \in \mathcal{K}^{\geq -1}$ by lemma 59.4.10(4) because $Z \in \mathcal{K}^{\geq -1}$, the object N lies in $\mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq 0} = \mathcal{K}^\heartsuit$. Let $T \in \mathcal{K}^\heartsuit$. As $T[1] \in \mathcal{K}^{\leq -1}$, composition with α_Z^{-1} is a bijection $\mathrm{Hom}(T[1], \tau^{\leq -1} Z) \to \mathrm{Hom}(T[1], Z)$ by proposition 59.4.9(2), and applying the bijection $[-1]$ on Hom groups turns it into the bijection $\varphi \mapsto \alpha_Z^{-1}[-1] \circ \varphi$ from $\mathrm{Hom}(T, N)$ to $\mathrm{Hom}(T, Z[-1])$. The first sequence of (59.3) for (f, g, h) gives the exact sequence

$$0 = \mathrm{Hom}(T, Y[-1]) \to \mathrm{Hom}(T, Z[-1]) \xrightarrow{(-h[-1])_*} \mathrm{Hom}(T, X) \xrightarrow{f_*} \mathrm{Hom}(T, Y)$$

where $\mathrm{Hom}(T, Y[-1]) = 0$ because $T \in \mathcal{K}^{\leq 0}$ and $Y[-1] \in \mathcal{K}^{\geq 1}$. The map $(h[-1])_* = -(-h[-1])_*$ has the same kernel and image, so $\varphi \mapsto k\varphi$ is a bijection from $\mathrm{Hom}(T, N)$ onto

$\{\psi \in \mathrm{Hom}(T,X) \mid f\psi = 0\}$, the universal property of a kernel of f. So $\mathcal{K}^\heartsuit$ has kernels and cokernels.

Step 5: $\mathcal{K}^\heartsuit$ is abelian. Let f be a monomorphism of $\mathcal{K}^\heartsuit$. Its kernel N from Step 4 is a zero object by lemma 55.1.4, so $\tau^{\leq -1}Z \cong N[1] \cong 0$, and $Z \in \mathcal{K}^{\geq 0}$ by lemma 59.4.10(2) with $n = -1$. With Step 2, $Z \in \mathcal{K}^\heartsuit$. For $T \in \mathcal{K}^\heartsuit$ the first sequence of (59.3) gives the exact sequence

$$0 = \mathrm{Hom}(T, Z[-1]) \to \mathrm{Hom}(T,X) \xrightarrow{f_*} \mathrm{Hom}(T,Y) \xrightarrow{g_*} \mathrm{Hom}(T,Z)$$

the first group vanishing because $Z[-1] \in \mathcal{K}^{\geq 1}$. So f is a kernel of $g\colon Y \to Z$ in $\mathcal{K}^\heartsuit$. Now let f be an epimorphism. Its cokernel C from Step 3 is a zero object, so $Z \in \mathcal{K}^{\leq -1}$ by lemma 59.4.10(1) with $n = -1$, and with Step 2, $Z[-1] \in \mathcal{K}^{\leq 0} \cap \mathcal{K}^{\geq 0} = \mathcal{K}^\heartsuit$. For $T \in \mathcal{K}^\heartsuit$ the second sequence of (59.3) gives the exact sequence

$$0 = \mathrm{Hom}(Z,T) \to \mathrm{Hom}(Y,T) \xrightarrow{f^*} \mathrm{Hom}(X,T) \to \mathrm{Hom}(Z[-1],T)$$

whose last map is composition with $-h[-1]$, the first group vanishing because $Z \in \mathcal{K}^{\leq -1}$. So f is a cokernel of $-h[-1]\colon Z[-1] \to X$ in $\mathcal{K}^\heartsuit$. Every monomorphism of $\mathcal{K}^\heartsuit$ is therefore a kernel and every epimorphism a cokernel, and $\mathcal{K}^\heartsuit$ is abelian by definition 55.1.6. This proves (1) and (2).

Step 6: Exactness in $\mathcal{K}^\heartsuit$. In the abelian category $\mathcal{K}^\heartsuit$, the sequence $0 \to X \to Y \to Z \to 0$ is exact if and only if f is a kernel of g and g is a cokernel of f. If both hold, f is a monomorphism and g an epimorphism by lemma 55.1.3, which is exactness at X and at Z (example 55.1.14), and at Y the composite $\mathrm{coker} f \circ \ker g$ is $g \circ f = 0$. Conversely, suppose the sequence is exact. Then g is an epimorphism, hence a cokernel by definition 55.1.6, hence the cokernel of its kernel $\ker g\colon K \to Y$ by lemma 55.1.7. Exactness at Y gives $gf = 0$, so $f = (\ker g)a$ for some $a\colon X \to K$, and $(\mathrm{coker} f)(\ker g) = 0$, so $\ker g$ factors through the kernel of $\mathrm{coker} f$. That kernel is f, since f is a monomorphism, hence a kernel, hence the kernel of its cokernel by the same two results. Writing $\ker g = fb$, the identities $f = fba$ and $\ker g = (\ker g)ab$ give $ba = \mathrm{id}_X$ and $ab = \mathrm{id}_K$, as f and $\ker g$ are monomorphisms. So f is a kernel of g, and g, the cokernel of $\ker g$, is a cokernel of f.

Step 7: Exact sequences and triangles. Suppose (f,g,h) is distinguished with $X, Y, Z \in \mathcal{K}^\heartsuit$. The exact sequence of Step 5 for monomorphisms used only $Z \in \mathcal{K}^\heartsuit$, and it shows that f is a kernel of g. The exact sequence of Step 3 shows that g^* is a bijection from $\mathrm{Hom}(Z,T)$ onto $\{\psi | \psi f = 0\}$ for every $T \in \mathcal{K}^\heartsuit$, so g is a cokernel of f. By Step 6 the sequence is exact. Conversely, let the sequence be exact, and choose by (TR1) a distinguished triangle (f,g',h') on (X,Y,Z'). Since f is a monomorphism, Step 5 puts Z' in $\mathcal{K}^\heartsuit$, and the previous argument makes g' a cokernel of f. Cokernels are unique up to unique isomorphism, so $g = \varphi g'$ for an isomorphism $\varphi\colon Z' \to Z$, and $(\mathrm{id}_X, \mathrm{id}_Y, \varphi)$ is an isomorphism of triangles from (f,g',h') to $(f,g,h'\varphi^{-1})$, which is therefore distinguished by (TR1). For uniqueness, let (f,g,h) and (f,g,h_1) both be distinguished. (TR3) gives $\kappa\colon Z \to Z$ with $(\mathrm{id}_X, \mathrm{id}_Y, \kappa)$ a morphism from the first to the second, so $\kappa g = g$ and $h_1\kappa = h$. Then $(\kappa - \mathrm{id}_Z)g = 0$, and in the second sequence of (59.3) for (f,g,h) and $T = Z$, the kernel of g^* on $\mathrm{Hom}(Z,Z)$ is the image of $\mathrm{Hom}(X[1],Z)$, which is zero because $X[1] \in \mathcal{K}^{\leq -1}$ and $Z \in \mathcal{K}^{\geq 0}$. So $\kappa = \mathrm{id}_Z$ and $h_1 = h$, completing the proof.

Theorem 59.4.13 is [8, Thm. 1.3.6], and (1) is also [53, Thm. IV.4.4]. By (3), the short exact sequences of $\mathcal{K}^\heartsuit$ are the distinguished triangles with all three vertices in $\mathcal{K}^\heartsuit$, and the third edge of such a triangle is determined by the other two. The heart does not determine $\mathcal{K}$: in example 59.4.3 it is zero whatever $\mathcal{K}$ is.

Example 59.4.14: Kernel and Cokernel of Multiplication by 2 on $\mathbb{Z}/4$

In the standard t-structure on $D(\mathbf{Ab})$, let $f\colon \mathbb{Z}/4 \to \mathbb{Z}/4$ be multiplication by 2, both objects in degree 0. By example 59.3.8, its mapping cone triangle on $(\mathbb{Z}/4, \mathbb{Z}/4, MC(f))$ is distinguished in $D(\mathbf{Ab})$, and $MC(f)$ is the complex $\mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4$ in degrees -1 and 0, the complex Y of example 59.3.2. Both $H^{-1}(MC(f))$ and $H^0(MC(f))$ are isomorphic to $\mathbb{Z}/2$ there, so $MC(f) \in D^{\leq 0} \cap D^{\geq -1}$, as theorem 59.4.13(2) requires, and $MC(f)$ is not in the heart. For the standard t-structure the truncation functors $\tau^{\leq -1}$ and $\tau^{\geq 0}$ are the canonical truncations, by the choice in Step 1 of the proof of proposition 59.4.9 and the paragraph after that proof, and example 59.3.5 computes them for $MC(f)$: $\tau^{\leq -1}MC(f)$ is $\{0, 2\}$ in degree -1, and $\tau^{\geq 0}MC(f)$ is $(\mathbb{Z}/4)/\{0, 2\}$ in degree 0. So the kernel $\big(\tau^{\leq -1}MC(f)\big)[-1]$ and the cokernel $\tau^{\geq 0}MC(f)$ that theorem 59.4.13(2) gives are isomorphic to $\{0, 2\}$ and $(\mathbb{Z}/4)/\{0, 2\}$ in degree 0. The equivalence H^0 of theorem 59.3.7 carries them to the kernel and cokernel of multiplication by 2 computed in $\mathbf{Ab}$. Neither is zero, so f is neither a monomorphism nor an epimorphism of the heart.

For the standard t-structure, H^n_t is ordinary cohomology (example 59.4.12), which carries distinguished triangles to long exact sequences. For every t-structure, H^0_t is a cohomological functor $\mathcal{K} \to \mathcal{K}^\heartsuit$. A triangle whose first vertex lies in $\mathcal{K}^{\leq 0}$ goes to a right exact sequence in the heart, a triangle whose third vertex lies in $\mathcal{K}^{\geq 0}$ to a left exact one, and the octahedral axiom splits an arbitrary triangle into one of each.

Corollary 59.4.15: H^0_t Is a Cohomological Functor

Let $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ be a t-structure on $\mathcal{K}$. Then $H^0_t\colon \mathcal{K} \to \mathcal{K}^\heartsuit$ is a cohomological functor in the sense of definition 57.1.6. Consequently every distinguished triangle (u, v, w) on (X, Y, Z) gives a long exact sequence in $\mathcal{K}^\heartsuit$

$$\cdots \to H^n_t(X) \to H^n_t(Y) \to H^n_t(Z) \to H^{n+1}_t(X) \to H^{n+1}_t(Y) \to \cdots$$

***Proof*:**

Write H^0 for H^0_t, which is additive because $\tau^{\leq 0}$ and $\tau^{\geq 0}$ are (proposition 59.4.9). In the abelian category $\mathcal{K}^\heartsuit$ (theorem 59.4.13), a pair $P \xrightarrow{a} Q \xrightarrow{b} R$ with $ba = 0$ is exact at Q as soon as a is a kernel of b or b is a cokernel of a, since then $\operatorname{coker} a \circ \ker b$ is $\operatorname{coker} a \circ a = 0$, respectively $b \circ \ker b = 0$ (definition 55.1.13). If a and b are replaced by $\mu a \nu$ and $b\mu^{-1}$ for isomorphisms μ and ν, a kernel stays a kernel, and if they are replaced by $\mu a \nu$ and $\lambda b \mu^{-1}$, a cokernel stays a cokernel. The proof establishes one of the two conditions, case by case, using four facts.

(P) Maps out of $H^0(U)$ for $U \in \mathcal{K}^{\leq 0}$. By lemma 59.4.10(1), α^0_U is an isomorphism. Put $\theta_U := \beta^{-1}_{\tau^{\leq 0}U} \circ (\alpha^0_U)^{-1}\colon U \to H^0(U)$, which is natural in $U \in \mathcal{K}^{\leq 0}$ by the naturality of α^0 and β^{-1}. For $T \in \mathcal{K}^\heartsuit$, precomposition with θ_U is a bijection $\operatorname{Hom}(H^0(U), T) \to \operatorname{Hom}(U, T)$, by proposition 59.4.9(2) for β^{-1}, as $T \in \mathcal{K}^{\geq 0}$.

(P) Maps into $H^0(V)$ for $V \in \mathcal{K}^{\geq 0}$.* By lemma 59.4.10(4), $\tau^{\leq 0}V \in \mathcal{K}^{\geq 0}$, so $\beta^{-1}_{\tau^{\leq 0}V}$ is an isomorphism by lemma 59.4.10(2) with $n = -1$. Put $\kappa_V := \alpha^0_V \circ (\beta^{-1}_{\tau^{\leq 0}V})^{-1} \colon H^0(V) \to V$, natural in $V \in \mathcal{K}^{\geq 0}$. For $T \in \mathcal{K}^{\heartsuit}$, composition with κ_V is a bijection $\mathrm{Hom}(T, H^0(V)) \to \mathrm{Hom}(T, V)$, by proposition 59.4.9(2) for α^0, as $T \in \mathcal{K}^{\leq 0}$.

(E) $H^0(\alpha^0_X)$ is an isomorphism for every X. Naturality of α^0 at the morphism α^0_X gives $\alpha^0_X \circ \tau^{\leq 0}(\alpha^0_X) = \alpha^0_X \circ \alpha^0_{\tau^{\leq 0}X}$, so $\tau^{\leq 0}(\alpha^0_X) = \alpha^0_{\tau^{\leq 0}X}$ by the injectivity in proposition 59.4.9(2), and this is an isomorphism by lemma 59.4.10(1), as $\tau^{\leq 0}X \in \mathcal{K}^{\leq 0}$. Applying $\tau^{\geq 0}$ gives the claim.

Case 1: $X, Y, Z \in \mathcal{K}^{\leq 0}$. Then $H^0(v)$ is a cokernel of $H^0(u)$. For $T \in \mathcal{K}^{\heartsuit}$ the second sequence of (59.3) gives the exact sequence $0 = \mathrm{Hom}(X[1], T) \to \mathrm{Hom}(Z, T) \xrightarrow{v^*} \mathrm{Hom}(Y, T) \xrightarrow{u^*} \mathrm{Hom}(X, T)$, the first group vanishing because $X[1] \in \mathcal{K}^{\leq -1}$ and $T \in \mathcal{K}^{\geq 0}$. By (P) and the naturality of θ it is isomorphic to the sequence

$$0 \to \mathrm{Hom}(H^0(Z), T) \xrightarrow{H^0(v)^*} \mathrm{Hom}(H^0(Y), T) \xrightarrow{H^0(u)^*} \mathrm{Hom}(H^0(X), T)$$

which is therefore exact for every $T \in \mathcal{K}^{\heartsuit}$. That is the statement that $H^0(v)$ is a cokernel of $H^0(u)$.

Case 1: $X, Y, Z \in \mathcal{K}^{\geq 0}$. Then $H^0(u)$ is a kernel of $H^0(v)$.* For $T \in \mathcal{K}^{\heartsuit}$ the first sequence of (59.3) gives the exact sequence $0 = \mathrm{Hom}(T, Z[-1]) \to \mathrm{Hom}(T, X) \xrightarrow{u_*} \mathrm{Hom}(T, Y) \xrightarrow{v_*} \mathrm{Hom}(T, Z)$, the first group vanishing because $T \in \mathcal{K}^{\leq 0}$ and $Z[-1] \in \mathcal{K}^{\geq 1}$. By (P*) and the naturality of κ it is isomorphic to $0 \to \mathrm{Hom}(T, H^0(X)) \to \mathrm{Hom}(T, H^0(Y)) \to \mathrm{Hom}(T, H^0(Z))$ with maps $H^0(u)_*$ and $H^0(v)_*$, which says that $H^0(u)$ is a kernel of $H^0(v)$.

Case 2: $X \in \mathcal{K}^{\leq 0}$. Then $H^0(v)$ is a cokernel of $H^0(u)$. By proposition 59.4.9(2), $u = \alpha^0_Y u'$ for a unique $u' \colon X \to \tau^{\leq 0}Y$. Choose a distinguished triangle (u', r, e) on $(X, \tau^{\leq 0}Y, W)$ and apply (TR4) to the composable pair $X \xrightarrow{u'} \tau^{\leq 0}Y \xrightarrow{\alpha^0_Y} Y$, with (u', r, e) as the triangle on the first map, the truncation triangle $(\alpha^0_Y, \beta^0_Y, \partial^0_Y)$ on the second, and (u, v, w) on the composite. It gives a distinguished triangle $(f, g, r[1]\,\partial^0_Y)$ on $(W, Z, \tau^{\geq 1}Y)$ satisfying, among the four identities of (TR4), $fr = v\alpha^0_Y$. Rotating (u', r, e) gives the distinguished triangle $(r, e, -u'[1])$ on $(\tau^{\leq 0}Y, W, X[1])$, whose outer vertices lie in $\mathcal{K}^{\leq 0}$, so $W \in \mathcal{K}^{\leq 0}$ by lemma 59.4.10(3). The triangle $(f, g, r[1]\,\partial^0_Y)$ on $(W, Z, \tau^{\geq 1}Y)$ therefore has $W \in \mathcal{K}^{\leq 0}$ and $\tau^{\geq 1}Y \in \mathcal{K}^{\geq 1}$, and proposition 59.4.9(3) gives an isomorphism $\varphi \colon W \to \tau^{\leq 0}Z$ with $\alpha^0_Z \varphi = f$. Then $\alpha^0_Z \varphi r = fr = v\alpha^0_Y$. Case 1 applies to (u', r, e), whose three vertices lie in $\mathcal{K}^{\leq 0}$: $H^0(r)$ is a cokernel of $H^0(u')$. Finally $H^0(u) = H^0(\alpha^0_Y)H^0(u')$, and applying H^0 to $\alpha^0_Z \varphi r = v\alpha^0_Y$ gives $H^0(v) = H^0(\alpha^0_Z)H^0(\varphi)H^0(r)H^0(\alpha^0_Y)^{-1}$, where $H^0(\alpha^0_Y)$ and $H^0(\alpha^0_Z)$ are isomorphisms by (E), and $H^0(\varphi)$ is one because φ is. So $H^0(v)$ is a cokernel of $H^0(u)$.

(E) $H^0(\beta_P^{-1})$ is an isomorphism for every P.* Case 2 applies to the truncation triangle $(\alpha_P^{-1}, \beta_P^{-1}, \partial_P^{-1})$, whose first vertex lies in $\mathcal{K}^{\leq -1} \subseteq \mathcal{K}^{\leq 0}$, so $H^0(\beta_P^{-1})$ is a cokernel of $H^0(\alpha_P^{-1})$. The source of the latter is zero: $\tau^{\leq 0}\tau^{\leq -1}P \cong \tau^{\leq -1}P$ by lemma 59.4.10(1), and $\tau^{\geq 0}$ of an object of $\mathcal{K}^{\leq -1}$ is zero by lemma 59.4.10(1) with $n = -1$. The identity of $H^0(P)$ is a cokernel of the morphism from a zero object, and cokernels are unique up to isomorphism, so $H^0(\beta_P^{-1})$ is an isomorphism.

Case 2: $Z \in \mathcal{K}^{\geq 0}$. Then $H^0(u)$ is a kernel of $H^0(v)$.* Choose a distinguished triangle $(u\alpha_X^{-1}, y, e)$ on $(\tau^{\leq -1}X, Y, V)$ and apply (TR4) to $\tau^{\leq -1}X \xrightarrow{\alpha_X^{-1}} X \xrightarrow{u} Y$, with the truncation triangle $(\alpha_X^{-1}, \beta_X^{-1}, \partial_X^{-1})$ on the first map, (u, v, w) on the second and $(u\alpha_X^{-1}, y, e)$ on the composite. It gives a distinguished triangle $(f, g, \beta_X^{-1}[1]\, w)$ on $(\tau^{\geq 0}X, V, Z)$ with $v = gy$ and $yu = f\beta_X^{-1}$. Its outer vertices lie in $\mathcal{K}^{\geq 0}$, so $V \in \mathcal{K}^{\geq 0}$ by lemma 59.4.10(3). Then $(u\alpha_X^{-1}, y, e)$ is distinguished on $(\tau^{\leq -1}X, Y, V)$ with $\tau^{\leq -1}X \in \mathcal{K}^{\leq -1}$ and $V \in \mathcal{K}^{\geq 0}$, and proposition 59.4.9(3) with $n = -1$ gives an isomorphism $\psi\colon V \to \tau^{\geq 0}Y$ with $\psi y = \beta_Y^{-1}$. Hence $\beta_Y^{-1}u = \psi yu = \psi f\beta_X^{-1}$. Case 1* applies to $(f, g, \beta_X^{-1}[1]\, w)$, whose three vertices lie in $\mathcal{K}^{\geq 0}$: $H^0(f)$ is a kernel of $H^0(g)$. Applying H^0 to $\beta_Y^{-1}u = \psi f\beta_X^{-1}$ and to $v = g\psi^{-1}\beta_Y^{-1}$ gives

$$H^0(u) = \mu\, H^0(f)\, H^0(\beta_X^{-1}), \qquad H^0(v) = H^0(g)\, \mu^{-1}, \qquad \mu := H^0(\beta_Y^{-1})^{-1} H^0(\psi)$$

with μ and $H^0(\beta_X^{-1})$ isomorphisms by (E*). So $H^0(u)$ is a kernel of $H^0(v)$.

The general case. Let (u, v, w) be any distinguished triangle on (X, Y, Z). Choose a distinguished triangle $(u\alpha_X^0, y, e)$ on $(\tau^{\leq 0}X, Y, U)$ and apply (TR4) to $\tau^{\leq 0}X \xrightarrow{\alpha_X^0} X \xrightarrow{u} Y$, with the truncation triangle $(\alpha_X^0, \beta_X^0, \partial_X^0)$ on the first map, (u, v, w) on the second and $(u\alpha_X^0, y, e)$ on the composite. It gives a distinguished triangle $(f, g, \beta_X^0[1]\, w)$ on $(\tau^{\geq 1}X, U, Z)$ with $v = gy$. Rotating it gives the distinguished triangle $(g, \beta_X^0[1]\, w, -f[1])$ on $(U, Z, (\tau^{\geq 1}X)[1])$, whose third vertex lies in $\mathcal{K}^{\geq 0}$. Case 2, applied to $(u\alpha_X^0, y, e)$, whose first vertex lies in $\mathcal{K}^{\leq 0}$, shows that $H^0(y)$ is a cokernel of $H^0(u)H^0(\alpha_X^0)$, hence of $H^0(u)$, as $H^0(\alpha_X^0)$ is an isomorphism by (E). Case 2*, applied to the rotated triangle, shows that $H^0(g)$ is a kernel, hence a monomorphism by lemma 55.1.3. So $\ker H^0(v) = \ker(H^0(g)H^0(y)) = \ker H^0(y)$, and $\operatorname{coker} H^0(u) \circ \ker H^0(v) = H^0(y) \circ \ker H^0(y) = 0$. Together with $H^0(v)H^0(u) = H^0(vu) = 0$ (lemma 57.1.7), this is exactness at $H^0(Y)$, so H^0 is cohomological. The long exact sequence follows by applying this to the rotations of (u, v, w) and splicing the resulting exact sequences, with $H^0(X[n]) = H_t^n(X)$, completing the proof.

The corollary is the last assertion of [8, Thm. 1.3.6] and is [53, Thm. IV.4.11(a)]. For the standard t-structure it returns the long exact cohomology sequence of a distinguished triangle of $D(\mathcal{A})$, by example 59.4.12.

Example 59.4.16: The Four-Term Sequence of Multiplication by 2

Apply corollary 59.4.15 to the mapping cone triangle of $f = 2\colon \mathbb{Z}/4 \to \mathbb{Z}/4$ from example 59.4.14. As $\mathbb{Z}/4$ in degree 0 has $H_t^n = 0$ for $n \neq 0$, and $MC(f)$ has $H_t^n = 0$ for $n \neq -1, 0$, the long exact sequence reduces, after applying the equivalence of theorem 59.3.7, which preserves kernels and cokernels, and example 59.4.12, to the exact sequence

$$0 \to H^{-1}(MC(f)) \to \mathbb{Z}/4 \xrightarrow{2} \mathbb{Z}/4 \to H^0(MC(f)) \to 0$$

Exactness on the left makes the first map an injection onto $\ker(2) = \{0, 2\}$, and exactness on the right makes the last map a surjection with kernel $\{0, 2\}$. So the long exact sequence of the triangle is the four-term sequence $0 \to \ker f \to \mathbb{Z}/4 \to \mathbb{Z}/4 \to \operatorname{coker} f \to 0$, and it recovers both computations of example 59.4.14 at once.

In $D(\mathcal{A})$ a complex lying in every $D^{\leq n}$, or in every $D^{\geq n}$, has zero cohomology and so is zero (proposition 57.2.12). The axioms do not give this for an arbitrary t-structure: if X is a nonzero object of $\mathcal{K}$, then X lies in every $\mathcal{K}^{\leq n}$ for the t-structure of example 59.4.3. Nondegeneracy, the first

condition in definition 59.4.17, imposes this vanishing on a t-structure. Boundedness, the second, asks that every object lie in $\mathcal{K}^{\leq b} \cap \mathcal{K}^{\geq a}$ for some integers a and b. When $\mathcal{A}$ has a nonzero object it fails for the standard t-structure on $D(\mathcal{A})$, where a single complex can have nonzero cohomology in infinitely many degrees.

Definition 59.4.17: Nondegenerate and Bounded t-Structures

A t-structure $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ on $\mathcal{K}$ is *nondegenerate* if every object lying in $\mathcal{K}^{\leq n}$ for all $n \in \mathbb{Z}$ is a zero object, and every object lying in $\mathcal{K}^{\geq n}$ for all $n \in \mathbb{Z}$ is a zero object. It is *bounded* if every $X \in \mathcal{K}$ lies in $\mathcal{K}^{\leq b} \cap \mathcal{K}^{\geq a}$ for some integers a and b.

Example 59.4.18: The Standard t-Structure Is Nondegenerate and Not Bounded

An object X of $D^{\leq n}$ for every n, or of $D^{\geq n}$ for every n, has $H^i(X) = 0$ for all i by example 59.4.2, so X is exact and $X \cong 0$ in $D(\mathcal{A})$ by proposition 57.2.12. So the standard t-structure is nondegenerate. If $\mathcal{A}$ has a nonzero object M, the complex with M in every degree and all differentials zero has $H^i = M$ for every i, so it lies in no $D^{\leq b}$, and the standard t-structure is not bounded. The objects lying in some $D^{\leq b} \cap D^{\geq a}$ are the complexes with bounded cohomology, which form the subcategory $D^b(\mathcal{A})$ of box 57.2.5, and the truncation argument there shows that each such X is isomorphic in $D(\mathcal{A})$ to the bounded complex $\tau^{\geq a}\tau^{\leq b}X$. The t-structure of example 59.4.3 on a category with a nonzero object X is degenerate, since $X \in \mathcal{K}^{\leq n}$ for every n.

Besides its standard t-structure, the constructible derived category of a stratified space carries the perverse t-structure, whose heart, the category of perverse sheaves, is abelian by theorem 59.4.13. Its construction is the subject of the *Perverse Sheaves* volume [38]. A t-structure on a stable ∞-category is a t-structure in the sense of definition 59.4.1 on its homotopy category. There the enhancement provides functorial cones [27], which the axioms of a triangulated category do not give (box 57.1.4).

Exercise 59.4.1

1. Let $\mathcal{K}$ be a triangulated category, let $\mathcal{K}^{\leq 0}$ be the full subcategory of zero objects, and let $\mathcal{K}^{\geq 0} = \mathcal{K}$. Show that $(\mathcal{K}^{\leq 0}, \mathcal{K}^{\geq 0})$ is a t-structure, that its heart consists of the zero objects, and that it is nondegenerate if and only if every object of $\mathcal{K}$ is a zero object.
2. Show that a bounded t-structure is nondegenerate.
3. Let $X, Y \in \mathcal{K}^{\heartsuit}$ and $n < 0$. Show that $\mathrm{Hom}_{\mathcal{K}}(X, Y[n]) = 0$.
4. Let $T \in \mathcal{K}^{\heartsuit}$. Show that $H^0_t(T) \cong T$ and that $H^n_t(T) \cong 0$ for every $n \neq 0$.
5. Let $X \in \mathcal{K}^{\leq 0}$ and $Y \in \mathcal{K}^{\geq 0}$. Show that $f \mapsto H^0_t(f)$ is a bijection $\mathrm{Hom}_{\mathcal{K}}(X, Y) \to \mathrm{Hom}_{\mathcal{K}^{\heartsuit}}(H^0_t X, H^0_t Y)$.
6. In the standard t-structure on $D(\mathbf{Ab})$, let $f\colon \mathbb{Z}/4 \to \mathbb{Z}/8$ be the homomorphism $x \mapsto 4x$, both objects in degree 0. Compute the cohomology of $MC(f)$, decide whether f is a monomorphism or an epimorphism of the heart, and identify, through the equivalence of theorem 59.3.7, the kernel and cokernel that theorem 59.4.13(2) produces.
7. Let $X, Z \in \mathcal{K}^{\heartsuit}$, and let $i_X\colon X \to X \oplus Z$ and $p_Z\colon X \oplus Z \to Z$ be the inclusion and projection of the biproduct. Use theorem 59.4.13(3) and lemma 57.1.7 to show that $(i_X, p_Z, 0)$ is a distinguished triangle on $(X, X \oplus Z, Z)$.

8. Suppose the t-structure is nondegenerate.
    1. Show that if $X \in \mathcal{K}^{\geq 0}$ and $H_t^0(X) \cong 0$, then $X \in \mathcal{K}^{\geq 1}$, and that if $X \in \mathcal{K}^{\leq 0}$ and $H_t^0(X) \cong 0$, then $X \in \mathcal{K}^{\leq -1}$.
    2. Deduce that $X \cong 0$ whenever $H_t^n(X) \cong 0$ for every $n \in \mathbb{Z}$. (Treat $X \in \mathcal{K}^{\geq 0}$ and $X \in \mathcal{K}^{\leq 0}$ first, then apply the long exact sequence of corollary 59.4.15 to the truncation triangle of X.)
    3. Show that a morphism f of $\mathcal{K}$ is an isomorphism if and only if $H_t^n(f)$ is an isomorphism for every n.

60

Spectral Sequences

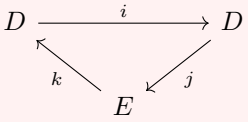
The derived functors of chapter 56 measure the failure of a single functor to be exact, and the long exact sequence of theorem 56.3.11 turns that measurement into something computable. Both tools carry the same limitation: each relates the cohomology of one object to the cohomology of two others, and no more. An object assembled from many pieces produces not one long exact sequence but a whole family of them at once, one for each stage of the assembly, and no finite amount of splicing turns that family into an answer. A module carrying a filtration $M = M_0 \supseteq M_1 \supseteq \cdots$ (section 25.2) is the basic case; a functor that factors through a third abelian category is another, and the double complexes of section 56.5 are a third.

A spectral sequence is the bookkeeping that assembles such a family. It produces a sequence of *pages* $E_1, E_2, E_3, \ldots$, each the cohomology of the one before it, beginning with a crude first approximation to the answer and correcting it repeatedly until the corrections run out. This chapter builds the machine and then gives the three standard sources of one. Section 60.1 isolates the algebraic mechanism, Massey's exact couple, from which every page and every differential is generated by a single operation. Section 60.2 constructs the spectral sequence of a filtered complex and proves the convergence and comparison theorems that make it usable. Section 60.3 treats the two spectral sequences of a double complex, completing the computations of section 56.5.1 that were deferred to this chapter. Section 60.4 constructs the spectral sequence of a composite of derived functors, the form in which the machine is most often applied. Section 60.5 closes with hypercohomology, the derived functors of a functor applied to a complex rather than an object.

60.1 Exact Couples and Derived Couples

The obstacle a spectral sequence exists to overcome is visible already in the simplest case. A short exact sequence of complexes $0 \to A_\bullet \to C_\bullet \to C_\bullet/A_\bullet \to 0$ yields a long exact sequence relating the three cohomologies, but that sequence does not determine $H_\bullet(C)$ from $H_\bullet(A)$ and $H_\bullet(C/A)$: it

determines only the two ends of a short exact sequence



$$0 \to \operatorname{coker}\partial \to H_n(C) \to \ker \partial \to 0$$

and the extension itself is extra information the sequence does not carry. With one layer the ambiguity is a single extension problem. With a filtration of many layers there is one such problem per layer, and there are also correction terms of a different kind: a cohomology class of one layer may fail to extend over the next layer but succeed over the one after, and nothing in any individual long exact sequence detects that.

The device that organizes all of these at once packages every long exact sequence of the filtration into a single self-regenerating triangle. Its two vertices carry different roles: one is the answer being approximated, the other the auxiliary object that remembers how the layers are glued.

Definition 60.1.1: Exact Couple

Let $\mathcal{A}$ be an abelian category. An *exact couple* in $\mathcal{A}$ is a pair of objects D and E together with three morphisms

such that the triangle is exact at each of its three corners:

$$\operatorname{im} i = \ker j, \qquad \operatorname{im} j = \ker k, \qquad \operatorname{im} k = \ker i$$

The composite $d := j \circ k \colon E \to E$ is the *differential* of the couple, and the couple is written (D, E, i, j, k).

The data should be read as a compression of a long exact sequence, or rather of all of them simultaneously. In the filtered case treated in section 60.2, the object D collects the cohomologies of the stages of the filtration, the object E collects the cohomologies of the successive layers, the map i is induced by the inclusion of one stage in the next, the map j is the passage to the layer, and k is the connecting homomorphism. Exactness at the three corners is precisely the exactness of every one of those long exact sequences. Of the two objects only E is meant to be looked at, since it is the approximation to the answer; D is the auxiliary object, and it is the auxiliary object that makes the approximation improvable.

Two of the three exactness conditions are spent constructing the next stage, and one is spent immediately, on the claim that d deserves its name.

Lemma 60.1.2: The Differential of an Exact Couple Squares to Zero

Let (D, E, i, j, k) be an exact couple. Then $d \circ d = 0$, so (E, d) is a differential object and its cohomology

$$H(E, d) = \frac{\ker d}{\operatorname{im} d}$$

is defined.

***Proof*:**
Expand the composite and regroup:

$$d \circ d = (j \circ k) \circ (j \circ k) = j \circ (k \circ j) \circ k$$

Exactness at the corner E gives $\operatorname{im} j = \ker k$, so every morphism factoring through j is annihilated by k, that is $k \circ j = 0$. Hence $d \circ d = j \circ 0 \circ k = 0$, as we sought to show.

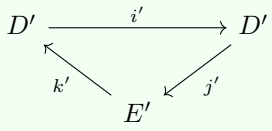
Only exactness at E was used. The remaining two conditions are exactly what is needed to promote $H(E, d)$ from a bare cohomology object to the E-term of a new exact couple, and it is that promotion which makes the construction repeat. The new auxiliary object is the image of i, and the new maps are induced by the old ones.

60.1.3 Convention: Elements in an Abelian Category The constructions below are phrased with elements, in the style of a diagram chase. This is legitimate in any abelian category: by the Freyd-Mitchell theorem (theorem 55.1.15), a small abelian category admits a fully faithful exact embedding into R-Mod for some ring R, and a diagram whose exactness is verified in R-Mod is exact in $\mathcal{A}$ because the embedding reflects exactness. Every statement in this section may therefore be proved for modules and read off for a general $\mathcal{A}$. The standard sources of exact couples, filtered complexes and double complexes of modules or of sheaves, are in any case module-like.

Definition 60.1.4: Derived Couple

Let (D, E, i, j, k) be an exact couple with differential $d = j \circ k$. Its *derived couple* (D', E', i', j', k') consists of the objects

$$D' := \operatorname{im} i, \qquad E' := H(E, d) = \frac{\ker d}{\operatorname{im} d}$$



together with the morphisms

1. $i' := i|_{D'} \colon D' \to D'$, the restriction of i to its image;
2. $j' \colon D' \to E'$ defined by $j'(i(x)) := [\, j(x) \,]$ for $x \in D$;
3. $k' \colon E' \to D'$ defined by $k'([e]) := k(e)$ for $e \in \ker d$.

The name is older than, and unrelated to, the derived categories of chapter 57; it originates in Massey's work in algebraic topology. Three of the four items above require an argument before the definition is even meaningful: that i carries D' into itself, that j' is independent of the choice of preimage, and that k' both lands in D' and is independent of the representative cycle. Those checks and the exactness of the result are one theorem.

Theorem 60.1.5: The Derived Couple is an Exact Couple

Let (D, E, i, j, k) be an exact couple. Then the morphisms i', j' and k' of definition 60.1.4 are well defined, and the triangle

is an exact couple.

***Proof*:**

Step 1: The three maps are well defined. For i', note that $i(D') = i(i(D)) \subseteq i(D) = D'$, so restricting i to D' does indeed produce an endomorphism of D'.

For j', two things must be checked. First, $j(x)$ is a cycle for every $x \in D$: applying the differential gives $d(j(x)) = j(k(j(x))) = 0$, since $k \circ j = 0$ by exactness at E. So the class $[j(x)] \in E'$ makes sense. Second, the class does not depend on the choice of x. Suppose $i(x) = i(x')$. Then $x - x' \in \ker i = \mathrm{im} k$ by exactness at the target corner, say $x - x' = k(e)$ for some $e \in E$. Applying j gives

$$j(x) - j(x') = j(k(e)) = d(e) \in \mathrm{im} d$$

so $[j(x)] = [j(x')]$ in $E' = \ker d / \mathrm{im} d$.

For k', again two checks. First, k carries cycles into D': if $d(e) = 0$ then $j(k(e)) = 0$, so $k(e) \in \ker j = \mathrm{im} i = D'$ by exactness at the source corner. Second, the value is independent of the representative. If $e - e' = d(f) = j(k(f))$ for some $f \in E$, then

$$k(e) - k(e') = k(j(k(f))) = (k \circ j)(k(f)) = 0$$

again because $k \circ j = 0$. So k' is well defined.

Step 2: Exactness at the corner receiving i', that is $\mathrm{im} i' = \ker j'$. For the inclusion $\mathrm{im} i' \subseteq \ker j'$, take $y = i(x) \in D'$ and compute

$$j'(i'(y)) = j'(i(i(x))) = [\, j(i(x)) \,] = [0] = 0$$

the last equality because $\mathrm{im} i = \ker j$. For the reverse inclusion, let $y = i(x) \in D'$ satisfy $j'(y) = 0$, that is $[j(x)] = 0$, so $j(x) = d(e) = j(k(e))$ for some $e \in E$. Then $j(x - k(e)) = 0$, so $x - k(e) \in \ker j = \mathrm{im} i$, say $x - k(e) = i(z)$. Applying i and using $i \circ k = 0$ (exactness at the corner where k arrives) gives

$$y = i(x) = i(k(e)) + i(i(z)) = i(i(z)) = i'(i(z))$$

and $i(z) \in D'$, so $y \in \mathrm{im} i'$.

Step 3: Exactness at E', that is $\mathrm{im} j' = \ker k'$. For $\mathrm{im} j' \subseteq \ker k'$, take $y = i(x) \in D'$ and compute

$$k'(j'(y)) = k'([\, j(x) \,]) = k(j(x)) = 0$$

using $k \circ j = 0$. For the reverse inclusion, let $[e] \in E'$ satisfy $k'([e]) = k(e) = 0$. Then $e \in \ker k = \mathrm{im} j$, say $e = j(x)$ for some $x \in D$. The element $i(x)$ lies in D' and $j'(i(x)) = [j(x)] = [e]$, so $[e] \in \mathrm{im} j'$.

Step 4: Exactness at the corner receiving k', that is $\mathrm{im} k' = \ker i'$. For $\mathrm{im} k' \subseteq \ker i'$, take $[e] \in E'$; then $i'(k'([e])) = i(k(e)) = 0$ since $\mathrm{im} k = \ker i$. For the reverse inclusion, let $y = i(x) \in D'$ satisfy $i'(y) = 0$, that is $i(i(x)) = 0$. Then $i(x) \in \ker i = \mathrm{im} k$, say $i(x) = k(e)$ for some $e \in E$. This e is a cycle:

$$d(e) = j(k(e)) = j(i(x)) = 0$$

because $\mathrm{im} i = \ker j$. Hence $[e] \in E'$ and $k'([e]) = k(e) = i(x) = y$, so $y \in \mathrm{im} k'$.

All six inclusions hold, so the derived triangle is exact at each corner, completing the proof.

The theorem is the basis of the entire chapter. Because the derived couple is again an exact couple, the construction applies to it in turn, and iterating produces an infinite sequence of couples whose E-terms form a sequence of objects each of which is the cohomology of its predecessor. That sequence is the object the chapter is named for.

Definition 60.1.6: Spectral Sequence

Let $\mathcal{A}$ be an abelian category. A *spectral sequence* in $\mathcal{A}$ is a family $\{(E_r, d_r)\}_{r \geq r_0}$ of objects E_r of $\mathcal{A}$, each equipped with an endomorphism $d_r \colon E_r \to E_r$ satisfying $d_r \circ d_r = 0$, together with isomorphisms

$$E_{r+1} \cong H(E_r, d_r) = \frac{\ker d_r}{\mathrm{im} d_r}$$

for every $r \geq r_0$. The object E_r is the *r-th page*, d_r is the *r-th differential*, and r_0 is the *initial page*.

The spectral sequence is *bigraded* if each E_r carries a decomposition $E_r = \bigoplus_{p,q} E_r^{p,q}$ and each d_r is homogeneous of a fixed bidegree. Two conventions are in use. In the *homological* convention the pages are written $E^r_{p,q}$ and

$$d_r \colon E^r_{p,q} \to E^r_{p-r,\, q+r-1}$$

while in the *cohomological* convention they are written $E_r^{p,q}$ and

$$d_r \colon E_r^{p,q} \to E_r^{p+r,\, q-r+1}$$

Both differentials change the total degree $p + q$ by exactly one, downward in the homological convention and upward in the cohomological one. The two are exchanged by $E_r^{p,q} = E^r_{-p,-q}$.

The bidegrees are not a separate convention imposed on the definition; they are forced by the exact couple that generates the sequence, as the next result records. Every spectral sequence appearing in this book, and every one cited from it elsewhere in the series, arises from an exact couple in the manner described.

Theorem 60.1.7: The Spectral Sequence of an Exact Couple

Let $(D, E, i, j, k) = (D^1, E^1, i^{(1)}, j^{(1)}, k^{(1)})$ be an exact couple, and for $r \geq 1$ let $(D^{r+1}, E^{r+1}, i^{(r+1)}, j^{(r+1)}, k^{(r+1)})$ be the derived couple of the r-th one. Then $\{(E^r, d_r)\}_{r\geq 1}$, with $d_r = j^{(r)} \circ k^{(r)}$, is a spectral sequence, and $D^{r+1} = i^r(D)$ for every r.
Suppose in addition that D and E are bigraded and that i, j, k are homogeneous of bidegrees

$$\deg i = (1, -1), \qquad \deg j = (0, 0), \qquad \deg k = (-1, 0)$$

with the pages of the derived couples indexed by $D^{r+1}_{p,q} = i\big(D^r_{p-1,q+1}\big)$. Then

$$\deg i^{(r)} = (1, -1), \qquad \deg j^{(r)} = \big(-(r-1),\, r-1\big), \qquad \deg k^{(r)} = (-1, 0)$$

and consequently d_r is homogeneous of bidegree $(-r,\, r-1)$, so the sequence is bigraded in the homological convention of definition 60.1.6.

***Proof*:**
Step 1: The pages form a spectral sequence. By theorem 60.1.5 each derived couple is again an exact couple, so the construction may be iterated and every d_r satisfies $d_r \circ d_r = 0$ by lemma 60.1.2. By definition 60.1.4 the E-term of the derived couple is $E^{r+1} = H(E^r, d_r)$, which is the required isomorphism. The identity $D^{r+1} = i^r(D)$ follows by induction: it holds for $r = 0$ by convention, and if $D^r = i^{r-1}(D)$ then $D^{r+1} = i^{(r)}(D^r) = i(i^{r-1}(D)) = i^r(D)$, since $i^{(r)}$ is the restriction of i.

Step 2: The bidegree of $i^{(r)}$ and $k^{(r)}$. Each $i^{(r)}$ is a restriction of i to a subobject, so it is homogeneous of the same bidegree $(1, -1)$ for every r. Similarly $E^{r+1}_{p,q}$ is a subquotient of $E^r_{p,q}$ in the same bidegree, and $k^{(r+1)}$ is induced by $k^{(r)}$ on representatives, so $\deg k^{(r)} = (-1, 0)$ for every r by induction.

Step 3: The bidegree of $j^{(r)}$ shifts by $(-1, 1)$ at each stage. Fix r and suppose $\deg j^{(r)} = (a, b)$. By definition 60.1.4 the map $j^{(r+1)}$ is defined on an element of D^{r+1} written as $i(x)$ with $x \in D^r$, by $j^{(r+1)}(i(x)) = [\, j^{(r)}(x)\,]$. With the stated indexing, an element of $D^{r+1}_{p,q}$ is of the form $i(x)$ for $x \in D^r_{p-1,q+1}$, and $j^{(r)}(x)$ then lies in $E^r_{p-1+a,\, q+1+b}$. Hence $j^{(r+1)}$ carries $D^{r+1}_{p,q}$ into $E^{r+1}_{p+a-1,\, q+b+1}$, that is $\deg j^{(r+1)} = (a-1, b+1)$. Since $\deg j^{(1)} = (0, 0)$, induction gives $\deg j^{(r)} = (-(r-1), r-1)$.

Step 4: The bidegree of d_r. Combining Steps 2 and 3,

$$\deg d_r = \deg j^{(r)} + \deg k^{(r)} = \big(-(r-1),\, r-1\big) + (-1, 0) = (-r,\, r-1)$$

so $d_r \colon E^r_{p,q} \to E^r_{p-r,\, q+r-1}$, which is the homological convention of definition 60.1.6, completing the proof.

The bidegree computation is worth pausing over, because it explains what the higher pages are for. The differential d_1 moves one step in the filtration direction, d_2 moves two steps, and d_r moves r steps. Each derivation of the couple replaces D by $i(D)$, which is to say it discards the classes that

survive only one stage further and keeps those that survive r stages; the reach of the differential grows in step with that. A class killed by d_r and by no earlier differential encodes a gluing that spans exactly r layers of the filtration, information no single long exact sequence of the family can see. This is the precise sense in which the spectral sequence contains more than the collection of long exact sequences it was built from.

The simplest instance is a filtration with only two stages, where there is a single differential and the machine reduces to something already familiar.

Proposition 60.1.8: The Two-Step Filtration Recovers the Long Exact Sequence

Let $0 \to A_\bullet \xrightarrow{\iota} C_\bullet \xrightarrow{\pi} C_\bullet/A_\bullet \to 0$ be a short exact sequence of complexes in $\mathcal{A}$, and let $D = H_\bullet(A) \oplus H_\bullet(C)$ and $E = H_\bullet(A) \oplus H_\bullet(C/A)$ be the terms of the exact couple attached to the two-step filtration $0 \subseteq A_\bullet \subseteq C_\bullet$. Then:

1. the first page is $E^1 = H_\bullet(A) \oplus H_\bullet(C/A)$, with d_1 the connecting homomorphism $\partial\colon H_n(C/A) \to H_{n-1}(A)$ of theorem 56.1.18;
2. $E^2 = E^\infty$, that is $d_r = 0$ for all $r \geq 2$;
3. E^2 is the associated graded of $H_\bullet(C)$ for the induced two-step filtration, namely

$$E^2 \cong \operatorname{coker}\partial \oplus \ker \partial$$

with $\operatorname{coker}\partial$ the image of $H_n(A) \to H_n(C)$ and $\ker \partial$ its quotient.

***Proof*:**

Step 1: Identification of the first page. The filtration has stages $F_0 = A_\bullet$ and $F_1 = C_\bullet$, with $F_{-1} = 0$ and $F_p = C_\bullet$ for $p \geq 1$. The layers are $F_0/F_{-1} = A_\bullet$ and $F_1/F_0 = C_\bullet/A_\bullet$, and all other layers vanish. Since E^1 is by construction the sum of the cohomologies of the layers, $E^1 = H_\bullet(A) \oplus H_\bullet(C/A)$. The map k is the connecting homomorphism of the long exact sequence attached to the layer and j is the projection onto the layer, so on the summand $H_n(C/A)$ the composite $d_1 = j \circ k$ is the connecting homomorphism ∂ followed by the identification of $H_{n-1}(A)$ with the layer at filtration level zero, which is the identity. Hence $d_1 = \partial$ on that summand, and $d_1 = 0$ on $H_\bullet(A)$ because k vanishes there (its target is the cohomology of a layer at filtration level -1, which is zero).

Step 2: Degeneration after the second page. By theorem 60.1.7 the differential d_r has bidegree $(-r, r-1)$, so it decreases the filtration index by r. Only the filtration indices 0 and 1 carry nonzero terms, so for $r \geq 2$ the source and target of d_r cannot both be nonzero: a nonzero source at index 1 would have target at index $1 - r \leq -1$, and a source at index 0 would have target at index $-r < 0$. Hence $d_r = 0$ for $r \geq 2$ and the pages stabilize at E^2.

Step 3: Identification of the limit. By Step 1 the second page is the cohomology of $d_1 = \partial$, which is $\ker \partial$ in filtration index 1 and $\operatorname{coker}\partial$ in filtration index 0. The long exact sequence of theorem 56.1.18 reads

$$\cdots \to H_n(A) \xrightarrow{\iota_*} H_n(C) \xrightarrow{\pi_*} H_n(C/A) \xrightarrow{\partial} H_{n-1}(A) \to \cdots$$

Exactness at $H_n(C)$ gives $\mathrm{im}\iota_* = \ker \pi_*$, and exactness at $H_n(A)$ identifies $\mathrm{im}\iota_* \cong H_n(A)/\mathrm{im}\partial = \mathrm{coker}\partial$ in degree n; exactness at $H_n(C/A)$ identifies the quotient $H_n(C)/\mathrm{im}\iota_* \cong \mathrm{im}\pi_* = \ker \partial$. These two are precisely the graded pieces of $H_n(C)$ for the filtration induced by $A_\bullet \subseteq C_\bullet$, and they agree with the two summands of E^2 computed above, as we sought to show.

The proposition is the sanity check for the whole apparatus: in the one case where the answer is already known, the spectral sequence returns exactly the long exact sequence and nothing more. It also isolates what the machine does *not* do. The second page records $\ker \partial$ and $\mathrm{coker}\partial$ as separate graded pieces, but the extension

$$0 \to \mathrm{coker}\partial \to H_n(C) \to \ker \partial \to 0$$

is not part of the output. A spectral sequence delivers the associated graded of the answer, never the answer itself; recovering the latter requires solving the extension problems left behind. This is a permanent feature, not a defect of the two-step case, and it is stated in general in theorem 60.2.6.

A worked instance shows the bookkeeping.

Example 60.1.9: The Spectral Sequence of a Filtered Complex of Abelian Groups
Let $C_\bullet$ be the complex of abelian groups concentrated in degrees 1 and 0,

$$C_1 = \mathbb{Z} \xrightarrow{\cdot 2} C_0 = \mathbb{Z}$$

and let $A_\bullet \subseteq C_\bullet$ be the subcomplex with $A_1 = 0$ and $A_0 = 2\mathbb{Z}$. This is a subcomplex because $\partial(A_1) = 0 \subseteq A_0$. Filter by $F_0 = A_\bullet$ and $F_1 = C_\bullet$.

The cohomology of $C_\bullet$ itself is immediate: $H_1(C) = \ker(\cdot 2) = 0$ and $H_0(C) = \mathbb{Z}/2\mathbb{Z}$. The spectral sequence recomputes this from the two layers. The layer at level 0 is $A_\bullet$, with $H_0(A) = 2\mathbb{Z} \cong \mathbb{Z}$ and $H_1(A) = 0$. The layer at level 1 is $C_\bullet/A_\bullet$, which is $\mathbb{Z}$ in degree 1 and $\mathbb{Z}/2\mathbb{Z}$ in degree 0, with induced differential $1 \mapsto 2 \bmod 2 = 0$; so $H_1(C/A) = \mathbb{Z}$ and $H_0(C/A) = \mathbb{Z}/2\mathbb{Z}$. Indexing by $E^1_{p,q} = H_{p+q}(F_p/F_{p-1})$, the nonzero entries of the first page are

$$E^1_{0,0} = H_0(A) \cong \mathbb{Z}, \qquad E^1_{1,0} = H_1(C/A) \cong \mathbb{Z}, \qquad E^1_{1,-1} = H_0(C/A) \cong \mathbb{Z}/2\mathbb{Z}$$

The only possibly nonzero differential on this page is $d_1 \colon E^1_{1,0} \to E^1_{0,0}$, the connecting homomorphism $H_1(C/A) \to H_0(A)$. Compute it on the generator: the class of $1 \in (C/A)_1$ lifts to $1 \in C_1$, whose boundary is $2 \in C_0$, and 2 is the generator of $A_0 = 2\mathbb{Z}$. So d_1 sends a generator to a generator and is an isomorphism $\mathbb{Z} \to \mathbb{Z}$.

The second page therefore has $E^2_{1,0} = E^2_{0,0} = 0$, while $E^2_{1,-1} = \mathbb{Z}/2\mathbb{Z}$ survives untouched (the differential out of the spot $(1,-1)$ lands in $E^1_{0,-1} = H_{-1}(A) = 0$, and the one into it comes from $E^1_{2,-1} = 0$). By proposition 60.1.8 the pages stabilize here. Reading off total degrees: the diagonal $p+q=1$ is entirely zero, giving $H_1(C) = 0$, and the diagonal $p+q=0$ contains the single group $E^\infty_{1,-1} = \mathbb{Z}/2\mathbb{Z}$, giving $H_0(C) = \mathbb{Z}/2\mathbb{Z}$. Both agree with the direct computation, and because each diagonal contains at most one nonzero group there is no extension problem to solve.

Not every exact couple comes from a filtration. A single short exact sequence of complexes, read the other way round, produces one whose iteration does not terminate and whose limit is a statement about torsion.

Example 60.1.10: The Bockstein Exact Couple

Let p be a prime and $C_\bullet$ a complex of free abelian groups. Multiplication by p is injective on each C_n, so there is a short exact sequence of complexes

$$0 \to C_\bullet \xrightarrow{\cdot p} C_\bullet \to C_\bullet/pC_\bullet \to 0$$

Its long exact sequence in cohomology is exactly an exact couple, with

$$D = H_\bullet(C), \qquad E = H_\bullet(C/pC), \qquad i = (\cdot p), \qquad j = \text{reduction}, \qquad k = \partial$$

The differential $d_1 = j \circ k$ is the *Bockstein homomorphism*. By theorem 60.1.7 the r-th auxiliary object is $D^{r+1} = i^r(D) = p^r H_\bullet(C)$, so passing to the derived couple repeatedly divides out by higher and higher powers of p. When $H_\bullet(C)$ is finitely generated, an element of p-power torsion is annihilated by p^r for some r and therefore disappears from D^{r+1}, while a free generator survives every stage; the limit page is $\big(H_\bullet(C)/\text{torsion}\big) \otimes \mathbb{F}_p$.

The smallest case exhibits the mechanism. Take $C_1 = \mathbb{Z} \xrightarrow{\cdot p} C_0 = \mathbb{Z}$, so that $H_1(C) = 0$ and $H_0(C) = \mathbb{Z}/p\mathbb{Z}$ is pure torsion. Then $C_\bullet/pC_\bullet$ has zero differential, so $E^1 = H_\bullet(C/pC)$ is $\mathbb{F}_p$ in degrees 1 and 0. The connecting map k sends the degree-one generator to the class of 1 in $H_0(C) = \mathbb{Z}/p\mathbb{Z}$ (lift $\bar{1}$ to $1 \in C_1$, take the boundary p, and divide by p), and j sends that class to a generator of $H_0(C/pC) = \mathbb{F}_p$. So d_1 is an isomorphism $E^1_1 \to E^1_0$, giving $E^2 = 0 = E^\infty$. This matches the general description: $H_\bullet(C)$ is entirely torsion, so $(H_\bullet(C)/\text{torsion}) \otimes \mathbb{F}_p = 0$.

Exercise 60.1.1

1. Let (D, E, i, j, k) be an exact couple in which i is an isomorphism. Show that $E = 0$. Deduce that every page of the associated spectral sequence vanishes.
2. Let (D, E, i, j, k) be an exact couple. Show that $d = j \circ k$ vanishes if and only if $\ker i \subseteq \operatorname{im} i$. Then exhibit an exact couple with $d = 0$ but $k \neq 0$, so that a vanishing differential does not force the connecting map to vanish. (Take $D = \mathbb{Z}/4\mathbb{Z}$ and i multiplication by 2.)
3. Verify directly from definition 60.1.4 that the derived couple of the derived couple has $D'' = i^2(D)$, and that i'' is the restriction of i to $i^2(D)$, without appealing to theorem 60.1.7.
4. Let $C_\bullet$ be the complex $C_1 = \mathbb{Z} \xrightarrow{\cdot 6} C_0 = \mathbb{Z}$ filtered by $F_0 = A_\bullet$ with $A_1 = 0$, $A_0 = 3\mathbb{Z}$, and $F_1 = C_\bullet$. Compute the first page, the differential d_1, and the limit page, and check the answer against a direct computation of $H_\bullet(C)$.
5. In the Bockstein couple of example 60.1.10, take $C_\bullet$ to be $C_1 = \mathbb{Z} \xrightarrow{\cdot p^2} C_0 = \mathbb{Z}$. Show that $d_1 = 0$ but $d_2 \neq 0$, and that $E^3 = E^\infty = 0$. Explain how this illustrates the statement that d_r detects gluing spanning r stages.
6. Let $\mathcal{A}$ be an abelian category and (D, E, i, j, k) an exact couple with $E = 0$. Show that i is an isomorphism, so that the converse of exercise 60.1.1 (1) holds.

60.2 The Spectral Sequence of a Filtered Complex

The exact couples of section 60.1 were treated as abstract data. Their principal source is a complex equipped with a filtration, and this section carries out that construction, describes the pages explicitly enough to compute with, and proves the two theorems that make the output usable: a convergence theorem saying what the limit page computes, and a comparison theorem saying when two spectral sequences agree. These are the results cited from this chapter across the series, so both are proved in the generality in which they are used, for increasing filtrations of chain complexes and, in the restatement at the end of the section, for decreasing filtrations of cochain complexes.

Definition 60.2.1: Filtered Complex

Let $\mathcal{A}$ be an abelian category. A *filtered complex* is a chain complex $C_\bullet$ in $\mathcal{A}$ together with a family of subcomplexes $\{F_pC_\bullet\}_{p\in\mathbb{Z}}$ satisfying $F_pC_\bullet \subseteq F_{p+1}C_\bullet$ for every p. The filtration is called

1. *exhaustive* if $\bigcup_p F_pC_n = C_n$ for every n;
2. *bounded below* if for each n there is an $s(n)$ with $F_{s(n)}C_n = 0$;
3. *bounded* if it is bounded below and for each n there is a $t(n)$ with $F_{t(n)}C_n = C_n$.

The *associated graded* of the filtration is the complex $\mathrm{gr}_pC_\bullet = F_pC_\bullet/F_{p-1}C_\bullet$, and the filtration induced on homology is

$$F_pH_n(C) = \operatorname{im}\big(H_n(F_pC) \to H_n(C)\big)$$

Each inclusion $F_{p-1}C_\bullet \hookrightarrow F_pC_\bullet$ is a subcomplex inclusion in the sense of definition 56.1.7, so $\mathrm{gr}_pC_\bullet$ is again a complex.

Boundedness is the hypothesis that does the work later, and it is worth seeing why before it is used. In each fixed degree n a bounded filtration passes from 0 to all of C_n in finitely many steps, so any bookkeeping indexed by the filtration terminates in that degree after finitely many stages. Without some such condition the pages of the spectral sequence need not stabilize and the limit need not compute anything.

Every filtered complex produces an exact couple in one step: the long exact sequence of each pair $(F_pC_\bullet, F_{p-1}C_\bullet)$ gives the three maps, and the filtration index gives the bigrading.

Theorem 60.2.2: The Exact Couple of a Filtered Complex

Let $(C_\bullet, F_\bullet)$ be a filtered complex. Set

$$D^1_{p,q} = H_{p+q}(F_pC), \qquad E^1_{p,q} = H_{p+q}(\mathrm{gr}_pC)$$

and let i be induced by the inclusion $F_{p-1}C \hookrightarrow F_pC$, let j be induced by the projection $F_pC \to \mathrm{gr}_pC$, and let k be the connecting homomorphism of theorem 56.1.18 applied to

$$0 \to F_{p-1}C_\bullet \to F_pC_\bullet \to \mathrm{gr}_pC_\bullet \to 0$$

Then (D^1, E^1, i, j, k) is an exact couple with

$$\deg i = (1,-1), \qquad \deg j = (0,0), \qquad \deg k = (-1,0)$$

Consequently theorem 60.1.7 yields a spectral sequence with first page $E^1_{p,q} = H_{p+q}(\mathrm{gr}_pC)$ and differentials $d_r \colon E^r_{p,q} \to E^r_{p-r,\,q+r-1}$.
It is convenient to record one page earlier. Set

$$E^0_{p,q} := \mathrm{gr}_pC_{p+q}$$

with d_0 the differential induced by ∂ on the associated graded; then $E^1 = H(E^0, d_0)$, which is the identification just made, and the sequence is indexed from $r = 0$.

***Proof*:**
Step 1: Exactness. The displayed short exact sequence of complexes gives, by theorem 56.1.18, the long exact sequence

$$\cdots \to H_n(F_{p-1}C) \xrightarrow{i} H_n(F_pC) \xrightarrow{j} H_n(\mathrm{gr}_pC) \xrightarrow{k} H_{n-1}(F_{p-1}C) \to \cdots$$

Assembling these over all p and all n, the three maps i, j, k are defined on all of D^1 and E^1, and exactness of the triangle at each corner is exactness of the long exact sequences at the three types of term. This is exactly definition 60.1.1.

Step 2: Bidegrees. Write $n = p + q$. The map i carries $H_n(F_{p-1}C) = D^1_{p-1,q+1}$ to $H_n(F_pC) = D^1_{p,q}$, since $(p-1)+(q+1) = n$; hence $\deg i = (1,-1)$. The map j carries $H_n(F_pC) = D^1_{p,q}$ to $H_n(\mathrm{gr}_pC) = E^1_{p,q}$, so $\deg j = (0,0)$. The connecting map k carries $H_n(\mathrm{gr}_pC) = E^1_{p,q}$ to $H_{n-1}(F_{p-1}C) = D^1_{p-1,q}$, since $(p-1)+q = n-1$; hence $\deg k = (-1,0)$. These are the hypotheses of theorem 60.1.7, which then gives the spectral sequence and the stated bidegree of d_r, completing the proof.

The construction is quick, but the pages it produces are described only implicitly, as iterated subquotients of the first one. Computing with them, and proving anything about the limit, requires a description of E^r in terms of the original complex. The right notion is that of a chain which is a cycle only up to a given depth in the filtration.

Definition 60.2.3: Approximate Cycles

Let $(C_\bullet, F_\bullet)$ be a filtered complex and write $n = p+q$. For $r \geq 0$ set

$$Z^r_{p,q} = \{\, x \in F_pC_n \;:\; \partial x \in F_{p-r}C_{n-1} \,\}$$

the object of chains at filtration level p whose boundary drops r levels. By convention $Z^{-1}_{p,q} = F_pC_n$.

The objects $Z^r_{p,q}$ decrease in r, and their intersection over all r is, when the filtration is bounded below, the cycles of $C_\bullet$ lying in F_pC_n. An element of $Z^r_{p,q}$ is a class that survives to the r-th page: it is a cycle in the associated graded to accuracy r, and its failure to be a cycle of $C_\bullet$ is what d_r records.

Proposition 60.2.4: Explicit Description of the Pages

Let $(C_\bullet, F_\bullet)$ be a filtered complex and let $\{(E^r, d_r)\}$ be the spectral sequence of theorem 60.2.2. For every $r \geq 0$ there are isomorphisms

$$E^r_{p,q} \cong \frac{Z^r_{p,q}}{Z^{r-1}_{p-1,q+1} + \partial Z^{r-1}_{p+r-1,\,q-r+2}}$$

under which the differential d_r is induced by the boundary map ∂ of $C_\bullet$.

***Proof*:**
Write $\mathcal{E}^r_{p,q}$ for the right-hand side and $n = p+q$. The proof is an induction on r; the inductive statement is that $E^r \cong \mathcal{E}^r$ compatibly with the differentials, the differential on $\mathcal{E}^r$ being the one induced by ∂.

Step 1: The map induced by ∂ is a differential on $\mathcal{E}^r$. If $x \in Z^r_{p,q}$ then $\partial x \in F_{p-r}C_{n-1}$ and $\partial(\partial x) = 0 \in F_{p-2r}C_{n-2}$, so $\partial x \in Z^r_{p-r,\,q+r-1}$. Hence ∂ carries $Z^r_{p,q}$ into $Z^r_{p-r,q+r-1}$, and it carries the denominator at (p,q) into the denominator at $(p-r, q+r-1)$: the summand $Z^{r-1}_{p-1,q+1}$ is sent to $\partial Z^{r-1}_{p-1,q+1}$, which is literally the second summand of the target denominator, and the summand $\partial Z^{r-1}_{p+r-1,q-r+2}$ is sent to zero because $\partial\partial = 0$. So ∂ induces a map $\mathcal{E}^r_{p,q} \to \mathcal{E}^r_{p-r,q+r-1}$ squaring to zero.

Step 2: The base case $r = 0$. With the convention $Z^{-1}_{p,q} = F_pC_n$, the numerator is $Z^0_{p,q} = F_pC_n$ and the denominator is $F_{p-1}C_n + \partial F_{p-1}C_{n+1} = F_{p-1}C_n$, since $\partial F_{p-1}C_{n+1} \subseteq F_{p-1}C_n$. So $\mathcal{E}^0_{p,q} = F_pC_n / F_{p-1}C_n = \mathrm{gr}_pC_n$, which is $E^0_{p,q}$, and the induced differential is the one ∂ induces on the associated graded. Taking homology recovers $E^1_{p,q} = H_n(\mathrm{gr}_pC)$, matching theorem 60.2.2; the differential $d_1 = j \circ k$ is by construction the connecting homomorphism, which on representatives is ∂.

Step 3: The inductive step. Assume $E^r \cong \mathcal{E}^r$ compatibly with differentials. Then $E^{r+1} = H(E^r, d_r) \cong H(\mathcal{E}^r, \partial)$, so it suffices to identify the latter with $\mathcal{E}^{r+1}$. Abbreviate the denominator $D = Z^{r-1}_{p-1,q+1} + \partial Z^{r-1}_{p+r-1,q-r+2}$.

First the kernel. Let $x \in Z^r_{p,q}$ represent a class killed by d_r, so that ∂x lies in the denominator at $(p-r, q+r-1)$, namely $\partial x = z + \partial w$ with $z \in Z^{r-1}_{p-r-1,q+r}$ and $w \in Z^{r-1}_{p-1,q+1}$. Then $x - w$ still lies in F_pC_n, because $w \in F_{p-1}C_n$, and

$$\partial(x-w) = \partial x - \partial w = z \in F_{p-r-1}C_{n-1}$$

so $x - w \in Z^{r+1}_{p,q}$. Since $w \in D$, the classes of x and $x - w$ agree in $\mathcal{E}^r_{p,q}$. Hence $\ker d_r = (Z^{r+1}_{p,q} + D)/D$.

Next the image. A class in $\mathcal{E}^r_{p+r,q-r+1}$ is represented by some $y \in Z^r_{p+r,q-r+1}$, and d_r sends it to the class of ∂y. Hence $\mathrm{im} d_r = (\partial Z^r_{p+r,q-r+1} + D)/D$, and therefore

$$H(\mathcal{E}^r, \partial)_{p,q} = \frac{Z^{r+1}_{p,q} + D}{\partial Z^r_{p+r,q-r+1} + D} \cong \frac{Z^{r+1}_{p,q}}{Z^{r+1}_{p,q} \cap \left(\partial Z^r_{p+r,q-r+1} + D\right)}$$

the isomorphism being the second isomorphism theorem.

It remains to show that the intersection appearing there equals $Z^r_{p-1,q+1} + \partial Z^r_{p+r,q-r+1}$, which is exactly the denominator of $\mathcal{E}^{r+1}_{p,q}$. For the inclusion $\supseteq$, note $Z^r_{p-1,q+1} \subseteq Z^{r+1}_{p,q}$ (an element lies in $F_{p-1} \subseteq F_p$ and its boundary lies in F_{p-1-r}) and $Z^r_{p-1,q+1} \subseteq Z^{r-1}_{p-1,q+1} \subseteq D$; while $\partial Z^r_{p+r,q-r+1} \subseteq Z^{r+1}_{p,q}$ because such a boundary lies in F_pC_n and is itself a cycle. For the inclusion $\subseteq$, let $x \in Z^{r+1}_{p,q}$ be written as $x = \partial y + z + \partial w$ with $y \in Z^r_{p+r,q-r+1}$, $z \in Z^{r-1}_{p-1,q+1}$ and $w \in Z^{r-1}_{p+r-1,q-r+2}$. Then $z = x - \partial y - \partial w$ lies in $F_{p-1}C_n$ and $\partial z = \partial x \in F_{p-r-1}C_{n-1}$, so $z \in Z^r_{p-1,q+1}$. Moreover $w \in Z^{r-1}_{p+r-1,q-r+2}$ satisfies $w \in F_{p+r-1} \subseteq F_{p+r}$ and $\partial w \in F_{(p+r-1)-(r-1)} = F_p$, so $w \in Z^r_{p+r,q-r+1}$ and hence $\partial w \in \partial Z^r_{p+r,q-r+1}$. Therefore $x = z + \partial(y+w) \in Z^r_{p-1,q+1} + \partial Z^r_{p+r,q-r+1}$, as required.

Substituting gives $H(\mathcal{E}^r, \partial)_{p,q} \cong \mathcal{E}^{r+1}_{p,q}$. Write $\varphi_r \colon \mathcal{E}^r \to E^r$ for the isomorphism of the inductive statement. Composing with $E^{r+1} = H(E^r, d_r) \cong H(\mathcal{E}^r, \partial)$ gives φ_{r+1}, and since every isomorphism in this step is induced by the identity on representatives, φ_{r+1} sends the class of $x \in Z^{r+1}_{p,q}$ to the class of $\varphi_r[x]$ in $H(E^r, d_r)$.

Step 4: The isomorphism φ_r carries the map induced by ∂ to d_r. For $r = 0$ this is Step 2, so let $r \geq 1$. Each E^r is then a subquotient of E^1. For $e \in E^1$ write $\langle e \rangle_r \in E^r$ for its class whenever that class is defined: $\langle e \rangle_1 = e$, and $\langle e \rangle_{s+1}$ is the class of $\langle e \rangle_s$ in $H(E^s, d_s)$ when $d_s \langle e \rangle_s = 0$. For $x \in Z^r_{p,q}$ let $\bar{x}$ be its image in $\mathrm{gr}_p C_n$, a cycle because $\partial x \in F_{p-r}C_{n-1} \subseteq F_{p-1}C_{n-1}$. Step 3 at $r = 0$ gives $\varphi_1[x] = [\bar{x}]$, and the description of φ_{r+1} above then gives $\varphi_r[x] = \langle [\bar{x}] \rangle_r$ by induction. Iterating definition 60.1.4, whose maps are $k'([e]) = k(e)$ and $j'(i(y)) = [j(y)]$, gives

$$k^{(r)} \langle e \rangle_r = k(e), \qquad j^{(r)}\big(i^{r-1}(y)\big) = \langle j(y) \rangle_r \quad (y \in D^1)$$

where the class on the right is defined because at each stage $j^{(s)}$ takes values in $\ker k^{(s)} \subseteq \ker d_s$. The connecting homomorphism k of theorem 56.1.18 lifts the cycle $\bar{x}$ to x and applies ∂, so $k[\bar{x}]$ is the class of ∂x in $H_{n-1}(F_{p-1}C)$. Since ∂x is a cycle lying in $F_{p-r}C_{n-1}$, that class is $i^{r-1}(y)$ for y the class of ∂x in $H_{n-1}(F_{p-r}C)$, and $j(y)$ is the class of the image of ∂x in $\mathrm{gr}_{p-r}C_{n-1}$. Since $\partial x \in Z^r_{p-r,q+r-1}$ by Step 1, this gives

$$d_r\, \varphi_r[x] = j^{(r)} k^{(r)} \langle [\bar{x}] \rangle_r = j^{(r)}\big(i^{r-1}(y)\big) = \langle j(y) \rangle_r = \varphi_r[\partial x]$$

which closes the induction and completes the proof.

The formula repays reading slowly, because it makes the interpretive claim of section 60.1 precise. The numerator at page r consists of the chains whose boundary drops r filtration levels, and the denominator discards those already accounted for one level down together with the boundaries of chains that drop $r-1$ levels. Passing from page r to page $r+1$ tightens the requirement on the boundary by one level. A class that survives to page r and dies there is one that could be corrected to a cycle modulo F_{p-r} but not modulo F_{p-r-1}, which is the precise sense in which d_r detects gluing across r layers.

With the pages described, the limit can be identified. This is the theorem the rest of the series cites from this section.

Definition 60.2.5: Convergence of a Spectral Sequence

A bigraded spectral sequence $\{(E^r, d_r)\}$ *degenerates* at the spot (p,q) if the differentials into and out of that spot vanish for all sufficiently large r; the common value of $E^r_{p,q}$ for large r is then written $E^\infty_{p,q}$. The spectral sequence *converges* to a graded object $H_\bullet$ equipped with a filtration $F_\bullet H_\bullet$, written

$$E^1_{p,q} \implies H_{p+q}$$

if it degenerates at every spot, the filtration $F_\bullet H_n$ is bounded for each n (that is $F_pH_n = 0$ for p small and $F_pH_n = H_n$ for p large), and $E^\infty_{p,q} \cong F_pH_{p+q}/F_{p-1}H_{p+q}$ for all p,q. The boundedness clause is what lets a vanishing family of graded pieces be read back as a vanishing abutment; without it the graded pieces constrain only the successive quotients.

Theorem 60.2.6: Convergence for a Bounded Filtration

Let $(C_\bullet, F_\bullet)$ be a filtered complex whose filtration is bounded in the sense of definition 60.2.1. Then the spectral sequence of theorem 60.2.2 converges to $H_\bullet(C)$: it degenerates at every spot, and

$$E^\infty_{p,q} \cong \frac{F_pH_{p+q}(C)}{F_{p-1}H_{p+q}(C)}$$

for the filtration $F_pH_n(C) = \operatorname{im}(H_n(F_pC) \to H_n(C))$ of definition 60.2.1. Moreover that filtration of $H_n(C)$ is itself bounded, so $H_n(C)$ has a finite filtration whose graded pieces are the terms of the limit page on the diagonal $p+q=n$.

***Proof*:**
Fix n and let $s(m), t(m)$ be the bounds of definition 60.2.1 in degree m.

Step 1: Degeneration. Fix a spot (p,q) with $p+q=n$. The differential out of it lands in $E^r_{p-r,q+r-1}$, a subquotient of $E^1_{p-r,q+r-1} = H_{n-1}(\mathrm{gr}_{p-r}C)$. Once r is large enough that $p-r \le s(n-1)$, the complex $\mathrm{gr}_{p-r}C$ vanishes in degree $n-1$, so the target is zero. The differential into (p,q) comes from $E^r_{p+r,q-r+1}$, a subquotient of $H_{n+1}(\mathrm{gr}_{p+r}C)$; once $p+r-1 \ge t(n+1)$ one has $F_{p+r-1}C_{n+1} = F_{p+r}C_{n+1} = C_{n+1}$, so $\mathrm{gr}_{p+r}C$ vanishes in degree $n+1$ and the source is zero. Both hold for all large r, so $E^{r+1}_{p,q} = E^r_{p,q}$ eventually and $E^\infty_{p,q}$ is defined.

Step 2: The large-r value of the explicit description. Take r large enough that $F_{p-r}C_{n-1} = 0$ and $F_{p+r-1}C_{n+1} = C_{n+1}$, which is possible by boundedness. Write $Z_n = \ker(\partial\colon C_n \to C_{n-1})$

and $B_n = \operatorname{im}(\partial\colon C_{n+1} \to C_n)$. Then:

1. $Z^r_{p,q} = \{x \in F_pC_n : \partial x \in F_{p-r}C_{n-1} = 0\} = Z_n \cap F_pC_n$;
2. $Z^{r-1}_{p-1,q+1} = \{x \in F_{p-1}C_n : \partial x \in F_{p-r}C_{n-1} = 0\} = Z_n \cap F_{p-1}C_n$;
3. $\partial Z^{r-1}_{p+r-1,q-r+2} = \partial\{y \in F_{p+r-1}C_{n+1} : \partial y \in F_pC_n\} = \partial(C_{n+1}) \cap F_pC_n = B_n \cap F_pC_n$, using $F_{p+r-1}C_{n+1} = C_{n+1}$.

Substituting into proposition 60.2.4,

$$E^\infty_{p,q} \cong \frac{Z_n \cap F_pC_n}{(Z_n \cap F_{p-1}C_n) + (B_n \cap F_pC_n)}$$

Step 3: The same object is the graded piece of homology. By definition $F_pH_n(C)$ is the image of $H_n(F_pC)$ in $H_n(C)$, that is

$$F_pH_n(C) = \frac{(Z_n \cap F_pC_n) + B_n}{B_n} \cong \frac{Z_n \cap F_pC_n}{B_n \cap F_pC_n}$$

the isomorphism being the second isomorphism theorem. Taking the quotient by $F_{p-1}H_n(C)$, which under this identification is the image of $Z_n \cap F_{p-1}C_n$, gives

$$\frac{F_pH_n(C)}{F_{p-1}H_n(C)} \cong \frac{Z_n \cap F_pC_n}{(Z_n \cap F_{p-1}C_n) + (B_n \cap F_pC_n)}$$

which is the object computed in Step 2. Hence $E^\infty_{p,q} \cong \operatorname{gr}_pH_n(C)$.

Both sides were computed as subquotients of F_pC_n by the same formula, and the isomorphism between them is induced by the identity on representatives. A morphism of filtered complexes carries representatives to representatives and preserves every object appearing in that formula, so the identification is natural in $(C_\bullet, F_\bullet)$; this is what theorem 60.2.9 uses when it compares the two filtrations of homology.

Step 4: The induced filtration is bounded. If $p \le s(n)$ then $F_pC_n = 0$, so $H_n(F_pC) = 0$ and $F_pH_n(C) = 0$. If $p \ge t(n)$ then $F_pC_n = C_n$; taking p also at least $t(n+1)$ makes $F_pC_{n+1} = C_{n+1}$ as well, so every cycle and every boundary of degree n already lies at filtration level p and $F_pH_n(C) = H_n(C)$. Hence the filtration of $H_n(C)$ passes from 0 to everything in finitely many steps, completing the proof.

Two features of the statement deserve emphasis, both of them permanent. The limit page computes the *associated graded* of $H_n(C)$, not $H_n(C)$ itself; recovering the latter means solving the extension problems between successive graded pieces, exactly as in the two-step case of proposition 60.1.8. And convergence is a theorem about the filtration, not about the complex: boundedness is what forces the pages to stabilize, and without it the limit page can fail to compute anything.

The applications elsewhere in the series are stated for cochain complexes with decreasing filtrations, so the translation is recorded explicitly rather than left to the reader.

Corollary 60.2.7: Convergence for a Decreasing Filtration of a Cochain Complex

Let $(C^\bullet, d)$ be a cochain complex with a decreasing filtration $C^\bullet = F^0C^\bullet \supseteq F^1C^\bullet \supseteq \cdots$ compatible with d, that is $d(F^pC^n) \subseteq F^pC^{n+1}$, and suppose the filtration is exhaustive and bounded, so that for each n there is a P with $F^PC^n = 0$. Then there is a spectral sequence with

$$E_0^{p,q} = \frac{F^pC^{p+q}}{F^{p+1}C^{p+q}}, \qquad d_r \colon E_r^{p,q} \to E_r^{p+r,\,q-r+1}$$

each page the cohomology of the one before it, converging to $H^{p+q}(C)$:

$$E_1^{p,q} \implies H^{p+q}(C), \qquad E_\infty^{p,q} \cong \mathrm{gr}_F^p H^{p+q}(C) = \frac{F^pH^{p+q}(C)}{F^{p+1}H^{p+q}(C)}$$

where $F^pH^n(C) = \mathrm{im}\big(H^n(F^pC^\bullet) \to H^n(C^\bullet)\big)$.

***Proof*:**

Set $C_n = C^{-n}$ and $F_pC_\bullet = F^{-p}C^\bullet$. The differential d raises cochain degree by one and therefore lowers chain degree by one, so $(C_\bullet, F_\bullet)$ is a filtered chain complex in the sense of definition 60.2.1: the filtration is increasing because $F^\bullet$ is decreasing, it is exhaustive because $F^\bullet$ is, and it is bounded because for each n there is a P with $F^PC^n = 0$, giving $F_{-P}C_{-n} = 0$, while $F^0C^n = C^n$ gives $F_0C_{-n} = C_{-n}$.

Theorem 60.2.6 applies and gives a convergent spectral sequence with $E^0_{p,q} = \mathrm{gr}_pC_{p+q}$ and d_r of bidegree $(-r, r-1)$. Re-indexing by $E_r^{p,q} = E^r_{-p,-q}$, as in definition 60.1.6, turns the bidegree of d_r into $(r, -r+1)$ and turns the graded piece $\mathrm{gr}_{-p}H_{-p-q}(C_\bullet)$ into $\mathrm{gr}_F^pH^{p+q}(C^\bullet)$, which is the statement, as we sought to show.

The same re-indexing carries every other result of this section across, and it is worth saying so once rather than hedging at each use, since section 60.3 onward works exclusively with cochain complexes.

Corollary 60.2.8: The Cochain Form of the Section

Let $\mathcal{T}$ denote the translation $C_n = C^{-n}$, $F_p = F^{-p}$, $E_r^{p,q} = E^r_{-p,-q}$ of corollary 60.2.7. Under $\mathcal{T}$:

1. Theorem 60.2.9 holds for morphisms of cochain complexes with bounded decreasing filtrations: a morphism inducing an isomorphism on E_{r_0} for some r_0 induces one on E_∞ and on $H^\bullet$.
2. Definition 60.2.3, proposition 60.2.4 and definition 60.2.5 hold with the *bigrading* negated, the page index r unchanged. Explicitly $Z_r^{p,q} = \{x \in F^pC^{p+q} : dx \in F^{p+r}C^{p+q+1}\}$ and

$$E_r^{p,q} \cong \frac{Z_r^{p,q}}{Z_{r-1}^{p+1,q-1} + d\,Z_{r-1}^{p-r+1,\,q+r-2}}$$

***Proof*:**
$\mathcal{T}$ is an isomorphism between the category of cochain complexes with bounded decreasing filtrations and the category of chain complexes with bounded increasing filtrations, carrying morphisms to morphisms and the spectral sequence of one to the spectral sequence of the other, by the computation in the proof of corollary 60.2.7. A statement proved for one is therefore proved for the other; no hypothesis in theorem 60.2.9 or proposition 60.2.4 refers to the direction of the grading beyond boundedness, which $\mathcal{T}$ preserves, completing the proof.

The remaining tool is the one that lets a spectral sequence be recognized rather than computed: if two filtered complexes are compared by a map, and the comparison is an isomorphism on any single page, then it is an isomorphism on the abutment. This is what makes a spectral sequence an identification technique and not only a calculation.

Theorem 60.2.9: Comparison Theorem

Let $f\colon (C_\bullet, F_\bullet) \to (C'_\bullet, F'_\bullet)$ be a morphism of filtered complexes, that is a chain map with $f(F_pC_\bullet) \subseteq F'_pC'_\bullet$, and suppose both filtrations are bounded. Then f induces a morphism of spectral sequences $f^r\colon E^r_{p,q} \to E'^r_{p,q}$ commuting with the differentials, and if f^{r_0} is an isomorphism for some $r_0 \geq 0$, then:

1. f^r is an isomorphism for every $r \geq r_0$, and hence so is f^∞;
2. $f_*\colon H_n(C) \to H_n(C')$ is an isomorphism for every n.

***Proof*:**
Step 1: Functoriality. On the zeroth page f induces f^0 on gr_pC_{p+q} directly, and the identification $E^1 = H(E^0, d_0)$ of theorem 60.2.2 is natural in the filtered complex, so the case $r_0 = 0$ reduces to $r_0 = 1$. For the remaining pages: because f preserves the filtration, it carries the short exact sequences of theorem 60.2.2 for C to those for C', and the connecting homomorphism of theorem 56.1.18 is natural. So f induces a morphism of exact couples, and the construction of the derived couple in definition 60.1.4 is built from i, j, k alone and is therefore natural in the couple. Hence f induces f^r on every page, commuting with d_r.

Step 2: Isomorphism on all later pages. Suppose f^r is an isomorphism. Since f^r commutes with the differentials, it carries $\ker d_r$ isomorphically onto $\ker d'_r$ and $\mathrm{im} d_r$ isomorphically onto $\mathrm{im} d'_r$, so the induced map on the quotients is an isomorphism. That induced map is f^{r+1}, so the claim follows by induction from r_0.

Step 3: Isomorphism on the limit page. Both filtrations are bounded, so by Step 1 of the proof of theorem 60.2.6 each spot degenerates: there is an R depending on (p, q) with $E^r_{p,q} = E^\infty_{p,q}$ and $E'^r_{p,q} = E'^\infty_{p,q}$ for $r \geq R$. Taking $r \geq \max(R, r_0)$ and applying Step 2 gives $f^\infty_{p,q}$ an isomorphism.

Step 4: Isomorphism on homology. Fix n. By theorem 60.2.6 the filtrations $F_\bullet H_n(C)$ and $F'_\bullet H_n(C')$ are finite, and f_* respects them. Proceed by induction up the filtration. The bottom stage is zero on both sides. If f_* is an isomorphism $F_{p-1}H_n(C) \to F'_{p-1}H_n(C')$, then in the

commutative diagram of short exact sequences

$$\begin{array}{ccccccccc} 0 & \longrightarrow & F_{p-1}H_n(C) & \longrightarrow & F_pH_n(C) & \longrightarrow & E^{\infty}_{p,n-p} & \longrightarrow & 0 \\ & & \downarrow & & \downarrow & & \downarrow & & \\ 0 & \longrightarrow & F'_{p-1}H_n(C') & \longrightarrow & F'_pH_n(C') & \longrightarrow & E'^{\infty}_{p,n-p} & \longrightarrow & 0 \end{array}$$

the outer vertical maps are isomorphisms, the left one by the inductive hypothesis and the right one by Step 3. Each row is already a five-term exact sequence, so lemma 56.1.20 applies directly, with the outer maps $0 \to 0$ trivially epi and mono, and forces the middle map to be an isomorphism. Since the filtration is finite and exhausts $H_n(C)$, finitely many steps give that $f_*\colon H_n(C) \to H_n(C')$ is an isomorphism, completing the proof.

A first application of the machinery, and the one that recurs in section 60.5, is the crudest filtration a complex carries: truncate it.

Example 60.2.10: The Stupid Filtration of a Cochain Complex

Let $(C^\bullet, d)$ be a cochain complex concentrated in degrees $0 \le n \le N$, and define the *stupid filtration* (the *filtration bête*) by

$$F^pC^n = \begin{cases} C^n & n \ge p \\ 0 & n < p \end{cases}$$

This is a decreasing filtration compatible with d, since d raises degree, and it is exhaustive and bounded because $F^0C^\bullet = C^\bullet$ and $F^{N+1}C^\bullet = 0$. The graded pieces are $\mathrm{gr}^p_F C^n = C^n$ if $n = p$ and 0 otherwise, so the zeroth page has a single nonzero entry in each column,

$$E_0^{p,q} = \begin{cases} C^p & q = 0 \\ 0 & q \neq 0 \end{cases}$$

The differential d_0 has bidegree $(0,1)$ and so runs between entries with q differing by one; every such pair has a zero member, so $d_0 = 0$ and $E_1 = E_0$. The differential d_1 has bidegree $(1,0)$ and is the map induced by d, namely $d\colon C^p \to C^{p+1}$. Hence

$$E_2^{p,q} = \begin{cases} H^p(C^\bullet) & q = 0 \\ 0 & q \neq 0 \end{cases}$$

and every later differential has target or source zero, so $E_2 = E_\infty$. By corollary 60.2.7 the sequence converges to $H^{p+q}(C^\bullet)$, and indeed the single surviving entry on the diagonal $p+q=n$ is $H^n(C^\bullet)$, with no extension problem. The stupid filtration therefore returns the cohomology of the complex and nothing more, which is the correct answer and a useful check on the indexing conventions. It becomes informative only when the entries C^p are themselves replaced by objects with cohomology of their own, which is what section 60.5 does.

Cochain complexes from topology and geometry often carry a product, as singular cochains do under the cup product and differential forms under the wedge product, and a filtration may be compatible with it.

Theorem 60.2.11: Multiplicative Structure on the Spectral Sequence of a Filtered DG Algebra

Let R be a commutative ring and (A, d) a *differential graded* (DG) R-algebra: a graded R-algebra $A = \bigoplus_n A^n$, associative with unit $1 \in A^0$, together with an R-linear map d of degree $+1$ satisfying $d \circ d = 0$ and

$$d(xy) = (dx)\, y + (-1)^m x\, (dy) \qquad (x \in A^m)$$

Let $A = F^0 A \supseteq F^1 A \supseteq \cdots$ be a decreasing filtration by subcomplexes which is multiplicative, $F^p A \cdot F^{p'} A \subseteq F^{p+p'} A$, and bounded in each degree: for each n there is a P with $F^P A^n = 0$, as happens when $F^p A^n = 0$ for all $p > n$. Let $\{(E_r, d_r)\}_{r \geq 0}$ be the spectral sequence of corollary 60.2.7. Then:

1. Each page carries an associative, unital, R-bilinear product
$$E_r^{p,q} \otimes_R E_r^{p',q'} \to E_r^{p+p',\, q+q'}$$
induced by the product of A on representatives, with unit the class of 1 in $E_r^{0,0}$.
2. Each differential is a derivation: for $x \in E_r^{p,q}$ and $y \in E_r$,
$$d_r(xy) = d_r(x)\, y + (-1)^{p+q}\, x\, d_r(y)$$
3. The isomorphism $E_{r+1} \cong H(E_r, d_r)$ is an isomorphism of bigraded algebras, where $H(E_r, d_r)$ carries the product induced by that of E_r.
4. The filtration $F^p H(A) = \operatorname{im}\big(H(F^p A) \to H(A)\big)$ makes $H(A)$ a filtered algebra, $F^p H(A) \cdot F^{p'} H(A) \subseteq F^{p+p'} H(A)$, and the isomorphism $E_\infty^{p,q} \cong F^p H^{p+q}(A) / F^{p+1} H^{p+q}(A)$ of corollary 60.2.7 is an isomorphism of bigraded algebras $E_\infty \cong \operatorname{gr} H(A)$, where E_∞ carries the product of E_r for large r.
5. If E_{r_0} is graded commutative, that is $xy = (-1)^{(p+q)(p'+q')}\, yx$ for $x \in E_{r_0}^{p,q}$ and $y \in E_{r_0}^{p',q'}$, then so are E_∞ and E_r for every $r \geq r_0$. This holds with $r_0 = 0$ if A is graded commutative, and with $r_0 = 1$ if A is graded commutative up to a homotopy preserving the filtration: an R-bilinear map h with $h(A^m \times A^{m'}) \subseteq A^{m+m'-1}$, $h(F^p A \times F^{p'} A) \subseteq F^{p+p'} A$ and
$$xy - (-1)^{mm'}\, yx = d\, h(x, y) + h(dx, y) + (-1)^m h(x, dy) \qquad (x \in A^m,\ y \in A^{m'})$$

***Proof*:**
Weibel [101] 5.4.8 gives (1) to (4) for chain complexes, checking the Leibniz rule on the zeroth page and appealing to 5.2.13 for the later pages.[a]

Set $F^p A = A$ for $p < 0$. With $p_+ = \max(p, 0)$, the inclusion $F^p A \cdot F^{p'} A \subseteq F^{p+p'} A$ then holds for all integers p and p', because $F^p A \cdot F^{p'} A = F^{p_+} A \cdot F^{p'_+} A \subseteq F^{p_+ + p'_+} A \subseteq F^{p+p'} A$. The same holds for h in (5). Write $n = p + q$ and $n' = p' + q'$, and for $s \geq -1$ set

$$Z_s^{p,q} = \{\, x \in F^p A^n \ :\ dx \in F^{p+s} A^{n+1} \,\}$$

which is all of F^pA^n for $s \le 0$ because d preserves the filtration, in agreement with the convention $Z_{-1}^{p,q} = F^pA^n$ of definition 60.2.3. Set

$$D_r^{p,q} = Z_{r-1}^{p+1,\,q-1} + d\,Z_{r-1}^{p-r+1,\,q+r-2}$$

whose second summand is $d\big(F^{p-r+1}A^{n-1}\big) \cap F^pA^n$. By proposition 60.2.4 in the cochain form of corollary 60.2.8, $E_r^{p,q} = Z_r^{p,q}/D_r^{p,q}$ for every $r \ge 0$, with $d_r[x] = [dx]$, and by Step 3 of the proof of proposition 60.2.4 the isomorphism $E_{r+1} \cong H(E_r, d_r)$ sends the class of $x \in Z_{r+1}^{p,q}$ to the class of $[x]$. Fix $x \in Z_r^{p,q}$ and $y \in Z_r^{p',q'}$.

Step 1: Products of approximate cycles. The product xy lies in $F^{p+p'}A^{n+n'}$, and

$$d(xy) = (dx)\,y + (-1)^n x\,(dy) \in F^{p+r}A \cdot F^{p'}A + F^pA \cdot F^{p'+r}A \subseteq F^{p+p'+r}A$$

so $xy \in Z_r^{p+p',\,q+q'}$.

Step 2: $D_r^{p,q} \cdot y$ and $x \cdot D_r^{p',q'}$ lie in $D_r^{p+p',q+q'}$. Let $z \in Z_{r-1}^{p+1,q-1}$. Then $zy \in F^{p+p'+1}A$, and $d(zy) = (dz)\,y + (-1)^n z\,(dy)$ lies in $F^{p+r}A \cdot F^{p'}A + F^{p+1}A \cdot F^{p'+r}A \subseteq F^{p+p'+r}A$, so $zy \in Z_{r-1}^{p+p'+1,\,q+q'-1}$. Next let $w \in F^{p-r+1}A^{n-1}$ with $dw \in F^pA^n$, so that dw is a general element of the second summand of $D_r^{p,q}$. The Leibniz rule gives

$$(dw)\,y = d(wy) + (-1)^n w\,(dy)$$

The element wy lies in $F^{p+p'-r+1}A^{n+n'-1}$, and $d(wy) = (dw)\,y - (-1)^n w\,(dy)$ lies in $F^{p+p'}A + F^{p+p'+1}A = F^{p+p'}A$, so $d(wy) \in d\,Z_{r-1}^{p+p'-r+1,\,q+q'+r-2}$. The element $w\,(dy)$ lies in $F^{p-r+1}A \cdot F^{p'+r}A \subseteq F^{p+p'+1}A$, and $d\big(w\,(dy)\big) = (dw)(dy)$ lies in $F^{p+p'+r}A$, so $w\,(dy) \in Z_{r-1}^{p+p'+1,\,q+q'-1}$. Hence $D_r^{p,q} \cdot y \subseteq D_r^{p+p',q+q'}$. The same estimates, applied to xz for $z \in Z_{r-1}^{p'+1,q'-1}$ and to the identity $x\,(dw) = (-1)^n\big(d(xw) - (dx)\,w\big)$ for $w \in F^{p'-r+1}A^{n'-1}$ with $dw \in F^{p'}A^{n'}$, give $x \cdot D_r^{p',q'} \subseteq D_r^{p+p',q+q'}$.

Step 3: Statements (1) and (2). By Steps 1 and 2, $(x + D_r^{p,q})(y + D_r^{p',q'}) \subseteq xy + D_r^{p+p',q+q'}$, so $[x][y] = [xy]$ is a well defined R-bilinear map $E_r^{p,q} \times E_r^{p',q'} \to E_r^{p+p',q+q'}$. It is associative because the product of A is. The unit 1 lies in $Z_r^{0,0}$, since $1 \in F^0A^0$ and $d1 = d(1 \cdot 1) = 2\,d1$ forces $d1 = 0$, and its class is a two-sided unit. This proves (1). For (2), $dx \in Z_r^{p+r,q-r+1}$ and $dy \in Z_r^{p'+r,q'-r+1}$, and

$$d_r\big([x][y]\big) = [d(xy)] = [(dx)\,y] + (-1)^n[x\,(dy)] = d_r[x]\,[y] + (-1)^{p+q}[x]\,d_r[y]$$

Step 4: Statement (3). By (2) the product of two d_r-cycles is a d_r-cycle, and for a d_r-cycle a of total degree m and any $c \in E_r$,

$$a\,d_r(c) = (-1)^m d_r(ac), \qquad d_r(c)\,a = d_r(ca)$$

So $\ker d_r$ is a bigraded subalgebra containing the unit, $\operatorname{im} d_r$ is a two-sided ideal of it, and $H(E_r, d_r)$ inherits the product $[a][b] = [ab]$. The isomorphism $E_{r+1} \to H(E_r, d_r)$ sends the class of $x \in Z_{r+1}^{p,q}$ to the class of $[x]$, so it sends the class of xy to the class of $[xy] = [x][y]$, which is

the product of the images. It also sends the unit to the unit, so it is an isomorphism of bigraded algebras.

Step 5: Statement (4). Write Z^n and B^n for the cocycles and coboundaries of A in degree n. The argument of Step 4, applied to d on A, shows that $Z = \bigoplus_n Z^n$ is a subalgebra and $B = \bigoplus_n B^n$ a two-sided ideal of it, so $H(A) = Z/B$ is a graded algebra. A class lies in $F^pH^n(A)$ exactly when it has a representative in $Z^n \cap F^pA^n$. Classes in $F^pH(A)$ and $F^{p'}H(A)$ therefore have representatives $\alpha \in Z \cap F^pA$ and $\beta \in Z \cap F^{p'}A$, and their product has the representative $\alpha\beta \in Z \cap F^{p+p'}A$. This proves $F^pH(A) \cdot F^{p'}H(A) \subseteq F^{p+p'}H(A)$, and $F^0H(A) = H(A)$ because $F^0A = A$. Consequently

$$\big(a + F^{p+1}H(A)\big)\big(b + F^{p'+1}H(A)\big) = ab + F^{p+p'+1}H(A) \qquad \big(a \in F^pH(A),\ b \in F^{p'}H(A)\big)$$

is a well defined bigraded product on $\mathrm{gr}H(A)$.

Fix (p, q) and take r with $F^{p+r}A^{n+1} = 0$ and $p - r + 1 \leq 0$, which holds for all large r by boundedness. Then $F^{p-r+1}A^{n-1} = A^{n-1}$, and the explicit description reads

$$Z_r^{p,q} = Z^n \cap F^pA^n, \qquad Z_{r-1}^{p+1,q-1} = Z^n \cap F^{p+1}A^n, \qquad d\,Z_{r-1}^{p-r+1,\,q+r-2} = B^n \cap F^pA^n$$

These do not depend on r, so for all such r the page $E_r^{p,q}$ is one fixed quotient of $Z^n \cap F^pA^n$, and that quotient is $E_\infty^{p,q}$. Take r this large for the three spots (p, q), (p', q') and $(p+p', q+q')$ at once. The product of E_r then sends the classes of cocycles $x \in Z^n \cap F^pA^n$ and $y \in Z^{n'} \cap F^{p'}A^{n'}$ to the class of xy, independently of r, and this is the product of E_∞. By Steps 2 and 3 of the proof of theorem 60.2.6, carried to cochains as in corollary 60.2.7, the isomorphism $E_\infty^{p,q} \cong \mathrm{gr}^pH^n(A)$ sends the class of x to $[x] + F^{p+1}H^n(A)$. It therefore sends the class of xy to $[xy] + F^{p+p'+1}H(A)$, which is the product of $[x] + F^{p+1}H(A)$ and $[y] + F^{p'+1}H(A)$ in $\mathrm{gr}H(A)$. It also sends 1 to 1, so $E_\infty \cong \mathrm{gr}H(A)$ as bigraded algebras.

Step 6: Statement (5). If E_r is graded commutative then so is $H(E_r, d_r)$, whose product is computed on representatives, and so is E_{r+1} by (3). Induction from r_0 covers every E_r with $r \geq r_0$, and E_∞ follows because its product is that of E_r for large r. If A is graded commutative then so is E_0, by (1). Suppose now that h is as in (5) and $r \geq 1$. Put $v = h(x, y)$ and $u = h(dx, y) + (-1)^n h(x, dy)$, so that $xy - (-1)^{nn'}yx = dv + u$. The element u lies in $F^{p+p'+r}A \subseteq F^{p+p'+1}A$, and $du = d(xy) - (-1)^{nn'}d(yx)$ lies in $F^{p+p'+r}A$ by Step 1, so $u \in Z_{r-1}^{p+p'+1,\,q+q'-1}$. The element v lies in $F^{p+p'}A^{n+n'-1} \subseteq F^{p+p'-r+1}A^{n+n'-1}$, and $dv = xy - (-1)^{nn'}yx - u$ lies in $F^{p+p'}A$, so $dv \in d\,Z_{r-1}^{p+p'-r+1,\,q+q'+r-2}$. Hence $xy - (-1)^{nn'}yx \in D_r^{p+p',q+q'}$, that is $[x][y] = (-1)^{nn'}[y][x]$ in E_r, and in particular E_1 is graded commutative, completing the proof.

[a] That appeal is not formal. The differential d_{r+1} is not determined by (E_r, d_r), so the Leibniz rule for d_r implies nothing about d_{r+1}. Step 3 below verifies it on every page from representatives in A.

Statement (2) is the one computations use: a derivation is determined by its values on a set of algebra generators, so on a page generated by a few classes the whole differential is fixed by its values on those classes.

Exercise 60.2.1

1. Let $(C_\bullet, F_\bullet)$ be a filtered complex whose filtration has exactly three nonzero stages, $0 = F_{-1} \subseteq F_0 \subseteq F_1 \subseteq F_2 = C_\bullet$. Show that $d_r = 0$ for $r \geq 3$, so that $E^3 = E^\infty$. Generalize to a filtration with N stages.

2. Show that the filtration induced on $H_n(C)$ in definition 60.2.1 is increasing, and that a morphism of filtered complexes $f\colon (C_\bullet, F_\bullet) \to (C'_\bullet, F'_\bullet)$ satisfies $f_*\big(F_pH_n(C)\big) \subseteq F'_pH_n(C')$. (This is the compatibility used in Step 4 of the proof of theorem 60.2.9.)

3. A spectral sequence *degenerates at* E^r if $d_s = 0$ for all $s \geq r$. Show that if the spectral sequence of a bounded filtered complex degenerates at E^1, then for every n the object $H_n(C)$ has a finite filtration with graded pieces $H_n(\mathrm{gr}_pC)$. Show by example that this does not force $H_n(C) \cong \bigoplus_p H_n(\mathrm{gr}_pC)$.

4. Verify proposition 60.2.4 directly at $r = 1$ by computing both sides for the filtered complex of example 60.1.9, and confirm that the differential induced by ∂ is the map computed there.

5. Let $f\colon (C_\bullet, F_\bullet) \to (C'_\bullet, F'_\bullet)$ be a morphism of bounded filtered complexes which is an isomorphism on E^2 but not on E^1. Show that f_* is still an isomorphism on homology, and construct such an f with $E^1 \neq E'^1$.

60.3 The Two Spectral Sequences of a Double Complex

A double complex carries two filtrations of its total complex, one by columns and one by rows, and section 60.2 converts each into a spectral sequence. Both converge to the homology of the same total complex, and that coincidence is the source of most of the identifications homological algebra makes: whenever one filtration degenerates for an easy reason and the other computes something of interest, the two are forced to agree. Section 56.5 promised this machinery twice, once for the cohomology of double complexes and once for the balancing of Tor and Ext, and this section delivers both.

Throughout, $A = \{A_{p,q}\}$ is a double complex in the sense of definition 56.5.1, with horizontal differential $d^h\colon A_{p,q} \to A_{p-1,q}$ and vertical differential $\delta^v\colon A_{p,q} \to A_{p,q-1}$ satisfying $d^hd^h = 0$, $\delta^v\delta^v = 0$ and $d^h\delta^v + \delta^vd^h = 0$. The total complex is $\mathrm{Tot}(A)_n = \bigoplus_{p+q=n} A_{p,q}$ with differential $d = d^h + \delta^v$, as in proposition 56.5.2; anticommutativity is exactly what makes $d \circ d = 0$. Write

$$H^h_p(A)_\bullet, \qquad H^v_q(A)_\bullet$$

for the homology of the rows and of the columns respectively, each of which is again a complex under the differential the other direction induces.

Definition 60.3.1: The Column and Row Filtrations

Let A be a double complex. The *column filtration* and the *row filtration* of $\mathrm{Tot}(A)$ are

$$^{\mathrm{I}}F_p\mathrm{Tot}(A)_n = \bigoplus_{\substack{p'+q'=n \\ p' \leq p}} A_{p',q'}, \qquad ^{\mathrm{II}}F_p\mathrm{Tot}(A)_n = \bigoplus_{\substack{p'+q'=n \\ q' \leq p}} A_{p',q'}$$

The double complex is *first-quadrant* if $A_{p,q} = 0$ whenever $p < 0$ or $q < 0$.

Both are filtrations by subcomplexes, and for the reason that each differential moves in only one of

the two directions: d^h lowers p' and leaves q' unchanged, while δ^v lowers q' and leaves p' unchanged. So d carries ${}^{\mathrm{I}}F_p$ into itself, and likewise for ${}^{\mathrm{II}}F_p$. The two differ only in which coordinate is being watched, which is why the same total complex acquires two different, and generally inequivalent, approximations to its homology.

Theorem 60.3.2: The Two Spectral Sequences of a Double Complex

Let A be a first-quadrant double complex. Then the column and row filtrations of $\mathrm{Tot}(A)$ give two spectral sequences, both converging to $H_\bullet(\mathrm{Tot}(A))$, with second pages

$$ {}^{\mathrm{I}}E^2_{p,q} = H^h_p\big(H^v_q(A)\big) \implies H_{p+q}(\mathrm{Tot}(A)) $$

$$ {}^{\mathrm{II}}E^2_{p,q} = H^v_p\big(H^h_q(A)\big) \implies H_{p+q}(\mathrm{Tot}(A)) $$

***Proof*:**

Step 1: Boundedness. Fix n. Since A is first-quadrant, $A_{p',q'} = 0$ unless $0 \le p' \le n$ on the diagonal $p' + q' = n$. Hence ${}^{\mathrm{I}}F_{-1}\mathrm{Tot}(A)_n = 0$ and ${}^{\mathrm{I}}F_n\mathrm{Tot}(A)_n = \mathrm{Tot}(A)_n$, so the column filtration is bounded in the sense of definition 60.2.1; the same argument applies to the row filtration. Theorem 60.2.6 therefore applies to each and gives convergence to $H_\bullet(\mathrm{Tot}(A))$ once the pages are identified.

Step 2: The zeroth and first pages of the column filtration. By definition 60.2.1 the graded piece is

$$ \mathrm{gr}_p\mathrm{Tot}(A)_n = \frac{{}^{\mathrm{I}}F_p\mathrm{Tot}(A)_n}{{}^{\mathrm{I}}F_{p-1}\mathrm{Tot}(A)_n} = A_{p,\,n-p} $$

so ${}^{\mathrm{I}}E^0_{p,q} = A_{p,q}$. The induced differential is the part of $d = d^h + \delta^v$ that preserves the filtration index p. The summand d^h lowers p, so it vanishes on the graded piece; the summand δ^v preserves p. Hence $d^0 = \delta^v$ and

$$ {}^{\mathrm{I}}E^1_{p,q} = H_q\big(A_{p,\bullet},\, \delta^v\big) = H^v_q(A)_p $$

the homology of the p-th column.

Step 3: The second page of the column filtration. By theorem 60.2.2 the differential d^1 has bidegree $(-1, 0)$, so it runs ${}^{\mathrm{I}}E^1_{p,q} \to {}^{\mathrm{I}}E^1_{p-1,q}$; by proposition 60.2.4 it is induced by the differential of $\mathrm{Tot}(A)$ on representatives. A representative of a class in ${}^{\mathrm{I}}E^1_{p,q}$ is an element of $A_{p,q}$ killed by δ^v, and applying $d = d^h + \delta^v$ to it gives d^h of it, an element of $A_{p-1,q}$. So d^1 is the map induced by d^h on vertical homology, and

$$ {}^{\mathrm{I}}E^2_{p,q} = H_p\big(H^v_q(A)_\bullet,\, d^h\big) = H^h_p\big(H^v_q(A)\big) $$

Step 4: The row filtration. The argument is identical with the two coordinates exchanged. The graded piece of the row filtration at index p in total degree n is $A_{n-p,\,p}$, so ${}^{\mathrm{II}}E^0_{p,q} = A_{q,p}$, and the differential preserving the index p is now d^h. Hence ${}^{\mathrm{II}}E^1_{p,q} = H_q(A_{\bullet,p}, d^h) = H^h_q(A)_p$, and the next differential is induced by δ^v, giving ${}^{\mathrm{II}}E^2_{p,q} = H^v_p(H^h_q(A))$. Both converge to the homology of the same total complex by Step 1, completing the proof.

The two sequences are not related by any map; they are two different routes to one answer, and the content of the theorem is that the answer is the same. The standard way to exploit this is to arrange for one of them to collapse. A double complex whose columns are exact except in one spot, for instance, has a first page concentrated in a single row, and then every differential from the second page onward has a zero source or a zero target.

Lemma 60.3.3: Collapse Along a Single Row

Let $\{(E^r, d_r)\}$ be a spectral sequence with $E^2_{p,q} = 0$ for all $q \neq 0$. Then $E^2 = E^\infty$, and if the sequence converges to $H_\bullet$ then $H_n \cong E^2_{n,0}$ for every n.

***Proof*:**
The differential d_r has bidegree $(-r, r-1)$ by theorem 60.1.7. For $r \geq 2$ the differential out of the spot $(p, 0)$ lands in $(p-r,\, r-1)$, which has second index $r-1 \geq 1$ and so vanishes; the differential into $(p, 0)$ comes from $(p+r,\, 1-r)$, which has negative second index and so vanishes. Every other spot is already zero. Hence $d_r = 0$ for all $r \geq 2$ and $E^2 = E^\infty$.

For the abutment, the diagonal $p + q = n$ of the limit page contains the single nonzero group $E^\infty_{n,0}$. By definition 60.2.5 the filtration of H_n is bounded and has these as graded pieces; a bounded filtration whose graded pieces vanish outside one step has exactly one nonzero step, so $H_n \cong E^\infty_{n,0} = E^2_{n,0}$, as we sought to show.

Both results are used in section 60.4 and section 60.5 for cochain double complexes, whose differentials raise indices. As with corollary 60.2.8, the translation is recorded once.

Corollary 60.3.4: The Cochain Form of the Double-Complex Sequences

Let $A^{\bullet,\bullet}$ be a cochain double complex concentrated in non-negative bidegrees, with differentials raising the two indices. Then the column and row filtrations of $\mathrm{Tot}(A)$ give two spectral sequences converging to $H^{p+q}(\mathrm{Tot}(A))$, with second pages

$$ {}^{\mathrm{I}}E_2^{p,q} = H_h^p\big(H_v^q(A)\big), \qquad {}^{\mathrm{II}}E_2^{p,q} = H_v^p\big(H_h^q(A)\big) $$

and lemma 60.3.3 holds in the form: if $E_2^{p,q} = 0$ for all $q \neq 0$ then $E_2 = E_\infty$ and $H^n \cong E_2^{n,0}$; symmetrically if $E_2^{p,q} = 0$ for all $p \neq 0$ then $H^n \cong E_2^{0,n}$.

***Proof*:**
Apply the translation $\mathcal{T}$ of corollary 60.2.8 in both indices, setting $A_{p,q} = A^{-p,-q}$. This turns a cochain double complex concentrated in non-negative bidegrees into a chain double complex concentrated in non-positive ones, which is bounded on diagonals in the sense of exercise 60.3.1 (5); theorem 60.3.2 and lemma 60.3.3 apply to it, and negating every index returns the displayed statements. The column form of the collapse is exercise 60.3.1 (4), translated the same way, completing the proof.

The lemma turns theorem 60.3.2 into an identification technique, and the standard application is the one section 56.5 deferred: that Tor may be computed by resolving either variable.

Corollary 60.3.5: Balancing Tor

Let R be a ring, M a right R-module and N a left R-module, and let $P_\bullet \to M$ and $Q_\bullet \to N$ be projective resolutions. Then

$$H_n\big(P_\bullet \otimes_R N\big) \cong H_n\big(\mathrm{Tot}(P_\bullet \otimes_R Q_\bullet)\big) \cong H_n\big(M \otimes_R Q_\bullet\big)$$

for every n. In particular $\mathrm{Tor}_n^R(M,N)$ may be computed by resolving either variable, recovering the Tor half of theorem 56.5.8 as the degenerate case of theorem 60.3.2.

***Proof*:**
Let $A_{p,q} = P_p \otimes_R Q_q$, with horizontal differential induced by that of $P_\bullet$ and vertical differential induced by that of $Q_\bullet$, the latter twisted by the sign $(-1)^p$ so that the two anticommute as definition 56.5.1 requires. Both resolutions are supported in non-negative degrees, so A is first-quadrant and theorem 60.3.2 applies.

Step 1: The column filtration. Each P_p is projective, hence a direct summand of a free module, hence flat, so the functor $P_p \otimes_R -$ is exact. Therefore it commutes with homology and

$${}^{\mathrm{I}}E^1_{p,q} = H_q\big(P_p \otimes_R Q_\bullet\big) \cong P_p \otimes_R H_q(Q_\bullet)$$

Since $Q_\bullet \to N$ is a resolution, $H_q(Q_\bullet)$ is N for $q = 0$ and zero otherwise. So the first page is concentrated in the row $q = 0$, where it is $P_p \otimes_R N$, and the second page is

$${}^{\mathrm{I}}E^2_{p,0} = H_p\big(P_\bullet \otimes_R N\big)$$

with ${}^{\mathrm{I}}E^2_{p,q} = 0$ for $q \neq 0$. By lemma 60.3.3, $H_n(\mathrm{Tot}(A)) \cong H_n(P_\bullet \otimes_R N)$.

Step 2: The row filtration. Symmetrically, each Q_q is flat, so ${}^{\mathrm{II}}E^1_{p,q} = H_q(P_\bullet \otimes_R Q_p) \cong H_q(P_\bullet) \otimes_R Q_p$, which is $M \otimes_R Q_p$ for $q = 0$ and zero otherwise. Hence ${}^{\mathrm{II}}E^2_{p,0} = H_p(M \otimes_R Q_\bullet)$ with the other rows zero, and lemma 60.3.3 gives $H_n(\mathrm{Tot}(A)) \cong H_n(M \otimes_R Q_\bullet)$.

Both computations describe the homology of the same total complex, so the two are isomorphic, completing the proof.

The argument is worth contrasting with the one given in section 56.5. There the comparison was made by hand, through an explicit quasi-isomorphism between the total complex and each of its edges. Here it is a two-line consequence of a general theorem, and the same two lines apply verbatim to Ext, to group cohomology, and to any other derived functor of a bifunctor. That is the characteristic economy of the method: the work moves once into theorem 60.2.6 and is then reused without repetition.

Exercise 60.3.1

1. Let A be a first-quadrant double complex all of whose columns are exact. Show that $\mathrm{Tot}(A)$ is acyclic. Deduce proposition 56.5.4 for first-quadrant double complexes.

2. State and prove the analogue of corollary 60.3.5 for Ext, using a projective resolution of M and an injective resolution of N. Identify which functor plays the role of $P_p \otimes_R -$ in Step 1, and which exactness property replaces flatness.

3. Let A be the first-quadrant double complex with $A_{0,0} = A_{1,0} = \mathbb{Z}$, $A_{0,1} = A_{1,1} = \mathbb{Z}$, horizontal differentials the identity, and vertical differentials the identity, with the sign twist making it anticommute. Compute both spectral sequences and $H_\bullet(\mathrm{Tot}(A))$, and check that the two agree.

4. Show that a spectral sequence with $E^2_{p,q} = 0$ for all $p \neq 0$ also collapses, and that $H_n \cong E^2_{0,n}$. (No quadrant hypothesis is needed.) (This is the column analogue of lemma 60.3.3.)

5. The first-quadrant hypothesis in theorem 60.3.2 is used in exactly one place. Identify it, and show that the theorem still holds for any double complex that is *bounded on diagonals*, meaning that for each n only finitely many $A_{p,q}$ with $p+q=n$ are nonzero. Then show that a double complex with $A_{p,q} \neq 0$ for every $p, q \in \mathbb{Z}$ fails this condition, so that theorem 60.2.6 does not apply to either filtration.

60.4 The Grothendieck Spectral Sequence

Derived functors were built in section 56.3 one functor at a time. In practice a functor of interest is often a composite: global sections of a sheaf factor through pushforward along a map, invariants under a group factor through invariants under a normal subgroup, and global Hom factors through sheaf Hom. In each case the derived functors of the two factors are understood and the derived functors of the composite are what is wanted. The relation between them is not an equality, and it is not captured by any exact sequence; it is a spectral sequence, and it is the form in which the machinery of this chapter is most often used elsewhere in the series.

The construction needs one tool beyond section 60.3: a way to resolve a whole complex, rather than a single object, by injectives, in a manner compatible with the complex's own cohomology. That is the Cartan-Eilenberg resolution, and it is built by applying the horseshoe lemma twice.

Definition 60.4.1: Cartan-Eilenberg Resolution

Let $\mathcal{A}$ be an abelian category with enough injectives and $C^\bullet$ a cochain complex in $\mathcal{A}$ bounded below. A *Cartan-Eilenberg resolution* of $C^\bullet$ is a double complex $I^{\bullet,\bullet}$ of injective objects, bounded below, together with an augmentation $C^p \to I^{p,0}$ for each p, such that for every p the induced augmentations make each of

$$I^{p,\bullet}, \qquad B^p\big(I^{\bullet,\bullet}\big), \qquad Z^p\big(I^{\bullet,\bullet}\big), \qquad H^p\big(I^{\bullet,\bullet}\big)$$

an injective resolution of C^p, of $B^p(C^\bullet)$, of $Z^p(C^\bullet)$ and of $H^p(C^\bullet)$ respectively, where B^p, Z^p and H^p are taken in the first (horizontal) direction.

The three extra conditions are what make the resolution usable: without them a levelwise injective resolution of each C^p carries no information about the cohomology of $C^\bullet$, and the whole point is that the resolution should compute that cohomology as well as the individual terms.

Theorem 60.4.2: Existence of Cartan-Eilenberg Resolutions

Every bounded-below cochain complex in an abelian category with enough injectives admits a Cartan-Eilenberg resolution.

***Proof*:**

Step 1: Choices. For each p, use that $\mathcal{A}$ has enough injectives (definition 56.2.3) to choose injective resolutions

$$B^p(C^\bullet) \to \mathcal{B}^{p,\bullet}, \qquad H^p(C^\bullet) \to \mathcal{H}^{p,\bullet}$$

Since $C^\bullet$ is bounded below, so are all of these.

Step 2: Resolving the cycles. The definition of cohomology gives a short exact sequence

$$0 \to B^p(C^\bullet) \to Z^p(C^\bullet) \to H^p(C^\bullet) \to 0$$

Its two ends are already resolved by Step 1, so the horseshoe lemma (lemma 56.3.7), in its injective form, produces an injective resolution $Z^p(C^\bullet) \to \mathcal{Z}^{p,\bullet}$ fitting into a degreewise split short exact sequence of complexes $0 \to \mathcal{B}^{p,\bullet} \to \mathcal{Z}^{p,\bullet} \to \mathcal{H}^{p,\bullet} \to 0$.

Step 3: Resolving the terms. The complex $C^\bullet$ also gives, for each p, a short exact sequence

$$0 \to Z^p(C^\bullet) \to C^p \to B^{p+1}(C^\bullet) \to 0$$

whose outer terms are resolved by $\mathcal{Z}^{p,\bullet}$ from Step 2 and $\mathcal{B}^{p+1,\bullet}$ from Step 1. Applying lemma 56.3.7 again yields an injective resolution $C^p \to I^{p,\bullet}$ with $I^{p,q} \cong \mathcal{Z}^{p,q} \oplus \mathcal{B}^{p+1,q}$ in each degree, compatibly with the two inclusions.

Step 4: The horizontal differential. Define $I^{p,q} \to I^{p+1,q}$ as the composite

$$I^{p,q} \twoheadrightarrow \mathcal{B}^{p+1,q} \hookrightarrow \mathcal{Z}^{p+1,q} \hookrightarrow I^{p+1,q}$$

using the splitting of Step 3 for the first map and the inclusion of Step 2 for the second. The composite of two consecutive such maps is zero, because the image of the first lands in $\mathcal{Z}^{p+1,q}$, which the projection to $\mathcal{B}^{p+2,q}$ annihilates. So $I^{\bullet,\bullet}$ is a double complex of injectives, after the usual sign twist making the two differentials anticommute as definition 56.5.1 requires.

Step 5: The conditions hold. By construction $I^{p,\bullet}$ is an injective resolution of C^p, which is the first condition. By Step 4 the horizontal cycles are $Z^p(I^{\bullet,q}) = \mathcal{Z}^{p,q}$ and the horizontal boundaries are $B^p(I^{\bullet,q}) = \mathcal{B}^{p,q}$, which are injective resolutions of $Z^p(C^\bullet)$ and $B^p(C^\bullet)$ by Steps 2 and 1. The quotient $\mathcal{Z}^{p,q}/\mathcal{B}^{p,q} \cong \mathcal{H}^{p,q}$ is an injective resolution of $H^p(C^\bullet)$ by Step 1 and the splitting of Step 2. The augmentations are compatible with the horizontal differential by construction, since d^h was defined through the factorization $C^p \twoheadrightarrow B^{p+1} \hookrightarrow Z^{p+1} \hookrightarrow C^{p+1}$ that the differential of $C^\bullet$ itself factors through. All four conditions of definition 60.4.1 hold, completing the proof.

Existence is only half of what the resolution is used for. The spectral sequences built from it in section 60.4 and section 60.5 are asserted to be natural, and proposition 60.5.2 compares the

resolutions of two different complexes; both need to know that a morphism of complexes lifts to the resolutions. The object-level comparison theorem (lemma 56.2.13 and its dual) does not give this, since a Cartan-Eilenberg resolution is constrained not only degreewise but also on cycles, boundaries and cohomology. The lift has to be built through the same two horseshoes that produced the resolution, and the functoriality of that construction, lemma 56.3.8, is what the proof below uses at each of them.

Theorem 60.4.3: Comparison Theorem for Cartan-Eilenberg Resolutions

Let $f^\bullet\colon C^\bullet \to \widetilde{C}^\bullet$ be a morphism of bounded-below cochain complexes in an abelian category with enough injectives, and let $J^{\bullet,\bullet}$ and $\widetilde{J}^{\bullet,\bullet}$ be Cartan-Eilenberg resolutions of $C^\bullet$ and $\widetilde{C}^\bullet$. Then $f^\bullet$ lifts to a morphism of double complexes

$$\tilde{f}^{\bullet,\bullet}\colon J^{\bullet,\bullet} \to \widetilde{J}^{\bullet,\bullet}$$

compatible with the augmentations, and any two such lifts are homotopic. Consequently the induced maps on Z^p, B^p and H^p in the horizontal direction are the resolutions of $Z^p(f)$, $B^p(f)$ and $H^p(f)$.

***Proof*:**

Step 1: Lifts on the building blocks. The morphism $f^\bullet$ induces $B^p(f)\colon B^p(C^\bullet) \to B^p(\widetilde{C}^\bullet)$ and $H^p(f)\colon H^p(C^\bullet) \to H^p(\widetilde{C}^\bullet)$ for every p. By definition 60.4.1 the objects $\mathcal{B}^{p,\bullet}$ and $\mathcal{H}^{p,\bullet}$ occurring in J are injective resolutions of $B^p(C^\bullet)$ and $H^p(C^\bullet)$, and likewise for $\widetilde{J}$. The dual of lemma 56.2.13 therefore lifts $B^p(f)$ and $H^p(f)$ to morphisms of those resolutions, each unique up to homotopy.

Step 2: Lifts on cycles. Apply lemma 56.3.8 to the morphism of short exact sequences

$$\big(0 \to B^p(C) \to Z^p(C) \to H^p(C) \to 0\big) \longrightarrow \big(0 \to B^p(\widetilde{C}) \to Z^p(\widetilde{C}) \to H^p(\widetilde{C}) \to 0\big)$$

induced by $f^\bullet$, with the lifts of Step 1 on the two ends. This produces a lift $\mathcal{Z}^{p,\bullet} \to \widetilde{\mathcal{Z}}^{p,\bullet}$ of $Z^p(f)$.

Step 3: Lifts on the terms. Apply lemma 56.3.8 again, now to

$$\big(0 \to Z^p(C) \to C^p \to B^{p+1}(C) \to 0\big) \longrightarrow \big(0 \to Z^p(\widetilde{C}) \to \widetilde{C}^p \to B^{p+1}(\widetilde{C}) \to 0\big)$$

with the lift of Step 2 on the left end and that of Step 1 on the right. This produces $\tilde{f}^{p,\bullet}\colon J^{p,\bullet} \to \widetilde{J}^{p,\bullet}$ lifting f^p.

Step 4: Compatibility with the horizontal differential. For any Cartan-Eilenberg resolution the horizontal differential factors as $J^{p,q} \twoheadrightarrow \mathcal{B}^{p+1,q} \hookrightarrow \mathcal{Z}^{p+1,q} \hookrightarrow J^{p+1,q}$: it factors through its image $\mathcal{B}^{p+1,q}$ by definition, and that image lies in $\mathcal{Z}^{p+1,q}$ because $d^h \circ d^h = 0$. Each of the three maps is respected by the lifts of Steps 1 to 3, the projection and the two inclusions being the structure maps of the splittings. Hence $\tilde{f}^{\bullet,\bullet}$ commutes with d^h, and it commutes with d^v because each $\tilde{f}^{p,\bullet}$ is a morphism of resolutions. So it is a morphism of double complexes.

Step 5: Uniqueness up to homotopy. Let $\tilde{f}$ and $\tilde{g}$ both lift $f^\bullet$. In each column their difference lifts the zero morphism $C^p \to \widetilde{C}^p$, so by the dual of lemma 56.2.4 it is null-homotopic: there are $s^{p,\bullet}$ with $d^v s + s d^v = \tilde{f} - \tilde{g}$ in each column.

Producing a homotopy of *double* complexes, that is one which additionally satisfies $s d^h = d^h s$, requires choosing those column homotopies compatibly. This is a third induction of the same shape as lemma 56.3.8: choose null-homotopies on $\mathcal{B}^{p,\bullet}$ and $\mathcal{H}^{p,\bullet}$ by the object-level uniqueness of Step 1, extend over the first horseshoe to $\mathcal{Z}^{p,\bullet}$ by an obstruction computation of the same shape as the one for θ^q, and extend again over the second to $J^{p,\bullet}$. The bookkeeping is routine and carries no idea not already in lemma 56.3.8, so it is not repeated; it is carried out in *An Introduction to Homological Algebra* [101].

For the final clause, let $\tilde{f}$ be any lift. Its restriction to horizontal cocycles, coboundaries and cohomology is determined by its compatibility with the augmentations, since those subquotients are computed from d^h and $\tilde{f}$ commutes with d^h by Step 4; so on H^p it is a lift of $H^p(f)$, whether or not it is the one built in Steps 1 to 3. This completes the proof.

With the tool in hand, the theorem itself is a two-filtration argument of exactly the kind section 60.3 was written for. The hypothesis to watch is the one relating the two functors: the first must carry injectives to objects on which the second's higher derived functors vanish.

Definition 60.4.4: Acyclic for a Left-Exact Functor

Let $G\colon \mathcal{B} \to \mathcal{C}$ be a left-exact additive functor between abelian categories. An object B of $\mathcal{B}$ is *G-acyclic* if $R^i G(B) = 0$ for all $i \geq 1$. This is the right-derived counterpart of definition 56.3.14. Injective objects are G-acyclic for every left-exact G, since an injective I has $0 \to I \to I \to 0$ as an injective resolution; and a resolution by G-acyclic objects computes $R^\bullet G$. The latter is the dual of theorem 56.3.16, which is stated there for right-exact functors and left-derived functors; the statement needed here is its image under passage to the opposite categories, where projectives become injectives and $\mathbf{L}_i$ becomes R^i.

Theorem 60.4.5: The Grothendieck Spectral Sequence

Let $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$ be abelian categories with $\mathcal{A}$ and $\mathcal{B}$ having enough injectives, and let

$$F\colon \mathcal{A} \to \mathcal{B}, \qquad G\colon \mathcal{B} \to \mathcal{C}$$

be left-exact additive functors. Suppose F carries injective objects of $\mathcal{A}$ to G-acyclic objects of $\mathcal{B}$. Then for every object A of $\mathcal{A}$ there is a first-quadrant cohomological spectral sequence, natural in A,

$$E_2^{p,q} = R^p G\big(R^q F(A)\big) \implies R^{p+q}(G \circ F)(A)$$

***Proof*:**

Step 1: Setup. Choose an injective resolution $A \to I^\bullet$ in $\mathcal{A}$. Then $R^q F(A) = H^q(F(I^\bullet))$ by definition of the right-derived functors (definition 56.3.1 in its dual form). The complex $F(I^\bullet)$ is bounded below, so by theorem 60.4.2 it admits a Cartan-Eilenberg resolution $J^{\bullet,\bullet}$. Apply G to

obtain a first-quadrant double complex $G(J^{\bullet,\bullet})$ in $\mathcal{C}$, and consider the two spectral sequences of corollary 60.3.4 converging to $H^\bullet(\mathrm{Tot}(G(J^{\bullet,\bullet})))$.

Step 2: The filtration that collapses. Take first the filtration whose first page is obtained by computing cohomology in the resolution direction. For each fixed p, the complex $J^{p,\bullet}$ is an injective resolution of $F(I^p)$, so

$$H^q\big(G(J^{p,\bullet})\big) = R^qG\big(F(I^p)\big)$$

By hypothesis I^p is injective and F carries injectives to G-acyclics, so $F(I^p)$ is G-acyclic and this vanishes for $q \geq 1$, leaving $G(F(I^p))$ when $q = 0$. Hence this first page is concentrated in the single row $q = 0$, where it is the complex $G(F(I^\bullet))$, and its second page is

$$H^p\big(GF(I^\bullet)\big) = R^p(G \circ F)(A)$$

the last equality because $I^\bullet$ is an injective resolution of A. By corollary 60.3.4,

$$H^n\big(\mathrm{Tot}(G(J^{\bullet,\bullet}))\big) \cong R^n(G \circ F)(A)$$

Step 3: The filtration that computes. Take now the other filtration, whose first page is the cohomology in the p direction. Because $J^{\bullet,\bullet}$ is a Cartan-Eilenberg resolution, the horizontal cocycles, coboundaries and cohomology are injective resolutions of those of $F(I^\bullet)$. The short exact sequences relating them therefore have injective outer terms in each degree, hence are degreewise split, exactly as spelled out in Step 2 of theorem 60.5.3. A functor preserves split exactness, so applying G commutes with taking horizontal cohomology:

$$H^p\big(G(J^{\bullet,q})\big) \cong G\big(H^p(J^{\bullet,q})\big)$$

By definition 60.4.1 the complex $H^a(J^{\bullet,\bullet})$ is an injective resolution of $H^a(F(I^\bullet)) = R^aF(A)$, where a denotes the degree in $F(I^\bullet)$ and the resolution degree is the remaining direction. This is the row filtration of corollary 60.3.4, whose index swap makes the filtration index, here the resolution degree, the *first* spectral index. Writing p for that resolution degree and q for a, taking cohomology in the resolution direction therefore gives

$$E_2^{p,q} = R^pG\big(R^qF(A)\big)$$

Step 4: Conclusion. Both spectral sequences converge to the cohomology of the same total complex by corollary 60.3.4. Step 2 identifies that cohomology as $R^n(G \circ F)(A)$ and Step 3 identifies the second page of the other as $R^pG(R^qF(A))$, giving

$$E_2^{p,q} = R^pG\big(R^qF(A)\big) \implies R^{p+q}(G \circ F)(A)$$

For naturality in A, let $a\colon A \to A'$ be a morphism. The dual of lemma 56.2.13 lifts it to a morphism of injective resolutions $I^\bullet \to I'^\bullet$, unique up to homotopy; applying F gives a morphism $F(I^\bullet) \to F(I'^\bullet)$, and theorem 60.4.3 lifts that to a morphism of the chosen Cartan-Eilenberg resolutions, again unique up to homotopy. Applying G and totalizing yields a morphism of filtered complexes, hence a morphism of spectral sequences by Step 1 of theorem 60.2.9. Homotopic lifts induce the same map on E_r for every $r \geq 2$. This needs an argument, because the homotopy

has bidegree $(0,-1)$ and the filtration in play is by resolution degree, so it does *not* preserve the filtration: it lowers it by one. The standard filtration-shift estimate covers the gap. For a class represented by $x \in Z_r^p$, the two totalized lifts differ by $Ds(x) + s(Dx)$, where s is the totalized homotopy and D the total differential; here $s(x) \in F^{p-1}$ so $Ds(x) \in dF^{p-1}$, which dies in E_r for $r \geq 2$, and $Dx \in F^{p+r}$ so $s(Dx) \in F^{p+r-1}$, which also dies in E_r for $r \geq 2$. Hence the morphism of spectral sequences from page two onward depends only on a, which is all the naturality statement asserts. This completes the proof.

The shape of the conclusion deserves comment, because it is easy to misread. The spectral sequence does not say that $R^n(GF)$ is built from the groups $R^pG(R^qF)$ by any simple rule; it says there is a filtration of $R^n(GF)(A)$ whose graded pieces are subquotients of those groups, obtained after running the differentials. Only in the corners is the information immediate, and the standard exact sequence extracted from those corners is the following, which is how the theorem is most often applied in low degrees.

Nothing in that extraction uses where the spectral sequence came from. It uses only that the sequence is first-quadrant and converges, so it is worth recording at that generality: the same five terms appear for the spectral sequence of a double complex, or of any filtered complex meeting the hypotheses of corollary 60.2.7, and that is the form in which it is applied outside this book.

Both maps at the ends of that sequence are instances of a general construction, and in applications they are identified with concrete maps. In a first-quadrant spectral sequence the corner spots $(p,0)$ and $(0,q)$ each meet the abutment in only one way.

Proposition 60.4.6: Edge Morphisms

Let $E_2^{p,q} \Rightarrow H^{p+q}$ be a first-quadrant cohomological spectral sequence converging in the sense of definition 60.2.5. Then for every $p, q \geq 0$ there are canonical morphisms

$$E_2^{p,0} \longrightarrow H^p, \qquad H^q \longrightarrow E_2^{0,q}$$

called the *edge morphisms*, given respectively by the composites

$$E_2^{p,0} \twoheadrightarrow E_\infty^{p,0} = F^pH^p \hookrightarrow H^p, \qquad H^q \twoheadrightarrow H^q/F^1H^q = E_\infty^{0,q} \hookrightarrow E_2^{0,q}$$

They are natural in the spectral sequence.
For the Grothendieck spectral sequence of theorem 60.4.5 the two edge morphisms are the natural maps

$$R^pG\big(F(A)\big) \longrightarrow R^p(G \circ F)(A), \qquad R^q(G \circ F)(A) \longrightarrow G\big(R^qF(A)\big)$$

***Proof*:**
Step 1: The two composites are defined. Fix p. Every differential out of $(p,0)$ lands in $(p+r, 1-r)$, which has negative second index for $r \geq 2$, and every differential into it comes from $(p-r, r-1)$, which has negative first index once $r > p$. So $E_\infty^{p,0}$ is a quotient of $E_2^{p,0}$, the successive pages being obtained by killing images. The filtration of H^p is finite with $F^{p+1}H^p = 0$, because $E_\infty^{a,b} = 0$ for $a > p$ on the diagonal $a + b = p$ by first-quadrantness, so $E_\infty^{p,0} = F^pH^p/F^{p+1}H^p = F^pH^p$, a subobject of H^p. Composing gives the first morphism.

Dually, every differential into $(0,q)$ comes from $(-r, q+r-1)$, which has negative first index, so $E_\infty^{0,q}$ is a subobject of $E_2^{0,q}$, obtained by taking successive kernels. And $E_\infty^{0,q} = F^0H^q/F^1H^q = H^q/F^1H^q$, since $F^0H^q = H^q$ by exhaustiveness. Composing gives the second morphism.

Step 2: Naturality. A morphism of spectral sequences compatible with the abutments respects the pages, hence the successive kernels and images defining E_∞, and respects the filtration of the abutment. Each edge morphism is built only from those data, so the two squares commute.

Step 3: The Grothendieck case. Substituting $E_2^{p,q} = R^pG(R^qF(A))$ and $H^n = R^n(G\circ F)(A)$ gives $E_2^{p,0} = R^pG(R^0F(A)) = R^pG(F(A))$, since $R^0F = F$ by left exactness of F, and $E_2^{0,q} = R^0G(R^qF(A)) = G(R^qF(A))$ likewise. So the two edge morphisms take the displayed shape. That they are the *natural* maps, that is the ones induced by the comparison of an injective resolution of A with a Cartan-Eilenberg resolution of F applied to it, is Step 2 together with the naturality of theorem 60.4.5, completing the proof.

Proposition 60.4.7: The Five-Term Exact Sequence of a First-Quadrant Spectral Sequence

Let $E_2^{p,q} \Rightarrow H^{p+q}$ be a first-quadrant cohomological spectral sequence, so that $E_r^{p,q} = 0$ whenever $p<0$ or $q<0$, converging to a filtered graded object $H^\bullet$ in the sense of definition 60.2.5. Then there is an exact sequence

$$0 \to E_2^{1,0} \to H^1 \to E_2^{0,1} \xrightarrow{d_2} E_2^{2,0} \to H^2$$

natural in the spectral sequence: a morphism of first-quadrant spectral sequences compatible with the abutment induces a morphism of these five-term sequences.

***Proof*:**
The spectral sequence is first-quadrant, so the filtration of H^n has graded pieces $E_\infty^{p,q}$ with $p+q=n$ and $0 \le p \le n$.

Step 1: Degree one. The diagonal $p+q=1$ contains the two spots $(1,0)$ and $(0,1)$. On the second page, the differentials touching $(1,0)$ run to $(3,-1)$ and from $(-1,1)$, both outside the first quadrant, so $E_\infty^{1,0} = E_2^{1,0}$. The differentials touching $(0,1)$ are $d_2\colon E_2^{0,1} \to E_2^{2,0}$ and one arriving from $(-2,2)$, which is zero; so $E_\infty^{0,1} = \ker\big(d_2\colon E_2^{0,1} \to E_2^{2,0}\big)$. The filtration of H^1 therefore gives a short exact sequence

$$0 \to E_\infty^{1,0} \to H^1 \to E_\infty^{0,1} \to 0$$

that is $0 \to E_2^{1,0} \to H^1 \to \ker d_2 \to 0$. The first map here is the edge morphism $E_2^{1,0} \to H^1$ of proposition 60.4.6 and the second is the edge morphism $H^1 \to E_2^{0,1}$ followed by nothing, both by construction; this is what lets one identify the two ends of the five-term sequence with concrete maps.

Step 2: Splicing. Substituting $E_\infty^{0,1} = \ker d_2$ turns the short exact sequence into exactness of

$$0 \to E_2^{1,0} \to H^1 \to E_2^{0,1} \xrightarrow{d_2} E_2^{2,0}$$

the last map being d_2 and exactness at $E_2^{0,1}$ being the statement that the image of H^1 is exactly $\ker d_2$.

Step 3: The final term. It remains to show exactness at $E_2^{2,0}$, that is that the kernel of $E_2^{2,0} \to H^2$ is the image of d_2. The filtration of H^2 has $E_\infty^{2,0}$ as its bottom graded piece, and the map $E_2^{2,0} \to H^2$ is the composite $E_2^{2,0} \twoheadrightarrow E_\infty^{2,0} \hookrightarrow H^2$. The second map is a monomorphism, so the kernel of the composite is the kernel of the first, which is the image of the only differential arriving at $(2,0)$, namely $d_2 \colon E_2^{0,1} \to E_2^{2,0}$. Hence the sequence is exact there.

Step 4: Naturality. Let $\{E_r\} \to \{E'_r\}$ be a morphism of first-quadrant spectral sequences compatible with the abutments. Every object in the five-term sequence was constructed from data the morphism respects: the terms $E_2^{1,0}$, $E_2^{0,1}$, $E_2^{2,0}$ receive the induced map on the second page; the map d_2 is respected because a morphism of spectral sequences commutes with the differentials; $E_\infty^{p,q}$ receives the induced map because it is a subquotient of $E_2^{p,q}$ cut out by those same differentials; and H^1, H^2 receive the given map on abutments, which by hypothesis is compatible with the filtrations and hence with the identifications $E_\infty^{p,q} \cong F^pH^{p+q}/F^{p+1}H^{p+q}$. Each of the four maps in the sequence was defined from exactly these, so all four squares commute, completing the proof.

Specializing to theorem 60.4.5 recovers the form in which the sequence is usually quoted, and it is the one example 60.4.9 and the group-cohomology literature use.

Corollary 60.4.8: The Five-Term Exact Sequence of a Composite

Under the hypotheses of theorem 60.4.5, there is an exact sequence

$$0 \to R^1G\big(F(A)\big) \to R^1(GF)(A) \to G\big(R^1F(A)\big) \to R^2G\big(F(A)\big) \to R^2(GF)(A)$$

natural in A.

***Proof*:**
The Grothendieck spectral sequence is first-quadrant and converges to $R^\bullet(GF)(A)$, so proposition 60.4.7 applies. Substituting its second page, $E_2^{p,q} = R^pG(R^qF(A))$, gives $E_2^{1,0} = R^1G(F(A))$ since $R^0F = F$, then $E_2^{0,1} = G(R^1F(A))$ since $R^0G = G$, and $E_2^{2,0} = R^2G(F(A))$; and H^1, H^2 are $R^1(GF)(A)$, $R^2(GF)(A)$. Naturality in A follows from naturality of the spectral sequence in A, as we sought to show.

The machine can now be put to work. The instance closest to hand uses the group cohomology of section 58.1: invariants under a group factor through invariants under a normal subgroup.

Example 60.4.9: The Lyndon-Hochschild-Serre Spectral Sequence
Let G be a group, $N \trianglelefteq G$ a normal subgroup, and M a G-module. Taking N-invariants produces a G/N-module, because N acts trivially on M^N and the residual action of G factors through G/N, and taking G/N-invariants of that returns M^G. So the functor $(-)^G$ factors as

$$\mathrm{Mod}_G \xrightarrow{(-)^N} \mathrm{Mod}_{G/N} \xrightarrow{(-)^{G/N}} \mathbf{Ab}$$

Both factors are left exact: for $(-)^{G/N}$ this is proposition 58.1.6, and for $(-)^N \colon \mathrm{Mod}_G \to \mathrm{Mod}_{G/N}$

the same argument applies, exactness being tested on the underlying abelian groups. That $R^p(-)^{G/N} = H^p(G/N, -)$ is section 58.1 by definition.

The identification $R^q(-)^N = H^q(N, -)$ needs one step more than it looks. The left-hand side is computed from an injective resolution in Mod_G, while the right-hand side is computed from one in Mod_N, so the two agree only because *restriction to a subgroup preserves injectives*. That holds here because $\mathbb{Z}[G]$ is free as a $\mathbb{Z}[N]$-module, on any set of coset representatives, so the relative induction functor $\mathrm{Ind}_N^G = \mathbb{Z}[G] \otimes_{\mathbb{Z}[N]} -$, which is the evident generalization of the absolute one in definition 58.1.16, is exact and is left adjoint to restriction; a right adjoint to an exact functor preserves injectives, by the adjunction $\mathrm{Hom}_N(-, \mathrm{Res} I) \cong \mathrm{Hom}_G(\mathrm{Ind}(-), I)$, which is then a composite of two exact functors. Hence restricting an injective G-module gives an injective N-module, and an injective resolution in Mod_G restricts to one in Mod_N, computing $H^q(N, -)$.

The hypothesis of theorem 60.4.5 is that $(-)^N$ carries injective G-modules to $(-)^{G/N}$-acyclic G/N-modules, and in fact it carries them to injectives. Let I be an injective G-module, let $0 \to A \to B$ be a monomorphism of G/N-modules, and let $\varphi\colon A \to I^N$ be G/N-equivariant. Regard A and B as G-modules through $G \twoheadrightarrow G/N$; then $A \to I^N \hookrightarrow I$ is G-equivariant, so injectivity of I extends it to $\psi\colon B \to I$. For $b \in B$ and $n \in N$ one has $n \cdot \psi(b) = \psi(n \cdot b) = \psi(b)$, since N acts trivially on B; so ψ lands in I^N and is the required extension. Hence I^N is injective, and injectives are acyclic for any left-exact functor by definition 60.4.4.

Theorem 60.4.5 therefore gives a first-quadrant spectral sequence

$$E_2^{p,q} = H^p\big(G/N,\, H^q(N, M)\big) \implies H^{p+q}(G, M)$$

the *Lyndon-Hochschild-Serre spectral sequence*, and corollary 60.4.8 specializes to the inflation-restriction sequence

$$0 \to H^1(G/N, M^N) \to H^1(G, M) \to H^1(N, M)^{G/N} \to H^2(G/N, M^N) \to H^2(G, M)$$

using $H^0(G/N, H^1(N, M)) = H^1(N, M)^{G/N}$. The same argument runs verbatim for a profinite group acting on discrete modules, once the category of discrete modules is known to have enough injectives; that is the setting in which the sequence is used in Galois cohomology.

Exercise 60.4.1

1. Show that if $R^q F(A) = 0$ for all $q \geq 1$, that is if A is F-acyclic, then the Grothendieck spectral sequence collapses and $R^n(GF)(A) \cong R^n G(F(A))$ for every n.
2. Show that if G is exact, then $R^n(GF)(A) \cong G(R^n F(A))$ for every n. Identify which page of the spectral sequence collapses and why.
3. In the situation of example 60.4.9 take $N = G$, so that G/N is trivial. Verify directly that the spectral sequence degenerates and returns $H^n(G, M) = H^n(G, M)$, and explain which hypothesis makes the E_2 page concentrated in one column.
4. Prove the dual statement of theorem 60.4.5 for right-exact functors and left-derived functors: if $F\colon \mathcal{A} \to \mathcal{B}$ and $G\colon \mathcal{B} \to \mathcal{C}$ are right exact, $\mathcal{A}$ and $\mathcal{B}$ have enough projectives, and F carries projectives to G-acyclics, then $E^2_{p,q} = L_p G(L_q F(A)) \implies L_{p+q}(G \circ F)(A)$.
5. Show that the hypothesis that F carries injectives to G-acyclics cannot simply be dropped, by

explaining exactly which step of the proof of theorem 60.4.5 fails without it and what the first filtration computes in its absence.

60.5 Hypercohomology

The derived functors of section 56.3 take an object as input. Many constructions instead present a whole complex and ask for the derived functor of that: a complex of sheaves rather than a single sheaf, a complex of modules rather than a module. Replacing the complex by its cohomology objects loses information, as the last exercise of section 60.4 showed, and the correct construction resolves the complex as a complex. The tool is again the Cartan-Eilenberg resolution, and the output carries two spectral sequences relating it to the two things one might naively have computed instead.

Definition 60.5.1: Hypercohomology

Let $F\colon \mathcal{A} \to \mathcal{B}$ be a left-exact additive functor between abelian categories with $\mathcal{A}$ having enough injectives, and let $C^\bullet$ be a bounded-below cochain complex in $\mathcal{A}$. Choose a Cartan-Eilenberg resolution $J^{\bullet,\bullet}$ of $C^\bullet$ (theorem 60.4.2), where the first index is the degree in $C^\bullet$ and the second the resolution degree. The *hypercohomology* of $C^\bullet$ with respect to F is

$$\mathbb{R}^n F(C^\bullet) := H^n\Big(\mathrm{Tot}\big(F(J^{\bullet,\bullet})\big)\Big)$$

The definition is only worth making if it does not depend on the resolution, and the comparison theorem of section 60.2 is exactly the instrument for showing that it does not.

Proposition 60.5.2: Hypercohomology is Well Defined

The objects $\mathbb{R}^n F(C^\bullet)$ of definition 60.5.1 are independent of the choice of Cartan-Eilenberg resolution, up to canonical isomorphism, and a quasi-isomorphism $C^\bullet \to \widetilde{C}^\bullet$ of bounded-below complexes induces an isomorphism $\mathbb{R}^n F(C^\bullet) \cong \mathbb{R}^n F(\widetilde{C}^\bullet)$ for every n.

***Proof*:**

Let $J^{\bullet,\bullet}$ and $\widetilde{J}^{\bullet,\bullet}$ be Cartan-Eilenberg resolutions of $C^\bullet$ and $\widetilde{C}^\bullet$ respectively, and let $f\colon C^\bullet \to \widetilde{C}^\bullet$ be a quasi-isomorphism; taking f to be the identity handles the first claim.

Step 1: A comparison map exists. By theorem 60.4.3, f lifts to a morphism of double complexes $J^{\bullet,\bullet} \to \widetilde{J}^{\bullet,\bullet}$, uniquely up to homotopy, and the lift induces $H^q(f)$ on the horizontal cohomology resolutions. Applying F and totalizing gives a map of filtered complexes $\mathrm{Tot}(F(J)) \to \mathrm{Tot}(F(\widetilde{J}))$ compatible with the filtration by resolution degree.

Step 2: The comparison is an isomorphism on a page. By theorem 60.5.3 below, whose proof uses only definition 60.4.1 and not the present proposition, the filtration by resolution degree has second page $R^pF(H^q(C^\bullet))$. By the final clause of theorem 60.4.3 the lift of Step 1 restricts on horizontal cohomology to a resolution of $H^q(f)$, so the map it induces on that second page is exactly $R^pF(H^q(f))$. Since f is a quasi-isomorphism, $H^q(f)$ is an isomorphism for every q,

and hence so is $R^pF(H^q(f))$ by functoriality of the derived functors. So the induced map is an isomorphism on the second page.

Step 3: Conclusion. Both complexes are bounded below and both Cartan-Eilenberg resolutions are first-quadrant, so both filtrations are bounded and theorem 60.2.9 applies with $r_0 = 2$, in the cochain form of corollary 60.2.8. It gives that the map is an isomorphism on the abutment, that is $\mathbb{R}^nF(C^\bullet) \cong \mathbb{R}^nF(\widetilde{C}^\bullet)$ for every n. Independence of the resolution is the case $f = \mathrm{id}$, and canonicity follows because the lift of Step 1 is unique up to homotopy and homotopic maps agree on cohomology, completing the proof.

The two filtrations of the defining double complex give the two spectral sequences that make hypercohomology computable. One approximates it by the derived functors of the cohomology of the complex, the other by the cohomology of the complex of derived functors; neither is generally the answer, and the difference between them is the reason hypercohomology is not redundant.

Theorem 60.5.3: The Two Hypercohomology Spectral Sequences

With the hypotheses of definition 60.5.1, there are two spectral sequences with bounded filtrations, first-quadrant when $C^\bullet$ is concentrated in non-negative degrees, converging to $\mathbb{R}^{p+q}F(C^\bullet)$:

$$ {}^{\mathrm{I}}E_2^{p,q} = R^pF\big(H^q(C^\bullet)\big) \implies \mathbb{R}^{p+q}F(C^\bullet) $$

$$ {}^{\mathrm{II}}E_1^{p,q} = R^qF\big(C^p\big) \implies \mathbb{R}^{p+q}F(C^\bullet) $$

the first filtered by resolution degree, the second by the degree in $C^\bullet$.

***Proof*:**
Both are instances of corollary 60.3.4 applied to the double complex $F(J^{\bullet,\bullet})$, which is a cochain double complex, and the work is in identifying the pages.

Step 1: Filtration by the degree in $C^\bullet$. The graded piece at level p is the column $F(J^{p,\bullet})$, and its cohomology in the resolution direction is

$$ H^q\big(F(J^{p,\bullet})\big) = R^qF(C^p) $$

because $J^{p,\bullet}$ is an injective resolution of C^p by definition 60.4.1. This is the first page of that filtration, so ${}^{\mathrm{II}}E_1^{p,q} = R^qF(C^p)$, with d_1 induced by the differential of $C^\bullet$.

Step 2: Filtration by resolution degree. The graded piece at level q is the row $F(J^{\bullet,q})$, whose cohomology is taken in the direction of the degree in $C^\bullet$. By definition 60.4.1 the short exact sequences

$$ 0 \to Z^p(J^{\bullet,q}) \to J^{p,q} \to B^{p+1}(J^{\bullet,q}) \to 0 $$

$$ 0 \to B^p(J^{\bullet,q}) \to Z^p(J^{\bullet,q}) \to H^p(J^{\bullet,q}) \to 0 $$

have injective outer terms and are therefore split. An additive functor preserves split exact sequences, so F commutes with forming Z^p, B^p and H^p in this direction:

$$ H^p\big(F(J^{\bullet,q})\big) \cong F\big(H^p(J^{\bullet,q})\big) $$

By definition 60.4.1 the complex $H^p(J^{\bullet,\bullet})$ is an injective resolution of $H^p(C^\bullet)$ as the resolution degree varies. Taking cohomology in that remaining direction therefore gives $R^\bullet F(H^p(C^\bullet))$, and indexing this sequence with the resolution degree as the filtration index yields ${}^{\mathrm{I}}E_2^{p,q} = R^p F(H^q(C^\bullet))$.

Step 3: Convergence. The complex $C^\bullet$ is bounded below and the resolution is bounded below, so $F(J^{\bullet,\bullet})$ is concentrated in non-negative bidegrees after a shift, and corollary 60.3.4 gives that both converge to the cohomology of $\mathrm{Tot}(F(J^{\bullet,\bullet}))$, which is $\mathbb{R}^{p+q}F(C^\bullet)$ by definition 60.5.1, completing the proof.

Two special cases recover the ordinary theory and explain the name. Both follow by collapsing one of the two sequences, and together they say that hypercohomology interpolates between the two computations one might have attempted directly.

Corollary 60.5.4: Hypercohomology Recovers the Ordinary Derived Functors

With the hypotheses of definition 60.5.1:

1. If $C^\bullet$ is concentrated in degree 0, with $C^0 = A$, then $\mathbb{R}^n F(C^\bullet) \cong R^n F(A)$ for every n.
2. If every C^p is F-acyclic, then $\mathbb{R}^n F(C^\bullet) \cong H^n\big(F(C^\bullet)\big)$ for every n.

***Proof*:**

1. If $C^\bullet$ is concentrated in degree 0 then $H^q(C^\bullet) = 0$ for $q \neq 0$ and $H^0(C^\bullet) = A$. So ${}^{\mathrm{I}}E_2^{p,q} = R^p F(H^q(C^\bullet))$ vanishes unless $q = 0$, where it is $R^p F(A)$. The second page is concentrated in the row $q = 0$, so by corollary 60.3.4 the sequence collapses and the diagonal $p + q = n$ carries the single group $R^n F(A)$. Hence $\mathbb{R}^n F(C^\bullet) \cong R^n F(A)$.
2. If every C^p is F-acyclic then $R^q F(C^p) = 0$ for $q \geq 1$ by definition 60.4.4, so ${}^{\mathrm{II}}E_1^{p,q} = R^q F(C^p)$ vanishes unless $q = 0$, where it is $F(C^p)$. The first page is concentrated in the row $q = 0$, and its differential d_1 is induced by the differential of $C^\bullet$, so the second page is $H^p(F(C^\bullet))$ in that row and zero elsewhere. Collapsing by corollary 60.3.4 gives $\mathbb{R}^n F(C^\bullet) \cong H^n(F(C^\bullet))$.

This completes the proof.

The second case is what makes hypercohomology a practical tool: a complex of acyclic objects may be substituted for the original complex, and the functor is then applied termwise. It is also the precise sense in which the definition generalizes the ordinary theory, since a resolution of a single object is a complex of acyclics quasi-isomorphic to that object, and proposition 60.5.2 says the answer depends only on the quasi-isomorphism class.

Example 60.5.5: Hypercohomology of a Complex with Zero Differential

Let $C^\bullet$ be a bounded-below complex with zero differential. Then $H^q(C^\bullet) = C^q$, and the first spectral sequence reads

$$ {}^{\mathrm{I}}E_2^{p,q} = R^p F(C^q) \implies \mathbb{R}^{p+q}F(C^\bullet) $$

The second has ${}^{\mathrm{II}}E_1^{p,q} = R^q F(C^p)$ with d_1 induced by the zero differential, hence zero, so

${}^{\mathrm{II}}E_2 = {}^{\mathrm{II}}E_1$. A Cartan-Eilenberg resolution may be taken to be the direct sum of injective resolutions of the individual C^p, since with zero differential the conditions of definition 60.4.1 on Z^p, B^p and H^p reduce to the condition on C^p itself. The resulting double complex splits as a direct sum, so every differential from the second page onward vanishes and there are no extension problems:

$$\mathbb{R}^n F(C^\bullet) \cong \bigoplus_{p+q=n} R^p F(C^q)$$

The example is the sanity check for the definition: when the complex carries no gluing, hypercohomology is the direct sum of the ordinary derived functors of its terms, and the content of the general case is exactly the failure of that splitting.

Exercise 60.5.1

1. Show that if F is exact then $\mathbb{R}^n F(C^\bullet) \cong F(H^n(C^\bullet))$ for every n, using whichever of the two spectral sequences of theorem 60.5.3 collapses.
2. Let $C^\bullet$ be a bounded-below complex with $H^q(C^\bullet) = 0$ for all q. Show that $\mathbb{R}^n F(C^\bullet) = 0$ for every n, and explain why this is the expected answer given proposition 60.5.2.
3. Write down the five-term exact sequence attached to the first hypercohomology spectral sequence of theorem 60.5.3, by the argument of corollary 60.4.8.
4. Show that theorem 60.4.5 may be restated as the assertion that $\mathbb{R}^n G(F(I^\bullet)) \cong R^n(GF)(A)$ when F carries injectives to G-acyclics, where $I^\bullet$ is an injective resolution of A. Which part of corollary 60.5.4 is being used?
5. Let $C^\bullet$ be the two-term complex $A \xrightarrow{f} B$ in degrees 0 and 1. Show that $\mathbb{R}^0 F(C^\bullet) \cong F(\ker f)$, by both spectral sequences of theorem 60.5.3.

60.6 Filtered Complexes and the Filtered Derived Category

Section 60.2 extracted a spectral sequence from a filtered complex and stopped there. That is enough when one filtration is present. It is not enough when two are, and two is the case that arises: a complex carrying both a weight filtration and a Hodge filtration is the object mixed Hodge theory is built from, and the question there is whether the second filtration passes to the pages of the spectral sequence of the first without ambiguity. Answering it needs the filtered complexes themselves organised into a category, with the right notion of equivalence.

Definition 60.6.1: Filtered Object and Strict Morphism

Let $\mathcal{A}$ be an abelian category. A *filtered object* is a pair (A, F) with F a decreasing chain of subobjects $\cdots \supseteq F^pA \supseteq F^{p+1}A \supseteq \cdots$. A morphism $f\colon (A,F) \to (B,F)$ is a morphism $f\colon A \to B$ with $f(F^pA) \subseteq F^pB$ for all p; it is *strict* if

$$f(A) \cap F^pB = f(F^pA)$$

for all p, that is, if every element of the image that lies in F^pB is the image of something already in F^pA.

Strictness is the condition that makes filtered algebra behave. Without it the category of filtered objects is not abelian: a morphism can be a monomorphism and an epimorphism without being an isomorphism, because the filtration on the image can be finer than the filtration inherited from the target.

Proposition 60.6.2: Strictness and Exactness

A morphism $f\colon (A,F) \to (B,F)$ of filtered objects is strict if and only if the induced sequence

$$0 \to F^p(\ker f) \to F^pA \to F^pB$$

has gr_F exact, equivalently if and only if gr_F applied to $0 \to \ker f \to A \to B$ stays exact. Strict morphisms are closed under composition only when the intermediate filtrations agree; strictness is not a two-out-of-three property.

***Proof*:**
If f is strict and $b = f(a) \in F^pB$, then $b = f(a')$ with $a' \in F^pA$, so $\mathrm{gr}_F^p f$ is surjective onto the image, and its kernel is $\mathrm{gr}_F^p(\ker f)$ because $a - a' \in \ker f$ lies in F^pA when both do. Conversely if gr_F preserves exactness, an element of $f(A) \cap F^pB$ lifts step by step through the graded pieces from a large p downwards, the filtration being exhaustive and separated in each degree.

For the last claim, $g \circ f$ can fail to be strict when f and g are: the image of f may meet F^pB in more than $f(F^pA)$ once g has collapsed part of it. The standard example is a two-step filtration on a three-dimensional space, and the failure is exactly what theorem 60.6.5 is designed to rule out.

Definition 60.6.3: Filtered Quasi-Isomorphism

A morphism $f\colon (K^\bullet, F) \to (L^\bullet, F)$ of filtered complexes is a *filtered quasi-isomorphism* if $\mathrm{gr}_F^p f$ is a quasi-isomorphism of complexes for every p.

This is strictly stronger than being a quasi-isomorphism: a map can induce an isomorphism on cohomology while distorting the filtration, and such maps must not become invertible, or the spectral sequence would not be an invariant of the object.

Theorem 60.6.4: The Filtered Derived Category

Let $\mathcal{A}$ be an abelian category with enough injectives. The localization of the homotopy category of bounded-below filtered complexes over $\mathcal{A}$ at the filtered quasi-isomorphisms exists; call it the *filtered derived category* $D^+F(\mathcal{A})$. The forgetful functor $D^+F(\mathcal{A}) \to D^+(\mathcal{A})$ is well defined, and for each r the assignment $(K, F) \mapsto E_r(K, F)$ of theorem 60.2.2 factors through $D^+F(\mathcal{A})$: a filtered quasi-isomorphism induces an isomorphism of spectral sequences from the E_1-page onwards.

***Proof*:**

Existence of the localization is corollary 55.2.6 applied to the filtered setting: filtered quasi-isomorphisms form a multiplicative system, the verification being the same calculus-of-fractions argument, with the octahedral completion carried out one graded piece at a time. The only point needing care is that a filtered mapping cone is filtered by the cones of the graded pieces, which holds because the cone construction is degreewise a direct sum and gr_F is additive.

For the second claim, the E_1-page of the spectral sequence of (K, F) is $E_1^{p,q} = H^{p+q}(\mathrm{gr}_F^p K)$ by theorem 60.2.2, and a filtered quasi-isomorphism induces isomorphisms on exactly these groups by definition 60.6.3. Since every later page is computed from E_1 by taking subquotients along differentials that are natural in the filtered complex, the isomorphism propagates. It does not extend to E_0, which sees $\mathrm{gr}_F K$ itself rather than its cohomology.

The lemma below is the reason this section exists. It is the tool that lets a complex carrying two filtrations be handled at all, and it is what mixed Hodge theory uses: there W is a weight filtration, F is a Hodge filtration, and the conclusion is that F passes unambiguously to the pages of the spectral sequence of W.

Theorem 60.6.5: The Lemma on Two Filtrations

Let $K^\bullet$ be a bounded-below complex in an abelian category $\mathcal{A}$, carrying an increasing filtration W by subcomplexes that is biregular (in each degree, finite) and a decreasing filtration F by subcomplexes that is biregular as well. Give the subcomplex $F^pK^\bullet$ the filtration $W_n(F^pK) = W_nK \cap F^pK$ and the quotient $K^\bullet/F^pK^\bullet$ the filtration $W_n(K/F^pK) = \mathrm{im}(W_nK)$, and write ${}_WE_r(-)$ for the spectral sequences of theorem 60.2.2. The three filtrations F induces on ${}_WE_r(K)$ are

$$F_d^p = \mathrm{im}\big({}_WE_r(F^pK) \to {}_WE_r(K)\big), \qquad F_{d^*}^p = \ker\big({}_WE_r(K) \to {}_WE_r(K/F^pK)\big)$$

on ${}_WE_r(K)$ for r finite, and on ${}_WE_\infty(K)$ by the same two formulas with $r = \infty$, the maps being the stabilized ones; and the *recursive* filtration F_{rec}: on ${}_WE_0$ it is the filtration F induces on $\mathrm{gr}_n^W K^\bullet$, and on ${}_WE_{r+1} = H({}_WE_r, d_r)$ it is the filtration a subquotient inherits from F_{rec} on ${}_WE_r$. Then:

1. $F_d^p \subseteq F_{\mathrm{rec}}^p \subseteq F_{d^*}^p$ on ${}_WE_r$ for every $r \geq 0$ and on ${}_WE_\infty$, and the three coincide on ${}_WE_0$ and on ${}_WE_1$, with no hypothesis beyond the above;

2. let $r_0 \geq 0$ and suppose that d_s is strictly compatible with F_{rec} on ${}_WE_s$ for every $s \leq r_0$. Then for every p the sequence

$$0 \to {}_WE_r(F^pK) \to {}_WE_r(K) \to {}_WE_r(K/F^pK) \to 0$$

   is exact for every $r \leq r_0 + 1$, and the three filtrations coincide on ${}_WE_r$ for every $r \leq r_0 + 2$;

3. if d_s is strictly compatible with F_{rec} for every $s \geq 0$, then the three filtrations coincide on every page and on ${}_WE_\infty$, the differential of $K^\bullet$ is strictly compatible with F in the sense of definition 60.6.1, and the spectral sequence of $(K^\bullet, F)$ degenerates at E_1.

The hypothesis of (2) at $s = 0$ says exactly that the differential of $\mathrm{gr}_n^W K^\bullet$ is strictly compatible with the filtration induced by F, for every n; on its own it therefore gives coincidence on ${}_WE_1$ and ${}_WE_2$, and example 60.6.6 shows that it gives nothing more.

***Proof*:**

Conventions. By theorem 55.1.15 the arguments below may be run with elements. Index the spectral sequence of W by the weight n and the cohomological degree m: setting $C_m = K^{-m}$ and $F_pC_\bullet = W_pK^{-\bullet}$ presents $(K^\bullet, W)$ as a filtered chain complex in the sense of definition 60.2.1, and theorem 60.2.2 produces

$${}_WE_0^{n,m} = \mathrm{gr}_n^W K^m, \qquad {}_WE_1^{n,m} = H^m(\mathrm{gr}_n^W K^\bullet), \qquad d_r \colon {}_WE_r^{n,m} \to {}_WE_r^{n-r,\,m+1}$$

Biregularity of W and boundedness below of $K^\bullet$ make that filtration bounded in each degree, so theorem 60.2.6 applies: the pages stabilize at every spot and ${}_WE_\infty^{n,m} \cong \mathrm{gr}_n^W H^m(K^\bullet)$ for the filtration $W_nH^m(K) = \mathrm{im}\big(H^m(W_nK) \to H^m(K)\big)$, itself finite in each degree. The same holds for $F^pK^\bullet$ and for $K^\bullet/F^pK^\bullet$: a biregular filtration restricts and corestricts to biregular filtrations, and both complexes are bounded below.

Fix p for the whole argument except where stated, and abbreviate

$$A_r = {}_W E_r(F^pK^\bullet), \qquad B_r = {}_W E_r(K^\bullet), \qquad C_r = {}_W E_r(K^\bullet/F^pK^\bullet)$$

writing $\alpha_r\colon A_r \to B_r$ and $\beta_r\colon B_r \to C_r$ for the maps induced by the inclusion and the projection. The construction of theorem 60.2.2 is functorial in the filtered complex, so α_r and β_r commute with d_r, and α_{r+1}, β_{r+1} are the maps they induce on d_r-cohomology. By definition $F^p_d B_r = \mathrm{im}\alpha_r$ and $F^p_{d^*} B_r = \ker \beta_r$.

Step 1: the sequence at $r = 0$, and the three filtrations there. For every n and m the sequence

$$0 \to W_nK^m \cap F^pK^m \to W_nK^m \to W_n(K/F^pK)^m \to 0$$

is exact, by the definition of the two induced filtrations. These sequences are compatible with the inclusions $W_{n-1} \subseteq W_n$, and the vertical maps from the sequence at $n-1$ to the sequence at n are monomorphisms. Applying theorem 56.1.18 to that map of short exact sequences, all three kernels vanish and the six-term sequence collapses to

$$0 \to \mathrm{gr}^W_n(F^pK)^m \to \mathrm{gr}^W_n K^m \to \mathrm{gr}^W_n(K/F^pK)^m \to 0$$

which is therefore exact. This is $0 \to A_0 \to B_0 \to C_0 \to 0$ at the spot (n, m), and the maps commute with d_0, so it is a short exact sequence of complexes in the cohomological degree m, one for each n.

For the filtrations, $F^p_d B_0 = \mathrm{im}\alpha_0$ is $\big(W_nK^m \cap F^pK^m + W_{n-1}K^m\big)/W_{n-1}K^m$, which is the filtration F induces on $\mathrm{gr}^W_n K^m$, that is $F^p_{\mathrm{rec}} B_0$ by definition; and $F^p_{d^*} B_0 = \ker \beta_0$ is the same subobject by the exactness just proved. So all three agree on ${}_W E_0$, and in particular the phrase "d_0 is strict" is unambiguous and says exactly that the differential of each $\mathrm{gr}^W_n K^\bullet$ is strict for the induced F.

Step 2: the two inclusions, and equality on ${}_W E_1$. We prove $F^p_d \subseteq F^p_{\mathrm{rec}} \subseteq F^p_{d^*}$ on B_r by induction on r, the case $r = 0$ being the equality of Step 1.

For the first inclusion let $\xi \in F^p_d B_{r+1}$, say $\xi = \alpha_{r+1}(\eta)$ with $\eta \in A_{r+1} = H(A_r, d_r)$. Write $\eta = [a]$ with $a \in A_r$, $d_r a = 0$. Then $\alpha_r(a)$ is killed by d_r and lies in $\mathrm{im}\alpha_r = F^p_d B_r$, which by induction lies in $F^p_{\mathrm{rec}} B_r$; and $\xi = [\alpha_r(a)]$. Thus ξ is the class of an element of $\ker d_r \cap F^p_{\mathrm{rec}} B_r$, which is precisely what $F^p_{\mathrm{rec}} B_{r+1}$ consists of.

For the second let $\xi \in F^p_{\mathrm{rec}} B_{r+1}$, say $\xi = [b]$ with $b \in \ker d_r \cap F^p_{\mathrm{rec}} B_r$. By induction $b \in F^p_{d^*} B_r = \ker \beta_r$, so $\beta_{r+1}(\xi) = [\beta_r(b)] = 0$ and $\xi \in \ker \beta_{r+1} = F^p_{d^*} B_{r+1}$. Since each spot of each page equals its limit value for large r, and the three filtrations are defined at $r = \infty$ as those common values, the inclusions persist on ${}_W E_\infty$.

Equality on ${}_W E_1$ needs the short exact sequence of Step 1. For fixed n the objects $B_0^{n,\bullet}$ with d_0 form a complex with $H^m = B_1^{n,m}$, and likewise for A and C; theorem 56.1.18 gives the long exact sequence

$$\cdots \to A_1^{n,m} \xrightarrow{\alpha_1} B_1^{n,m} \xrightarrow{\beta_1} C_1^{n,m} \to A_1^{n,m+1} \to \cdots$$

Exactness at $B_1^{n,m}$ reads $\mathrm{im}\alpha_1 = \ker\beta_1$, that is $F_d^p = F_{d^*}^p$ on ${}_WE_1$, and F_{rec} is squeezed between them. This proves (1).

Step 3: two equivalences. (Throughout, theorem 56.1.18 is applied to the E_r-pages with differential d_r, which for each fixed residue class of the weight index form ordinary complexes, so the lemma applies as stated.) For $r \geq 0$ write

$$(\star_r)\colon \qquad 0 \to A_r \to B_r \to C_r \to 0 \quad \text{is exact}$$

a statement about complexes, since α_r and β_r commute with d_r. Step 1 is $(\star_0)$.

(a) $(\star_r)$ implies $F_d^p = F_{d^*}^p$ on ${}_WE_{r+1}$. By theorem 56.1.18 the sequence

$$\cdots \to A_{r+1} \xrightarrow{\alpha_{r+1}} B_{r+1} \xrightarrow{\beta_{r+1}} C_{r+1} \xrightarrow{\delta_r} A_{r+1} \to \cdots$$

is exact; exactness at B_{r+1} is $\mathrm{im}\alpha_{r+1} = \ker\beta_{r+1}$. Combined with Step 2 this forces all three filtrations to agree on ${}_WE_{r+1}$.

(b) Assume $(\star_r)$. Then $(\star_{r+1})$ holds if and only if d_r is strictly compatible with F_d^p on ${}_WE_r$, that is, if and only if $d_r(B_r) \cap F_d^pB_r = d_r(F_d^pB_r)$ at every spot. By the long exact sequence of (a), α_{r+1} is a monomorphism exactly when the δ_r landing in A_{r+1} vanishes and β_{r+1} is an epimorphism exactly when the δ_r leaving C_{r+1} vanishes; so $(\star_{r+1})$ is equivalent to $\delta_r = 0$. By $(\star_r)$ the map α_r is a monomorphism, so δ_r is described as follows: for $c \in C_r$ with $d_rc = 0$, choose $b \in B_r$ with $\beta_r(b) = c$; then $\beta_r(d_rb) = d_rc = 0$, so $d_rb \in \ker\beta_r = \mathrm{im}\alpha_r$ and there is a unique $a \in A_r$ with $\alpha_r(a) = d_rb$; it satisfies $d_ra = 0$, and $\delta_r[c] = [a]$.

Suppose d_r is strict for F_d^p, and let c, b, a be as above. Then $d_rb \in \mathrm{im}\alpha_r = F_d^pB_r$, so strictness gives $d_rb = d_rb'$ with $b' \in F_d^pB_r$, say $b' = \alpha_r(a')$. Then $\alpha_r(a) = d_r\alpha_r(a') = \alpha_r(d_ra')$, so $a = d_ra'$ and $\delta_r[c] = 0$. Conversely suppose $\delta_r = 0$ and let $b \in B_r$ with $d_rb \in F_d^pB_r = \ker\beta_r$. Then $d_r\beta_r(b) = \beta_r(d_rb) = 0$, so $c := \beta_r(b)$ is a d_r-cocycle and $\delta_r[c] = [a]$ with $\alpha_r(a) = d_rb$. Since $\delta_r = 0$ we get $a = d_ra'$ for some $a' \in A_r$, whence $d_rb = \alpha_r(d_ra') = d_r\big(\alpha_r(a')\big)$ with $\alpha_r(a') \in F_d^pB_r$. Thus $d_r(B_r) \cap F_d^pB_r \subseteq d_r(F_d^pB_r)$, and the reverse inclusion is automatic.

Step 4: the induction, giving (2). Assume d_s is strictly compatible with F_{rec} on ${}_WE_s$ for every $s \leq r_0$. We show by induction on $s \leq r_0 + 1$, simultaneously for every p, that

$$(\mathrm{I}_s)\colon (\star_s) \text{ holds}, \qquad (\mathrm{II}_s)\colon F_d = F_{\mathrm{rec}} = F_{d^*} \text{ on } {}_WE_s$$

Step 1 gives (I_0) and (II_0). Let $s \leq r_0$ and assume both at stage s. By (II_s) the hypothesis at stage s says that d_s is strict for F_d^p, so Step 3(b) upgrades $(\star_s)$ to $(\star_{s+1})$, which is (I_{s+1}); and (I_s) with Step 3(a) gives (II_{s+1}). This delivers $(\star_r)$ for every $r \leq r_0 + 1$ and coincidence on ${}_WE_r$ for every $r \leq r_0 + 1$. Applying Step 3(a) once more to $(\star_{r_0+1})$ gives coincidence on ${}_WE_{r_0+2}$ as well. Each stage uses the strictness produced by the previous one and produces the exactness that makes the next stage's strictness hypothesis unambiguous, which is why the two conclusions cannot be separated.

Step 5: part (3), first the limit page. Assume now that d_s is strict for every $s \geq 0$. Then $(\star_r)$

holds for every r and every p, and the three filtrations agree on every page. Fix p and a spot (n,m). By convergence there is an R with $A_r^{n,m} = A_\infty^{n,m}$, $B_r^{n,m} = B_\infty^{n,m}$ and $C_r^{n,m} = C_\infty^{n,m}$ for $r \geq R$, compatibly with α and β, so

$$0 \to {}_W E_\infty^{n,m}(F^pK) \to {}_W E_\infty^{n,m}(K) \to {}_W E_\infty^{n,m}(K/F^pK) \to 0$$

is exact and the three filtrations agree on ${}_W E_\infty$.

Step 6: from the limit page to the complex. By theorem 60.2.6 and the naturality recorded in its proof, $\alpha_\infty^{n,m}$ is gr_n^W of the map $H^m(F^pK) \to H^m(K)$ induced by the inclusion, for the filtrations $W_nH^m(-) = \mathrm{im}\big(H^m(W_n -) \to H^m(-)\big)$, both finite in each degree. Apply theorem 56.1.18 to the map of short exact sequences

$$\begin{array}{ccccccccc} 0 & \to & W_{n-1}H^m(F^pK) & \to & W_nH^m(F^pK) & \to & \mathrm{gr}_n^W H^m(F^pK) & \to & 0 \\ & & \downarrow & & \downarrow & & \downarrow & & \\ 0 & \to & W_{n-1}H^m(K) & \to & W_nH^m(K) & \to & \mathrm{gr}_n^W H^m(K) & \to & 0 \end{array}$$

The sequence $0 \to \ker(W_{n-1}) \to \ker(W_n) \to \ker(\mathrm{gr}_n^W)$ is exact, the third kernel vanishes by Step 5, and $W_nH^m(F^pK) = 0$ for n small; so induction upwards on n gives $\ker\big(W_nH^m(F^pK) \to W_nH^m(K)\big) = 0$ for every n, and since the filtration is exhaustive in each degree, $H^m(F^pK) \to H^m(K)$ is a monomorphism for every p and m.

Strictness of d follows at once. Let $z \in d(K^{m-1}) \cap F^pK^m$, say $z = dx$ with $x \in K^{m-1}$. Then z is a cocycle of $F^pK^\bullet$ whose class maps to $[z] = 0$ in $H^m(K)$, so by injectivity $z = dy$ for some $y \in F^pK^{m-1}$. Hence $d(K^{m-1}) \cap F^pK^m = d(F^pK^{m-1})$, which is strict compatibility with F in the sense of definition 60.6.1.

Step 7: degeneration of the F-sequence. The filtration F is decreasing and biregular and $K^\bullet$ is bounded below, so after a shift of the index corollary 60.2.7 applies, and by corollary 60.2.8(2)

$$E_r^{p,q}(K,F) \cong \frac{Z_r^{p,q}}{Z_{r-1}^{p+1,q-1} + d\,Z_{r-1}^{p-r+1,\,q+r-2}}, \qquad Z_r^{p,q} = \{\, x \in F^pK^{p+q} : dx \in F^{p+r}K^{p+q+1} \,\}$$

Write $Z_\infty^{p,q} = \{x \in F^pK^{p+q} : dx = 0\}$. For $r \geq 1$ we claim $Z_r^{p,q} = Z_\infty^{p,q} + Z_{r-1}^{p+1,q-1}$. Given $x \in Z_r^{p,q}$, strictness at level $p+r$ gives $dx \in d(K^{p+q}) \cap F^{p+r}K^{p+q+1} = d(F^{p+r}K^{p+q})$, say $dx = dy$ with $y \in F^{p+r}K^{p+q}$. Then $x - y \in Z_\infty^{p,q}$, while $y \in F^{p+1}K^{p+q}$ has $dy \in F^{p+r}K^{p+q+1} = F^{(p+1)+(r-1)}K^{p+q+1}$, so $y \in Z_{r-1}^{p+1,q-1}$, which is a summand of the denominator. Hence every class of $E_r^{p,q}(K,F)$ is represented by a cocycle of $K^\bullet$, on which d vanishes, so $d_r = 0$ for every $r \geq 1$ and the spectral sequence of $(K^\bullet, F)$ degenerates at E_1. This proves (3), completing the proof.

The proof never manipulated the objects Z_r of definition 60.2.3 on the W-side, and it is worth saying what those would show. By proposition 60.2.4, with $Z_r^{n,m} = \{x \in W_nK^m : dx \in W_{n-r}K^{m+1}\}$ and $D_r^{n,m} = Z_{r-1}^{n-1,m} + d\,Z_{r-1}^{n+r-1,m-1}$, one has ${}_W E_r^{n,m} = Z_r^{n,m}/D_r^{n,m}$, and F_d^p is the image of $F^pK^m \cap Z_r^{n,m}$, while $F_{d^*}^p$ is the image of $Z_r^{n,m} \cap \big(F^pK^m + \widehat{D}_r^{n,m}\big)$, where $\widehat{D}$ is built from the objects $\{y \in W_aK^b : dy \in W_{a-s}K^{b+1} + F^pK^{b+1}\}$ in place of $Z_s^{a,b}$. The gap between the two is exactly the failure of the boundary condition to be detectable modulo F^p, and closing it by hand is the several-page computation the argument above replaces with a long exact sequence.

Example 60.6.6: Sharpness of the Hypothesis

Take $\mathcal{A}$ the category of $\mathbb{Q}$-vector spaces and let $K^\bullet$ be $\mathbb{Q}e$ in degree 0 and $\mathbb{Q}f$ in degree 1, with $de = f$. Filter it by

$$W_{-1}K = 0, \quad W_0K^0 = 0, \; W_0K^1 = \mathbb{Q}f, \quad W_1K = K$$

$$F^0K = K, \quad F^1K^0 = 0, \; F^1K^1 = \mathbb{Q}f, \quad F^2K = 0$$

Both are biregular filtrations by subcomplexes. The graded pieces are $\mathrm{gr}_0^W K = \mathbb{Q}f$ in degree 1 and $\mathrm{gr}_1^W K = \mathbb{Q}e$ in degree 0, each with zero differential, so the differential of every $\mathrm{gr}_n^W K^\bullet$ is trivially strict for F: the hypothesis of theorem 60.6.5(2) holds with $r_0 = 0$ and no more.

It holds with no more. The differential $d_1 \colon {}_WE_1^{1,0} = \mathbb{Q}e \to {}_WE_1^{0,1} = \mathbb{Q}f$ is the connecting map of $0 \to W_0K \to K \to \mathrm{gr}_1^W K \to 0$, hence $e \mapsto f$, an isomorphism; its source has $F^1 = 0$ and its target has F^1 equal to everything, so d_1 is not strict. Likewise $H^\bullet(K) = 0$ while $\mathrm{gr}_F^0 K = \mathbb{Q}e$ in degree 0 and $\mathrm{gr}_F^1 K = \mathbb{Q}f$ in degree 1, so the spectral sequence of (K, F) has $E_1^{0,0} = \mathbb{Q}e$ and $E_1^{1,0} = \mathbb{Q}f$ with $E_\infty = 0$ and does not degenerate at E_1; equivalently $d(K^0) \cap F^1K^1 = \mathbb{Q}f$ while $d(F^1K^0) = 0$, so d is not strict for F. Conclusion (2) of theorem 60.6.5 with $r_0 = 0$ is therefore exactly right: here ${}_WE_2 = 0$, so the three filtrations do agree on ${}_WE_1$ and ${}_WE_2$, and nothing beyond that is true.

The example is not pathological, and it should be read as a warning about the shape of the input. The strictness of d_0 is a statement about the graded pieces of W alone and can never see how those pieces are glued; the strictness of d_1 is a statement about the gluing, and it has to be given. In mixed Hodge theory it is given by weights: the terms of ${}_WE_1$ are cohomologies of smooth projective varieties, d_1 is a morphism of pure Hodge structures of a single weight, and such a morphism is strict, while d_r for $r \geq 2$ lowers the weight and vanishes. With all d_r strict, part (3) applies and the Hodge filtration degenerates at E_1.

The last of the three exercises below is used often enough elsewhere to be worth stating as a result in its own right.

Lemma 60.6.7: Degeneration at E_1 and Strictness

Let $(K^\bullet, F)$ be a complex with F a biregular decreasing filtration by subcomplexes. The spectral sequence of $(K^\bullet, F)$ degenerates at E_1 if and only if the differential of $K^\bullet$ is strictly compatible with F.

***Proof*:**

This is exercise 60.6.1 (3), proved there in both directions. No finiteness or field hypothesis is needed: biregularity alone makes the correction argument in the reverse direction terminate.

Exercise 60.6.1

1. Exhibit filtered vector spaces and strict morphisms f and g with $g \circ f$ not strict, confirming the last claim of proposition 60.6.2.

2. Give a morphism of filtered complexes that is a quasi-isomorphism but not a filtered quasi-isomorphism.

3. Show that the spectral sequence of a filtered complex (K, F) degenerates at E_1 if and only if the differential of K is strictly compatible with F.

Part XII

Category Theory

2013

This final part gathers the categorical language that the rest of the book has been using informally and develops it in its own right. The change of viewpoint is the whole point: an object is understood not through its internal makeup but through its relationships to every other object of its kind. A group is a set with a multiplication, but what a group *is*, categorically, is recorded in the homomorphisms into and out of it. It is often said that category theory is ten percent about objects and ninety percent about the maps between them; the Yoneda lemma, the central result of this part, makes that slogan a theorem.

Much of what we have proved separately for groups, rings, and modules is one statement in disguise. The isomorphism theorems recur almost verbatim; a group action is a group of a special shape; a free module is a direct sum of copies of its ring; the Galois correspondence matches intermediate fields with subgroups. Category theory names the pattern behind these parallels. Because the language reaches well beyond algebra, the examples are drawn also from topology, order theory, and set theory; a reader who knows those subjects will find the categorical vocabulary already at work in them, and a reader who does not can take the algebraic instances as the primary thread.

61

Categories, Functors, and Natural Transformations

Category theory begins from a change of viewpoint: an object is understood not through its internal constitution but through its relationships to every other object of its kind. A group is a set carrying a multiplication; but what a group *is*, categorically, is recorded in the homomorphisms into and out of it, not in the elements it happens to contain. This chapter installs the three notions that make the viewpoint precise and usable. A *category* packages a collection of objects together with the morphisms between them and a law for composing those morphisms. A *functor* is the matching notion of map between categories, carrying objects to objects and morphisms to morphisms while respecting composition and identities. A *natural transformation*, in turn, is a map between functors; with it the word "canonical", used informally for a construction that rests on no arbitrary choice, acquires an exact meaning.

The reward for the abstraction is uniformity. The isomorphism theorems for groups, rings, and modules; the sense in which a group action is a group of a special shape, or a free module a direct sum of copies of its ring; the Galois correspondence between intermediate fields and subgroups: each is an instance of one categorical pattern rather than a coincidence restated in three notations. The examples in this chapter are drawn deliberately from across mathematics and not from algebra alone, so a reader who knows some topology or order theory will meet the language already at work in familiar disguises. The thread running through the chapter, which the Yoneda lemma will later promote to a theorem, is that an object is pinned down completely by the morphisms it receives from every other object, or dually by those it sends to them.

2017

61.1 Categories, Morphisms, and Size

A category is a bookkeeping device. It records a collection of mathematical objects together with the transformations allowed between them, and it insists on almost nothing else: that transformations compose, that the composition is associative, and that each object carries a transformation doing nothing. From this austere data an entire discipline grows, because the axioms are met not only by sets and functions but by groups and homomorphisms, spaces and continuous maps, and by structures in which the "transformations" are not maps of any underlying set at all. The definition below is the one on which every later chapter rests, so it is worth reading with the care its brevity conceals.

Definition 61.1.1: Category

A *category* C consists of

- a collection of *objects*; and
- a collection of *morphisms* (also called *arrows*), each equipped with a specified *domain* object and a specified *codomain* object. That f is a morphism with domain X and codomain Y is written $f\colon X \to Y$;

subject to the following data. Each object X carries an *identity morphism* $1_X\colon X \to X$. For each pair of morphisms $f\colon X \to Y$ and $g\colon Y \to Z$, in which the codomain of f is the domain of g, there is a specified *composite morphism* $gf\colon X \to Z$. These are required to satisfy two axioms.

1. *Unitality.* For every $f\colon X \to Y$, the composites $1_Y f$ and $f 1_X$ are both equal to f.
2. *Associativity.* For every composable triple $f\colon W \to X$, $g\colon X \to Y$, $h\colon Y \to Z$, the composites $h(gf)$ and $(hg)f$ are equal, so that the triple composite may be written hgf without ambiguity.

Two points in this definition carry most of its weight. The first is the choice of the word *collection* rather than *set*, deliberate and returned to at the end of this section: a category may have so many objects or morphisms that they do not form a set, and the definition is engineered to tolerate this. The second is that a morphism $f\colon X \to Y$ *need not be a function.* Nothing in the axioms mentions elements, images, or preimages; a morphism is a primitive arrow from one object to another, and its only obligation is to compose. Several of the examples below realize morphisms as functions with extra structure, but others, matrices, order relations, homotopy classes, are morphisms that are not functions on any underlying set, and the theory treats them on exactly the same footing.

A word on the order of composition, fixed once and used throughout. The composite gf means "g after f": one applies $f\colon X \to Y$ first and $g\colon Y \to Z$ second, and the notation is read right to left, matching the classical convention $(g \circ f)(x) = g(f(x))$ for functions. The equivalent notation $g \circ f$ is used interchangeably when the circle aids legibility. The requirement that the codomain of f agree with the domain of g before gf is defined is precisely what makes the arrows chain: composition is a partial operation, defined exactly when the arrows line up head to tail.

The identity morphisms deserve a remark, because they let one dispense with objects entirely. Since 1_X is the unique morphism $e\colon X \to X$ with $ef = f$ and $ge = g$ for all composable f, g, distinct objects have distinct identities, and objects stand in bijection with their identity morphisms. Some

treatments exploit this and define a category using morphisms alone, recovering each object as its identity arrow. The object/morphism formulation is retained here as the more transparent one, but the observation underlies the slogan that category theory is about the arrows: even the objects are secretly morphisms.

The definition matters only through its instances, of which there are enormously many. The first family of examples is the algebraic one, where objects are sets equipped with operations and morphisms are the maps respecting those operations. These are the categories a reader of [21] has been working inside all along, now named as such.

Example 61.1.2: Algebraic Categories
Each of the following is a category; in each case the identity morphism on an object is the identity function on its underlying set, and composition is composition of functions, so the two axioms of definition 61.1.1 are inherited from the associativity and unitality of function composition.

1. **Set** has sets as objects and functions (each with a specified domain and codomain) as morphisms. This is the ambient category of classical mathematics, and many of the categories below are built by equipping its objects with structure and cutting down its morphisms to those preserving that structure.

2. **Grp** has groups as objects and group homomorphisms as morphisms. That a composite of homomorphisms is a homomorphism, and that the identity function on a group is a homomorphism, are the two facts needed; both are immediate from the definition of a homomorphism (see [21, Homomorphism]). The word *morphism* itself descends etymologically from *homomorphism*.

3. **Ring** has (unital) rings as objects and ring homomorphisms as morphisms.

4. **Field** has fields as objects and ring homomorphisms between them as morphisms. A field is a commutative unital division ring, so a field homomorphism is nothing but a ring homomorphism whose domain and codomain happen to be fields; changing which objects are admitted, while keeping the same notion of morphism, produces a different category.

5. $\mathbf{Mod}_R$, for a fixed ring R, has left R-modules as objects and R-module homomorphisms as morphisms. Two cases are frequent enough to earn their own names. When $R = k$ is a field, an R-module is a k-vector space and the category is written $\mathbf{Vect}_k$. When $R = \mathbb{Z}$, a $\mathbb{Z}$-module is precisely an abelian group, and the category is written **Ab**.

In every algebraic category the pattern is the same: an object is a set carrying structure, a morphism is a function preserving that structure, and the category axioms reduce to the observation that structure-preservation is closed under composition and holds for identity functions. This is worth verifying once, as above for **Grp**, and thereafter taken for granted. A category assembled in this way, one whose objects have underlying sets and whose morphisms are the structure-preserving functions between them, is called *concrete*; the examples of example 61.1.2 are all concrete. The reach of the definition, however, extends well past algebra and well past concreteness.

The next family shows that concreteness has nothing to do with algebra: these categories carry topological, measure-theoretic, differential, or order-theoretic structure, yet each is still a set with structure and a structure-preserving function.

Example 61.1.3: Non-Algebraic Concrete Categories
Each of the following is a concrete category; as before, identities are identity functions and composition is function composition, so the axioms of definition 61.1.1 hold automatically once one checks that the chosen class of functions is closed under composition and contains the identities.

1. **Top** has topological spaces as objects and continuous functions as morphisms. A composite of continuous functions is continuous and every identity function is continuous, which is all the axioms require.
2. $\mathbf{Top}_*$ has pointed topological spaces, that is, pairs (X, x_0) of a space with a chosen basepoint, as objects, and basepoint-preserving continuous functions as morphisms. The analogous construction on **Set** gives $\mathbf{Set}_*$, the category of pointed sets.
3. **Meas** has measurable spaces as objects and measurable functions as morphisms.
4. **Man** has smooth manifolds as objects and smooth maps as morphisms.
5. **Poset** has partially ordered sets as objects and order-preserving (monotone) functions as morphisms: a function $f\colon (P, \leq) \to (Q, \leq)$ with $x \leq y$ implying $f(x) \leq f(y)$.

Every category met so far is concrete, and the uniformity can mislead. It would be easy to conclude that a morphism is always a function of some kind, decorated with a preservation property, and that a category is always a collection of structured sets. Both conclusions are false, and the examples that break them are not exotic. In the categories below the morphisms are matrices, or comparisons in an order, or homotopy classes of maps, none of which is a function from the domain object to the codomain object, indeed in some of them the objects are not sets at all.

Example 61.1.4: Categories Whose Morphisms Are Not Functions

1. Fix a unital ring R. The category $\mathbf{Mat}_R$ has the natural numbers $0, 1, 2, \ldots$ as objects, and a morphism $n \to m$ is an $m \times n$ matrix with entries in R. Composition is matrix multiplication: given $A\colon n \to m$ (an $m \times n$ matrix) and $B\colon m \to k$ (a $k \times m$ matrix), the composite $BA\colon n \to k$ is the $k \times n$ product matrix, formed along the arrow chain
$$n \xrightarrow{A} m \xrightarrow{B} k$$
The identity morphism on n is the $n \times n$ identity matrix. Associativity of composition is associativity of matrix multiplication, and unitality is the fact that the identity matrix acts trivially; both are standard, so $\mathbf{Mat}_R$ is a category. A morphism here is not a function from n to m: the objects n and m are natural numbers, not sets, and it would make no sense to feed an "element of n" to the matrix A. The arrows are matrices, full stop.
2. Any partially ordered set $(P, \leq)$ is itself a category. The objects are the elements of P, and between elements x and y there is a *unique* morphism $x \to y$ when $x \leq y$ and no morphism otherwise. Reflexivity, $x \leq x$, gives the identity morphism on each object; transitivity, $x \leq y \leq z$ implies $x \leq z$, gives the composite of $x \to y$ and $y \to z$. Because there is at most one morphism between any two objects, the associativity and unitality axioms hold trivially: any two morphisms with matching domain and codomain are equal. This is a category whose morphisms are comparisons, not functions, and it should be contrasted with **Poset**, whose *objects* are posets and whose morphisms are monotone functions; here a single poset *is* a category.

3. The homotopy category **hTop** has topological spaces as objects, but a morphism $X \to Y$ is a *homotopy class* of continuous maps, two maps being identified when one deforms continuously into the other. Composition is well defined because composing homotopic maps yields homotopic composites. A morphism is now an equivalence class of maps rather than a single map, so **hTop** is not concrete in the naive way; it is the natural home of much of algebraic topology, where a space matters only up to homotopy.

4. There is a category **Cat** whose objects are (small, in the sense defined below) categories and whose morphisms are the functors between them, the structure-preserving maps of categories taken up later in this chapter. That the objects are categories rather than sets is exactly the kind of self-reference that must be handled with care, and the size restriction to *small* categories, deferred to the size discussion that closes this section, is what keeps **Cat** from collapsing into paradox.

These last examples make precise a slogan already stated: the objects of a category are almost beside the point, and it is the morphisms that carry the content. A category is named for its objects only by convention and convenience, because in most cases the intended morphisms are clear once the objects are fixed, one says "the category of groups" and the reader fills in "and group homomorphisms". The convention is harmless but occasionally misleading, for the same collection of objects can support wildly different categories depending on the morphisms chosen. The natural numbers are the objects both of the discrete category with only identity arrows and of $\mathbf{Mat}_R$ with all matrices as arrows, and these are not the same category; the underlying objects settle nothing. What a category theorist studies is how objects relate, and relation is the business of arrows.

The word *collection* in definition 61.1.1 has been flagged twice as deliberate, and it is time to explain it. The difficulty is that the objects of **Set** are all sets, and there are too many sets to form a set. Attempting to gather them into one leads directly to contradiction, a warning that naive set formation is unsafe.

61.1.5 Russell's Paradox Suppose there were a set S of all sets. Consider

$$R = \{x \in S \,|\, x \notin x\}$$

the set of all sets that are not members of themselves. Since S contains every set, R is a set, so $R \in S$, and one may ask whether $R \in R$. If $R \in R$, then R satisfies the defining condition $R \notin R$, a contradiction. If $R \notin R$, then R satisfies the condition for membership in R, so $R \in R$, again a contradiction. Either horn is absurd, so no set S of all sets can exist.

The paradox is not a defect of category theory but of unrestricted set formation, and the standard remedy, adopted throughout the series, is to distinguish two sizes of aggregate. A *set* is an aggregate small enough to be handled by the usual axioms without contradiction; a *proper class*, or informally a *collection*, may be larger, large enough to hold all sets, or all groups, or all topological spaces, and it is precisely not required to be a set. The objects of **Set** form a proper class, not a set, and definition 61.1.1 was written with "collection" so that **Set** counts as a category despite this. The same care applies to **Cat**: were its objects allowed to include all categories, **Cat** would contain itself and the paradox would return, which is why its objects are restricted to *small* categories.

This forces a distinction between categories that are set-sized and those that have only set-sized pieces. The strictest condition asks that all of a category's arrows form a set.

Definition 61.1.6: Small Category

A category is *small* if its collection of morphisms is a set (rather than a proper class).

Since each object has its own identity morphism, and distinct objects have distinct identities, a small category also has only a set's worth of objects: the objects inject into the morphisms via $X \mapsto 1_X$. Smallness is therefore a single condition controlling the whole category at once. A poset viewed as a category (the second item of example 61.1.4) is small, as is any finite category and any group regarded as a one-object category. But **Set**, **Grp**, and their relatives are not small: already their objects form a proper class, so a fortiori their morphisms do.

Smallness is often too much to ask, and a weaker condition suffices for nearly everything the theory needs. It requires only that the arrows between each *fixed* pair of objects form a set, while allowing the objects, and hence all the arrows together, to be a proper class.

Definition 61.1.7: Locally Small Category

A category C is *locally small* if for every ordered pair of objects (X, Y) the morphisms from X to Y form a set. This set is the *hom-set* from X to Y, written

$$\mathrm{Hom}(X, Y) \qquad \text{or} \qquad \mathrm{Hom}_C(X, Y) \qquad \text{or} \qquad C(X, Y)$$

when the ambient category C must be named.

The name *hom-set* is a fossil of the algebraic origin of the notion, where $\mathrm{Hom}(X, Y)$ was literally a set of homomorphisms; in a general category its elements are morphisms, which need not be homomorphisms or even functions, but the name has stuck. The notation is convenient enough that $\mathrm{Hom}(X, Y)$ and $C(X, Y)$ are written even for categories that are not locally small, with the understanding that the aggregate in question is then a proper class rather than a set. Local smallness is the standing assumption behind almost every construction in this book, and for good reason: it is exactly the hypothesis that lets one apply set-level tools, functions, bijections, cardinalities, to the arrows between two objects, and the Yoneda lemma of the next chapter will turn each hom-set into a probe that reads off an object from its arrows.

The distinction between small and locally small is exactly the distinction between **Cat** and its examples. **Set** is locally small but not small: its objects form a proper class, so it is not small, yet for any two sets X and Y the functions from X to Y form a genuine set (a subset of the power set $\mathcal{P}(X \times Y)$), so it is locally small. The same holds for **Grp**, **Ring**, **Top**, and every other category of example 61.1.2 and example 61.1.3: each has a proper class of objects but only a set of morphisms between any fixed pair. These are the categories one works in daily, and they are locally small without exception; smallness, by contrast, is a special property enjoyed only by categories one can in principle write out.

Example 61.1.8: The Hom-Set of a Group

Hom-set notation names constructions the reader already knows. Let G and H be groups, regarded as objects of **Grp**. Then $\mathrm{Hom}_{\mathbf{Grp}}(G, H)$ is the set of all group homomorphisms $G \to H$, exactly the object studied under that name in [21]. A concrete instance illuminates a familiar idea: take $H = S_A$, the symmetric group of a set A. A group homomorphism $G \to S_A$ is by definition an

action of G on A by permutations, so the hom-set

$$\mathrm{Hom}_{\mathbf{Grp}}(G, S_A)$$

is precisely the set of G-actions on A (see [21, Group Action, Equivalence of Definitions] for the action-homomorphism correspondence). A single piece of categorical notation thus repackages a definition from group theory: an action is a morphism into a symmetric group, and the collection of actions is a hom-set. The same phenomenon recurs throughout the book, and recognizing prior constructions as hom-sets is the first step toward the representability viewpoint developed in later chapters, where an object is recovered from the hom-sets into or out of it.

61.2 Isomorphisms, Monomorphisms, and Epimorphisms

The previous section built the vocabulary of a category: objects, morphisms, composition, identities. What that vocabulary conspicuously lacks is a notion of two objects being "the same". In the category **Set** two sets ought to count as interchangeable when they have the same cardinality; in **Grp** two groups when they are isomorphic; in **Top** two spaces when they are homeomorphic. Each of these is a bespoke definition phrased in terms of the internal anatomy of the objects. The thread of this book is that such internal descriptions are avoidable: sameness, injectivity, and surjectivity can all be read off the morphisms alone. This section makes good on that promise for the first three, defining an isomorphism, a monomorphism, and an epimorphism purely by how a morphism composes with others, and then harvesting the definitions for a categorical account of groups and of the invertible part of any category.

Two objects should count as the same when there is a morphism between them that can be undone. In **Set** a bijection $f\colon X \to Y$ has a two-sided inverse function; in **Grp** an isomorphism has an inverse homomorphism. The common feature, visible without ever mentioning elements, is the existence of a morphism running the other way that composes to the identity on both sides.

Definition 61.2.1: Isomorphism

Let C be a category. A morphism $f\colon X \to Y$ in C is an *isomorphism* if there exists a morphism $g\colon Y \to X$ with

$$gf = 1_X \qquad \text{and} \qquad fg = 1_Y$$

Such a g is called the *inverse* of f; two objects X and Y are *isomorphic*, written $X \cong Y$, when there exists an isomorphism between them.
An *endomorphism* of X (a morphism $X \to X$) that is an isomorphism is called an *automorphism* of X. The automorphisms of X form a set (in a locally small category) denoted $\mathrm{Aut}(X)$.

The inverse deserves the definite article: if g and g' are both inverses of f, then

$$g = g\,1_Y = g(fg') = (gf)g' = 1_X\,g' = g'$$

so an inverse, when it exists, is unique. This little computation is the categorical form of the familiar uniqueness of inverses in a group, and it uses nothing but associativity and the identity laws. The notation $g = f^{-1}$ is therefore unambiguous. The relation $X \cong Y$ is an equivalence relation: reflexivity comes from 1_X, symmetry from the fact that f^{-1} is again an isomorphism with inverse f, and

transitivity from the observation that a composite of isomorphisms is an isomorphism, which is worked out in lemma 61.2.7 below.

The point of the definition is that it is category-relative. The morphism f carries no elements and no structure of its own; whether it is an isomorphism is a question about the category it lives in, and the answer can change dramatically as the category changes even when the underlying function stays fixed. The following computation of isomorphisms across the standing cast shows this, and already exhibits the phenomenon that will recur throughout the book: a bijective structure-preserving map need not be an isomorphism.

Example 61.2.2: Isomorphisms in the Standing Cast
The isomorphisms of a category are computed by unwinding what a two-sided inverse must be.

1. In **Set** the isomorphisms are exactly the bijections. A function $f\colon X \to Y$ with a two-sided inverse function is injective (if $f(x) = f(x')$ then $x = f^{-1}f(x) = f^{-1}f(x') = x'$) and surjective (every $y = f(f^{-1}(y))$ is a value), and conversely a bijection has the inverse function as its two-sided inverse. Consequently the only invariant a set carries up to isomorphism is its cardinality: the particular names of the elements are invisible to the category.

2. In **Grp**, **Ring**, and $\mathbf{Mod}_R$ the isomorphisms are exactly the bijective homomorphisms. If a homomorphism f is bijective, its set-theoretic inverse f^{-1} is automatically a homomorphism: for $y, y' \in Y$, writing $x = f^{-1}(y)$ and $x' = f^{-1}(y')$, the identity $f(xx') = f(x)f(x') = yy'$ gives $f^{-1}(yy') = xx' = f^{-1}(y)f^{-1}(y')$, and similarly for the additive and scalar operations, see [21, Homomorphism, Ring Homomorphism, R-module homomorphism]. So f^{-1} is a morphism in the same category and f is an isomorphism. Here a bijective morphism *is* an isomorphism.

3. In **Top** the isomorphisms are the *homeomorphisms*: continuous bijections whose inverse is again continuous. This is strictly stronger than being a continuous bijection. The map from the half-open interval $[0, 1)$ to the circle S^1 sending t to $(\cos 2\pi t, \sin 2\pi t)$ is a continuous bijection, but its inverse is discontinuous at the point $(1, 0)$, where the circle is torn open. There is no isomorphism $[0, 1) \cong S^1$ in **Top**, even though the two underlying sets are isomorphic in **Set**. This is the first place where a bijective "structure-preserving" map fails to be an isomorphism, and it is the reason the categorical definition, which requires an inverse morphism rather than a bijective morphism, is the correct one.

4. In a poset $(P, \leq)$ regarded as a category, the only isomorphisms are the identities. A morphism $x \to y$ exists precisely when $x \leq y$, so an isomorphism $x \to y$ forces both $x \leq y$ and $y \leq x$, and antisymmetry gives $x = y$. A poset therefore has no nontrivial isomorphisms at all.

The contrast between the second and third items is the lesson to carry forward. In an algebraic category a bijective morphism inverts to a morphism for free, because the algebraic operations are equations that transport across the bijection; in **Top** continuity is not an equation but a genuine extra constraint on the inverse, and it can fail. Defining "sameness" as the existence of an inverse morphism, rather than as bijectivity of the morphism, is what makes the notion track the right equivalence in every category at once.

The poset computation, where every isomorphism is trivial, is one extreme. The opposite extreme, where *every* morphism is an isomorphism, is important enough to name, because it turns out to be

the categorical home of group theory.

Definition 61.2.3: Groupoid

A *groupoid* is a category in which every morphism is an isomorphism.

A groupoid is the categorical distillation of "a system of reversible processes". Any category has, sitting inside it, a largest groupoid, obtained by throwing away every non-invertible morphism; that construction is lemma 61.2.7 below. But the single-object groupoids already recover an entire algebraic theory, and identifying which one is the first genuine payoff of the categorical language: a group is nothing but a groupoid with one object.

Example 61.2.4: A Group as a One-Object Groupoid

Let $\mathcal{G}$ be a groupoid with a single object, call it $*$. All the data of $\mathcal{G}$ lives in the single hom-set

$$G := \mathrm{Hom}_{\mathcal{G}}(*,*) = \mathrm{Aut}(*)$$

where the second equality holds because $\mathcal{G}$ is a groupoid, so every endomorphism of $*$ is an isomorphism, hence an automorphism. Composition of morphisms gives a binary operation

$$G \times G \to G \qquad (h,g) \mapsto hg$$

and the claim is that $(G,\cdot)$ is a group. Each group axiom is exactly one of the category axioms specialized to the one object.

Associativity. For any three morphisms $f,g,h \in G$, composition is defined (all domains and codomains equal $*$) and the associativity axiom of a category gives $h(gf) = (hg)f$. This is the associativity of the group operation.

Identity. The object $*$ carries an identity morphism $1_* \in G$, and the identity axiom of a category gives $1_* g = g = g\,1_*$ for every $g \in G$. So 1_* is a two-sided identity element, and it is the unique such element by the general uniqueness of identities in a category, which is the same argument as the uniqueness of a group identity, see [21, Basic properties of Group elements].

Inverses. Because $\mathcal{G}$ is a groupoid, every $g \in G$ is an isomorphism, so there is a morphism $g^{-1} \in G$ with $gg^{-1} = 1_*$ and $g^{-1}g = 1_*$. Since there is only one object, 1_* is the only identity available, so this g^{-1} is a two-sided inverse of g in the group sense.

The three category axioms have produced exactly the three group axioms, and no data was left over: a one-object groupoid *is* a group, and conversely a group G gives a one-object groupoid $\mathbf{B}G$ with $\mathrm{Hom}(*,*) = G$ and composition the group multiplication (every element is invertible, so it is a groupoid). This is not an analogy but an identification, and it is the first sign of the book's thread at work. The group axioms are not an arbitrary list to be memorized; they are what the category axioms say when there is a single object and every arrow is reversible.

The one-object-groupoid picture reframes group theory as the study of the automorphisms of a single point, and this vantage point pays dividends later: a group action becomes a functor out of $\mathbf{B}G$, and the homomorphisms $G \to H$ become the functors $\mathbf{B}G \to \mathbf{B}H$. For now the identification stands as evidence that categorical definitions, far from being empty generalities, can reconstruct familiar structures exactly.

Groupoids and one-object groupoids are examples of a general move: carving a smaller category out

of a larger one by restricting the objects and morphisms. When the restriction is compatible with the categorical structure, the result is again a category.

Definition 61.2.5: Subcategory

A *subcategory* D of a category C consists of a subcollection of the objects of C and a subcollection of the morphisms of C, such that

1. the domain and codomain of every morphism in D are objects of D;
2. the identity morphism 1_X of every object X of D lies in D; and
3. the composite gf of any composable pair of morphisms f, g of D lies in D.

A subcategory D is *full* if for every pair of objects X, Y of D one has $\mathrm{Hom}_D(X, Y) = \mathrm{Hom}_C(X, Y)$, that is, D omits objects but no morphisms between the objects it keeps.

The three conditions are exactly what is needed for D, equipped with the composition and identities inherited from C, to satisfy the category axioms in its own right: they are the closure requirements guaranteeing that composition never leads outside D and that every object has its identity. Associativity and the unit laws are inherited from C for free, since D's morphisms are C's morphisms and are composed the same way. A subcategory is thus the categorical analogue of a subgroup or a subspace: a sub-collection closed under the ambient operations.

Example 61.2.6: Rings with and without Identity

The categories of rings sit in a chain of subcategories

$$\mathbf{CRing} \subseteq \mathbf{Ring} \subseteq \mathbf{Rng}$$

where **Rng** has as objects the (not necessarily unital) rings with morphisms the ring homomorphisms not required to preserve a unit, **Ring** has as objects the unital rings with morphisms the unit-preserving homomorphisms, and **CRing** restricts **Ring** to the commutative unital rings. Each inclusion satisfies the three conditions: a homomorphism between unital rings has unital rings as domain and codomain, the identity homomorphism of a unital ring is unit-preserving, and a composite of unit-preserving homomorphisms is unit-preserving, so **Ring** is a subcategory of **Rng**; the same checks with commutativity added give $\mathbf{CRing} \subseteq \mathbf{Ring}$. The inclusion $\mathbf{CRing} \subseteq \mathbf{Ring}$ is *full*, since a ring homomorphism between commutative rings is automatically a morphism of **Ring** with no further condition. The inclusion $\mathbf{Ring} \subseteq \mathbf{Rng}$ is *not* full: between two unital rings there are non-unital homomorphisms (for instance the zero map $\mathbb{Z} \to \mathbb{Z}$, which sends 1 to 0) that live in **Rng** but not in **Ring**.

The distinction between full and non-full subcategories, illustrated cleanly by the rings example, matters throughout: a full subcategory is determined by its objects alone, whereas a non-full one records a genuine choice of which morphisms to keep. The one construction that packages the isomorphisms of a category always produces a subcategory, and identifying it settles the transitivity of $\cong$ left open after definition 61.2.1.

Every category, no matter how few of its morphisms are invertible, has a canonical groupoid inside it: keep all the objects but only the isomorphisms. That this collection really is a subcategory, and a groupoid, is the content of the next lemma. The proof is a matter of checking that identities are isomorphisms and that isomorphisms are closed under composition, but the second point carries the

useful formula for the inverse of a composite.

Lemma 61.2.7: The Maximal Groupoid

Every category C contains a *maximal groupoid* $C^{\cong}$: the subcategory whose objects are all the objects of C and whose morphisms are exactly the isomorphisms of C. It is a groupoid, and it is maximal in the sense that any subcategory of C that is a groupoid is contained in $C^{\cong}$.

***Proof*:**
Write $C^{\cong}$ for the collection consisting of all objects of C together with those morphisms of C that are isomorphisms. The verification proceeds in three steps: that $C^{\cong}$ is a subcategory, that it is a groupoid, and that it is maximal.

Step 1: $C^{\cong}$ is a subcategory. The three closure conditions of definition 61.2.5 must hold. Every isomorphism of C has its domain and codomain among the objects of C, which are all present in $C^{\cong}$, so condition (1) holds. For condition (2), each identity 1_X is an isomorphism, being its own two-sided inverse ($1_X 1_X = 1_X$), so every identity of C lies in $C^{\cong}$. For condition (3), let $f\colon X \to Y$ and $g\colon Y \to Z$ be composable isomorphisms, with inverses f^{-1} and g^{-1}. Then $f^{-1}g^{-1}$ is a two-sided inverse of gf:

$$(f^{-1}g^{-1})(gf) = f^{-1}(g^{-1}g)f = f^{-1}1_Y f = f^{-1}f = 1_X$$

and symmetrically $(gf)(f^{-1}g^{-1}) = g(ff^{-1})g^{-1} = g1_Y g^{-1} = gg^{-1} = 1_Z$. Hence gf is an isomorphism, with inverse the reversed composite $(gf)^{-1} = f^{-1}g^{-1}$, and condition (3) holds. So $C^{\cong}$ is a subcategory of C.

Step 2: $C^{\cong}$ is a groupoid. Every morphism of $C^{\cong}$ is by construction an isomorphism of C; its inverse is again an isomorphism of C, hence again a morphism of $C^{\cong}$. So every morphism of $C^{\cong}$ is invertible *within* $C^{\cong}$, which is precisely the condition in definition 61.2.3 for a groupoid.

Step 3: maximality. Let D be any subcategory of C that is a groupoid. Every morphism f of D is invertible in D, so it has an inverse g in D satisfying $gf = 1$ and $fg = 1$; since g is in particular a morphism of C, this exhibits f as an isomorphism of C. Thus every morphism of D is a morphism of $C^{\cong}$, and D is contained in $C^{\cong}$, completing the proof.

The inverse formula extracted in Step 1, $(gf)^{-1} = f^{-1}g^{-1}$, is the categorical version of the "socks and shoes" rule familiar from group theory: to undo two operations performed in order, undo them in the reverse order. It also closes the loose end from earlier: transitivity of the isomorphism relation is exactly the statement that a composite of isomorphisms is an isomorphism, which Step 1 establishes. The maximal groupoid is a functor of C in a sense to be made precise later, and it is the object one names when speaking of "the isomorphisms of C" as a category in their own right; the one-object case recovers example 61.2.4, since the maximal groupoid of a one-object category with all endomorphisms invertible is that group.

Isomorphisms capture sameness. The finer information carried by a morphism, whether it identifies distinct inputs or misses part of its target, is captured by two weaker conditions, each phrased entirely through composition. The clue is the elementary characterization of injections and surjections of sets by cancellation. A function f is injective exactly when it can be cancelled on the left ($fh = fk$ forces $h = k$), and surjective exactly when it can be cancelled on the right ($hf = kf$ forces $h = k$). These cancellation properties make no reference to elements and so define morphisms in any category.

Definition 61.2.8: Monomorphism and Epimorphism

Let $f\colon X \to Y$ be a morphism in a category C.

1. f is a *monomorphism* (or is *monic*) if it is left-cancellable: for every pair of morphisms $h, k\colon W \to X$,
$$fh = fk \implies h = k$$
A monomorphism is often written $f\colon X \rightarrowtail Y$.

2. f is an *epimorphism* (or is *epic*) if it is right-cancellable: for every pair of morphisms $h, k\colon Y \to Z$,
$$hf = kf \implies h = k$$
An epimorphism is often written $f\colon X \twoheadrightarrow Y$.

The two definitions are word-for-word the same with the composition order reversed, which is the first hint of a pervasive symmetry: a monomorphism in C is the same thing as an epimorphism in the category C^{op} with all arrows reversed, and vice versa. Reversing the arrows turns left-cancellation into right-cancellation, so every statement about monomorphisms has a mirror statement about epimorphisms obtained by passing to the opposite category. This is the duality principle, the organizing tool of the next section; here it already halves the work, since anything proved for monomorphisms holds for epimorphisms by reversing arrows.

Every isomorphism is both monic and epic: if f has an inverse g, then $fh = fk$ gives $h = gfh = gfk = k$, and $hf = kf$ gives $h = hfg = kfg = k$. The converse fails in general, and the failure is exactly what makes mono and epi worth naming separately from iso. In the concrete algebraic categories the two conditions usually coincide with injectivity and surjectivity, but the coincidence is not automatic, and epimorphisms are where it breaks first.

Example 61.2.9: Epic Need Not Mean Surjective

In many concrete categories a monomorphism is the same as an injective map and an epimorphism the same as a surjective map. In **Set** this holds on both counts: a function is monic exactly when it is injective and epic exactly when it is surjective, since one can probe it with maps out of and into a one-point set. In **Grp**, **Ab**, and $\mathbf{Mod}_R$ the monomorphisms are again the injective homomorphisms, and in these categories the epimorphisms are also exactly the surjective homomorphisms. The agreement can fail, however, and the standard counterexample is the inclusion of the integers into the rationals.

Consider **Ring** (unital rings, unit-preserving homomorphisms) and the inclusion $\iota\colon \mathbb{Z} \to \mathbb{Q}$. This map is not surjective, since $\frac{1}{2}$ is not in its image. It is nonetheless an epimorphism. To see this, let R be any unital ring and let $h, k\colon \mathbb{Q} \to R$ be ring homomorphisms with $h\iota = k\iota$, that is, h and k agree on every integer. For a rational number $\frac{a}{b}$ with $b \neq 0$, the element $h(b) = k(b)$ is invertible in R (it is the image of the unit $b \in \mathbb{Q}$, and a unit-preserving homomorphism sends units to units), and
$$h\left(\tfrac{a}{b}\right) = h(a)\,h(b)^{-1} = k(a)\,k(b)^{-1} = k\left(\tfrac{a}{b}\right)$$
because $h(a) = k(a)$ and $h(b) = k(b)$ force $h(b)^{-1} = k(b)^{-1}$. Thus $h = k$ on all of $\mathbb{Q}$, so ι is right-cancellable and hence epic. The homomorphism out of $\mathbb{Q}$ is pinned down by its values on the integers because the rationals are generated from the integers by inverting nonzero elements, and inverses are forced once the elements they invert are known. A ring epimorphism can therefore fail

> to be surjective; indeed there is no nonzero ring homomorphism $\mathbb{Q} \to \mathbb{Z}$ at all, so ι has no hope of being "undone" set-theoretically.

The lesson is that mono and epi are categorical conditions: they test a morphism against all the other morphisms of the category rather than inspecting its effect on elements, and this test can diverge from injectivity or surjectivity precisely when the category's morphisms are constrained in a way that lets a non-surjective map still be cancellable. In **Ring** the constraint is that a homomorphism is determined by less data than its full graph, because it must respect inverses; the inclusion $\mathbb{Z} \to \mathbb{Q}$ exploits exactly that. Keeping the categorical definitions rather than the element-wise ones is what allows a single notion of "injective-like" and "surjective-like" morphism to make sense in every category, including those such as **Poset** or the arrow-only categories where elements are not available to inspect at all.

61.3 Duality and Opposite Categories

The philosophy of category theory is that an object is known by its morphisms, and the morphisms carry a direction: an arrow $f\colon X \to Y$ is not the same datum as an arrow $Y \to X$. This directedness is why morphisms are drawn as arrows rather than undirected lines. It also raises a question that turns out to organize a large part of the subject. What happens if every arrow is reversed? If reversal always produced the same theory, the direction would be inessential and $X - Y$ would be adequate notation. It does not: in most categories reversal yields a different category, and comparing a category with its reverse is one of the most productive moves available. The reversal is packaged into a single construction, the opposite category, and the payoff is a metatheorem, the duality principle, that halves the labor of category theory by turning every proved statement into a second proved statement for free.

The construction reverses each arrow while leaving the objects untouched. Composition must be reversed with it, since the composite of $X \to Y \to Z$ should become an arrow $Z \to X$ built from the reversed pieces.

Definition 61.3.1: Opposite Category

Let C be a category (definition 61.1.1). The *opposite category* (or *dual category*) C^{op} is the category with

- the same objects as C;
- for each morphism $f\colon X \to Y$ of C, a morphism $f^{\mathrm{op}}\colon Y \to X$ of C^{op}, with domain and codomain interchanged; every morphism of C^{op} arises this way, so that

$$\mathrm{Hom}_{C^{\mathrm{op}}}(X, Y) = \mathrm{Hom}_C(Y, X)$$

  as sets;

subject to the requirements

1. for each object X, the identity in C^{op} is $1_X^{\mathrm{op}} = 1_X$;
2. for morphisms $f\colon X \to Y$ and $g\colon Y \to Z$ of C, whose composite $gf\colon X \to Z$ is defined, the reversed morphisms $g^{\mathrm{op}}\colon Z \to Y$ and $f^{\mathrm{op}}\colon Y \to X$ are composable in C^{op}, with composite

$$f^{\mathrm{op}} g^{\mathrm{op}} = (gf)^{\mathrm{op}}$$

The composition rule is forced by the direction of the arrows and is worth reading slowly. In C the composite gf runs $X \to Y \to Z$. Reversing each arrow turns f into $f^{\mathrm{op}}\colon Y \to X$ and g into $g^{\mathrm{op}}\colon Z \to Y$, and the only way to compose these two is $Z \to Y \to X$, that is $f^{\mathrm{op}} g^{\mathrm{op}}$. The reversed composite therefore takes the label $(gf)^{\mathrm{op}}$, the reverse of the original composite. The rule $(gf)^{\mathrm{op}} = f^{\mathrm{op}} g^{\mathrm{op}}$ says exactly that reversal turns the order of composition around, the same order-reversal seen in the transpose of matrices $(AB)^{\top} = B^{\top} A^{\top}$ or the inverse of a product $(gh)^{-1} = h^{-1} g^{-1}$ in a group. The following square, the two ways of reading the composable pair $X \xrightarrow{f} Y \xrightarrow{g} Z$ and its reverse, records the construction.

The top row lives in C and the bottom row in C^{op}; the two rows carry the same objects and the same underlying arrows, only the directions and the composition order differ.

The construction is an involution: reversing twice restores the original category. Interchanging domain and codomain twice returns each arrow to its starting orientation, $1_X^{\mathrm{opop}} = 1_X$, and the composition rule applied twice gives $(f^{\mathrm{op}} g^{\mathrm{op}})^{\mathrm{op}} = g^{\mathrm{opop}} f^{\mathrm{opop}} = gf$, so $(C^{\mathrm{op}})^{\mathrm{op}} = C$ on the nose. This is what makes duality a tool rather than a mere relabeling: a category and its opposite stand on equal footing, and any construction available in one is available in the other by symmetry. There is no distinguished "forward" direction, only a chosen one.

The definition is uniform across all categories, but its content varies sharply with the category. The next example runs it through three of the standing cast to show that the opposite can be isomorphic

to the original, isomorphic in a less obvious way, or a category of an entirely different kind.

Example 61.3.2: Opposites of Posets, Groups, and Sets

1. *Posets.* A partially ordered set $(P, \leq)$ is a category with one object per element and a unique arrow $x \to y$ exactly when $x \leq y$ (definition 61.1.1). Reversing the arrows reverses the order: P^{op} has a unique arrow $x \to y$ exactly when $y \leq x$, so P^{op} is the poset $(P, \geq)$ with the order turned upside down. For the chain $(\mathbb{Z}, \leq)$ the covering arrows run

$$\cdots \longrightarrow -1 \longrightarrow 0 \longrightarrow 1 \longrightarrow 2 \longrightarrow \cdots$$

and in $(\mathbb{Z}, \leq)^{\mathrm{op}} = (\mathbb{Z}, \geq)$ they run the other way,

$$\cdots \longleftarrow -1 \longleftarrow 0 \longleftarrow 1 \longleftarrow 2 \longleftarrow \cdots$$

The opposite of a poset is again a poset, but usually a different one: a least element becomes a greatest element, an infimum becomes a supremum. This is the categorical root of the fact that every order-theoretic notion comes in a matched pair.

2. *Groups.* A group G is a one-object groupoid with $\mathrm{Hom}(*, *) = G$, composition given by the group multiplication. Its opposite G^{op} is again a one-object groupoid, hence again a group: the underlying set is the same, but the product is $g^{\mathrm{op}} h^{\mathrm{op}} = (hg)^{\mathrm{op}}$, so multiplication in G^{op} is the multiplication of G with the factors in reversed order. This G^{op} is the *opposite group*. It is isomorphic to G, but the isomorphism is not the identity map on the underlying set unless G is abelian; the natural isomorphism is inversion,

$$\varphi \colon G \to G^{\mathrm{op}}, \qquad \varphi(g) = g^{-1}$$

which is a homomorphism precisely because inversion reverses products,

$$\varphi(gh) = (gh)^{-1} = h^{-1} g^{-1}$$

the right-hand side being the product $\varphi(g)\varphi(h)$ computed in G^{op}. Passing to the opposite group is the same operation as passing between left and right actions. A left action of G on a set X is a rule with $(gh) \cdot x = g \cdot (h \cdot x)$; a right action satisfies $x \cdot (gh) = (x \cdot g) \cdot h$. Setting $g \cdot x := x \cdot g^{-1}$, or equivalently reading a right action of G as a left action of G^{op}, converts one into the other, and the order-reversal in G^{op} is exactly what makes the two associativity laws match. Dropping the requirement of inverses leaves a one-object category rather than a one-object groupoid, that is, a monoid; the opposite monoid M^{op} is defined by the same reversed product, and here M^{op} need not be isomorphic to M.

3. *Sets.* The opposite of **Set** is not **Set**. A morphism $X \to Y$ in $\mathbf{Set}^{\mathrm{op}}$ is, by definition, a function $Y \to X$, so composition in $\mathbf{Set}^{\mathrm{op}}$ is composition of functions read backwards. One is tempted to picture a morphism $f \colon X \to Y$ of $\mathbf{Set}^{\mathrm{op}}$ as "f run in reverse", a map $Y \to X$, but a function need not be invertible, so there is no such reverse function in general. What the reversed arrows track is not functions but relations. A function $f \colon A \to B$ is a relation that is single-valued (each $a \in A$ has exactly one image) and total (every $a \in A$ has an image); its reversed graph $\{(f(a), a) : a \in A\} \subseteq B \times A$ is a relation that is injective-on-the-nose (distinct a give distinct pairs) and surjective (every a appears), but is single-valued and total only when f is a bijection. So the arrows of $\mathbf{Set}^{\mathrm{op}}$ are reversed graphs of functions, which

> are relations of a constrained type, not functions. The precise statement is that $\mathbf{Set}^{\mathrm{op}}$ is equivalent to the category of complete atomic Boolean algebras (the powersets PX with their function-induced maps), not to **Set** itself. The takeaway needs no such machinery: reversing arrows in **Set** leaves the world of sets and functions entirely, so "the opposite" is a strictly new category, not a repackaging of the old one.

The three cases exhibit the full range. For a poset the opposite is another object of the same kind, obtained by an evident flip. For a group the opposite is again of the same kind and even isomorphic to the original, though by a map (inversion) that is invisible if one looks only at underlying sets. For **Set** the opposite is a category of a different nature altogether. In every case the objects are unchanged and only the direction of the arrows moves, yet the categories that result can be as close as isomorphic or as far apart as sets and Boolean algebras. This variability is what gives the next principle its force: a single argument, reinterpreted in the opposite category, can say something new precisely because the opposite category is different.

Everything so far concerns one category at a time. The reason opposite categories are indispensable is a metatheorem about the whole theory. Because the axioms of a category are self-dual, reversing every arrow in a valid argument produces another valid argument, so any statement proved for all categories automatically holds for all opposite categories, which is to say for all categories again with the arrows reversed. Stating this cleanly halves the work of the subject.

61.3.3 The Duality Principle Let S be a statement about categories, expressed in the language of objects, morphisms, domains, codomains, composites, and identities. Let S^{op} be the *dual statement*, obtained from S by reversing the direction of every morphism and the order of every composite (and leaving the objects, identities, and logical structure unchanged). Then S holds in a category C if and only if S^{op} holds in C^{op}. In particular, if S holds in *every* category, then so does S^{op}: each theorem of category theory yields a second theorem, its *dual*, for free.

The justification is immediate from the involution $(C^{\mathrm{op}})^{\mathrm{op}} = C$. A proof of S valid in every category is valid in particular in C^{op}; unwinding the definition of C^{op} (each arrow reversed, each composite reordered) turns the assertion "S holds in C^{op}" into the assertion "S^{op} holds in C". Since C was arbitrary, S^{op} holds in every category. There is nothing to check beyond the bookkeeping of reversal, and that bookkeeping is exactly the passage to the opposite category. The practical consequence is a discipline: a construction and its dual, conventionally distinguished by the prefix "co-", are literally the same construction performed in the opposite category. A colimit is a limit in C^{op}, a coproduct is a product in C^{op}, an initial object is a terminal object in C^{op}. To prove a fact about colimits, prove the corresponding fact about limits and read it in C^{op}; no separate argument is ever needed for the dual.

The cleanest illustration available at this stage is the pairing of monomorphisms with epimorphisms. Recall the definitions (definition 61.2.8): a morphism $f\colon X \to Y$ is a *monomorphism* if $fh = fk$ implies $h = k$ for all h, k into X, and an *epimorphism* if $hf = kf$ implies $h = k$ for all h, k out of Y. Written side by side, the epimorphism condition is the monomorphism condition with every composite reordered, which is to say read in the opposite category.

Proposition 61.3.4: Monomorphisms are Epimorphisms in the Opposite

Let C be a category and $f\colon X \to Y$ a morphism of C, with corresponding morphism $f^{\mathrm{op}}\colon Y \to X$ of C^{op}. Then f is a monomorphism in C if and only if f^{op} is an epimorphism in C^{op}. Dually, f is an epimorphism in C if and only if f^{op} is a monomorphism in C^{op}.

***Proof*:**
Fix $f\colon X \to Y$ in C. By definition 61.2.8, f is a monomorphism in C precisely when, for every object W and every pair of morphisms $h, k\colon W \to X$ of C,

$$fh = fk \implies h = k$$

Passing to C^{op}, the morphisms $h, k\colon W \to X$ of C become morphisms $h^{\mathrm{op}}, k^{\mathrm{op}}\colon X \to W$ of C^{op}, and $f^{\mathrm{op}}\colon Y \to X$ of C^{op} is composable before them. Applying the composition rule of definition 61.3.1 to the hypothesis and conclusion,

$$fh = fk \iff (fh)^{\mathrm{op}} = (fk)^{\mathrm{op}} \iff h^{\mathrm{op}} f^{\mathrm{op}} = k^{\mathrm{op}} f^{\mathrm{op}}$$

and $h = k \iff h^{\mathrm{op}} = k^{\mathrm{op}}$, since reversal is a bijection on morphisms. Substituting, the defining implication of a monomorphism for f in C reads

$$h^{\mathrm{op}} f^{\mathrm{op}} = k^{\mathrm{op}} f^{\mathrm{op}} \implies h^{\mathrm{op}} = k^{\mathrm{op}}$$

for all $h^{\mathrm{op}}, k^{\mathrm{op}}\colon X \to W$ of C^{op}. As W ranges over all objects and $h^{\mathrm{op}}, k^{\mathrm{op}}$ over all such pairs, this is exactly the condition that f^{op} be an epimorphism in C^{op} (definition 61.2.8). Hence f is a monomorphism in C if and only if f^{op} is an epimorphism in C^{op}. The second equivalence follows by applying the first to C^{op} in place of C and using $(C^{\mathrm{op}})^{\mathrm{op}} = C$, so that f^{op} is a monomorphism in C^{op} if and only if f is an epimorphism in C, as we sought to show.

The proposition is duality in miniature. Monomorphism and epimorphism are not two unrelated conditions that happen to resemble each other; they are a single condition read in the two directions, one the dual of the other. Anything proved about monomorphisms in every category, by the duality principle (box 61.3.3), holds verbatim for epimorphisms once every arrow is reversed, and conversely. This is why the two notions appear throughout the subject as an inseparable pair, and why the prefix "co-" recurs so insistently: it is the marker of a statement obtained by passing to the opposite category.

Duality is not confined to category theory as an internal bookkeeping device. Across mathematics one meets theorems asserting that two apparently unrelated classes of objects are opposite to each other, in the precise sense that one category is equivalent to the opposite of another. Each such theorem lets questions about one class be translated into questions about the other, often turning a hard geometric or analytic problem into a tractable algebraic one, and each is evidence that the reversal of arrows is a pervasive phenomenon. Three named examples indicate the range. *Gelfand duality* identifies the category of compact Hausdorff spaces with the opposite of the category of commutative unital C^*-algebras, sending a space X to its algebra $C(X)$ of continuous complex functions, so that the topology of X is recovered entirely from an algebra of functions on it. *Stone duality* identifies the category of Boolean algebras with the opposite of the category of compact Hausdorff totally disconnected spaces (Stone spaces), the algebraic and the topological faces of the same data. *Pontryagin duality* sends a locally compact abelian group G to its dual group $\hat{G} = \mathrm{Hom}(G, S^1)$ of

continuous characters and exhibits the category of locally compact abelian groups as equivalent to its own opposite, with the double dual $\hat{\hat{G}}$ canonically G again; it is the structural home of the Fourier transform. The proofs of these three belong to functional analysis, general topology, and harmonic analysis respectively and lie well beyond this chapter; they are cited here only as evidence that the opposite category, introduced above as a formal reversal of arrows, names a structure that recurs at the center of several mathematical disciplines.

61.4 Functors

Categories were built to record how objects of one kind relate to one another through their morphisms. The next question is the one that always follows the introduction of a new mathematical structure: what are the structure-preserving maps between two such structures? A map from one category to another must carry objects to objects and morphisms to morphisms, and it must respect the two pieces of data a category carries beyond its raw collections, composition and identities. Such a map is a *functor*, and it is the vehicle by which one part of mathematics is transported into another: the fundamental group turns spaces into groups, the spectrum turns rings into spaces, and the derivative turns smooth maps into linear ones. Each of these is a functor, and in each case the price of admission is exactly that composition be respected.

Definition 61.4.1: Functor

A *functor* $F\colon C \to D$ between categories C and D consists of

- an object Fc of D for each object c of C, and
- a morphism $Ff\colon Fc \to Fc'$ of D for each morphism $f\colon c \to c'$ of C, so that the domain and codomain of Ff are, respectively, F applied to the domain and codomain of f,

subject to the two axioms

1. (functoriality) $F(gf) = Fg\,Ff$ for every composable pair $f\colon c \to c'$, $g\colon c' \to c''$ of morphisms of C, and
2. (identities) $F(1_c) = 1_{Fc}$ for every object c of C.

A functor is thus a map of the underlying data of a category that preserves everything a category is made of: the assignment of domains and codomains, composition, and identities. The functoriality axiom is the substantive one. It says that F cannot see a composite gf as anything other than the composite $Fg\,Ff$ of the images, so a functor can never manufacture a relation between images that was not already present between the sources, nor destroy one that was. This is what makes a functor a faithful conduit of structure rather than an arbitrary reassignment: a commutative triangle in C is sent to a commutative triangle in D, so any equation between composites that holds in the source survives into the target. When $C = D$ the functor is an *endofunctor* of C.

The examples below are the standing cast the rest of the book returns to. Several are functors the reader has already met under other names; the point is that a single word now covers the powerset operation, the act of forgetting algebraic structure, the fundamental group, the derivative, and the notion of a group action all at once.

Example 61.4.2: Functors

1. *The covariant powerset endofunctor.* There is an endofunctor $P\colon \mathbf{Set} \to \mathbf{Set}$ sending a set A to its powerset PA, the set of all subsets of A, and sending a function $f\colon A \to B$ to the *direct image* function
$$Pf\colon PA \to PB \qquad A' \mapsto f(A')$$
where $f(A') = \{f(a) \mid a \in A'\}$. This is a functor: for $A' \subseteq A$ one has $(Pg\,Pf)(A') = g(f(A')) = (gf)(A') = P(gf)(A')$ because the image of a set under gf is the image under g of its image under f, and $P(1_A)(A') = 1_A(A') = A' = 1_{PA}(A')$, so P carries identities to identities.

2. *Forgetful functors.* There is a functor $U\colon \mathbf{Grp} \to \mathbf{Set}$ carrying each group to its underlying set and each group homomorphism to its underlying function. Functoriality and preservation of identities are immediate, since composition and identities of homomorphisms are computed as composition and identities of the underlying functions. A functor that discards part of the structure of its source is a *forgetful functor*. The same pattern gives $\mathbf{Mod}_R \to \mathbf{Ab}$ (forget the R-action, remember the underlying abelian group) and $\mathbf{Ring} \to \mathbf{Ab}$ (forget the multiplication, remember the additive group). These need not be inclusions: a single abelian group underlies many different rings, so $\mathbf{Ring} \to \mathbf{Ab}$ is far from injective on objects.

3. *The free-group functor.* In the opposite direction there is the *free functor* $F\colon \mathbf{Set} \to \mathbf{Grp}$ sending a set X to the free group FX on X and a function $f\colon X \to Y$ to the unique homomorphism $Ff\colon FX \to FY$ extending $x \mapsto f(x)$ on generators, see [21, Universal Property Of Free Groups]. Uniqueness of the extending homomorphism forces $F(gf)$ and $Fg\,Ff$ to agree, since both extend $x \mapsto g(f(x))$, and $F(1_X)$ and 1_{FX} both extend $x \mapsto x$, so F is a functor.

4. *The fundamental group.* The fundamental group is the functor $\pi_1\colon \mathbf{Top}_* \to \mathbf{Grp}$ from pointed spaces and basepoint-preserving continuous maps to groups: it sends a pointed space (X, x_0) to its fundamental group $\pi_1(X, x_0)$ of homotopy classes of loops at x_0, and a pointed map $f\colon (X, x_0) \to (Y, y_0)$ to the induced homomorphism $f_*\colon \pi_1(X, x_0) \to \pi_1(Y, y_0)$, $[\gamma] \mapsto [f \circ \gamma]$. That $(g \circ f)_* = g_*\, f_*$ and $(1_X)_* = 1_{\pi_1(X, x_0)}$ is exactly the functoriality of π_1, developed in [76].

5. *The derivative and the chain rule.* Let $\mathbf{Euclid}_*$ be the category whose objects are pointed finite-dimensional Euclidean spaces $(\mathbb{R}^n, a)$ and whose morphisms $(\mathbb{R}^n, a) \to (\mathbb{R}^m, b)$ are differentiable maps f with $f(a) = b$. The derivative is a functor
$$D\colon \mathbf{Euclid}_* \to \mathbf{Mat}_{\mathbb{R}} \qquad D(\mathbb{R}^n, a) = n, \qquad Df = \text{the Jacobian of } f \text{ at } a$$
sending a pointed Euclidean space to its dimension (an object of $\mathbf{Mat}_{\mathbb{R}}$) and a pointed differentiable map to its Jacobian matrix at the marked point. For composable $f\colon (\mathbb{R}^n, a) \to (\mathbb{R}^m, b)$ and $g\colon (\mathbb{R}^m, b) \to (\mathbb{R}^k, c)$, functoriality reads
$$D(gf) = Dg\, Df$$
the Jacobian of the composite equals the product of the Jacobian of g at b with the Jacobian of f at a. This equation is the chain rule; that D preserves identities is the statement that the derivative of an identity map is the identity matrix. The chain rule is the functoriality of the derivative.

6. *A group as a one-object category.* A group G is a category $\mathbf{B}G$ with a single object $*$, one morphism $* \to *$ for each element of G, composition given by the group operation, and 1_* the identity element. A functor $X\colon \mathbf{B}G \to C$ is then precisely an *action of G on an object of C*: it chooses an object $X*$ of C and, for each $g \in G$, an endomorphism $g_*\colon X* \to X*$, subject to
$$(hg)_* = h_*\, g_* \qquad \text{and} \qquad e_* = 1_{X*}$$
which are the functoriality and identity axioms written out. These are exactly the axioms of an action. Specializing the target recovers the familiar notions: a functor $\mathbf{B}G \to \mathbf{Set}$ is a G-set, a functor $\mathbf{B}G \to \mathbf{Vect}_k$ is a k-linear representation of G, and a functor $\mathbf{B}G \to \mathbf{Top}$ is a G-space. The three classical settings in which a group acts are three choices of target for one functor.

The last two examples repay a second look. The chain rule, which is usually presented as a formula to be memorized, is nothing more than the assertion that one particular assignment respects composition; once the derivative is recognized as a functor, the chain rule is not a theorem to be proved separately but the definition of what it means for D to be one. The one-object viewpoint is the same economy applied to group actions: rather than three definitions of a G-set, a G-representation, and a G-space, there is a single definition, a functor out of $\mathbf{B}G$, whose three instances differ only in where the arrows land. This is the recurring dividend of the categorical language, that constructions which look unrelated turn out to be one construction viewed through different targets.

Duality (definition 61.3.1) gives a second kind of functor. Reversing the arrows of the source category before applying a functor produces a map that turns composition around, and this arrow-reversing behavior is so common that it is given its own name.

Definition 61.4.3: Contravariant Functor

A *contravariant functor* F from C to D is a functor $F\colon C^{\mathrm{op}} \to D$. Unwinding the definition of the opposite category (definition 61.3.1), a contravariant functor assigns

- an object Fc of D to each object c of C, and
- a morphism $Ff\colon Fc' \to Fc$ of D to each morphism $f\colon c \to c'$ of C, reversing domain and codomain,

subject to

1. $F(gf) = Ff\, Fg$ for every composable pair $f\colon c \to c'$, $g\colon c' \to c''$ of C, and
2. $F(1_c) = 1_{Fc}$ for each object c of C.

For emphasis, a functor in the sense of definition 61.4.1 is called *covariant*.

The single point of difference is the reversal in the first axiom: a covariant functor sends gf to $Fg\,Ff$, whereas a contravariant functor sends it to $Ff\,Fg$, varying *contrary* to the direction of composition. This is not a new species of object but a bookkeeping convenience: a contravariant functor $C \to D$ is literally a covariant functor $C^{\mathrm{op}} \to D$, so every theorem about functors applies to contravariant ones after the source is replaced by its opposite. The examples are as ubiquitous as the covariant ones, and each is built by the same move, sending a map to a map that goes the other way.

Example 61.4.4: Contravariant Functors

1. *The linear dual.* The dual-space construction is a contravariant functor $(-)^*\colon \mathbf{Vect}_k^{\mathrm{op}} \to \mathbf{Vect}_k$ carrying a vector space V to its dual $V^* = \mathrm{Hom}_k(V,k)$ and a linear map $f\colon V \to W$ to the transpose $f^*\colon W^* \to V^*$ given by precomposition,
$$f^*(\varphi) = \varphi \circ f \qquad (\varphi\colon W \to k)$$
The reversal is forced by precomposition: since f^* eats a functional on W and returns one on V, it points from W^* to V^*. For composable $f\colon U \to V$ and $g\colon V \to W$ one computes $(gf)^*(\varphi) = \varphi \circ g \circ f = f^*(g^*(\varphi))$, so $(gf)^* = f^*g^*$, and $(1_V)^*(\varphi) = \varphi = 1_{V^*}(\varphi)$; the arrows reverse exactly as the definition requires.

2. *The contravariant powerset.* There is a contravariant functor $P\colon \mathbf{Set}^{\mathrm{op}} \to \mathbf{Set}$ sending a set A to PA and a function $f\colon A \to B$ to the *preimage* function
$$f^{-1}\colon PB \to PA \qquad B' \mapsto f^{-1}(B') = \{a \in A \,|\, f(a) \in B'\}$$
In contrast to the covariant powerset of example 61.4.2, which uses direct image and preserves the direction of f, the preimage points the other way. Functoriality holds because $(gf)^{-1}(C') = f^{-1}(g^{-1}(C'))$ for $C' \subseteq C$, which is the identity $(gf)^{-1} = f^{-1}g^{-1}$, and $(1_A)^{-1} = 1_{PA}$.

3. *The prime spectrum.* The spectrum is a contravariant functor $\mathrm{Spec}\colon \mathbf{CRing}^{\mathrm{op}} \to \mathbf{Top}$ sending a commutative ring R to its prime spectrum $\mathrm{Spec}\, R$ and a ring homomorphism $\varphi\colon R \to S$ to the map
$$\varphi^*\colon \mathrm{Spec}\, S \to \mathrm{Spec}\, R \qquad \mathfrak{p} \mapsto \varphi^{-1}(\mathfrak{p})$$
taking a prime $\mathfrak{p}$ of S to its preimage $\varphi^{-1}(\mathfrak{p})$, which is a prime of R because the preimage of a prime ideal under a ring homomorphism is prime. The contravariance is again a matter of preimages: φ runs from R to S, but φ^* runs from $\mathrm{Spec}\, S$ to $\mathrm{Spec}\, R$. Functoriality follows from $(\psi\varphi)^{-1}(\mathfrak{p}) = \varphi^{-1}(\psi^{-1}(\mathfrak{p}))$.

4. *The opens of a space.* For a topological space X, let $\mathcal{O}(X)$ be the set of open subsets of X, partially ordered by inclusion and so a poset. This is a contravariant functor $\mathcal{O}\colon \mathbf{Top}^{\mathrm{op}} \to \mathbf{Poset}$: a continuous map $f\colon X \to Y$ is sent to the preimage map
$$f^{-1}\colon \mathcal{O}(Y) \to \mathcal{O}(X) \qquad U \mapsto f^{-1}(U)$$
which lands in $\mathcal{O}(X)$ precisely because f is continuous, and which preserves inclusions since $U \subseteq V$ gives $f^{-1}(U) \subseteq f^{-1}(V)$. Functoriality is once more the composite-of-preimages identity $(gf)^{-1}(U) = f^{-1}(g^{-1}(U))$.

The four contravariant examples are variations on a single theme: each sends a map to its associated preimage or precomposition, and preimage inverts the direction of the arrow. The dual space, the contravariant powerset, the spectrum, and the opens of a space are the same movement performed in four categories. Set against the covariant powerset, which uses direct image and so preserves direction, they display in the sharpest possible terms the difference between forward transport by image and backward transport by preimage.

One property holds for every functor, covariant or contravariant, and it is the first indication that a

functor is a genuine conduit of categorical structure rather than an arbitrary map: a functor cannot tell isomorphic objects apart, because it carries the very equations that witness an isomorphism.

Lemma 61.4.5: Functors Preserve Isomorphisms

Let $F\colon C \to D$ be a functor. If $f\colon x \to y$ is an isomorphism in C, then $Ff\colon Fx \to Fy$ is an isomorphism in D, with inverse $F(f^{-1})$. In particular, $x \cong y$ in C implies $Fx \cong Fy$ in D.

***Proof*:**
Let $f\colon x \to y$ be an isomorphism in C with inverse $g = f^{-1}\colon y \to x$, so that $gf = 1_x$ and $fg = 1_y$ (definition 61.2.1). Applying F and using the functoriality and identity axioms of definition 61.4.1,

$$Fg\,Ff = F(gf) = F(1_x) = 1_{Fx}$$

so $Fg\colon Fy \to Fx$ is a left inverse of Ff. The same computation with the roles of f and g interchanged gives

$$Ff\,Fg = F(fg) = F(1_y) = 1_{Fy}$$

so Fg is also a right inverse of Ff. Thus Ff is an isomorphism with two-sided inverse $Fg = F(f^{-1})$, and $Fx \cong Fy$, as we sought to show.

The proof used only the two functor axioms, and it applies verbatim to a contravariant functor: there the images of f and g compose in the opposite order, but the two products $Ff\,Fg$ and $Fg\,Ff$ still equal 1_{Fx} and 1_{Fy} in some order, so Ff remains invertible. Every functor therefore respects the categorical notion of sameness, which is why a functorial invariant, one whose value is a functor, can be used to distinguish objects: if $Fx \ncong Fy$ then $x \ncong y$. This is the mechanism behind the fundamental group as a tool in topology, since π_1, being a functor, sends homeomorphic pointed spaces to isomorphic groups, so non-isomorphic fundamental groups certify that two spaces are not homeomorphic.

Isomorphisms are the only class of maps a functor is guaranteed to preserve. Functors need not preserve monomorphisms or epimorphisms (definition 61.2.8). The spectrum shows the failure: the inclusion $\mathbb{Z} \hookrightarrow \mathbb{Q}$ is an epimorphism in **CRing** (example 61.2.9), yet Spec reverses it, and its image $\operatorname{Spec}\mathbb{Q} \to \operatorname{Spec}\mathbb{Z}$ is a monomorphism rather than an epimorphism, so the epi property is not carried across. What a functor does preserve, by the identical one-line argument that proves lemma 61.4.5, is any mono or epi that *splits*: if f has a one-sided inverse s with $sf = 1$, then applying F gives $Fs\,Ff = 1$, so Ff retains that one-sided inverse and remains a split monomorphism, and dually for a split epimorphism. The equations a splitting provides survive because a functor preserves exactly the equations between composites, and nothing more.

61.5 Natural Transformations

Functors compare categories; natural transformations compare functors. This third layer is what makes the categorical vocabulary powerful enough to say precisely what mathematicians have always meant by a construction being *canonical*, or *basis-free*, or *independent of choices*. The guiding example is one every reader has met in linear algebra. A finite-dimensional vector space V is isomorphic to its dual V^*, but only after a basis is chosen; change the basis and the isomorphism changes. Yet V is

also isomorphic to its double dual V^{**}, and this time no choice is needed at all: a single formula, valid for every V and compatible with every linear map, produces the isomorphism. The distinction between these two isomorphisms, one requiring a choice and one not, is not a vague matter of taste. It is captured exactly by whether a family of maps assembles into a natural transformation. The section develops the double-dual example first, extracts the general definition, packages functors and their transformations into a category of their own, and closes with the notion of sameness that naturality makes available for categories themselves: equivalence.

The dual space is the starting point. For a field k and a vector space V, the linear dual is $V^* = \mathrm{Hom}_k(V, k)$, the space of linear functionals on V; this is the object developed in Core Algebra, and its basic properties are cited rather than reproved here (see [21, Dual Space]). When V is finite-dimensional, V^* has the same dimension as V, so the two are isomorphic. An isomorphism is built by choosing a basis $e_1, \dots, e_n$ of V and sending e_i to the dual basis vector e_i^*, the functional determined by $e_i^*(e_j) = \delta_{ij}$. This map is a linear isomorphism, but it depends on the basis: a different basis of V yields a different isomorphism $V \to V^*$, and there is no way to single one out. The double dual behaves differently, and pinning down that difference is the object of the example.

Example 61.5.1: The Double Dual of a Vector Space

Let k be a field and V a vector space over k. Its *double dual* is $V^{**} = \mathrm{Hom}_k(V^*, k) = \mathrm{Hom}_k(\mathrm{Hom}_k(V, k), k)$. For each vector $v \in V$ define the *evaluation map* $\mathrm{ev}_V(v)\colon V^* \to k$ by

$$\mathrm{ev}_V(v)(\varphi) = \varphi(v) \qquad (\varphi \in V^*)$$

so $\mathrm{ev}_V(v)$ is the functional on V^* that reads off the value of a given functional at v. This assembles into a single map $\mathrm{ev}_V\colon V \to V^{**}$, $v \mapsto \mathrm{ev}_V(v)$, defined without any reference to a basis.

Step 1: $\mathrm{ev}_V(v)$ *is linear for each* v. For $\varphi, \psi \in V^*$ and $c \in k$,

$$\mathrm{ev}_V(v)(\varphi + \psi) = (\varphi + \psi)(v) = \varphi(v) + \psi(v) = \mathrm{ev}_V(v)(\varphi) + \mathrm{ev}_V(v)(\psi)$$

and $\mathrm{ev}_V(v)(c\varphi) = (c\varphi)(v) = c\,\varphi(v) = c\,\mathrm{ev}_V(v)(\varphi)$, using the vector-space structure on V^*. So $\mathrm{ev}_V(v) \in V^{**}$.

Step 2: ev_V *is linear in* v. For $v, w \in V$ and $c \in k$, the identity of functionals $\mathrm{ev}_V(v + w) = \mathrm{ev}_V(v) + \mathrm{ev}_V(w)$ is checked by evaluating both sides at an arbitrary $\varphi \in V^*$:

$$\mathrm{ev}_V(v + w)(\varphi) = \varphi(v + w) = \varphi(v) + \varphi(w) = \mathrm{ev}_V(v)(\varphi) + \mathrm{ev}_V(w)(\varphi)$$

and likewise $\mathrm{ev}_V(cv)(\varphi) = \varphi(cv) = c\,\varphi(v) = c\,\mathrm{ev}_V(v)(\varphi)$, so $\mathrm{ev}_V(cv) = c\,\mathrm{ev}_V(v)$. The linearity of ev_V is inherited from the linearity of the functionals it evaluates against.

Step 3: ev_V *is injective.* Suppose $v \neq 0$. Extend v to a basis of V and let $\varphi \in V^*$ be the coordinate functional with $\varphi(v) = 1$ (see [21, Vector Space has Basis, Universal Property of Free Modules] for the existence of such a functional). Then $\mathrm{ev}_V(v)(\varphi) = \varphi(v) = 1 \neq 0$, so $\mathrm{ev}_V(v) \neq 0$. Thus $\ker \mathrm{ev}_V = 0$.

Step 4: in finite dimension ev_V *is an isomorphism.* If $\dim V = n < \infty$ then $\dim V^* = n$ and $\dim V^{**} = n$, so ev_V is an injective linear map between spaces of equal finite dimension and is therefore an isomorphism. Hence $V \cong V^{**}$ with no choice of basis.

Step 5: the evaluation maps are compatible with every linear map. Given a linear map $f\colon V \to W$, the dual map $f^*\colon W^* \to V^*$ is $f^*(\psi) = \psi \circ f$, and the double dual map $f^{**}\colon V^{**} \to W^{**}$ is

$f^{**} = (f^*)^*$, so $f^{**}(\Phi) = \Phi \circ f^*$ for $\Phi \in V^{**}$. The square

$$\begin{array}{ccc} V & \xrightarrow{\mathrm{ev}_V} & V^{**} \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f^{**}} \\ W & \xrightarrow[\mathrm{ev}_W]{} & W^{**} \end{array}$$

commutes. Indeed, for $v \in V$ and any $\psi \in W^*$,

$$f^{**}(\mathrm{ev}_V(v))(\psi) = \mathrm{ev}_V(v)(f^*\psi) = (f^*\psi)(v) = \psi(f(v)) = \mathrm{ev}_W(f(v))(\psi)$$

so $f^{**} \circ \mathrm{ev}_V = \mathrm{ev}_W \circ f$ as maps $V \to W^{**}$.

The five steps isolate exactly what is meant by canonicity. The map ev_V is defined by one formula that mentions only the data present in every vector space, so it exists for all V simultaneously (Steps 1 and 2), it is an isomorphism whenever V is finite-dimensional (Steps 3 and 4), and Step 5 shows that the whole family $\{\mathrm{ev}_V\}_V$ is compatible with the maps between spaces: transporting a vector along f and then evaluating gives the same answer as evaluating and then transporting along f^{**}. The isomorphism $V \cong V^*$ has no analogue of Step 5, precisely because it is built from a basis rather than from a formula uniform in V. The commuting square of Step 5 is the whole content of naturality, and abstracting it gives the central definition.

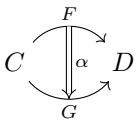
Definition 61.5.2: Natural Transformation

Let C and D be categories and let $F, G \colon C \to D$ be functors. A *natural transformation* $\alpha \colon F \Rightarrow G$ assigns to each object c of C a morphism

$$\alpha_c \colon Fc \to Gc$$

in D, called the *component* of α at c, such that for every morphism $f \colon c \to c'$ in C the *naturality square*

$$\begin{array}{ccc} Fc & \xrightarrow{\alpha_c} & Gc \\ {\scriptstyle Ff}\downarrow & & \downarrow{\scriptstyle Gf} \\ Fc' & \xrightarrow[\alpha_{c'}]{} & Gc' \end{array}$$



commutes, that is,

$$Gf \circ \alpha_c = \alpha_{c'} \circ Ff$$

A natural transformation $\alpha \colon F \Rightarrow G$ is a *natural isomorphism* if every component α_c is an isomorphism in D. When a natural isomorphism $F \Rightarrow G$ exists, the functors are *naturally isomorphic*, written $F \cong G$.

A natural transformation is a family of morphisms, one per object of the source category, wired together by the naturality condition so that the family respects every morphism of the source. The double arrow $\Rightarrow$ marks the new altitude: an ordinary morphism $\to$ connects objects, a functor $\to$ connects categories, and a natural transformation $\Rightarrow$ connects functors. It is often drawn as a 2-cell

filling the region between two parallel functors,

which records the shape of the data: two functors $C \to D$ and a transformation between them. The naturality square is the substantive clause. Without it a family $\{\alpha_c\}$ is just an unstructured collection of morphisms; with it, α interacts coherently with all of C, and this coherence is what earns the word "natural". A useful reading of the square is that α commutes with change of object: whether one applies α before or after transporting along f, the result is the same.

The double-dual example is now an instance of the definition, and naming the two functors involved makes the fit exact.

Example 61.5.3: Evaluation as a Natural Isomorphism

Take $C = D = \mathbf{Vect}_k$. The identity functor $\mathrm{Id}\colon \mathbf{Vect}_k \to \mathbf{Vect}_k$ sends each space to itself and each linear map to itself. The *double dual functor* $(-)^{**}\colon \mathbf{Vect}_k \to \mathbf{Vect}_k$ sends V to V^{**} and $f\colon V \to W$ to $f^{**}\colon V^{**} \to W^{**}$; it is a covariant functor because dualizing twice restores the original variance (each application of $(-)^*$ is contravariant, and the composite of two contravariant functors is covariant, cf. definition 61.4.3).

The evaluation maps of example 61.5.1 are the components of a natural transformation

$$\mathrm{ev}\colon \mathrm{Id} \Rightarrow (-)^{**}$$

with component $\mathrm{ev}_V\colon V \to V^{**}$ at each space V. The naturality square at a linear map $f\colon V \to W$ is

$$\begin{array}{ccc} V & \xrightarrow{\mathrm{ev}_V} & V^{**} \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f^{**}} \\ W & \xrightarrow[\mathrm{ev}_W]{} & W^{**} \end{array}$$

which is exactly the commuting square proved in Step 5 of example 61.5.1. Restricting to the full subcategory of finite-dimensional spaces, every component ev_V is an isomorphism (Step 4), so ev is a natural isomorphism there and $\mathrm{Id} \cong (-)^{**}$. This is the precise sense in which a finite-dimensional space is canonically its own double dual: not only that each V is isomorphic to V^{**}, but that the isomorphisms are the components of a single natural transformation.

The single dual admits no such transformation, and the reason is worth isolating carefully, since it is a matter of variance. Each application of $(-)^*$ is contravariant, so the single dual is a functor $(-)^*\colon \mathbf{Vect}_k^{\mathrm{op}} \to \mathbf{Vect}_k$, not an endofunctor of $\mathbf{Vect}_k$; the symbol $\mathrm{Id} \Rightarrow (-)^*$ does not even typecheck, because a natural transformation compares two functors of the same variance and the naturality square would need its right edge $f^*\colon W^* \to V^*$ to point the same way as $f\colon V \to W$, which it does not. The comparison is made on the groupoid $\mathbf{Vect}_k^{\mathrm{fd},\cong}$ of finite-dimensional spaces and their isomorphisms, where every morphism is invertible and variance is immaterial; there both Id and $(-)^*$ are genuine endofunctors, so a natural isomorphism $\mathrm{Id} \cong (-)^*$ is a meaningful thing to ask for. None exists: the family of basis-dependent isomorphisms $V \to V^*$ does *not* assemble into a natural transformation, because the naturality square fails for the isomorphisms of V that rescale the chosen basis. Naturality is exactly the property the basis-free construction has and the basis-dependent one lacks.

The contrast in the example is worth stating as a principle. A construction is canonical precisely when it is natural, that is, when its instances at the various objects are the components of a natural transformation. Any construction that requires an arbitrary choice, a basis, a splitting, a lift, fails to be natural, because different choices produce components that violate the naturality square. The vocabulary of natural transformations turns the informal "no choices were made" into a checkable condition on a commuting diagram.

Once natural transformations are in hand, functors between two fixed categories become the objects of a category in their own right, with natural transformations as the morphisms. This packaging is not a formality: it is the setting in which diagrams, presheaves, and much of the rest of the subject live, and it is where the double-dual isomorphism becomes an isomorphism in the literal categorical sense. To build it, one needs to know how natural transformations compose. Given $\alpha\colon F \Rightarrow G$ and $\beta\colon G \Rightarrow H$ between functors $F, G, H\colon C \to D$, the composite is defined componentwise by $(\beta\alpha)_c = \beta_c \circ \alpha_c$, and the identity transformation $1_F\colon F \Rightarrow F$ has components $(1_F)_c = 1_{Fc}$.

Definition 61.5.4: Functor Category

Let C and D be categories. The *functor category* $[C, D]$ (also written D^C) has

- as objects, the functors $F\colon C \to D$;
- as morphisms $F \to G$, the natural transformations $\alpha\colon F \Rightarrow G$.

The identity morphism on a functor F is the natural transformation 1_F with components $(1_F)_c = 1_{Fc}$, and the composite of $\alpha\colon F \Rightarrow G$ with $\beta\colon G \Rightarrow H$ is the natural transformation $\beta\alpha\colon F \Rightarrow H$ with components $(\beta\alpha)_c = \beta_c \circ \alpha_c$.

The definition asserts that $[C, D]$ is a category, and this must be verified: the proposed composite and identities have to be natural transformations, and they have to satisfy the category axioms. The verification is short, and doing it in full shows how the naturality squares of the factors combine.

***Proof*:**
Two things require checking: that $\beta\alpha$ and 1_F are natural transformations, and that composition is associative and unital.

Step 1: the componentwise composite is natural. Let $\alpha\colon F \Rightarrow G$ and $\beta\colon G \Rightarrow H$ be natural, and let $f\colon c \to c'$ be a morphism in C. Naturality of α gives $Gf \circ \alpha_c = \alpha_{c'} \circ Ff$, and naturality of β gives $Hf \circ \beta_c = \beta_{c'} \circ Gf$. Then

$$Hf \circ (\beta\alpha)_c = Hf \circ \beta_c \circ \alpha_c = \beta_{c'} \circ Gf \circ \alpha_c = \beta_{c'} \circ \alpha_{c'} \circ Ff = (\beta\alpha)_{c'} \circ Ff$$

so the naturality square for $\beta\alpha$ commutes. Diagrammatically, the two naturality squares stack vertically and the outer rectangle is what commutes:

$$\begin{array}{ccccc} Fc & \xrightarrow{\alpha_c} & Gc & \xrightarrow{\beta_c} & Hc \\ {\scriptstyle Ff}\downarrow & & \downarrow{\scriptstyle Gf} & & \downarrow{\scriptstyle Hf} \\ Fc' & \xrightarrow[\alpha_{c'}]{} & Gc' & \xrightarrow[\beta_{c'}]{} & Hc' \end{array}$$

Step 2: the identity is natural. For 1_F with components 1_{Fc} and any $f\colon c \to c'$, both routes around the square equal Ff, since $Ff \circ 1_{Fc} = Ff = 1_{Fc'} \circ Ff$. So 1_F is a natural transformation.

Step 3: the category axioms. Composition and identities in $[C, D]$ are defined componentwise, and in each component they are ordinary composition and identities in D. Associativity and the unit laws therefore hold component by component, inherited from the corresponding axioms in D. For a third composable transformation $\gamma\colon H \Rightarrow K$ and each object c,

$$((\gamma\beta)\alpha)_c = \gamma_c\beta_c\alpha_c = (\gamma(\beta\alpha))_c, \qquad (1_G\,\alpha)_c = \alpha_c = (\alpha\,1_F)_c$$

A pair of natural transformations agreeing in every component are equal, so these componentwise identities give the required equalities of natural transformations. Thus $[C, D]$ satisfies the category axioms, completing the proof.

The functor category is the natural home for the double-dual isomorphism. In $[\mathbf{Vect}_k, \mathbf{Vect}_k]$ the transformation $\mathrm{ev}\colon \mathrm{Id} \Rightarrow (-)^{**}$ of example 61.5.3 is a morphism, and because every component is an isomorphism (in finite dimensions) it is an isomorphism in the functor category: the componentwise inverse ev^{-1}, with components $(\mathrm{ev}_V)^{-1}$, is again natural and is a two-sided inverse to ev. So the statement "V is canonically isomorphic to V^{**}" becomes the statement "Id and $(-)^{**}$ are isomorphic objects of the functor category". The composition just defined, taking place along the objects of C, is the *vertical* composition of natural transformations; there is a second, *horizontal* composition that composes transformations between functors that themselves compose, developed when it is needed. Functor categories are already familiar in disguise: when C is a small category and $D = \mathbf{Set}$, an object of $[C, \mathbf{Set}]$ is a diagram of sets shaped like C, and morphisms of diagrams are exactly natural transformations.

Natural isomorphism is also the ingredient needed to fix the notion of sameness for categories themselves. The obvious candidate, isomorphism of categories, asks too much. Two categories C and D would be isomorphic if there were functors $F\colon C \to D$ and $G\colon D \to C$ with $GF = \mathrm{Id}_C$ and $FG = \mathrm{Id}_D$ on the nose, meaning $GFc = c$ for every object c and $GFf = f$ for every morphism. In practice this equality-on-objects requirement is almost never met by the functors one cares about, because the objects of C and D are typically built from different raw material even when the categories carry the same mathematical content. What one wants is that GFc be canonically isomorphic to c, not equal to it, uniformly in c; and "canonically isomorphic, uniformly in c" is precisely a natural isomorphism $GF \cong \mathrm{Id}_C$. Weakening equality to natural isomorphism gives the right notion.

Definition 61.5.5: Equivalence of Categories

An *equivalence of categories* between C and D consists of functors $F\colon C \to D$ and $G\colon D \to C$ together with natural isomorphisms

$$\eta\colon \mathrm{Id}_C \Rightarrow GF \qquad \text{and} \qquad \varepsilon\colon FG \Rightarrow \mathrm{Id}_D$$

(each component an isomorphism). When such data exist, F is an *equivalence*, G is a *quasi-inverse* of F, and the categories C and D are *equivalent*, written $C \simeq D$.

An equivalence relaxes the two rigid equations $GF = \mathrm{Id}_C$ and $FG = \mathrm{Id}_D$ of an isomorphism to the two natural isomorphisms $GF \cong \mathrm{Id}_C$ and $FG \cong \mathrm{Id}_D$. The functor F need not hit every object of D on the nose, nor establish a bijection between objects; it need only do so up to isomorphism and in a way compatible with all morphisms. This is the correct notion of sameness for categories: it identifies categories that carry the same mathematical information even when their objects are packaged differently, and essentially every "two descriptions of the same theory" result in mathematics is an equivalence rather than an isomorphism of categories.

There is a second characterization of equivalences that is usually easier to check than exhibiting a quasi-inverse, phrased entirely in terms of the single functor F. Recall from definition 61.4.1 that F acts on hom-sets by $f \mapsto Ff$; call F *full* if each of these maps $\mathrm{Hom}_C(c, c') \to \mathrm{Hom}_D(Fc, Fc')$ is surjective, *faithful* if each is injective, and *fully faithful* if each is a bijection. Call F *essentially surjective* if every object d of D is isomorphic to Fc for some object c of C. The two conditions together say that F is a bijection on morphisms between any two objects and hits every object up to isomorphism.

Proposition 61.5.6: Characterization of Equivalences

A functor $F\colon C \to D$ is an equivalence of categories if and only if F is full, faithful, and essentially surjective.

The forward direction is elementary and can be given now; the converse requires building a quasi-inverse object by object, and its construction is deferred to the chapter on the Yoneda lemma, where the tools for choosing the components coherently are in place.

***Proof*:**
Only the forward implication is proved here; for the converse, the construction of a quasi-inverse from full faithfulness and essential surjectivity is carried out once the necessary machinery is available, and is taken up later in the book.

Suppose F is an equivalence, with quasi-inverse G and natural isomorphisms $\eta\colon \mathrm{Id}_C \Rightarrow GF$ and $\varepsilon\colon FG \Rightarrow \mathrm{Id}_D$.

Step 1: F is essentially surjective. For any object d of D, the component $\varepsilon_d\colon FGd \to d$ is an isomorphism, so $d \cong Fc$ for $c = Gd$. Every object of D is thus isomorphic to one in the image of F.

Step 2: F is faithful. Let $f, g\colon c \to c'$ satisfy $Ff = Fg$. Applying G gives $GFf = GFg$. Naturality of η at the morphism f gives $GFf \circ \eta_c = \eta_{c'} \circ f$, and likewise for g, so

$$\eta_{c'} \circ f = GFf \circ \eta_c = GFg \circ \eta_c = \eta_{c'} \circ g$$

Since $\eta_{c'}$ is an isomorphism it is monic, and cancelling it gives $f = g$. Thus F is faithful. The identical argument applied to G (with the natural isomorphism ε in place of η) shows G is faithful as well.

Step 3: F is full. Let $h\colon Fc \to Fc'$ be any morphism in D. Set $f = \eta_{c'}^{-1} \circ Gh \circ \eta_c\colon c \to c'$, a morphism of C built from $Gh\colon GFc \to GFc'$ and the isomorphisms η_c, $\eta_{c'}$. Naturality of η at f reads $GFf \circ \eta_c = \eta_{c'} \circ f$, and substituting the definition of f gives $\eta_{c'} \circ f = Gh \circ \eta_c$, whence $GFf = Gh$. Because G is faithful (Step 2), $GFf = Gh$ forces $Ff = h$. So every $h\colon Fc \to Fc'$ is Ff for some f, and F is full, as we sought to show.

The two descriptions of an equivalence serve different purposes. The definition in terms of a quasi-inverse and two natural isomorphisms is the one to use when the inverse construction is at hand and one wants to transport structure back and forth. The characterization by full faithfulness and essential surjectivity is the one to use when only F is given and building an explicit G would be laborious: three conditions on a single functor replace the search for a partner. A concrete instance shows the second criterion at work.

Example 61.5.7: Matrices as an Equivalence

Let k be a field, let $\mathbf{Vect}_k^{\mathrm{fd}}$ be the category of finite-dimensional k-vector spaces and linear maps, and let $\mathbf{Mat}_k$ be the category whose objects are the natural numbers $0, 1, 2, \ldots$ and whose morphisms $m \to n$ are the $n \times m$ matrices over k, with composition given by matrix multiplication and identities the identity matrices (this is the matrix category $\mathbf{Mat}_k$ of example 61.1.4, specialized to $R = k$). Define $F\colon \mathbf{Mat}_k \to \mathbf{Vect}_k^{\mathrm{fd}}$ by $F(n) = k^n$ on objects and by sending an $n \times m$ matrix A to the linear map $k^m \to k^n$, $x \mapsto Ax$.

The claim is that F is an equivalence, verified through proposition 61.5.6.

- *Fully faithful.* A linear map $k^m \to k^n$ is represented, with respect to the standard bases, by a unique $n \times m$ matrix, and every such matrix arises this way. So $\mathbf{Mat}_k(m, n) \to \mathrm{Hom}_k(k^m, k^n)$, $A \mapsto (x \mapsto Ax)$, is a bijection: F is full and faithful.
- *Essentially surjective.* Every finite-dimensional space V has a basis of some size n, and choosing one gives an isomorphism $V \cong k^n = F(n)$ (see [21, Vector Space has Basis, Basis iff Free]). So every object of $\mathbf{Vect}_k^{\mathrm{fd}}$ is isomorphic to one in the image of F.

Hence F is an equivalence, and $\mathbf{Mat}_k \simeq \mathbf{Vect}_k^{\mathrm{fd}}$.

The equivalence in the example is not an isomorphism of categories, and the reason is instructive. The objects of $\mathbf{Mat}_k$ are natural numbers, while the objects of $\mathbf{Vect}_k^{\mathrm{fd}}$ are vector spaces; there are a proper class of two-dimensional spaces but only one object 2 in $\mathbf{Mat}_k$, so no functor can be a bijection on objects and $GF = \mathrm{Id}$ cannot hold on the nose. Yet the two categories carry identical information: linear algebra on finite-dimensional spaces is the theory of matrices up to change of basis, and the equivalence is the exact expression of that identity. This is the recurring pattern. Equivalence, not isomorphism, is the notion of sameness for categories, because it records that two categories have the same objects and morphisms up to canonical isomorphism, which is all that the categorical viewpoint, where an object is known only through its morphisms, can or should ask.

62

The Yoneda Lemma and Representability

Chapter 1 built the categorical language and returned to one thread: an object is determined by its morphisms. This chapter makes it a theorem. The *representable functor* $\mathrm{Hom}(c, -)$ records how an object c maps to every other; the *Yoneda lemma* computes its natural transformations into any set-valued functor, and the *Yoneda embedding* recovers c from the presheaf it represents. Along the way we settle questions left open in Chapter 1, among them the converse of the equivalence characterization (proposition 61.5.6).

62.1 Representable Functors

The first step toward the Yoneda lemma is to package the morphisms out of a fixed object as a functor. Fixing an object c of a locally small category and letting the second slot of the hom-set vary produces a set-valued functor; the functors that arise this way, and the objects that produce them, are the subject of this section. A functor isomorphic to one of these is *representable*, and the isomorphism is pinned down by a single element, the universal element.

We work throughout in a locally small category C (definition 61.1.7), so that each collection $\mathrm{Hom}_C(x, y)$ is a set.

Definition 62.1.1: Representable Functor

Let C be locally small and c an object of C. The *covariant hom-functor*

$$\mathrm{Hom}(c,-)\colon C \to \mathbf{Set}$$

sends an object x to the set $\mathrm{Hom}(c,x)$ and a morphism $f\colon x \to y$ to *post-composition*

$$f_*\colon \mathrm{Hom}(c,x) \to \mathrm{Hom}(c,y), \qquad f_*(h) = fh$$

The *contravariant hom-functor*

$$\mathrm{Hom}(-,c)\colon C^{\mathrm{op}} \to \mathbf{Set}$$

sends x to $\mathrm{Hom}(x,c)$ and $f\colon x \to y$ to *pre-composition*

$$f^*\colon \mathrm{Hom}(y,c) \to \mathrm{Hom}(x,c), \qquad f^*(h) = hf$$

A functor $F\colon C \to \mathbf{Set}$ is *representable* if there is an object c and a natural isomorphism $F \cong \mathrm{Hom}(c,-)$; the object c is a *representing object* for F. Dually, a functor $F\colon C^{\mathrm{op}} \to \mathbf{Set}$ is *representable* if $F \cong \mathrm{Hom}(-,c)$ for some c.

Functoriality of $\mathrm{Hom}(c,-)$ is the two composition laws of C: for $f\colon x \to y$ and $g\colon y \to z$ one has $(gf)_*(h) = gfh = g_*(f_*(h))$, so $(gf)_* = g_*f_*$, and $(1_x)_*(h) = h$, so $(1_x)_* = 1_{\mathrm{Hom}(c,x)}$. The same identities read backwards give $(gf)^* = f^*g^*$, the order-reversal that makes $\mathrm{Hom}(-,c)$ contravariant. A representing object, if one exists, is a solution to the problem posed by F: it is an object whose maps out of it (or into it) reproduce the sets Fx compatibly with all the morphisms of C. Chapter 1 already showed how much a hom-set encodes, since a morphism is an isomorphism exactly when post-composition with it is a bijection of hom-sets for every test object (example 61.1.8 recorded the first instances); here the hom-set is promoted from a single set to a functor.

Example 62.1.2: The Underlying Set of a Group

The forgetful functor $U\colon \mathbf{Grp} \to \mathbf{Set}$, sending a group to its underlying set and a homomorphism to its underlying function, is representable, and the integers $\mathbb{Z}$ represent it. A homomorphism $\mathbb{Z} \to G$ is determined by the image of the generator 1, and any element of G is a legitimate image, so

$$\mathrm{Hom}_{\mathbf{Grp}}(\mathbb{Z},G) \cong UG, \qquad \varphi \mapsto \varphi(1)$$

This bijection is natural in G: for a homomorphism $\psi\colon G \to H$ the square comparing $\varphi \mapsto \varphi(1)$ on either side commutes, since $(\psi\varphi)(1) = \psi(\varphi(1))$. So $U \cong \mathrm{Hom}_{\mathbf{Grp}}(\mathbb{Z},-)$. That $\mathbb{Z}$ is the free group on one generator ([21, Free Groups]) is exactly the statement that it represents the underlying-set functor.

A representing object is a compressed description of a whole functor, and the examples of most interest name a construction the reader already knows. Before collecting more of them it is worth isolating the contravariant case, where the objects of the represented functor are the presheaves.

Definition 62.1.3: Presheaf

A *presheaf* on a category C is a functor $F\colon C^{\mathrm{op}} \to \mathbf{Set}$. Presheaves on C, together with natural transformations between them, form the *presheaf category*

$$\mathbf{PSh}(C) = [C^{\mathrm{op}}, \mathbf{Set}]$$

the functor category (definition 61.5.4) of contravariant set-valued functors on C.

For each object c the contravariant hom-functor $\mathrm{Hom}(-, c)$ is a presheaf, the *presheaf represented by* c; a presheaf isomorphic to some $\mathrm{Hom}(-, c)$ is representable in the sense of definition 62.1.1. The two variances are best seen together. Holding neither slot of the hom-set fixed gives a functor of both arguments at once.

Definition 62.1.4: The Two-Sided Hom-Bifunctor

Let C be locally small. The *hom-bifunctor*

$$\mathrm{Hom}(-,-)\colon C^{\mathrm{op}} \times C \to \mathbf{Set}$$

sends an object (x, y) to $\mathrm{Hom}(x, y)$ and a morphism $(f, g)\colon (x, y) \to (x', y')$, i.e. a pair $f\colon x' \to x$ in C and $g\colon y \to y'$ in C, to

$$\mathrm{Hom}(x, y) \to \mathrm{Hom}(x', y'), \qquad h \mapsto ghf$$

Functoriality is one line: given a second pair $(f', g')\colon (x', y') \to (x'', y'')$, composing the induced maps sends h to $g'(ghf)f' = (g'g)h(ff')$, which is the map induced by the composite $(f', g')(f, g) = (ff', g'g)$ in $C^{\mathrm{op}} \times C$; and the identity pair $(1_x, 1_y)$ induces $h \mapsto h$. Fixing the first slot at c recovers $\mathrm{Hom}(c, -)$ and fixing the second recovers $\mathrm{Hom}(-, c)$, so the bifunctor is the common source of both hom-functors.

The definition of representability quantifies over all objects and all elements at once, through the natural isomorphism. It has a pointwise reformulation carried by a single piece of data. An isomorphism $F \cong \mathrm{Hom}(c, -)$ is pinned down by where the identity 1_c goes, and the element of Fc it corresponds to satisfies a universal property that says exactly "every element of every Fd factors through it uniquely."

Definition 62.1.5: Universal Element

Let $F\colon C \to \mathbf{Set}$. A *universal element* of F is a pair (c, x) with c an object of C and $x \in Fc$ such that for every object d and every $y \in Fd$ there is a unique morphism $f\colon c \to d$ with $(Ff)(x) = y$.

The pair (c, x) is universal in that every element of the functor is obtained from x by transport along a unique morphism. The following makes precise that a universal element is the same data as a representation.

Proposition 62.1.6: Representability by a Universal Element

A functor $F\colon C \to \mathbf{Set}$ is representable if and only if it has a universal element. Explicitly, a natural isomorphism $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$ corresponds to the universal element (c,x) with $x = \alpha_c(1_c)$, and conversely every universal element arises this way from a unique natural isomorphism.

***Proof*:**

Step 1: A representation gives a universal element. Suppose $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$ is a natural isomorphism, and set $x = \alpha_c(1_c) \in Fc$. Fix an object d and an element $y \in Fd$. Naturality of α at a morphism $f\colon c \to d$ is the commuting square

$$\begin{array}{ccc} \mathrm{Hom}(c,c) & \xrightarrow{\alpha_c} & Fc \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle Ff} \\ \mathrm{Hom}(c,d) & \xrightarrow[\alpha_d]{} & Fd \end{array}$$

Chasing 1_c around it gives $\alpha_d(f) = \alpha_d(f_*(1_c)) = (Ff)(\alpha_c(1_c)) = (Ff)(x)$. Thus for every $f \in \mathrm{Hom}(c,d)$,

$$\alpha_d(f) = (Ff)(x) \tag{62.1}$$

Since α_d is a bijection, for the given $y \in Fd$ there is exactly one $f\colon c \to d$ with $\alpha_d(f) = y$, that is, exactly one f with $(Ff)(x) = y$. So (c,x) is a universal element.

Step 2: A universal element gives a representation. Conversely, let (c,x) be a universal element of F. Define, for each object d, a map

$$\alpha_d\colon \mathrm{Hom}(c,d) \to Fd, \qquad \alpha_d(f) = (Ff)(x)$$

The universal property says precisely that for each $y \in Fd$ there is a unique $f\colon c \to d$ with $(Ff)(x) = y$, which is the statement that α_d is a bijection. The maps α_d are natural: for $g\colon d \to d'$ and $f\colon c \to d$,

$$\alpha_{d'}(g_*(f)) = \alpha_{d'}(gf) = (F(gf))(x) = (Fg)((Ff)(x)) = (Fg)(\alpha_d(f))$$

so the naturality square for g commutes. Hence $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$ is a natural isomorphism, and F is representable.

Step 3: The two constructions are inverse. A representation α produces $x = \alpha_c(1_c)$, and (62.1) shows that the representation rebuilt from x in Step 2 has components $f \mapsto (Ff)(x) = \alpha_d(f)$, recovering α. In the other direction, the representation built from (c,x) in Step 2 sends 1_c to $(F1_c)(x) = x$, recovering the element. So the correspondence is a bijection between representations and universal elements, completing the proof.

The proposition converts a question about a natural isomorphism, which involves a component at every object, into a question about one element and its universal property. Verifying representability then reduces to exhibiting a single x and checking that every y factors through it uniquely, as the following examples show.

Example 62.1.7: Representable Functors

1. The identity functor on **Set** is representable, with representing object a one-point set $1 = \{*\}$. A function $1 \to X$ is a choice of a point of X, so $\mathrm{Hom}_{\mathbf{Set}}(1, X) \cong X$ by $\varphi \mapsto \varphi(*)$, naturally in X. The universal element is the pair $(1, *)$: every element y of every set X is $(Ff)(*) = f(*)$ for the unique $f\colon 1 \to X$ with $f(*) = y$.

2. The contravariant powerset $P\colon \mathbf{Set}^{\mathrm{op}} \to \mathbf{Set}$, sending a set X to its powerset PX and a function $f\colon X \to Y$ to the preimage map $f^{-1}\colon PY \to PX$, is a representable presheaf. Let $2 = \{0, 1\}$. A subset $A \subseteq X$ is the same data as its indicator function $\chi_A\colon X \to 2$, with $\chi_A(a) = 1$ exactly when $a \in A$, and this correspondence is a bijection

$$PX \cong \mathrm{Hom}_{\mathbf{Set}}(X, 2), \qquad A \mapsto \chi_A$$

   It is natural in X: for $f\colon X \to Y$ and $B \subseteq Y$, the indicator of $f^{-1}(B)$ is $\chi_B \circ f$, which is exactly $f^*(\chi_B)$. So $P \cong \mathrm{Hom}_{\mathbf{Set}}(-, 2)$, and 2 is the representing object. The universal element is the pair $(2, U)$ with $U = \{1\} \subseteq 2$: every subset $A \subseteq X$ is the preimage $\chi_A^{-1}(U)$ under a unique map $X \to 2$.

62.2 The Yoneda Lemma

The representable functor $\mathrm{Hom}(c, -)$ of definition 62.1.1 records how c maps to every object of C. This section computes the natural transformations out of it. The answer, the Yoneda lemma, is that a natural transformation from $\mathrm{Hom}(c, -)$ to a set-valued functor F is the same thing as a single element of Fc: the whole transformation is pinned down by where it sends the identity 1_c. The embedding of the next section and everything that follows rest on this computation. The mechanism can be described before any proof. A natural transformation $\alpha\colon \mathrm{Hom}(c, -) \Rightarrow F$ has, at each object d, a component $\alpha_d\colon \mathrm{Hom}(c, d) \to Fd$. The set $\mathrm{Hom}(c, c)$ holds a distinguished element, the identity 1_c, and α_c sends it to some $\alpha_c(1_c) \in Fc$. Naturality forces every other value of every component to be determined by this one element: for $f\colon c \to d$, naturality applied to f and evaluated at 1_c expresses $\alpha_d(f)$ through $\alpha_c(1_c)$. Reading off $\alpha_c(1_c)$ is thus a map from natural transformations to Fc, and the lemma is that it is a bijection.

Theorem 62.2.1: The Yoneda Lemma

Let C be a locally small category, c an object of C, and $F\colon C \to \mathbf{Set}$ a functor. Evaluation at the identity,

$$\Phi\colon \mathrm{Nat}(\mathrm{Hom}(c, -), F) \to Fc, \qquad \Phi(\alpha) = \alpha_c(1_c)$$

is a bijection, natural in both c and F.

The proof produces an explicit inverse and checks that the two maps compose to the identity in each order. The inverse takes an element $x \in Fc$ and builds a natural transformation from it; the functoriality of F is what makes that transformation natural.

***Proof*:**
Step 1: the inverse map. Fix $x \in Fc$. Define a family $\Psi(x)$ by giving, at each object d, the component

$$\Psi(x)_d \colon \mathrm{Hom}(c,d) \to Fd, \qquad \Psi(x)_d(f) = (Ff)(x)$$

for $f \colon c \to d$, where $Ff \colon Fc \to Fd$ is the action of F on f. This is well-defined: Ff is a function $Fc \to Fd$ and $x \in Fc$, so $(Ff)(x) \in Fd$.

The claim is that $\Psi(x)$ is a natural transformation $\mathrm{Hom}(c,-) \Rightarrow F$. Let $g \colon d \to d'$ be a morphism of C. The functor $\mathrm{Hom}(c,-)$ sends g to post-composition $g_* \colon \mathrm{Hom}(c,d) \to \mathrm{Hom}(c,d')$, $g_*(f) = gf$. The naturality square to check is

$$\begin{array}{ccc} \mathrm{Hom}(c,d) & \xrightarrow{\Psi(x)_d} & Fd \\ {\scriptstyle g_*}\downarrow & & \downarrow{\scriptstyle Fg} \\ \mathrm{Hom}(c,d') & \xrightarrow[\Psi(x)_{d'}]{} & Fd' \end{array}$$

Chase $f \colon c \to d$ around both routes. Down then across gives $\Psi(x)_{d'}(g_*(f)) = \Psi(x)_{d'}(gf) = (F(gf))(x)$; across then down gives $(Fg)(\Psi(x)_d(f)) = (Fg)((Ff)(x))$. These agree because F is a functor, $F(gf) = Fg \circ Ff$, so

$$(F(gf))(x) = (Fg \circ Ff)(x) = (Fg)((Ff)(x))$$

The square commutes for every g, so $\Psi(x)$ is natural, and $\Psi \colon Fc \to \mathrm{Nat}(\mathrm{Hom}(c,-),F)$, $x \mapsto \Psi(x)$, is a well-defined candidate inverse to Φ.

Step 2: Φ and Ψ are mutually inverse. There are two composites to compute.

First, $\Phi\Psi = 1_{Fc}$. For $x \in Fc$,

$$\Phi(\Psi(x)) = \Psi(x)_c(1_c) = (F1_c)(x) = 1_{Fc}(x) = x$$

using that F preserves identities, $F1_c = 1_{Fc}$. This direction is immediate.

Second, $\Psi\Phi$ is the identity on $\mathrm{Nat}(\mathrm{Hom}(c,-),F)$. Let $\alpha \colon \mathrm{Hom}(c,-) \Rightarrow F$ be given and put $x = \Phi(\alpha) = \alpha_c(1_c)$. Two natural transformations agree exactly when all components agree, so it suffices to show $\Psi(x)_d = \alpha_d$ for every d. Fix d and $f \colon c \to d$. Naturality of α at f is the commuting square

$$\begin{array}{ccc} \mathrm{Hom}(c,c) & \xrightarrow{\alpha_c} & Fc \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle Ff} \\ \mathrm{Hom}(c,d) & \xrightarrow[\alpha_d]{} & Fd \end{array}$$

Evaluate it at $1_c \in \mathrm{Hom}(c,c)$. Down then across gives $\alpha_d(f_*(1_c)) = \alpha_d(f1_c) = \alpha_d(f)$; across then down gives $(Ff)(\alpha_c(1_c)) = (Ff)(x)$. Equating the routes,

$$\alpha_d(f) = (Ff)(x) = \Psi(x)_d(f)$$

Since f and d were arbitrary, $\alpha_d = \Psi(x)_d$ for all d, so $\alpha = \Psi(\Phi(\alpha))$. Both composites are identities, so Φ is a bijection with inverse Ψ.

Step 3: naturality of the bijection. The source and target of Φ each depend on the pair (c,F), and the claim is that Φ commutes with change of F and change of c. Consider F first, with c

fixed. A natural transformation $\theta\colon F \Rightarrow G$ acts on the target by its component $\theta_c\colon Fc \to Gc$ and on the source by post-composition $\alpha \mapsto \theta\alpha$, carrying $\mathrm{Hom}(c,-) \Rightarrow F$ to $\mathrm{Hom}(c,-) \Rightarrow G$. Naturality in F is the square

$$\begin{array}{ccc} \mathrm{Nat}(\mathrm{Hom}(c,-),F) & \xrightarrow{\Phi_F} & Fc \\ {\scriptstyle \theta\circ(-)}\downarrow & & \downarrow{\scriptstyle \theta_c} \\ \mathrm{Nat}(\mathrm{Hom}(c,-),G) & \xrightarrow[\Phi_G]{} & Gc \end{array}$$

For $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$, down then across gives $\Phi_G(\theta\alpha) = (\theta\alpha)_c(1_c) = \theta_c(\alpha_c(1_c))$, since composition of natural transformations is componentwise (definition 61.5.4); across then down gives $\theta_c(\Phi_F(\alpha)) = \theta_c(\alpha_c(1_c))$. The two agree, so Φ is natural in F.

Now fix F and vary c. A morphism $h\colon c \to c'$ acts on the target by $Fh\colon Fc \to Fc'$. On the source it acts by precomposition with the representable's own functoriality: h induces $\mathrm{Hom}(h,-)\colon \mathrm{Hom}(c',-) \Rightarrow \mathrm{Hom}(c,-)$, whose component $\mathrm{Hom}(h,d)$ at d sends $k \in \mathrm{Hom}(c',d)$ to $kh \in \mathrm{Hom}(c,d)$, and a transformation $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$ is carried to $\alpha \circ \mathrm{Hom}(h,-)\colon \mathrm{Hom}(c',-) \Rightarrow F$. Naturality in c is the square

$$\begin{array}{ccc} \mathrm{Nat}(\mathrm{Hom}(c,-),F) & \xrightarrow{\Phi_c} & Fc \\ {\scriptstyle (-)\circ\mathrm{Hom}(h,-)}\downarrow & & \downarrow{\scriptstyle Fh} \\ \mathrm{Nat}(\mathrm{Hom}(c',-),F) & \xrightarrow[\Phi_{c'}]{} & Fc' \end{array}$$

Take $\alpha\colon \mathrm{Hom}(c,-) \Rightarrow F$. Across then down gives $Fh(\Phi_c(\alpha)) = (Fh)(\alpha_c(1_c))$. Down then across gives

$$\Phi_{c'}(\alpha \circ \mathrm{Hom}(h,-)) = \big(\alpha \circ \mathrm{Hom}(h,-)\big)_{c'}(1_{c'}) = \alpha_{c'}\big(\mathrm{Hom}(h,c')(1_{c'})\big) = \alpha_{c'}(1_{c'}\, h) = \alpha_{c'}(h)$$

To match the two, apply naturality of α (a transformation $\mathrm{Hom}(c,-) \Rightarrow F$) at the morphism $h\colon c \to c'$: its square is

$$\begin{array}{ccc} \mathrm{Hom}(c,c) & \xrightarrow{\alpha_c} & Fc \\ {\scriptstyle h_*}\downarrow & & \downarrow{\scriptstyle Fh} \\ \mathrm{Hom}(c,c') & \xrightarrow[\alpha_{c'}]{} & Fc' \end{array}$$

Evaluated at $1_c \in \mathrm{Hom}(c,c)$, down then across gives $\alpha_{c'}(h_*(1_c)) = \alpha_{c'}(h1_c) = \alpha_{c'}(h)$; across then down gives $(Fh)(\alpha_c(1_c))$. Hence $\alpha_{c'}(h) = (Fh)(\alpha_c(1_c))$, which is exactly the equality of the two routes around the outer square. So Φ is natural in c, completing the proof.

Out of a lone element $x \in Fc$ the map Ψ manufactures an entire natural family $\{(Ff)(x)\}_f$, one function per object, coherent across every morphism. Nothing beyond the functoriality of F went into the construction, which is why the correspondence is as tight as it is: the data of a natural transformation, a priori a large amount of information spread over all objects, collapses to one point of a single set.

A first payoff sets $F = \mathrm{Hom}(c',-)$ for a second object c'. Then $Fc = \mathrm{Hom}(c',c)$, and the lemma reads $\mathrm{Nat}(\mathrm{Hom}(c,-),\mathrm{Hom}(c',-)) \cong \mathrm{Hom}(c',c)$: natural transformations between two representables are exactly the morphisms of C in the reverse direction. This is the computation on which the next

section builds the Yoneda embedding.

Example 62.2.2: The Underlying Set as a Representable

Let $F\colon \mathbf{Grp} \to \mathbf{Set}$ be the forgetful functor, sending a group to its underlying set. It is represented by the free group $\mathbb{Z}$ on one generator: a homomorphism $\mathbb{Z} \to G$ is determined by, and freely choosable as, the image of the generator 1, so evaluation at 1 gives a bijection $\mathrm{Hom}_{\mathbf{Grp}}(\mathbb{Z}, G) \cong FG$ natural in G (definition 62.1.1). The Yoneda lemma names the element of $F\mathbb{Z} = \mathbb{Z}$ that encodes this: it is

$$\Phi(\alpha) = \alpha_{\mathbb{Z}}(1_{\mathbb{Z}}) \in F\mathbb{Z} = \mathbb{Z}$$

the image, under the natural isomorphism $\alpha\colon \mathrm{Hom}(\mathbb{Z}, -) \Rightarrow F$, of the identity homomorphism $1_{\mathbb{Z}}$. Tracing the definitions, $\alpha_{\mathbb{Z}}(1_{\mathbb{Z}})$ is the generator $1 \in \mathbb{Z}$, and the whole isomorphism α is recovered from it by $\alpha_G(\varphi) = (F\varphi)(1) = \varphi(1)$, the image of the generator under $\varphi\colon \mathbb{Z} \to G$. The single element $1 \in \mathbb{Z}$ carries the entire natural family.

The presheaf version is the same statement read in C^{op}. Recall the duality principle (box 61.3.3): a statement provable for every locally small category holds equally for every opposite. Applying the Yoneda lemma in C^{op} turns the covariant representable $\mathrm{Hom}_{C^{\mathrm{op}}}(c, -)$ into the contravariant $\mathrm{Hom}_C(-, c)$, and a covariant functor $C^{\mathrm{op}} \to \mathbf{Set}$ is a presheaf on C (definition 62.1.3). No new argument is needed.

Corollary 62.2.3: The Yoneda Lemma, Presheaf Form

Let C be a locally small category, c an object of C, and $F\colon C^{\mathrm{op}} \to \mathbf{Set}$ a presheaf. Evaluation at the identity,

$$\mathrm{Nat}(\mathrm{Hom}(-, c), F) \to Fc, \qquad \alpha \mapsto \alpha_c(1_c)$$

is a bijection, natural in c and F.

***Proof*:**

The Yoneda lemma holds in every locally small category, and by the duality principle it applies in particular to C^{op}, which is again locally small (box 61.3.3). Applied there to the object c and the functor F, the covariant representable of C^{op} at c is $\mathrm{Hom}_{C^{\mathrm{op}}}(c, -) = \mathrm{Hom}_C(-, c)$ read in the free variable, and a functor $F\colon C^{\mathrm{op}} \to \mathbf{Set}$ is precisely a covariant functor on C^{op}. So theorem 62.2.1 yields the bijection $\mathrm{Nat}(\mathrm{Hom}_C(-, c), F) \cong Fc$, with the same evaluation-at-1_c map and the same naturality in c and F, as required.

The two forms are one theorem seen from two sides, and both will be used: the covariant form for functors out of C, the presheaf form for the embedding $c \mapsto \mathrm{Hom}(-, c)$ into presheaves.

The lemma also closes the loop with the universal element of section 62.1. An element $x \in Fc$ is called universal when every $y \in Fd$ arises as $(Ff)(x)$ for a unique $f\colon c \to d$ (definition 62.1.5), and F is representable exactly when such an x exists. Under the Yoneda bijection x corresponds to the transformation $\Psi(x)\colon \mathrm{Hom}(c, -) \Rightarrow F$ with $\Psi(x)_d(f) = (Ff)(x)$, and x is universal precisely when every $\Psi(x)_d$ is a bijection, that is, when $\Psi(x)$ is a natural isomorphism. So the representable-iff-universal-element statement is the Yoneda lemma specialized to a representable F: the universal element is the point of Fc that Yoneda hands back, and for $F = \mathrm{Hom}(c, -)$ itself it is the identity 1_c, the element from which the whole representable is generated.

62.3 The Yoneda Embedding

The Yoneda lemma of the previous section computes the natural transformations out of a representable functor. Read one way, it is a calculation; read another, it says that the assignment $c \mapsto \mathrm{Hom}(-, c)$ loses no information. This section makes that reading precise. Packaging the contravariant representables into a single functor $\mathbf{y}\colon C \to \mathbf{PSh}(C)$, the presheaf form of the lemma becomes the statement that $\mathbf{y}$ is fully faithful, and full faithfulness in turn says that an object is recovered, up to isomorphism, from the presheaf it represents.

Recall from definition 62.1.3 that $\mathbf{PSh}(C) = [C^{\mathrm{op}}, \mathbf{Set}]$ is the category of presheaves on C, whose objects are the contravariant set-valued functors and whose morphisms are natural transformations. Each object c of C gives such a presheaf, the represented $\mathrm{Hom}(-, c)$ of definition 62.1.1; each morphism of C gives a natural transformation between two of them. Assembling these into a functor is the content of the first definition.

Definition 62.3.1: The Yoneda Embedding

Let C be a locally small category (definition 61.1.7). The *Yoneda embedding* is the functor

$$\mathbf{y}\colon C \to \mathbf{PSh}(C)$$

defined as follows. On an object c, it is the represented presheaf

$$\mathbf{y}(c) = \mathrm{Hom}(-, c) \in \mathbf{PSh}(C)$$

On a morphism $f\colon c \to d$, it is the natural transformation

$$\mathbf{y}(f) = \mathrm{Hom}(-, f)\colon \mathrm{Hom}(-, c) \Rightarrow \mathrm{Hom}(-, d)$$

whose component at an object x is post-composition with f,

$$\mathrm{Hom}(-, f)_x\colon \mathrm{Hom}(x, c) \to \mathrm{Hom}(x, d), \qquad g \mapsto fg$$

That $\mathbf{y}$ is a functor is exactly the statement that its two clauses respect composition and identities, and both follow from the category axioms of C. The verification is short and worth doing once, because it exhibits how the unit and associativity laws of composition become the functoriality of $\mathbf{y}$.

***Proof*:**
Two checks are needed: that each $\mathbf{y}(f)$ is a natural transformation, and that $\mathbf{y}$ preserves composites and identities.

Step 1: $\mathbf{y}(f)$ is natural. Fix $f\colon c \to d$ and a morphism $h\colon x' \to x$ in C. The presheaf $\mathrm{Hom}(-, c)$ sends h to pre-composition $\mathrm{Hom}(h, c)\colon \mathrm{Hom}(x, c) \to \mathrm{Hom}(x', c)$, $g \mapsto gh$, and similarly for $\mathrm{Hom}(-, d)$. Naturality of $\mathbf{y}(f) = \mathrm{Hom}(-, f)$ at h is the commuting of

$$\begin{array}{ccc} \mathrm{Hom}(x, c) & \xrightarrow{g \mapsto fg} & \mathrm{Hom}(x, d) \\ {\scriptstyle g \mapsto gh}\downarrow & & \downarrow{\scriptstyle g \mapsto gh} \\ \mathrm{Hom}(x', c) & \xrightarrow[g \mapsto fg]{} & \mathrm{Hom}(x', d) \end{array}$$

Both routes send $g\colon x \to c$ to $f(gh)$: down-then-across gives $f(gh)$, across-then-down gives $(fg)h$, and these agree by associativity of composition in C. So $\mathbf{y}(f)$ is natural.

Step 2: $\mathbf{y}$ *preserves composition.* Let $f\colon c \to d$ and $f'\colon d \to e$. Both $\mathbf{y}(f'f)$ and $\mathbf{y}(f')\mathbf{y}(f)$ are natural transformations $\mathrm{Hom}(-,c) \Rightarrow \mathrm{Hom}(-,e)$, so it suffices to compare their components at each object x. On $g\colon x \to c$,

$$\mathbf{y}(f'f)_x(g) = (f'f)g, \qquad \big(\mathbf{y}(f')\mathbf{y}(f)\big)_x(g) = f'(fg)$$

and $(f'f)g = f'(fg)$ by associativity. Hence $\mathbf{y}(f'f) = \mathbf{y}(f')\mathbf{y}(f)$.

Step 3: $\mathbf{y}$ *preserves identities.* The component of $\mathbf{y}(1_c)$ at x sends $g\colon x \to c$ to $1_c g = g$, so it is the identity function on $\mathrm{Hom}(x,c)$. As this holds for every x, $\mathbf{y}(1_c) = 1_{\mathrm{Hom}(-,c)}$, the identity natural transformation on $\mathbf{y}(c)$.

Naturality of each $\mathbf{y}(f)$, preservation of composites, and preservation of identities together make $\mathbf{y}$ a functor, completing the proof.

The proof isolates a small dictionary: associativity of composition in C becomes both the naturality of each $\mathbf{y}(f)$ and the functoriality of $\mathbf{y}$, and the left unit law becomes the preservation of identities. The embedding carries an object to the record of all maps into it and a morphism to post-composition with that morphism, and this record transforms functorially because composition does. A concrete category shows the abstract assignment.

Example 62.3.2: The Yoneda Embedding of a Poset

Let P be a poset, regarded as a category with a single morphism $x \to y$ whenever $x \leq y$ and none otherwise (definition 61.1.1). For objects x, y the hom-set $\mathrm{Hom}(x,y)$ is a one-element set when $x \leq y$ and empty otherwise, so a presheaf $\mathrm{Hom}(-,c) = \mathbf{y}(c)$ on P is the indicator of the down-set of c: for each object x,

$$\mathrm{Hom}(x,c) = \begin{cases} \{*\} & x \leq c \\ \varnothing & x \not\leq c \end{cases}$$

Thus $\mathbf{y}(c)$ records precisely which elements lie below c, that is, the principal down-set $\downarrow c = \{x \in P \,|\, x \leq c\}$. A morphism $c \leq d$ in P gives the natural transformation $\mathbf{y}(c \leq d)\colon \mathrm{Hom}(-,c) \Rightarrow \mathrm{Hom}(-,d)$, which at each x is the unique function from $\mathrm{Hom}(x,c)$ to $\mathrm{Hom}(x,d)$; such a function exists as a morphism of presheaves exactly because $x \leq c \leq d$ forces $x \leq d$, so the down-set of c is contained in that of d. The embedding $\mathbf{y}\colon P \to \mathbf{PSh}(P)$ is therefore the assignment $c \mapsto \downarrow c$ sending each element to its principal down-set, ordered by inclusion. Since $c \leq d$ if and only if $\downarrow c \subseteq \downarrow d$, distinct elements have distinct down-sets and the order is faithfully reproduced: $\mathbf{y}$ is the poset embedding of P into its lattice of down-sets. This is the order-theoretic case of the full faithfulness proved next.

The example already displays the pattern of the general theorem. The embedding of a poset is injective on objects and reflects the order, so the whole of P can be read off from its image in $\mathbf{PSh}(P)$. For a general category the statement is not that $\mathbf{y}$ is injective on objects, which is too rigid, but that it is a bijection on morphisms between any two objects, full and faithful in the sense recalled from proposition 61.5.6. This is where the Yoneda lemma does the work: its presheaf form, applied to a represented presheaf, is precisely the assertion that $\mathbf{y}$ is fully faithful.

Theorem 62.3.3: The Yoneda Embedding is Fully Faithful

Let C be a locally small category. For all objects c, d of C the function

$$\mathrm{Hom}_C(c,d) \to \mathrm{Hom}_{\mathbf{PSh}(C)}\big(\mathbf{y}(c),\mathbf{y}(d)\big) = \mathrm{Nat}\big(\mathrm{Hom}(-,c),\mathrm{Hom}(-,d)\big), \qquad f \mapsto \mathbf{y}(f)$$

is a bijection. Equivalently, the Yoneda embedding $\mathbf{y}\colon C \to \mathbf{PSh}(C)$ is full and faithful.

***Proof*:**
Apply the presheaf form of the Yoneda lemma, corollary 62.2.3, to the presheaf $F = \mathrm{Hom}(-,d)$ and the object c. It gives a bijection

$$\mathrm{Nat}\big(\mathrm{Hom}(-,c),\mathrm{Hom}(-,d)\big) \xrightarrow{\cong} \big(\mathrm{Hom}(-,d)\big)(c) = \mathrm{Hom}_C(c,d) \tag{62.2}$$

natural in c and d. The bijection of (62.2) sends a natural transformation $\alpha\colon \mathrm{Hom}(-,c) \Rightarrow \mathrm{Hom}(-,d)$ to the element $\alpha_c(1_c) \in \mathrm{Hom}_C(c,d)$, the image of the identity 1_c under the component of α at c. The claimed map $f \mapsto \mathbf{y}(f)$ runs the other way, so it suffices to check that the two are mutually inverse. In fact $f \mapsto \mathbf{y}(f)$ is exactly the inverse produced by corollary 62.2.3, and identifying it is the whole content of the theorem.

Step 1: the Yoneda bijection sends $\mathbf{y}(f)$ to f. Take $\alpha = \mathbf{y}(f) = \mathrm{Hom}(-,f)$ for a morphism $f\colon c \to d$. Its component at c is post-composition with f, so it sends the identity to

$$\big(\mathbf{y}(f)\big)_c(1_c) = f \circ 1_c = f$$

Thus the composite $\mathrm{Hom}_C(c,d) \to \mathrm{Nat}(\mathrm{Hom}(-,c),\mathrm{Hom}(-,d)) \to \mathrm{Hom}_C(c,d)$, first $f \mapsto \mathbf{y}(f)$ and then the bijection of (62.2), is the identity on $\mathrm{Hom}_C(c,d)$.

Step 2: the other composite is the identity. The map of (62.2) is already a bijection by corollary 62.2.3, and Step 1 shows $f \mapsto \mathbf{y}(f)$ is a right inverse to it. A right inverse to a bijection is its two-sided inverse, so $f \mapsto \mathbf{y}(f)$ is itself a bijection, inverse to the Yoneda bijection. Concretely, starting from a natural transformation α, its image $f = \alpha_c(1_c)$ satisfies $\mathbf{y}(f) = \alpha$: for any object x and any $g\colon x \to c$, naturality of α at g applied to 1_c gives

$$\alpha_x(g) = \alpha_x\big(\mathrm{Hom}(g,c)(1_c)\big) = \mathrm{Hom}(g,d)\big(\alpha_c(1_c)\big) = \alpha_c(1_c) \circ g = fg = \big(\mathbf{y}(f)\big)_x(g)$$

so $\alpha = \mathbf{y}(f)$, recovering the second half of the inverse relation.

The two composites being identities, $f \mapsto \mathbf{y}(f)$ is a bijection

$$\mathrm{Hom}_C(c,d) \xrightarrow{\cong} \mathrm{Nat}(\mathrm{Hom}(-,c),\mathrm{Hom}(-,d))$$

for every pair c, d. This is exactly the statement that $\mathbf{y}$ is full (the map is surjective, so every natural transformation between representables is $\mathbf{y}(f)$ for some f) and faithful (the map is injective, so $\mathbf{y}(f)$ determines f), as we sought to show.

Full faithfulness is the sharpest possible statement that $\mathbf{y}$ loses no information at the level of morphisms. Every natural transformation between the presheaves $\mathrm{Hom}(-,c)$ and $\mathrm{Hom}(-,d)$ is post-composition with a unique morphism $c \to d$: there are no natural transformations between representables beyond the ones the category already gives. The functor $\mathbf{y}$ therefore identifies the hom-

set $\mathrm{Hom}_C(c,d)$ with the hom-set $\mathrm{Hom}_{\mathbf{PSh}(C)}(\mathbf{y}(c),\mathbf{y}(d))$ without collapsing or inventing morphisms, so C sits inside $\mathbf{PSh}(C)$ as a full subcategory (up to the identification of objects with the presheaves they represent). The step from this to objects is one general fact about fully faithful functors: they detect isomorphisms as well as reflect the morphisms that witness them.

Before stating the corollary, it is worth pinning the one property of fully faithful functors it rests on. A functor always preserves isomorphisms (lemma 61.4.5): if f is invertible, so is Ff. A fully faithful functor also *reflects* them, and this is the new content. Suppose $Ff\colon Fc \to Fd$ is an isomorphism with inverse $k\colon Fd \to Fc$. Because F is full, $k = Fg$ for some $g\colon d \to c$; because F is faithful, the equations $Fg \circ Ff = 1_{Fc} = F(1_c)$ and $Ff \circ Fg = 1_{Fd} = F(1_d)$, which say $F(gf) = F(1_c)$ and $F(fg) = F(1_d)$, force $gf = 1_c$ and $fg = 1_d$. So f is an isomorphism (definition 61.2.1) with inverse g. A morphism whose image under a fully faithful functor is invertible is therefore already invertible.

Corollary 62.3.4: Objects are Determined by their Points

Let C be a locally small category. Two objects c, d of C are isomorphic in C if and only if the represented presheaves $\mathbf{y}(c) = \mathrm{Hom}(-,c)$ and $\mathbf{y}(d) = \mathrm{Hom}(-,d)$ are isomorphic in $\mathbf{PSh}(C)$. An object of C is determined, up to isomorphism, by the presheaf it represents, its *functor of points*.

***Proof*:**
The Yoneda embedding $\mathbf{y}$ is full and faithful by theorem 62.3.3. If $c \cong d$ in C, then $\mathbf{y}$ preserves the isomorphism (lemma 61.4.5), giving $\mathbf{y}(c) \cong \mathbf{y}(d)$ in $\mathbf{PSh}(C)$. Conversely, suppose $\varphi\colon \mathbf{y}(c) \to \mathbf{y}(d)$ is an isomorphism of presheaves. By fullness $\varphi = \mathbf{y}(f)$ for some $f\colon c \to d$, and $\mathbf{y}(f)$ is an isomorphism, so by the reflection of isomorphisms established above f is itself an isomorphism. Hence $c \cong d$ in C, as we sought to show.

This is the precise form of the chapter's thread: an object is known, up to isomorphism, by how everything maps into it. The functor of points $\mathrm{Hom}(-,c)$ carries the full isomorphism type of c, so two objects with naturally isomorphic points are the same object seen twice.

62.4 Applications

The embedding of section 62.3 converts three recurring questions into questions about hom-functors, where they become easy. This section collects the payoffs. First, a representing object is pinned down not just up to isomorphism but up to a *unique* isomorphism, so "the" representing object is a legitimate phrase. Second, the deferred converse from Chapter 1 falls out: a full, faithful, essentially surjective functor is an equivalence (proposition 61.5.6). Third, a concrete instance of corollary 62.3.4: an object of a category is recovered, up to isomorphism, from its functor of points.

A representing object for a set-valued functor F is any object c together with a natural isomorphism $F \cong \mathrm{Hom}(c,-)$. Two such objects are isomorphic by the general principle that represented functors determine their representing object (corollary 62.3.4), but more is true: the isomorphism between them is forced, with no freedom of choice. This is what justifies treating the representing object as canonical data attached to F.

Corollary 62.4.1: Uniqueness of Representing Objects

Let C be a locally small category and $F\colon C \to \mathbf{Set}$ a functor. If $\varphi\colon F \Rightarrow \mathrm{Hom}(c,-)$ and $\varphi'\colon F \Rightarrow \mathrm{Hom}(c',-)$ are natural isomorphisms, then there is a unique isomorphism $u\colon c' \to c$ in C for which the induced natural isomorphism $\mathrm{Hom}(u,-)\colon \mathrm{Hom}(c,-) \Rightarrow \mathrm{Hom}(c',-)$ equals $\varphi'\varphi^{-1}$. In particular the representing object of F, when it exists, is unique up to a unique isomorphism.

***Proof*:**

Write ψ for the composite $\varphi'\varphi^{-1}\colon \mathrm{Hom}(c,-) \Rightarrow \mathrm{Hom}(c',-)$, a natural isomorphism, being a composite of natural isomorphisms.

The covariant hom-functors are the objects in the image of the covariant embedding $c \mapsto \mathrm{Hom}(c,-)$, which sends C^{op} fully faithfully into $[C,\mathbf{Set}]$. This is the covariant analog of theorem 62.3.3 and is read off the Yoneda lemma directly: applying theorem 62.2.1 to the functor $F = \mathrm{Hom}(c',-)$ gives a bijection

$$\mathrm{Nat}\big(\mathrm{Hom}(c,-),\,\mathrm{Hom}(c',-)\big) \;\cong\; \mathrm{Hom}(c',-)(c) \;=\; \mathrm{Hom}(c',c)$$

natural in both variables. Tracing the Yoneda bijection, a morphism $v\colon c' \to c$ corresponds to the natural transformation $\mathrm{Hom}(v,-)$ whose component at x is $g \mapsto gv$; and every natural transformation $\mathrm{Hom}(c,-) \Rightarrow \mathrm{Hom}(c',-)$ arises this way from a unique such v. Applying this to ψ yields a unique $u\colon c' \to c$ with $\mathrm{Hom}(u,-) = \psi = \varphi'\varphi^{-1}$.

It remains to check u is an isomorphism. Applying the same bijection to $\psi^{-1}\colon \mathrm{Hom}(c',-) \Rightarrow \mathrm{Hom}(c,-)$ produces a unique $w\colon c \to c'$ with $\mathrm{Hom}(w,-) = \psi^{-1}$. Since $c \mapsto \mathrm{Hom}(c,-)$ is a functor $C^{\mathrm{op}} \to [C,\mathbf{Set}]$, precomposition is sent to composition of natural transformations, so $\mathrm{Hom}(uw,-) = \mathrm{Hom}(w,-)\mathrm{Hom}(u,-) = \psi^{-1}\psi = \mathrm{id}$ and likewise $\mathrm{Hom}(wu,-) = \mathrm{id}$. Faithfulness of the embedding (again theorem 62.2.1, whose bijection is injective) forces $uw = \mathrm{id}_c$ and $wu = \mathrm{id}_{c'}$, so u is an isomorphism with inverse w. Uniqueness of u is the uniqueness already given by the Yoneda bijection, completing the proof.

The statement isolates the mechanism behind the familiar slogan that universal objects are unique "up to canonical isomorphism". The isomorphism u is not merely one of possibly several: it is singled out by the requirement that it intertwine the two representations φ, φ', and full faithfulness of the embedding says there is exactly one morphism doing so. Every construction recognized by a universal property in the chapters to come (products, kernels, tensor products) inherits this uniqueness for free, which is why one speaks of *the* product rather than a product.

The second application discharges a debt from Chapter 1. There the notion of an equivalence of categories was introduced (definition 61.5.5), and proposition 61.5.6 showed that an equivalence is necessarily full, faithful, and essentially surjective. The converse was deferred, because constructing the quasi-inverse requires choosing, for each object of the target, an object of the source mapping to it, and then transporting morphisms along those choices coherently. The bookkeeping is exactly the naturality that the Yoneda circle of ideas trains one to handle, so this is the natural place to settle it.

Proposition 62.4.2: Full, Faithful, Essentially Surjective Implies Equivalence

Let $F\colon C \to D$ be a functor that is full, faithful, and essentially surjective. Then F is an equivalence of categories: there exist a functor $G\colon D \to C$ and natural isomorphisms $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ and $\eta\colon \mathrm{id}_C \Rightarrow GF$.

***Proof*:**

Step 1: Define G on objects. For each object d of D, essential surjectivity gives an object of C mapping isomorphically to d. Choose one such object, call it Gd, together with an isomorphism $\varepsilon_d\colon F(Gd) \to d$ in D. This is one simultaneous choice over all objects of D, the only appeal to choice in the argument; it is harmless, and when D is small it is a choice from a set.

Step 2: Define G on morphisms. Given $g\colon d \to d'$ in D, consider the morphism

$$\varepsilon_{d'}^{-1}\, g\, \varepsilon_d\colon F(Gd) \to F(Gd')$$

Because F is full and faithful, the map $\mathrm{Hom}_C(Gd, Gd') \to \mathrm{Hom}_D(F(Gd), F(Gd'))$ induced by F is a bijection. Hence there is a unique morphism $Gg\colon Gd \to Gd'$ in C with

$$F(Gg) \;=\; \varepsilon_{d'}^{-1}\, g\, \varepsilon_d \tag{62.3}$$

Existence gives G a value; uniqueness is what makes the value well-defined and, as we now see, functorial.

Step 3: G is a functor. For the identity id_d, the morphism $\varepsilon_d^{-1}\,\mathrm{id}_d\,\varepsilon_d = \mathrm{id}_{F(Gd)} = F(\mathrm{id}_{Gd})$, so by the uniqueness in (62.3) the unique preimage is id_{Gd}, giving $G(\mathrm{id}_d) = \mathrm{id}_{Gd}$. For composability $d \xrightarrow{g} d' \xrightarrow{g'} d''$, faithfulness lets us compare $G(g'g)$ and $(Gg')(Gg)$ by comparing their images under F. Applying F and using (62.3) termwise,

$$F\big((Gg')(Gg)\big) = F(Gg')\,F(Gg) = \big(\varepsilon_{d''}^{-1}\, g'\, \varepsilon_{d'}\big)\big(\varepsilon_{d'}^{-1}\, g\, \varepsilon_d\big) = \varepsilon_{d''}^{-1}\, g' g\, \varepsilon_d = F\big(G(g'g)\big)$$

where the middle equality cancels $\varepsilon_{d'}\varepsilon_{d'}^{-1} = \mathrm{id}$. Faithfulness then gives $(Gg')(Gg) = G(g'g)$, so G is a functor.

Step 4: $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ is a natural isomorphism. Each component $\varepsilon_d\colon F(Gd) \to d$ is an isomorphism by construction, so it suffices to check naturality. For $g\colon d \to d'$, rewriting (62.3) as $g\,\varepsilon_d = \varepsilon_{d'}\,F(Gg)$ is exactly the statement that the square

$$\begin{array}{ccc} F(Gd) & \xrightarrow{\varepsilon_d} & d \\ {\scriptstyle F(Gg)}\downarrow & & \downarrow{\scriptstyle g} \\ F(Gd') & \xrightarrow[\varepsilon_{d'}]{} & d' \end{array}$$

commutes. Thus ε is natural, and being componentwise an isomorphism it is a natural isomorphism.

Step 5: Construct $\eta\colon \mathrm{id}_C \Rightarrow GF$. For an object c of C, the object $GF(c)$ comes with the chosen isomorphism $\varepsilon_{Fc}\colon F(GFc) \to Fc$. Since F is full and faithful, the isomorphism $\varepsilon_{Fc}^{-1}\colon Fc \to F(GFc)$ has a unique preimage $\eta_c\colon c \to GF(c)$ with

$$F(\eta_c) \;=\; \varepsilon_{Fc}^{-1} \tag{62.4}$$

Each η_c is an isomorphism: its inverse is the preimage of ε_{Fc} under the same bijection, and faithfulness turns the identities $F(\eta_c)\,\varepsilon_{Fc} = \mathrm{id}$ and vice versa into identities in C, as in the argument of corollary 62.4.1. For naturality, let $f\colon c \to c'$. Applying F to both candidate composites and using (62.4) together with (62.3) for the morphism Ff,

$$F\big(GF(f)\big)\,F(\eta_c) = \big(\varepsilon_{Fc'}^{-1}\,(Ff)\,\varepsilon_{Fc}\big)\,\varepsilon_{Fc}^{-1} = \varepsilon_{Fc'}^{-1}\,(Ff) = F(\eta_{c'})\,F(f)$$

so $F\big(GF(f)\,\eta_c\big) = F\big(\eta_{c'}\,f\big)$, and faithfulness gives $GF(f)\,\eta_c = \eta_{c'}\,f$. Hence η is a natural isomorphism $\mathrm{id}_C \Rightarrow GF$.

With G a functor and ε, η natural isomorphisms, F and G are quasi-inverse, so F is an equivalence of categories, as we sought to show.

Together with proposition 61.5.6 this completes the characterization: a functor is an equivalence if and only if it is full, faithful, and essentially surjective. The "if" direction just proved is the useful one in practice, since it lets one certify an equivalence without ever exhibiting the inverse functor. One checks three local conditions, two of them (fullness, faithfulness) about hom-sets and one (essential surjectivity) about the image on objects, and the quasi-inverse is then guaranteed to exist. The proof also shows the quasi-inverse is far from unique as bare data, since it depends on the choices in Step 1, yet any two such choices yield equivalent functors, matching the uniqueness pattern of corollary 62.4.1.

The last application unpacks corollary 62.3.4. That corollary says an object is determined up to isomorphism by the functor it represents, its functor of points; two objects with naturally isomorphic points are isomorphic. On a category of algebraic objects this recovers the object from the ways of mapping it to arbitrary test objects, which is the content of the "functor of points" viewpoint that pervades algebraic geometry.

Example 62.4.3: Recovering a Ring from Its Points

Work in $C = \mathbf{Ring}$ (commutative rings with unit). Each ring R represents the covariant functor of points $\mathrm{Hom}(R, -)\colon \mathbf{Ring} \to \mathbf{Set}$, sending a ring A to the set $\mathrm{Hom}(R, A)$ of ring homomorphisms out of R. Suppose R and S are rings and

$$\Phi\colon \mathrm{Hom}(R, -) \Rightarrow \mathrm{Hom}(S, -)$$

is a natural isomorphism of these functors. Then $R \cong S$ as rings, and the isomorphism is canonical.

The point is the covariant form of corollary 62.3.4: represented functors determine their representing object, and here the representation is covariant, so the roles are dual to the presheaf statement. Concretely, apply corollary 62.4.1 with $F = \mathrm{Hom}(R, -)$. The two natural isomorphisms $\mathrm{id}\colon F \Rightarrow \mathrm{Hom}(R, -)$ and $\Phi\colon F \Rightarrow \mathrm{Hom}(S, -)$ represent the same F, so there is a unique isomorphism $u\colon S \to R$ with $\mathrm{Hom}(u, -) = \Phi$.

The isomorphism u can be named by hand, which shows the abstraction hides nothing. Chase the identity through the components. At $A = R$ the map $\Phi_R\colon \mathrm{Hom}(R, R) \to \mathrm{Hom}(S, R)$ carries id_R to a homomorphism $u\colon S \to R$, that is, set $u = \Phi_R(\mathrm{id}_R)$. For any A and any $f\colon R \to A$, naturality of Φ along f gives the square

$$\begin{array}{ccc} \mathrm{Hom}(R, R) & \xrightarrow{\Phi_R} & \mathrm{Hom}(S, R) \\ {\scriptstyle f\circ(-)}\downarrow & & \downarrow{\scriptstyle f\circ(-)} \\ \mathrm{Hom}(R, A) & \xrightarrow[\Phi_A]{} & \mathrm{Hom}(S, A) \end{array}$$

> Evaluating both routes at id_R gives $\Phi_A(f) = fu$, so Φ_A is precomposition with u, that is, $\Phi = \mathrm{Hom}(u, -)$. Running the same chase on Φ^{-1} produces $v = (\Phi^{-1})_S(\mathrm{id}_S)\colon R \to S$ with $\Phi^{-1} = \mathrm{Hom}(v, -)$. Then $\mathrm{Hom}(uv, -) = \mathrm{Hom}(v, -)\mathrm{Hom}(u, -) = \Phi^{-1}\Phi = \mathrm{id}$ forces $uv = \mathrm{id}_R$, and symmetrically $vu = \mathrm{id}_S$, so $u\colon S \to R$ is an isomorphism of rings with inverse v. The functor of points has recovered the ring.

The computation is the whole Yoneda lemma in miniature: the natural transformation Φ is completely determined by its value on a single element, the identity id_R, and that value is the morphism representing it. The same argument works verbatim in any locally small category, with **Ring** replaced by **Grp**, **Top**, or the category of schemes, and it is the reason the functor of points is a faithful record of the object rather than a lossy one.

63

Universal Properties, Limits, and Colimits

Chapters 1 and 2 built the categorical language and its central theorem; this chapter turns to construction. Products, quotients, kernels, unions, gluings: most objects mathematics builds are pinned down not by their elements but by a mapping property. This chapter isolates that pattern as a *universal property*, organizes the constructions it governs into *limits* and *colimits*, and computes them in the categories at hand.

63.1 Universal Properties and Universal Arrows

An object is often pinned down not by naming its elements but by a rule describing how it maps to, or receives maps from, every other object. The empty set is the set with a unique map to every set; the free group on a set X is the group into which every function from X extends uniquely. This section isolates the two building blocks of such descriptions. The first is the pair of extremal objects, *initial* and *terminal*, which sit at the ends of a category. The second, the *universal arrow*, relativizes them along a functor and turns out to be the general form of the universal element from definition 62.1.5.

Definition 63.1.1: Initial and Terminal Objects

Let C be a category. An object 0 of C is *initial* if for every object X there is exactly one morphism $0 \to X$. An object 1 of C is *terminal* if for every object X there is exactly one morphism $X \to 1$. An object that is both initial and terminal is a *zero object*.

The two notions are dual: a terminal object of C is an initial object of C^{op}, so every statement about one specializes to a statement about the other by box 61.3.3. Neither need exist, and when one does

it carries no further data beyond the bare mapping property; that austerity is what makes it useful.

Example 63.1.2: Initial and Terminal Objects in the Standing Cast
The following run through the standing cast.

1. In **Set** the empty set $\varnothing$ is initial: the empty function is the unique map $\varnothing \to X$ for every X. Every singleton $\{*\}$ is terminal, since a map $X \to \{*\}$ has no choice in where to send its elements. There is no zero object: $\varnothing$ is not terminal (no map $\{*\} \to \varnothing$ exists).
2. In **Grp** and in $\mathbf{Mod}_R$ the trivial object (the group $\{e\}$, the zero module 0) is both initial and terminal, hence a zero object. Every homomorphism to or from it is forced, since a homomorphism preserves the identity; this is the algebraic fact recorded for the trivial group in [21, Homomorphism To/From Trivial Group], and the zero-module case is the same computation.
3. In **Ring** (unital rings, $1 \neq 0$ not required) the ring $\mathbb{Z}$ is initial: for any ring R the unique homomorphism $\mathbb{Z} \to R$ sends n to $n \cdot 1_R$, forced because a ring map preserves 1. The zero ring, in which $1 = 0$, is terminal. Here the two extremes are distinct, so **Ring** has no zero object.
4. A poset $(P, \leq)$, viewed as a category with a unique arrow $x \to y$ when $x \leq y$, has an initial object exactly when P has a least element and a terminal object exactly when it has a greatest element.

The **Ring** example already exhibits the pattern the rest of the chapter formalizes: the map $\mathbb{Z} \to R$ is not just *some* distinguished morphism, it is the *unique* one, and that uniqueness is the whole content. A universal property is always a uniqueness statement of this kind.

The defining clause of an initial object, "exactly one morphism", has an immediate consequence: an initial object is determined by the property, not only up to isomorphism but up to a *unique* isomorphism. This is the prototype every universal-property uniqueness argument imitates, so it is worth seeing once in full.

Proposition 63.1.3: Initial and Terminal Objects are Unique up to Unique Isomorphism

If 0 and $0'$ are both initial objects of a category C, then there is a unique isomorphism $0 \to 0'$. Dually, any two terminal objects are related by a unique isomorphism.

***Proof*:**
Since 0 is initial, there is a unique morphism $u\colon 0 \to 0'$; since $0'$ is initial, there is a unique morphism $v\colon 0' \to 0$. The composite $vu\colon 0 \to 0$ is a morphism from 0 to itself, and 0 is initial, so there is only one such morphism. The identity id_0 is one, hence $vu = \mathrm{id}_0$. The same argument in C with the roles of 0 and $0'$ exchanged gives $uv = \mathrm{id}_{0'}$. Thus u is an isomorphism with inverse v, and it is the only morphism $0 \to 0'$ by initiality of 0, so it is the unique isomorphism. The terminal statement is the initial statement read in C^{op}, completing the proof.

The argument uses nothing about 0 except that maps out of it are forced. Every "unique up to unique isomorphism" claim for a universal construction, for products, kernels, free objects, limits,

runs the same way: two solutions each map uniquely to the other, and the round trips are identities because they compete with id for a slot the property allows only one morphism to fill. The reader may reduce any such uniqueness proof to proposition 63.1.3 by exhibiting the construction as an initial or terminal object of a suitable category, which is precisely the reduction the next two definitions make available.

Initial and terminal objects describe an object by its maps to or from *everything*. Most constructions of interest carry data along a functor: the free group on X is built from the set X through the forgetful functor $U\colon \mathbf{Grp} \to \mathbf{Set}$. The universal arrow relativizes the extremal notion to this setting.

Definition 63.1.4: Universal Arrow

Let $U\colon C \to D$ be a functor and d an object of D. A *universal arrow from d to U* is a pair (c, η) consisting of an object c of C and a morphism $\eta\colon d \to Uc$ in D with the following property: for every object x of C and every morphism $f\colon d \to Ux$ in D, there is a unique morphism $g\colon c \to x$ in C such that $f = (Ug) \circ \eta$. The defining equation is the commuting triangle

$$\begin{array}{ccc} d & \xrightarrow{\eta} & Uc \\ & \searrow^{f} & \downarrow{\scriptstyle Ug} \\ & & Ux \end{array}$$

Dually, a *universal arrow from U to d* is a pair (c, ε) with $\varepsilon\colon Uc \to d$ such that every $f\colon Ux \to d$ factors as $f = \varepsilon \circ (Ug)$ for a unique $g\colon x \to c$.

The pair (c, η) is universal in that η is the most efficient map from d into the image of U: any other map f from d into U is recovered from η by post-composing with a C-morphism, and in exactly one way. Setting $U = \mathrm{id}_D$ recovers the extremal case, an initial object of the coslice under d; the functor U is what makes the notion carry structure across categories.

This connects directly to the representability material of the previous chapter. A universal element of a functor $F\colon C \to \mathbf{Set}$ (definition 62.1.5) is an element $u \in Fc$ such that every $x \in Fa$ equals $Fg(u)$ for a unique $g\colon c \to a$; that is the special case of definition 63.1.4 in which $D = \mathbf{Set}$, the object d is a singleton $\{*\}$, and a map $\{*\} \to Fc$ is named by the element it picks out. Both say the same thing: the datum η (or u) generates every map into U (or every element of F) freely and uniquely. Equivalently, a universal arrow from d to U makes the functor $D(d, U-)$ representable (definition 62.1.1), represented by c with the element η corresponding under Yoneda; the connection to preservation of limits is taken up later in the chapter.

Example 63.1.5: The Universal Arrow of the Free Group

Take $U\colon \mathbf{Grp} \to \mathbf{Set}$ the forgetful functor and X a set. The free group FX carries the inclusion of generators $\eta\colon X \to UFX$. Given any group H and any function $f\colon X \to UH$, the universal property of the free group ([21, Universal Property Of Free Groups]) gives a unique homomorphism $g\colon FX \to H$ extending f on generators, so $f = (Ug) \circ \eta$. Thus (FX, η) is a universal arrow from X to U: the free group is exactly the solution to this universal problem, with η marking the generators.

The example is the template for "free" constructions in general, and the next definition packages the search for a universal arrow into a single object of a single category, so that finding one becomes

finding an initial object.

Definition 63.1.6: Comma Category

Let $F\colon A \to C$ and $G\colon B \to C$ be functors into a common category C. The *comma category* $F \downarrow G$ has as objects the triples (a, b, h) with a an object of A, b an object of B, and $h\colon Fa \to Gb$ a morphism of C. A morphism $(a, b, h) \to (a', b', h')$ is a pair $(p\colon a \to a',\ q\colon b \to b')$ making the square

$$\begin{array}{ccc} Fa & \xrightarrow{h} & Gb \\ {\scriptstyle Fp}\downarrow & & \downarrow{\scriptstyle Gq} \\ Fa' & \xrightarrow[h']{} & Gb' \end{array}$$

commute; composition and identities are computed componentwise in A and B.

Two special cases recur. Write $c\colon \mathbf{1} \to C$ for the functor from the one-object one-morphism category that picks out an object c. With $A = C$, $F = \mathrm{id}_C$ and $G = c$, an object of $\mathrm{id}_C \downarrow c$ is a morphism $a \to c$, and this comma category is the *slice category* C/c of objects over c. Dually, $c \downarrow \mathrm{id}_C$ has as objects the morphisms $c \to b$ and is the *coslice* c/C of objects under c. The unifying point is a single reformulation of definition 63.1.4.

Proposition 63.1.7: Universal Arrows are Initial Objects of a Comma Category

Let $U\colon C \to D$ be a functor and d an object of D, viewed as a functor $d\colon \mathbf{1} \to D$ from the one-object one-morphism category. A universal arrow from d to U is the same thing as an initial object of the comma category $d \downarrow U$.

***Proof*:**
An object of $d \downarrow U$ is a pair $(c, \eta\colon d \to Uc)$ with c an object of C, and a morphism $(c, \eta) \to (x, f)$ is a C-morphism $g\colon c \to x$ with $(Ug) \circ \eta = f$. To say (c, η) is initial is to say that for every (x, f) there is exactly one such g, which is verbatim the defining property of a universal arrow from d to U in definition 63.1.4, as we sought to show.

proposition 63.1.7 discharges the uniqueness of universal arrows into proposition 63.1.3: a universal arrow, being an initial object, is determined up to a unique isomorphism, so the free group, the initial ring, and every other solution of a universal problem is unique in the strongest sense available. The comma category is the "neighbouring category" whose initial object is the construction one is after, and the sections that follow build limits and colimits by finding exactly such extremal objects.

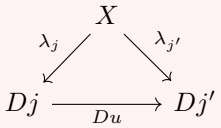
Example 63.1.8: Universal Arrows Across the Standing Cast
Each construction below is a universal arrow, read off from its factorization property.

1. *The integers as initial ring.* Let $U\colon \mathbf{Ring} \to \mathbf{Set}$ be the forgetful functor and $\{*\}$ a one-point set. A universal arrow from $\{*\}$ to U is a ring c together with a chosen element $\eta(*) \in Uc$ such that every pointed ring (R, r), with $r = f(*) \in UR$, receives a unique ring map $g\colon c \to R$ sending $\eta(*)$ to r. Take $c = \mathbb{Z}[x]$ with $\eta(*) = x$: a ring map $\mathbb{Z}[x] \to R$ is determined by, and freely specifies, the image of x ([21], universal property of the polynomial ring), so $(\mathbb{Z}[x], x)$

is the universal arrow. Forgetting the marked point instead, and taking U with no chosen element, the empty universal problem is solved by $\mathbb{Z}$ itself: $\mathbb{Z}$ is the initial object of **Ring** (example 63.1.2), the universal arrow from the empty set to U.

2. *Abelianization.* Let $U\colon \mathbf{Ab} \to \mathbf{Grp}$ be the inclusion of abelian groups into groups and let G be a group. The abelianization $G^{\mathrm{ab}} = G/[G,G]$ carries the quotient map $\eta\colon G \to U(G^{\mathrm{ab}})$. Every homomorphism $f\colon G \to UA$ into an abelian group A kills commutators, so it factors as $f = (Ug) \circ \eta$ through a unique homomorphism $g\colon G^{\mathrm{ab}} \to A$ ([21, Commutator Subgroup Properties]). Thus (G^{ab}, η) is a universal arrow from G to U, the best abelian approximation of G from the left.

The two items sit on opposite sides of a forgetful (or inclusion) functor. The polynomial ring is universal *from* a set *to* U, a free construction; abelianization is likewise a universal arrow from an object to an inclusion, a reflection into a subcategory. Both are computed the same way, by recognizing that a map out of the constructed object is forced by its effect on the universal datum η. The organizing principle behind such matched pairs of universal arrows, one for each object, is the subject of the chapter on adjunctions.



63.2 Limits

An initial object receives a unique map from nothing, a terminal object receives one from everything; both are universal against the empty diagram. A limit asks for more: a universal way to map compatibly into a whole configuration of objects and morphisms at once. Products, intersections, kernels, and fibered products are all this one requirement read against different shapes. This section isolates the shape as a small category J, packages a configuration as a functor out of it, and defines the limit as the terminal object among the compatible maps into it. The atomic cases, products and equalizers, are then shown to generate every limit.

We first fix what "a configuration" means. A configuration of objects and morphisms in $\mathbf{C}$ is exactly a functor into $\mathbf{C}$ whose domain records the shape; the domain is small so that the configuration has only a set's worth of pieces.

Definition 63.2.1: Diagram, Cone, and Limit

Let $\mathbf{C}$ be a category and J a small category, the *index category*. A *diagram* of shape J in $\mathbf{C}$ is a functor $D\colon J \to \mathbf{C}$ (definition 61.4.1); the object $D(j)$ is written Dj.
A *cone* over D with *apex* X is an object X of $\mathbf{C}$ together with a family of morphisms $\lambda_j\colon X \to Dj$, one for each object j of J, such that for every morphism $u\colon j \to j'$ in J the triangle

commutes, that is $Du \circ \lambda_j = \lambda_{j'}$. A morphism of cones $(X, \{\lambda_j\}) \to (Y, \{\mu_j\})$ is a morphism $f\colon X \to Y$ with $\mu_j \circ f = \lambda_j$ for every j. Cones over D and their morphisms form a category $\mathrm{Cone}(D)$.
A *limit* of D is a terminal object of $\mathrm{Cone}(D)$: a cone $(L, \{\pi_j\})$, the *limit cone*, such that every cone $(X, \{\lambda_j\})$ factors through it by a unique morphism $\langle \lambda_j \rangle\colon X \to L$ with $\pi_j \circ \langle \lambda_j \rangle = \lambda_j$ for all j. The apex L is written $\lim D$ or $\lim_J D$, and the π_j are its *projections*.

The commuting condition is the whole content of "compatible": a cone is not just a map into each Dj but a family that respects every morphism the shape imposes among the Dj. The limit is the cone through which all others factor, so a map into L is precisely a compatible family of maps into the diagram. This is the universal-arrow pattern of definition 63.1.4 for the diagonal functor $\Delta\colon \mathbf{C} \to [J, \mathbf{C}]$ sending X to the constant diagram at X: a cone with apex X is a natural transformation $\Delta X \Rightarrow D$ (definition 61.5.2), and the limit is the universal such X.

Being terminal in $\mathrm{Cone}(D)$ settles uniqueness at once.

Proposition 63.2.2: Uniqueness of Limits

If $(L, \{\pi_j\})$ and $(L', \{\pi'_j\})$ are both limits of $D\colon J \to \mathbf{C}$, there is a unique isomorphism $L \to L'$ commuting with the projections.

***Proof*:**
Both are terminal objects of $\mathrm{Cone}(D)$, and terminal objects are unique up to a unique isomorphism by proposition 63.1.3. The isomorphism is a morphism of cones, so it commutes with the projections by definition of $\mathrm{Cone}(D)$, completing the proof.

The limit is thus determined by D alone, and one speaks of "the" limit. The rest of the section reads specific shapes J off this single definition, then shows two of them suffice to build every other.

The simplest shapes carry no morphisms beyond identities, so the cone condition is vacuous and a cone is just a chosen map into each object.

Definition 63.2.3: Product

Let J be a *discrete* category (only identity morphisms) with objects indexed by a set I, and let D pick out a family $\{X_i\}_{i\in I}$. The limit of D, when it exists, is the *product* $\prod_{i\in I} X_i$, with projections $\pi_i\colon \prod_{i\in I} X_i \to X_i$. Its universal property: for every object X and every family $f_i\colon X \to X_i$ there is a unique $\langle f_i\rangle\colon X \to \prod_{i\in I} X_i$ with $\pi_i \circ \langle f_i\rangle = f_i$ for all i. When $I = \{1, 2\}$ the product is written $X_1 \times X_2$; when $I = \varnothing$ the limit over the empty diagram is a terminal object 1, the *empty product*.

A product is a single object out of which one can name any tuple of maps to the factors and nothing more; the projections read the coordinates back. There are no compatibility constraints because a discrete shape imposes none, so a map into $\prod_i X_i$ is exactly an unconstrained family of maps into the factors. The empty case is worth pausing on: with no factors to hit, the universal property says every object admits a unique map to the limit, which is the definition of a terminal object (definition 63.1.1).

Next introduce the shape with two parallel arrows between two objects. A cone must equalize the two composites, so it selects the part of the source on which they agree.

Definition 63.2.4: Equalizer

Let J be the category $\{\bullet \rightrightarrows \bullet\}$ with two objects and two parallel non-identity morphisms, and let D send it to a parallel pair $f, g\colon A \to B$ in $\mathbf{C}$. A cone over D is an object E with maps to A and to B making both triangles commute; the map to B is forced to be the common composite, so a cone is a morphism $e\colon E \to A$ with $fe = ge$. The limit is the *equalizer* of f and g: a morphism $e\colon E \to A$ with $fe = ge$ such that every $h\colon X \to A$ with $fh = gh$ factors as $h = e \circ \bar{h}$ for a unique $\bar{h}\colon X \to E$.

The equalizer is the categorical "locus where two maps agree": e is the universal way to map into A so that f and g become equal after the map. That universality forces e to be injective on maps.

Proposition 63.2.5: Equalizers are Monic

The equalizer $e\colon E \to A$ of a parallel pair $f, g\colon A \to B$ is a monomorphism.

***Proof*:**
Let $p, q\colon X \to E$ satisfy $ep = eq$, and set $h = ep$. Then $fh = fep = gep = gh$, so $h\colon X \to A$ satisfies $fh = gh$ and factors uniquely through e. Both p and q are factorizations of h through e: indeed $e \circ p = h$ and $e \circ q = eq = ep = h$. Uniqueness of the factorization gives $p = q$, so e is monic, as required.

That equalizers are monic recovers the intuition that "where f and g agree" is a subobject of the source A, and it is the ingredient that later lets equalizers cut a limit out of a product.

The third shape is the cospan: two arrows into a common target. Its limit combines a product with an agreement condition.

Definition 63.2.6: Pullback

Let J be the *cospan* category $\{\bullet \to \bullet \leftarrow \bullet\}$, and let D send it to a cospan $f\colon X \to Z$, $g\colon Y \to Z$ in $\mathbf{C}$. The limit is the *pullback* $X \times_Z Y$, with projections $p\colon X \times_Z Y \to X$ and $q\colon X \times_Z Y \to Y$ satisfying $fp = gq$, universal among such squares:

$$\begin{array}{ccc} X \times_Z Y & \xrightarrow{q} & Y \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle g} \\ X & \xrightarrow[f]{} & Z \end{array}$$

For every object W with maps $a\colon W \to X$, $b\colon W \to Y$ such that $fa = gb$, there is a unique $\langle a, b\rangle\colon W \to X \times_Z Y$ with $p\langle a, b\rangle = a$ and $q\langle a, b\rangle = b$.

A pullback is a product "constrained to agree over Z": it is the subobject of $X \times Y$ on which the two ways to reach Z coincide. When $Z = 1$ is terminal the agreement condition is vacuous and the pullback collapses to the product $X \times Y$, so the pullback refines the product. This one shape specializes to intersections of subobjects, preimages, fibers of a map, and fibered products of schemes, which is why it recurs throughout the series.

Each of these shapes should be seen at work in the category the reader knows best.

Example 63.2.7: Limits in Set

In **Set** each of the three limits above has a concrete description, and the universal property is verified by hand.

1. *Products.* The product $\prod_{i\in I} X_i$ is the cartesian product, the set of tuples $(x_i)_{i\in I}$ with $x_i \in X_i$, and π_i is the i-th coordinate. Given $f_i\colon X \to X_i$, the map $\langle f_i\rangle(x) = (f_i(x))_{i\in I}$ satisfies $\pi_i\langle f_i\rangle = f_i$, and any g with $\pi_i g = f_i$ has i-th coordinate f_i, so $g = \langle f_i\rangle$. The empty product is a one-element set $\{*\}$, terminal in **Set**. In **Grp**, **Ab**, and $\mathbf{Mod}_R$ the same underlying cartesian product carries the pointwise (coordinatewise) operations, and the projections are homomorphisms.

2. *Equalizers.* The equalizer of $f, g\colon A \to B$ is the subset

$$E = \{\, a \in A \,|\, f(a) = g(a) \,\}$$

with e the inclusion. If $h\colon X \to A$ satisfies $fh = gh$ then $f(h(x)) = g(h(x))$ for all x, so $h(x) \in E$; corestricting h to E gives the unique $\bar{h}$ with $e\bar{h} = h$. The inclusion is injective, illustrating proposition 63.2.5.

3. *Pullbacks.* The pullback of $f\colon X \to Z$ and $g\colon Y \to Z$ is the subset of $X \times Y$

$$X \times_Z Y = \{\, (x, y) \in X \times Y \,|\, f(x) = g(y) \,\}$$

with p, q the coordinate maps. Given $a\colon W \to X$ and $b\colon W \to Y$ with $fa = gb$, the map $w \mapsto (a(w), b(w))$ lands in $X \times_Z Y$ and is the unique factorization. Taking $g\colon \{z\} \hookrightarrow Z$ the inclusion of a point recovers the fiber $f^{-1}(z)$, and taking $X, Y \subseteq Z$ with f, g the inclusions recovers the intersection $X \cap Y$.

The three examples share a pattern: the limit is a subset of a product cut out by the equations the shape requires. The next theorem promotes that pattern to a construction, showing that products and equalizers alone build every limit.

Products handle the objects of a diagram, equalizers handle the constraints its morphisms impose. Stack every Dj into one product, stack every constraint into a second, and the two maps that express "constraint satisfied versus not" have an equalizer that is exactly the limit. This reduces the existence of all limits to two special cases.

Theorem 63.2.8: Limits from Products and Equalizers

Let $\mathbf{C}$ have all small products and all equalizers. Then $\mathbf{C}$ has all small limits. Explicitly, for a diagram $D\colon J \to \mathbf{C}$ with J small, form the products

$$P = \prod_{j \in J} Dj, \qquad Q = \prod_{u\colon j \to j' \text{ in } J} D(\operatorname{cod} u)$$

indexed by the objects and by the morphisms of J respectively. Let $s, t\colon P \to Q$ be the morphisms determined on the u-component $(u\colon j \to j')$ by

$$\rho_u \circ s = D(u) \circ \mathrm{pr}_j, \qquad \rho_u \circ t = \mathrm{pr}_{j'}$$

where $\mathrm{pr}_j\colon P \to Dj$ and $\rho_u\colon Q \to D(\operatorname{cod} u) = Dj'$ are the product projections. Then the equalizer $e\colon L \to P$ of s and t is a limit of D, with projections $\pi_j = \mathrm{pr}_j \circ e$.

***Proof*:**

The proof runs in three stages: define the two maps whose disagreement measures failure of the cone condition, check that the equalizer carries a cone, and check that this cone is terminal.

Step 1: The maps s and t. By the universal property of the product Q (definition 63.2.3), a morphism into Q is determined by its composite with each projection ρ_u. So the two displayed families of composites define s and t uniquely. Reading them off: for a point of P, thought of as an arbitrary family $(x_j)_j$ with $x_j\colon T \to Dj$ for a test object T, the u-component of s is $D(u) \circ x_j$ (push the source coordinate along $D(u)$), while the u-component of t is $x_{j'}$ (read off the target coordinate). A family (x_j) satisfies $s = t$ on the u-component precisely when $D(u) \circ x_j = x_{j'}$, which is the cone condition for the morphism u. Thus s and t agree on (x_j) if and only if (x_j) is a cone over D.

Step 2: The equalizer is a cone. Let $e\colon L \to P$ equalize s and t, so $se = te$. Set $\pi_j = \mathrm{pr}_j \circ e\colon L \to Dj$. For any $u\colon j \to j'$, compose $se = te$ with ρ_u:

$$\rho_u \circ s \circ e = \rho_u \circ t \circ e$$

The left side is $D(u) \circ \mathrm{pr}_j \circ e = D(u) \circ \pi_j$ and the right side is $\mathrm{pr}_{j'} \circ e = \pi_{j'}$. Hence $D(u) \circ \pi_j = \pi_{j'}$ for every u, so $(L, \{\pi_j\})$ is a cone over D.

Step 3: The cone is terminal. Let $(X, \{\lambda_j\})$ be any cone over D. By the universal property of P the family $\{\lambda_j\}$ determines a unique morphism $\ell\colon X \to P$ with $\mathrm{pr}_j \circ \ell = \lambda_j$ for all j. The cone condition $D(u) \circ \lambda_j = \lambda_{j'}$ says, on each u-component,

$$\rho_u \circ s \circ \ell = D(u) \circ \mathrm{pr}_j \circ \ell = D(u) \circ \lambda_j = \lambda_{j'} = \mathrm{pr}_{j'} \circ \ell = \rho_u \circ t \circ \ell$$

Since these hold for every u, and morphisms into Q are determined by their ρ_u-components, $s\ell = t\ell$. So ℓ equalizes s and t and factors uniquely as $\ell = e \circ \bar{\ell}$ for a unique $\bar{\ell}\colon X \to L$. Then

$$\pi_j \circ \bar{\ell} = \mathrm{pr}_j \circ e \circ \bar{\ell} = \mathrm{pr}_j \circ \ell = \lambda_j$$

so $\bar{\ell}$ is a morphism of cones $(X, \{\lambda_j\}) \to (L, \{\pi_j\})$. For uniqueness, suppose $\varphi\colon X \to L$ is any cone morphism, so $\pi_j \circ \varphi = \lambda_j$ for all j. Then $\mathrm{pr}_j \circ (e \circ \varphi) = \pi_j \circ \varphi = \lambda_j = \mathrm{pr}_j \circ \ell$ for every j, and the uniqueness clause of P's universal property forces $e \circ \varphi = \ell$. Since e is monic (proposition 63.2.5), $e \circ \varphi = e \circ \bar{\ell}$ gives $\varphi = \bar{\ell}$. Thus $\bar{\ell}$ is the unique cone morphism $X \to L$, so $(L, \{\pi_j\})$ is terminal in $\mathrm{Cone}(D)$ and is a limit of D, as we sought to show.

The construction is the abstract form of the **Set** computation in example 63.2.7: P is the product of the objects, s and t encode the two sides of each morphism-constraint, and the equalizer $L \subseteq P$ is the sub-configuration on which every constraint holds. What was "a subset of a product cut out by equations" in **Set** is now "an equalizer of two maps out of a product" in any category with those two limits, and the same argument gives the universal property. A category with all products and equalizers is therefore complete for all small diagrams, and to check completeness one need only give products and equalizers.

A limit is the universal way to map compatibly into an entire diagram at once, so that a single morphism into the apex is the same data as a family of morphisms into the diagram respecting its shape. Products and equalizers are the atomic cases, the first handling objects without constraint and the second handling a constraint without extra objects, and theorem 63.2.8 shows these two generate all the rest.

63.3 Colimits

Every construction of the previous section has a mirror image obtained by reversing all arrows. Where a limit sits at the tip of an incoming cone, its dual sits at the tip of an outgoing one; where a limit is a terminal cone, its dual is an initial cocone. This section develops that mirror image. The payoff is not only a second family of constructions but a method: because a colimit in C is exactly a limit in C^{op}, every theorem about limits transports across the duality principle (box 61.3.3) with no new proof, and the constructions themselves become recognizable as the coproducts, quotients, and gluings the reader already meets throughout algebra and topology.

The starting point is the dual of a cone. A cone over a diagram receives a compatible family of maps from a single apex; a cocone under a diagram emits a compatible family of maps into a single nadir.

Definition 63.3.1: Cocone and Colimit

Let $D\colon J \to C$ be a diagram. A *cocone* under D with *nadir* X is an object X of C together with a family of morphisms

$$\iota_j\colon Dj \to X, \qquad j \in J$$

one for each object of J, such that for every morphism $u\colon j \to k$ of J the triangle

$$\iota_k \circ Du = \iota_j$$

commutes. A *morphism of cocones* $(X, \{\iota_j\}) \to (Y, \{\kappa_j\})$ is a morphism $f\colon X \to Y$ of C with $f\iota_j = \kappa_j$ for every j.

A *colimit* of D is an *initial* cocone: a cocone $(L, \{\iota_j\})$ such that for every cocone $(X, \{\kappa_j\})$ under D there is a unique morphism $f\colon L \to X$ with $f\iota_j = \kappa_j$ for all j. The nadir L is written $\operatorname{colim}_J D$, and the maps ι_j are the *structure maps* (or *coprojections*) of the colimit.

The definition is definition 63.2.1 read backwards. A cocone under D is precisely a cone over the diagram $D^{\mathrm{op}}\colon J^{\mathrm{op}} \to C^{\mathrm{op}}$ obtained by reversing every arrow, and an initial cocone is a terminal cone in C^{op}. This is the organizing fact of the section.

Proposition 63.3.2: Colimits are Limits in the Opposite Category

Let $D\colon J \to C$ be a diagram and write $D^{\mathrm{op}}\colon J^{\mathrm{op}} \to C^{\mathrm{op}}$ for the same assignment on objects, regarded as a diagram in C^{op}. An object L with maps $\iota_j\colon Dj \to L$ is a colimit of D in C if and only if L with the same maps, now read as $\iota_j\colon L \to Dj$ in C^{op}, is a limit of D^{op} in C^{op}. Thus

$$\operatorname*{colim}_J D \text{ in } C \quad = \quad \lim_{J^{\mathrm{op}}} D^{\mathrm{op}} \text{ in } C^{\mathrm{op}}$$

***Proof*:**
Reversing arrows sends the compatibility condition $\iota_k \circ Du = \iota_j$ for a cocone under D to the condition $D^{\mathrm{op}}u \circ \iota_k = \iota_j$ for a cone over D^{op} in C^{op}, since composition in C^{op} is composition in C in the opposite order and each Du becomes $D^{\mathrm{op}}u$ pointing the other way. So cocones under D in C are the same data as cones over D^{op} in C^{op}, and a morphism of cocones $f\colon X \to Y$ in C is a morphism of cones $f\colon Y \to X$ in C^{op}. An initial object among cocones is therefore a terminal object among cones, so L is a colimit of D exactly when it is a limit of D^{op} in C^{op}, completing the proof.

This proposition permits a mechanical translation. Every notion of the previous section has a dual with the prefix "co": the terminal cone becomes the initial cocone, and each specific limit shape becomes a colimit shape by reversing the diagram J. The three shapes worth naming are the duals of the product, the equalizer, and the pullback. Their definitions are stated directly, but each one could equally be obtained by applying proposition 63.3.2 to the corresponding definition of section 63.2.

The first is the dual of the product (definition 63.2.3): a discrete diagram $\{X_i\}_{i \in I}$ with no nontrivial morphisms, whose colimit assembles the objects side by side rather than cutting out their common part.

Definition 63.3.3: Coproduct

Let $\{X_i\}_{i\in I}$ be a family of objects of C, viewed as a diagram on the discrete index category I. A *coproduct* of the family is a colimit: an object $\coprod_{i\in I} X_i$ together with *injections*

$$\iota_i \colon X_i \to \coprod_{i\in I} X_i$$

such that for every object Y and every family of morphisms $f_i \colon X_i \to Y$ there is a unique morphism $f \colon \coprod_{i\in I} X_i \to Y$ with $f\iota_i = f_i$ for all i. A binary coproduct is written $X_1 \sqcup X_2$.

A coproduct is the object into which every X_i maps and out of which maps are prescribed by naming one map from each summand independently. Where a product is determined by projections and its universal property governs *maps in*, a coproduct is determined by injections and governs *maps out*. The empty coproduct, indexed by $I = \varnothing$, is an object with a unique map to every Y and no data to specify: it is an initial object 0 (definition 63.1.1).

Example 63.3.4: Coproducts in the Standing Cast

The coproduct instantiates as a familiar assembly in each concrete category.

1. In **Set** the coproduct is the *disjoint union* $\coprod_i X_i$, the set of pairs (i, x) with $x \in X_i$, and $\iota_i(x) = (i, x)$. A family of functions $f_i \colon X_i \to Y$ assembles into the single function $(i, x) \mapsto f_i(x)$, which is the only function restricting to each f_i on the i-th copy. For two sets this is $X_1 \sqcup X_2$.

2. In **Grp** the coproduct is the *free product* $G_1 * G_2$: its elements are reduced words alternating between nonidentity elements of G_1 and of G_2, with ι_1, ι_2 the inclusions of the one-letter words. A pair of homomorphisms $f_i \colon G_i \to H$ extends to the unique homomorphism sending a word to the product of the images of its letters, each letter mapped by the f_i of the factor it comes from, and this assignment is forced ([21], free products). The free group on a set S is the coproduct of $|S|$ copies of $\mathbb{Z}$.

3. In **Ab** and in $\mathbf{Mod}_R$ the coproduct of a family is the *direct sum* $\bigoplus_i M_i$, the submodule of the product $\prod_i M_i$ consisting of tuples with finitely many nonzero entries, with ι_i the insertion into the i-th coordinate. A family $f_i \colon M_i \to N$ assembles into $(m_i)_i \mapsto \sum_i f_i(m_i)$, a finite sum because only finitely many m_i are nonzero ([21, Universal Property Of Coproducts In **Ab**, Direct Sums And Homomorphisms]). For finitely many summands the direct sum and the direct product coincide, so the biproduct $M_1 \oplus M_2$ is at once a product and a coproduct; this coincidence is a feature of additive categories, not a general phenomenon.

The contrast with products is sharpest in **Grp**: the product $G_1 \times G_2$ forces the two factors to commute, while the coproduct $G_1 * G_2$ imposes no relations at all between them.

The direct-sum example already shows the divergence between limits and colimits concretely: in **Set** the product is a Cartesian product and the coproduct a disjoint union, unrelated constructions, and in **Grp** the gap between $G_1 \times G_2$ and $G_1 * G_2$ is the gap between imposing all cross-relations and imposing none. The next shape is the dual of the equalizer (definition 63.2.4). Where an equalizer selects the sub-object on which two maps agree, its dual forms the quotient on which two maps are forced to agree.

Definition 63.3.5: Coequalizer

Let $f, g\colon A \to B$ be a parallel pair of morphisms in C. A *coequalizer* of f and g is a morphism $q\colon B \to Q$ with $qf = qg$ that is universal with this property: for every morphism $h\colon B \to Y$ satisfying $hf = hg$ there is a unique morphism $\bar{h}\colon Q \to Y$ with $\bar{h}q = h$.

The coequalizer is the colimit of the two-object diagram $A \rightrightarrows B$ whose only nontrivial morphisms are f and g: the condition $qf = qg$ is the cocone compatibility for that diagram, and universality is initiality among such cocones. The map q is the largest quotient of B on which f and g become equal, the categorical quotient. It is always epic, the dual of the fact that an equalizer is always monic.

Lemma 63.3.6: A Coequalizer is Epic

The coequalizer map $q\colon B \to Q$ of any parallel pair $f, g\colon A \to B$ is an epimorphism.

***Proof*:**
Suppose $s, t\colon Q \to Y$ satisfy $sq = tq$. Set $h = sq = tq\colon B \to Y$. Then $hf = sqf = sqg = hg$ using $qf = qg$, so h satisfies the coequalizing condition and factors uniquely through q. Both s and t are such factorizations, since $sq = h$ and $tq = h$, so uniqueness forces $s = t$. Thus q is epic, as we sought to show.

Example 63.3.7: The Coequalizer in Sets is a Quotient
For functions $f, g\colon A \to B$ in **Set**, let $\sim$ be the smallest equivalence relation on B containing every pair $(f(a), g(a))$ for $a \in A$. The coequalizer is the quotient set $Q = B/\!\sim$ with $q\colon B \to Q$ the quotient map. A function $h\colon B \to Y$ satisfies $hf = hg$ exactly when $h(f(a)) = h(g(a))$ for all a, that is, when h is constant on each generating pair, hence on each $\sim$-class; such an h descends to a unique $\bar{h}\colon Q \to Y$ with $\bar{h}q = h$. The generated equivalence relation is not just the set of pairs $(f(a), g(a))$: it is their reflexive, symmetric, transitive closure, since a quotient map respecting the relations must respect everything they entail. Taking g constant recovers, as a special case, the quotient of B collapsing a subset to a point.

The equivalence closure in example 63.3.7 is the concrete face of a general fact: a coequalizer imposes the relations $f = g$ together with every consequence forced by the category's own composition, exactly as a coproduct in **Grp** imposes no relations while a quotient group imposes stated ones. The last named shape is the dual of the pullback (definition 63.2.6), which glues two objects along a shared source rather than intersecting them over a shared target.

Definition 63.3.8: Pushout

Let $f\colon Z \to X$ and $g\colon Z \to Y$ be a pair of morphisms with common *source* Z. A *pushout* of f and g is a colimit of this diagram: an object $X \sqcup_Z Y$ with morphisms $i\colon X \to X \sqcup_Z Y$ and $j\colon Y \to X \sqcup_Z Y$ satisfying $if = jg$, universal among such cocones. For every object W with maps $p\colon X \to W$ and $q\colon Y \to W$ satisfying $pf = qg$ there is a unique $h\colon X \sqcup_Z Y \to W$ with $hi = p$ and $hj = q$.

A pushout glues X and Y along the images of Z: the map f marks a copy of Z inside X, the map g

marks a copy inside Y, and $X \sqcup_Z Y$ is the result of identifying the two marked copies. In **Set** it is the quotient of $X \sqcup Y$ by the relation $f(z) \sim g(z)$, which is why the pushout is the formal model of every "glue two pieces along a common part" construction. When $Z = 0$ is initial the constraint is vacuous and the pushout is the coproduct $X \sqcup Y$, exactly as a pullback over a terminal object is a product.

Example 63.3.9: Pushouts as Gluing
Two instances show the gluing.

1. In **Set**, if $Z \hookrightarrow X$ and $Z \hookrightarrow Y$ are inclusions of a common subset, the pushout $X \sqcup_Z Y$ is the union of X and Y overlapping exactly along Z: form the disjoint union $X \sqcup Y$ and identify each copy of a point of Z. Explicitly it is $(X \sqcup Y)/\!\sim$ with $\iota_1 f(z) \sim \iota_2 g(z)$, the coequalizer of the two maps $Z \rightrightarrows X \sqcup Y$ given by $\iota_1 f$ and $\iota_2 g$.
2. In **Top** the same colimit glues spaces. Taking X and Y to be two closed disks D^2 and $Z = S^1$ their common boundary circle, mapping into each by the boundary inclusion, the pushout $D^2 \sqcup_{S^1} D^2$ is the 2-sphere S^2: two disks glued along their boundary. This is the mechanism behind attaching cells and building spaces from simpler pieces, the staple of the algebraic topology of CW complexes.

The two constructions from which every colimit is built are now in hand: coproducts assemble a family of objects, and coequalizers impose relations. The dual of theorem 63.2.8 states that these two suffice, and its proof is that theorem read in the opposite category. The motivation is the same as in the limit case: to check that a category has all small colimits, it is enough to check two constructions rather than one for every diagram shape.

Theorem 63.3.10: Colimits from Coproducts and Coequalizers

Let C be a category with all small coproducts and all coequalizers. Then C has all small colimits. Concretely, the colimit of a diagram $D\colon J \to C$ with J small is the coequalizer of a canonical parallel pair of maps between two coproducts,

$$\coprod_{(u\colon\, j \to k) \in \operatorname{mor} J} Dj \;\rightrightarrows\; \coprod_{j \in \operatorname{ob} J} Dj \longrightarrow \operatorname*{colim}_J D$$

where the first coproduct is indexed by the morphisms of J and the second by its objects.

***Proof*:**
By proposition 63.3.2, a colimit of $D\colon J \to C$ is a limit of $D^{\mathrm{op}}\colon J^{\mathrm{op}} \to C^{\mathrm{op}}$. The hypotheses transport across the duality principle (box 61.3.3): a coproduct in C is a product in C^{op} and a coequalizer in C is an equalizer in C^{op}, so C having all small coproducts and coequalizers is C^{op} having all small products and equalizers. Theorem 63.2.8 then applies in C^{op} and produces the limit of D^{op}, hence the colimit of D. This proves existence; it remains only to record what the construction of that theorem becomes when read back in C.

The construction of theorem 63.2.8 builds a limit as an equalizer of two maps between the product $\prod_j Dj$ over the objects and the product $\prod_u D(\operatorname{cod} u)$ over the morphisms. Dualizing every arrow turns each product into a coproduct and the equalizer into a coequalizer, giving the coproduct $\coprod_j Dj$ over the objects, the coproduct $\coprod_u D(\operatorname{dom} u)$ over the morphisms, and

a coequalizer of two maps between them. Concretely, for a morphism $u\colon j \to k$ of J the u-th summand Dj of the source coproduct is sent by the two maps to the object coproduct in two ways: one injection includes Dj as the j-th summand directly, and the other sends it through $Du\colon Dj \to Dk$ into the k-th summand. Writing $\iota_j\colon Dj \to \coprod_j Dj$ for the coproduct injections, the two maps $s, t\colon \coprod_u Dj \to \coprod_j Dj$ are determined on the u-th summand by

$$s \circ \iota_u = \iota_j, \qquad t \circ \iota_u = \iota_k \circ Du$$

Their coequalizer $q\colon \coprod_j Dj \to Q$ forces $q\iota_j$ and $q\iota_k \circ Du$ to become equal for every u, since $qs = qt$ reads $q\iota_j = q\iota_k \circ Du$ on the u-th summand. This is exactly the cocone compatibility for the maps $q\iota_j$. So the maps $q\iota_j\colon Dj \to Q$ form a cocone under D, and the coequalizer's universal property makes it the initial one: a cocone $(Y, \{\kappa_j\})$ is a family with $\kappa_k \circ Du = \kappa_j$, which is a map $\langle \kappa_j \rangle\colon \coprod_j Dj \to Y$ coequalizing s and t, hence factoring uniquely through q. Thus $Q = \operatorname{colim}_J D$, completing the proof.

The theorem and its proof are the mirror of the limit case in the strict sense that not one line of new mathematics was needed: proposition 63.3.2 moves the problem to C^{op}, the duality principle converts the hypotheses, and theorem 63.2.8 does the work. The dual construction is worth carrying explicitly all the same, because the coequalizer of two maps between coproducts is how a colimit is computed: assemble every object of the diagram into one coproduct, then force the relations that the morphisms of J impose. The equalizer-of-products picture cut a sub-object out of an assembly; the coequalizer-of-coproducts picture builds an assembly and then collapses it.

This is the interpretive content of the whole duality. Limits and colimits are two readings of one definition, exchanged by reversing arrows, and the exchange is not a formal trick but a difference in operation. A limit intersects and cuts out: the product is the joint object seen from all its projections, the equalizer is the locus where two maps agree, the pullback is the fibered intersection over a shared target. A colimit glues and quotients: the coproduct sets objects side by side, the coequalizer imposes relations, the pushout glues along a shared source. The product cuts $\prod X_i$ down by an equalizer to enforce compatibility; the coproduct is quotiented by a coequalizer to enforce it. Each theorem, each construction, and each computation of section 63.2 therefore has a twin here, obtained for free by the duality principle, and the two families are the same mathematics viewed from opposite sides.

63.4 Computing (Co)limits

The previous sections built limits and colimits abstractly and reduced their existence to two special cases: products and equalizers on one side, coproducts and coequalizers on the other (theorem 63.2.8 and its dual). This section shows the constructions: a name for the categories in which every diagram has a limit; the working principle that in the algebraic categories a limit is computed on underlying sets while a colimit usually is not; the pointwise computation in functor and presheaf categories; and the functors that carry limits to limits, the representable ones foremost. That last result closes the loop with Chapter 2: an object sees limits through its hom-functor exactly because of Yoneda.

We fix conventions once. A category has *all small limits* if every diagram $D\colon J \to C$ indexed by a small category J has a limit, and likewise for colimits.

Definition 63.4.1: Complete and Cocomplete Categories

A category C is *complete* if it has all small limits, that is, if every diagram $D\colon J \to C$ with J small has a limit $\lim D$. It is *cocomplete* if it has all small colimits, that is, if every such diagram has a colimit $\operatorname{colim}_J D$.

Completeness is a strong hypothesis stated compactly, but it need never be checked diagram by diagram. Theorem 63.2.8 constructed the limit of an arbitrary diagram from a pair of products and one equalizer, so a category that has all small products and all equalizers already has all small limits. This is the only test one runs in practice.

Proposition 63.4.2: Completeness from Products and Equalizers

A category C is complete if and only if it has all small products and all equalizers. Dually, C is cocomplete if and only if it has all small coproducts and all coequalizers.

***Proof*:**
If C is complete it has, in particular, all products (limits of discrete diagrams) and all equalizers (limits over the parallel-pair shape), so the forward direction is immediate. Conversely, suppose C has all small products and all equalizers. Given any diagram $D\colon J \to C$ with J small, the construction of theorem 63.2.8 builds $\lim D$ as the equalizer of two maps between the product $\prod_j Dj$ over the objects of J and the product $\prod_u D(\operatorname{cod} u)$ over the morphisms of J; both products are small because J is small. Hence $\lim D$ exists, and C is complete. The colimit statement is the dual, obtained by applying the same argument in C^{op} (box 61.3.3): a coproduct in C is a product in C^{op}, a coequalizer in C is an equalizer in C^{op}, and completeness of C^{op} is cocompleteness of C, completing the proof.

The categories of the standing cast are all complete and cocomplete: **Set**, **Grp**, **Ab**, **Ring**, $\mathbf{Mod}_R$, and **Top** each have all small limits and colimits. For **Set** this is direct, and completeness of the rest follows from the next result once the limits are located inside **Set**. Cocompleteness holds too, but its proof is not dual in content: by proposition 63.4.2 it suffices to have all small coproducts and all coequalizers, and in the algebraic categories these are the free constructions and quotients of [21] (free products in **Grp**, direct sums in **Ab** and $\mathbf{Mod}_R$, and quotients by the relations generated for coequalizers), while **Top** carries the quotient and coproduct topologies. The second half of this section does not reprove these but illustrates the point that colimits are built by their own universal properties rather than read off underlying sets.

The pattern that makes limits computable in the algebraic categories is that the forgetful functor to **Set** does more than preserve them, it *creates* them: the underlying set of a limit is the limit of the underlying sets, and the algebraic structure on it is forced. A product of groups is the product set with coordinatewise multiplication; the equalizer of two homomorphisms is the subset where they agree, which is a subgroup because the operations are computed coordinatewise. The precise statement follows; the notion of creation is made formal later in this section (definition 63.4.6), but the content here is elementary and self-contained.

Proposition 63.4.3: Limits in the Algebraic Categories

Let C be any of **Grp**, **Ab**, **Ring**, or $\mathbf{Mod}_R$, and let $U\colon C \to \mathbf{Set}$ be the forgetful functor. Then C is complete, and U *creates* all small limits: for a diagram $D\colon J \to C$, every limit cone of UD in **Set** lifts to a unique cone in C lying over it, and that cone is a limit. In particular the underlying set of $\lim D$ is $\lim(UD)$, computed in **Set**, with the algebraic operations defined coordinatewise. Concretely:

1. *Products.* The product $\prod_i X_i$ has underlying set the Cartesian product $\prod_i UX_i$, with the operations applied coordinatewise; the projections $\pi_j\colon \prod_i X_i \to X_j$ are the coordinate projections.
2. *Equalizers.* The equalizer of two morphisms $f, g\colon X \to Y$ is the subobject $E = \{x \in UX \,|\, f(x) = g(x)\}$ with the operations inherited from X; the equalizing morphism $E \to X$ is the inclusion.

The same holds for **Top**, with the limit set carrying the initial topology for the cone maps.

***Proof*:**
By proposition 63.4.2 it suffices to treat products and equalizers and to assemble the general limit from these by theorem 63.2.8, since creation is inherited stage by stage: a functor that creates products and equalizers creates every limit built from them. For each of the two shapes the argument shows more than preservation. Starting from a limit cone in **Set** (the Cartesian product with its projections, or the agreement subset with its inclusion), the algebraic operations that turn it into a cone in C are forced coordinatewise, so the lift is unique; the lifted cone is then verified to be a limit in C; and U returns it to the given cone in **Set**. That is creation (definition 63.4.6), and preservation and completeness of C follow.

Step 1: Products. Take a small family $(X_i)_{i\in I}$ in C. Let P be the Cartesian product $\prod_i UX_i$ of underlying sets, an element of which is a family $(x_i)_i$ with $x_i \in UX_i$. Define the algebraic operations coordinatewise: for **Grp**, $(x_i)(y_i) = (x_iy_i)$ with identity (e_i) and inverse $(x_i)^{-1} = (x_i^{-1})$; for a ring or module the addition and multiplication (or scalar action) are applied in each coordinate. The group, ring, or module axioms hold in P because they hold in each X_i and are tested coordinatewise. The coordinate projections $\pi_j\colon P \to X_j$, $(x_i) \mapsto x_j$, are morphisms of C because the operations on P are coordinatewise. Given any Z in C with morphisms $h_i\colon Z \to X_i$, the set map $h\colon UZ \to P$, $z \mapsto (h_i(z))_i$, is the unique function with $\pi_j h = h_j$ for all j (this is the universal property of the product in **Set**), and it is a morphism of C because each h_i is and the operations on P are coordinatewise. So P with the π_j is the product in C, and $UP = \prod_i UX_i$ is the product in **Set**; thus U preserves it. The lift is unique: any operations on the set $\prod_i UX_i$ making the coordinate projections into morphisms of C must agree with each X_j in that coordinate, hence be the coordinatewise ones, so this is the only structure lying over the **Set** product. That is creation for the product shape.

Step 2: Equalizers. Take $f, g\colon X \to Y$ in C and set $E = \{x \in UX \,|\, f(x) = g(x)\} \subseteq UX$, which is the equalizer of Uf and Ug in **Set**. The subset E is closed under the operations of X: if $f(x) = g(x)$ and $f(x') = g(x')$ then, since f and g are morphisms, $f(xx') = f(x)f(x') = g(x)g(x') = g(xx')$, and likewise f and g agree on the identity, on inverses, and on scalar

multiples. Hence E is a subgroup, subring, or submodule of X, and with these inherited operations the inclusion $e\colon E \to X$ is a morphism of C with $fe = ge$. If $h\colon Z \to X$ satisfies $fh = gh$ then h lands in E at the level of sets, so it factors uniquely as $h = eh'$ through the set map $h'\colon UZ \to E$; and h' is a morphism of C because its composite with the inclusion is and E carries the inherited operations. So E is the equalizer in C, and UE is the equalizer in **Set**. Again the lift is unique: the subset E inherits its operations from X by restriction, the only structure making the inclusion a morphism, so the cone over the **Set** equalizer is forced. That is creation for the equalizer shape.

Step 3: Topological spaces. For **Top** the same two constructions work on underlying sets, and the topology is forced: the product carries the product topology (the coarsest making every projection continuous) and the equalizer carries the subspace topology. In each case this is the coarsest topology making the cone maps continuous, so a map out of a test space is continuous exactly when its composites with the cone maps are, which is the universal property. The initial topology is the unique one making the cone maps continuous while giving the universal property, so here too the lift over the **Set** limit is unique: $U\colon$ **Top** $\to$ **Set** creates these limits as well. By proposition 63.4.2 every category listed is complete with limits computed on underlying sets, completing the proof.

The proposition is what lets one compute in these categories at all: a limit is found by taking the limit of the underlying sets and then observing that the algebraic structure has nowhere else to go. The equalizer clause is the categorical form of a familiar move, that the locus where two homomorphisms agree is a subgroup. The kernel of a group or module homomorphism $f\colon G \to H$ is the special case where g is the trivial homomorphism (written $g = 0$ in the additive case), so such kernels are equalizers, and the general limit packages products with these agreement loci. In **Ring** the zero map is not a morphism, so a ring-map kernel is an ideal rather than an equalizer; the equalizer description here stays in the group and module setting.

The contrast the reader should carry forward is that colimits are not computed this way. The forgetful functor does not create colimits: the coproduct in **Grp** is the free product, whose underlying set is far larger than the disjoint union of the underlying sets.

Example 63.4.4: The Coproduct in Grp Is Not the Disjoint Union
In **Set** the coproduct is the disjoint union $X \sqcup Y$. In **Grp** the coproduct of G and H is the *free product* $G * H$, whose elements are the reduced words alternating between nontrivial elements of G and of H ([21], free products). Its universal property is the one required of a coproduct: a pair of homomorphisms $G \to K$ and $H \to K$ extends uniquely to $G * H \to K$. Take $G = H = \mathbb{Z}/2$, generated by a and b respectively. The disjoint union of the underlying sets has four elements, while $\mathbb{Z}/2 * \mathbb{Z}/2$ is infinite: it contains the distinct reduced words $a, b, ab, ba, aba, bab, \ldots$ and is isomorphic to the infinite dihedral group. So $U(G * H) \neq UG \sqcup UH$, and the forgetful functor does not preserve this coproduct. In **Ab** the coproduct of G and H is instead the direct sum $G \oplus H$, which for two groups agrees with the product, and its underlying set is $UG \times UH$, not $UG \sqcup UH$: even the abelian coproduct is not the set-level coproduct.

The lesson is that "compute on underlying sets" is a statement about limits, and that colimits in the algebraic categories must be built by their own universal property (free constructions, quotients, amalgamation) rather than read off the forgetful functor. Coequalizers, for instance, are quotients rather than subobjects.

The functor and presheaf categories behave better: there both limits and colimits are computed pointwise, one object of the indexing category at a time. This is what makes presheaf theory computable, and the reason presheaf categories inherit completeness and cocompleteness from **Set**.

Proposition 63.4.5: Pointwise Limits in Functor Categories

Let J be a small category and C a category, and let $[J, C]$ be the functor category (definition 61.5.4). Suppose C is complete. Then $[J, C]$ is complete, and limits are computed *pointwise*: for a diagram $F\colon I \to [J, C]$ indexed by a small category I, the limit $\lim_I F$ is the functor

$$\Big(\lim_I F\Big)(j) = \lim_I \big(F(-)(j)\big)$$

sending each object j of J to the limit in C of the diagram $i \mapsto F(i)(j)$. Dually, if C is cocomplete then $[J, C]$ is cocomplete, with colimits computed pointwise. In particular the presheaf category $\mathbf{PSh}(C) = [C^{\mathrm{op}}, \mathbf{Set}]$ (definition 62.3.1) is complete and cocomplete, and both are computed pointwise from **Set**.

***Proof*:**
Write $G_j = \lim_I \big(F(-)(j)\big)$ for the object of C obtained by taking, for a fixed j, the limit of the diagram $i \mapsto F(i)(j)$; it exists because C is complete. Let $\lambda_i^j\colon G_j \to F(i)(j)$ be the limit cone.

Step 1: The pointwise limits assemble into a functor. For a morphism $u\colon j \to j'$ in J and each i, the maps $F(i)(u)\colon F(i)(j) \to F(i)(j')$ are compatible with the diagram in I, since each $F(i)$ is a functor and the arrows of the diagram over I are natural transformations, so the family $\big(F(i)(u) \circ \lambda_i^j\big)_i$ is a cone over $i \mapsto F(i)(j')$. By the universal property of $G_{j'}$ there is a unique map $G(u)\colon G_j \to G_{j'}$ with $\lambda_i^{j'} \circ G(u) = F(i)(u) \circ \lambda_i^j$ for all i. Uniqueness makes G functorial: $G(1_j) = 1_{G_j}$ and $G(u'u) = G(u')G(u)$, because both sides satisfy the equations defining the induced map. So $G\colon J \to C$ is a functor, an object of $[J, C]$, and the maps $\lambda_i^\bullet\colon G \Rightarrow F(i)$ are natural transformations, a cone over F in $[J, C]$.

Step 2: This cone is a limit. Let H be a functor in $[J, C]$ with a cone $\mu_i\colon H \Rightarrow F(i)$. For each fixed j the components $(\mu_i)_j\colon H(j) \to F(i)(j)$ form a cone over $i \mapsto F(i)(j)$ in C, so there is a unique map $\varphi_j\colon H(j) \to G_j$ with $\lambda_i^j \circ \varphi_j = (\mu_i)_j$ for all i. The components φ_j are natural in j: for $u\colon j \to j'$, both $G(u)\varphi_j$ and $\varphi_{j'}H(u)$ are maps $H(j) \to G_{j'}$ that, after composing with each $\lambda_i^{j'}$, give $(\mu_i)_{j'}H(u) = F(i)(u)(\mu_i)_j$, so they agree by the uniqueness in the universal property of $G_{j'}$. Hence $\varphi\colon H \Rightarrow G$ is a natural transformation with $\lambda_i^\bullet \circ \varphi = \mu$, and it is the unique such because each φ_j was forced. So G with the cone $\lambda_i^\bullet$ is the limit of F in $[J, C]$. The colimit statement is the dual (box 61.3.3), and applying both to $C = \mathbf{Set}$, which is complete and cocomplete, gives the claim for $\mathbf{PSh}(C)$, completing the proof.

The proposition says that a (co)cone in $[J, C]$ is exactly an objectwise-compatible family of (co)cones in C: naturality is what glues the pointwise data into a morphism of functors, and the universal property is checked one object at a time. For presheaves this means every limit and colimit is computed in **Set** and then reassembled, so all the set-level formulas transfer verbatim. A product of presheaves is the objectwise product of sets, a colimit of presheaves is the objectwise colimit, and representable presheaves, while not closed under these operations, sit inside a category where every

limit and colimit exists.

Having located limits in specific categories, the next results treat how limits behave under functors. Three conditions arrange the possibilities: a functor may carry limit cones to limit cones, may detect a limit from its image, or may lift limits from the target to the source. These are preservation, reflection, and creation.

Definition 63.4.6: Preserving, Reflecting, and Creating Limits

Let $G\colon C \to D$ be a functor and $F\colon J \to C$ a diagram.

1. G *preserves* the limit of F if, whenever $(\lim F, \lambda)$ is a limit cone in C, its image $(G(\lim F), G\lambda)$ is a limit cone over GF in D.
2. G *reflects* limits if a cone (L, λ) over F in C is a limit cone whenever its image $(GL, G\lambda)$ is a limit cone over GF in D.
3. G *creates* the limit of F if, given any limit cone (M, μ) over GF in D, there is a cone (L, λ) over F in C with $GL = M$ and $G\lambda = \mu$, this cone is a limit of F, and it is the unique cone in C (up to the induced isomorphism) lying over (M, μ).

The dual notions, for colimits and cocones, are named identically.

Creation is the strongest of the three and is what proposition 63.4.3 really established: the forgetful functor $U\colon \mathbf{Grp} \to \mathbf{Set}$ creates limits, because a limit cone downstairs in **Set** lifts to a unique cone of groups, and that cone is a limit. Creation implies preservation and reflection together. Preservation alone is the condition that appears most often, and the hom-functor is the instance developed next. A morphism into a limit is the same data as a compatible family of morphisms into the diagram, which is precisely what the hom-set of the limit computes.

Proposition 63.4.7: Representable Functors Preserve Limits

Let C be a locally small category and c an object. The covariant hom-functor $\mathrm{Hom}(c, -)\colon C \to \mathbf{Set}$ (definition 62.1.1) preserves all limits that exist in C: for any diagram $D\colon J \to C$ with a limit,

$$\mathrm{Hom}\Big(c, \lim_J D\Big) \;\cong\; \lim_J \mathrm{Hom}(c, D-)$$

naturally in c, where the right-hand limit is taken in **Set**. Dually, $\mathrm{Hom}(-, c)\colon C^{\mathrm{op}} \to \mathbf{Set}$ sends colimits in C to limits in **Set**.

***Proof*:**
Let $(\lim_J D, \lambda)$ be the limit cone in C, with legs $\lambda_j\colon \lim_J D \to Dj$. Apply $\mathrm{Hom}(c, -)$: the images $(\lambda_j)_*\colon \mathrm{Hom}(c, \lim_J D) \to \mathrm{Hom}(c, Dj)$ form a cone over $\mathrm{Hom}(c, D-)$ in **Set**, since post-composition is functorial and the λ_j commute with the diagram. It remains to show this cone is a limit in **Set**, that is, that $\mathrm{Hom}(c, \lim_J D) \to \lim_J \mathrm{Hom}(c, Dj)$ is a bijection.

Step 1: The target is the set of compatible families. A limit in **Set** is the set of compatible families over the diagram (the equalizer inside a product built in theorem 63.2.8), so an element of $\lim_J \mathrm{Hom}(c, Dj)$ is a family $(g_j)_j$ with $g_j \in \mathrm{Hom}(c, Dj)$ such that for every morphism $u\colon j \to j'$

in J one has $Du \circ g_j = g_{j'}$. That is exactly a cone over D with apex c: a family of maps $g_j \colon c \to Dj$ compatible with the diagram.

Step 2: Cones with apex c correspond to maps into the limit. The universal property of $\lim_J D$ says precisely that cones over D with apex c are in bijection with morphisms $c \to \lim_J D$: to each cone (g_j) there is a unique $g \colon c \to \lim_J D$ with $\lambda_j g = g_j$, and every $g \colon c \to \lim_J D$ yields the cone $(\lambda_j g)_j$. Under the identification of Step 1, this bijection is exactly the map $g \mapsto ((\lambda_j)_* g)_j = (\lambda_j g)_j$, so $(\lambda_j)_* \colon \mathrm{Hom}(c, \lim_J D) \to \lim_J \mathrm{Hom}(c, Dj)$ is a bijection. Hence the cone is a limit, and $\mathrm{Hom}(c, -)$ preserves the limit of D. Naturality in c is functoriality of the two-sided hom-bifunctor (definition 62.1.4): a morphism $c' \to c$ induces compatible pre-composition maps on both sides.

Step 3: The dual. Applying the statement in C^{op} (box 61.3.3) gives the second claim. A colimit in C is a limit in C^{op}, and $\mathrm{Hom}_C(-, c) = \mathrm{Hom}_{C^{\mathrm{op}}}(c, -)$; the preservation of C^{op}-limits by $\mathrm{Hom}_{C^{\mathrm{op}}}(c, -)$ reads in C as $\mathrm{Hom}_C(\mathrm{colim}_J D, c) \cong \lim_J \mathrm{Hom}_C(D-, c)$, so $\mathrm{Hom}(-, c)$ carries colimits to limits, completing the proof.

This is the categorical version of a fact used constantly: to map into a limit is to map compatibly into each stage, and to map out of a colimit is to map compatibly out of each stage. It is why a homomorphism into a product is a tuple of homomorphisms, and why a homomorphism out of a quotient or a pushout is a compatible pair. The result also reads from the Yoneda side. By the Yoneda lemma (theorem 62.2.1) an object is determined by the functor $\mathrm{Hom}(-, c)$ it represents, and that functor turns colimits into limits, while $\mathrm{Hom}(c, -)$ preserves limits. So an object's behaviour under limits is legible through its hom-functors, the precise sense in which Chapter 2's lens on objects extends to the constructions of this chapter.

The results combine into a single computation. In **Set** a pullback is the fibered product, and the hom-functor preservation says a map into it is a compatible pair of maps into its factors. This one construction computes intersections and preimages at once.

Example 63.4.8: Pullbacks in Set as Fibered Products

Let $f \colon X \to Z$ and $g \colon Y \to Z$ be functions. Their pullback (definition 63.2.6) in **Set** is the fibered product

$$X \times_Z Y = \{(x, y) \in X \times Y \,|\, f(x) = g(y)\}$$

with the two projections to X and Y. This is a limit, computed on the underlying sets exactly as proposition 63.4.3 prescribes: it is the equalizer of $f \circ \pi_X$ and $g \circ \pi_Y$ inside the product $X \times Y$, so it is the subset where the two composites agree.

Two special cases recover familiar operations.

1. *Intersection.* Let $A, B \subseteq Z$ be subsets, with inclusions $f \colon A \hookrightarrow Z$ and $g \colon B \hookrightarrow Z$. Then $f(a) = g(b)$ forces $a = b$ as elements of Z, so

   $$A \times_Z B = \{(a, b) \in A \times B \,|\, a = b\} \cong A \cap B$$

   The pullback of two subobjects along their inclusions is their intersection.

2. *Preimage.* Let $g \colon Y \to Z$ be arbitrary and take $A \subseteq Z$ with inclusion $f \colon A \hookrightarrow Z$. Then

$A \times_Z Y = \{(a, y) \big| a = g(y)\}$, and the projection to Y identifies it with

$$\{y \in Y \big| g(y) \in A\} = g^{-1}(A)$$

the preimage. Pulling back a subobject along a map is taking its preimage.

The preservation result reads off the maps into $X \times_Z Y$: for a set W,

$$\mathrm{Hom}(W, X \times_Z Y) \cong \{(p, q) \big| p \colon W \to X,\ q \colon W \to Y,\ fp = gq\}$$

which is the equalizer of f_* and g_* inside $\mathrm{Hom}(W, X) \times \mathrm{Hom}(W, Y)$, precisely the pullback in **Set** of the induced hom-sets. So a map into the fibered product is a matching pair of maps into the factors, the concrete face of proposition 63.4.7.

64

Adjunctions

Chapters 1 through 3 built the vocabulary; adjunctions turn it into an organizing principle. An *adjunction* makes precise the sense in which one functor is the best approximate inverse of another: free constructions are adjoint to forgetful ones, colimits and limits to the diagonal, tensoring to hom. This chapter gives the definition in its three equivalent forms, works the examples, and proves the theorem every adjunction obeys, that right adjoints preserve limits, before asking when an adjoint exists at all.

64.1 Adjoint Functors

The previous chapter recognized free constructions, abelianization, and the initial ring as universal arrows, one for each object of a category (definition 63.1.4). When a functor gives such an arrow at *every* object in a coherent way, the two functors involved stand in the relationship this section defines. We give the definition first through a natural isomorphism of hom-sets, then repackage it through a unit and a counit, and prove that these two presentations and the object-by-object universal-arrow condition are the same data. The free-monoid construction runs alongside as the guiding example.

Definition 64.1.1: Adjunction

Let $F\colon C \to D$ and $G\colon D \to C$ be functors. An *adjunction* from F to G is a natural isomorphism

$$\Phi\colon \mathrm{Hom}_D(F-,-) \;\cong\; \mathrm{Hom}_C(-,G-)$$

of functors $C^{\mathrm{op}} \times D \to \mathbf{Set}$; componentwise, for each object c of C and d of D a bijection

$$\Phi_{c,d}\colon \mathrm{Hom}_D(Fc,d) \xrightarrow{\;\cong\;} \mathrm{Hom}_C(c,Gd)$$

natural in c and in d. When such an adjunction exists we say F is *left adjoint* to G and G is *right adjoint* to F, written $F \dashv G$. For a morphism $f\colon Fc \to d$, the corresponding morphism $\Phi_{c,d}(f)\colon c \to Gd$ is its *transpose* (or *adjunct*), and likewise $\Phi^{-1}_{c,d}(g)$ is the transpose of $g\colon c \to Gd$.

Naturality is the content of the definition. It says that transposition commutes with composition on both sides: for $u\colon c' \to c$ in C and $v\colon d \to d'$ in D, the transpose of $v \circ f \circ Fu$ is $Gv \circ \Phi_{c,d}(f) \circ u$. Concretely, the naturality square in the C-variable,

$$\begin{array}{ccc} \mathrm{Hom}_D(Fc,d) & \xrightarrow{\Phi_{c,d}} & \mathrm{Hom}_C(c,Gd) \\ {\scriptstyle (Fu)^*}\downarrow & & \downarrow{\scriptstyle u^*} \\ \mathrm{Hom}_D(Fc',d) & \xrightarrow[\Phi_{c',d}]{} & \mathrm{Hom}_C(c',Gd) \end{array}$$

commutes, where $(Fu)^*$ is precomposition with Fu and u^* is precomposition with u; the analogous square in the D-variable uses postcomposition with v and with Gv. The intuition is compact: a map out of the free object Fc is the same datum as a map into the underlying object Gd. The bijection lets one pass between the world where c lives and the world where d lives without loss, and naturality guarantees the passage respects every morphism in sight.

A first structural consequence, stated here and proved in section 64.3, is that either functor determines the other up to isomorphism: if $F \dashv G$ and $F \dashv G'$ then $G \cong G'$, and dually for left adjoints. The reason is that Gd represents the functor $c \mapsto \mathrm{Hom}_D(Fc,d)$, and a representing object is unique up to unique isomorphism (corollary 62.4.1). An adjoint is thus not extra structure to be chosen but a property that F may or may not have, pinned down when it holds.

Example 64.1.2: The Free Monoid and Underlying Set

Let $U\colon \mathbf{Mon} \to \mathbf{Set}$ send a monoid to its underlying set and a homomorphism to its underlying function, and let $F\colon \mathbf{Set} \to \mathbf{Mon}$ send a set X to the free monoid FX of finite words in the alphabet X under concatenation, with the empty word as identity ([21]). A monoid homomorphism $FX \to M$ is determined by its values on the length-one words, which are the elements of X, and any assignment of those values extends uniquely to a homomorphism because a word is a product of letters. Restriction to length-one words and free extension are mutually inverse, so

$$\mathrm{Hom}_{\mathbf{Mon}}(FX,M) \;\cong\; \mathrm{Hom}_{\mathbf{Set}}(X,UM)$$

and the bijection is natural in X and M: precomposing a homomorphism with Ff for $f\colon Y \to X$ corresponds to precomposing the associated function with f, and postcomposing with a homomorphism $M \to N$ corresponds to postcomposing with its underlying function. Thus $F \dashv U$.

The two hom-sets in example 64.1.2 are compared across a change of category, and the bijection is exactly the statement that FX is free on X. Every "free object" theorem in algebra is an instance of this pattern, and the adjunction packages all of them at once. The transpose of the identity of FX under this bijection is the map $X \to UFX$ sending each element to its length-one word, the insertion of generators; the transpose of the identity of UM is a homomorphism $FUM \to M$ evaluating a word of elements of M to their product. These two distinguished maps are the general phenomenon isolated next.

Passing to hom-sets and back is often less convenient than working with two natural transformations, one in each category, from which the whole bijection can be reconstructed. Taking transposes of identity morphisms produces them.

Definition 64.1.3: Unit and Counit

Let $F \dashv G$ with natural isomorphism Φ as in definition 64.1.1. The *unit* of the adjunction is the natural transformation

$$\eta \colon \mathrm{id}_C \Rightarrow GF$$

whose component at c is $\eta_c = \Phi_{c,Fc}(\mathrm{id}_{Fc}) \colon c \to GFc$, the transpose of id_{Fc}. The *counit* is the natural transformation

$$\varepsilon \colon FG \Rightarrow \mathrm{id}_D$$

whose component at d is $\varepsilon_d = \Phi^{-1}_{Gd,d}(\mathrm{id}_{Gd}) \colon FGd \to d$, the transpose of id_{Gd}.

That η and ε are natural transformations follows from the naturality of Φ: naturality in c, applied to the identity, moves η_c along any morphism $c \to c'$ as a component of GF requires, and the counit argument is dual. The unit $\eta_c \colon c \to GFc$ is a universal arrow from c to G in the sense of definition 63.1.4, as the equivalence theorem below makes precise, and the counit $\varepsilon_d \colon FGd \to d$ is a universal arrow from F to d. In example 64.1.2 the unit is the insertion of generators $X \to UFX$ and the counit $FUM \to M$ multiplies out a word of monoid elements.

The unit and counit recover the full hom-set bijection. The transpose of a morphism is obtained by whiskering with the appropriate one and then applying the functor, as the next proposition records; the formulas are the computational core of everything that follows.

Proposition 64.1.4: Transposition via the Unit and Counit

Let $F \dashv G$ with unit η and counit ε as in definition 64.1.3. For every $f \colon Fc \to d$ in D and every $g \colon c \to Gd$ in C,

$$\Phi_{c,d}(f) = Gf \circ \eta_c \colon c \to Gd \tag{64.1}$$

and

$$\Phi^{-1}_{c,d}(g) = \varepsilon_d \circ Fg \colon Fc \to d \tag{64.2}$$

These two assignments are mutually inverse.

***Proof*:**

Step 1: The formula for Φ. Fix $f \colon Fc \to d$. Naturality of Φ in the D-variable, applied to $f \colon Fc \to d$ regarded as a morphism advancing the second argument, gives a commuting square

$$\begin{array}{ccc} \mathrm{Hom}_D(Fc, Fc) & \xrightarrow{\Phi_{c,Fc}} & \mathrm{Hom}_C(c, GFc) \\ {\scriptstyle f_*}\downarrow & & \downarrow{\scriptstyle (Gf)_*} \\ \mathrm{Hom}_D(Fc, d) & \xrightarrow[\Phi_{c,d}]{} & \mathrm{Hom}_C(c, Gd) \end{array}$$

where f_* is postcomposition with f and $(Gf)_*$ is postcomposition with Gf. Chasing id_{Fc} around the square: down then right gives $\Phi_{c,d}(f \circ \mathrm{id}_{Fc}) = \Phi_{c,d}(f)$, while right then down gives $Gf \circ \Phi_{c,Fc}(\mathrm{id}_{Fc}) = Gf \circ \eta_c$ by the definition of the unit. The two are equal, which is (64.1).

Step 2: The formula for Φ^{-1}. The dual computation uses naturality of Φ in the C-variable. Fix $g\colon c \to Gd$ and apply naturality to g advancing the first argument:

$$\begin{array}{ccc} \mathrm{Hom}_D(FGd, d) & \xrightarrow{\Phi_{Gd,d}} & \mathrm{Hom}_C(Gd, Gd) \\ {\scriptstyle (Fg)^*}\downarrow & & \downarrow{\scriptstyle g^*} \\ \mathrm{Hom}_D(Fc, d) & \xrightarrow[\Phi_{c,d}]{} & \mathrm{Hom}_C(c, Gd) \end{array}$$

where $(Fg)^*$ and g^* are precomposition with Fg and g. Chase $\varepsilon_d \in \mathrm{Hom}_D(FGd, d)$ around the square. Right then down gives $g^*\big(\Phi_{Gd,d}(\varepsilon_d)\big) = g^*(\mathrm{id}_{Gd}) = g$, since $\Phi_{Gd,d}(\varepsilon_d) = \mathrm{id}_{Gd}$ by definition 64.1.3. Down then right gives $\Phi_{c,d}\big(\varepsilon_d \circ Fg\big)$. Equating the two, $\Phi_{c,d}(\varepsilon_d \circ Fg) = g$, and applying $\Phi_{c,d}^{-1}$ yields $\Phi_{c,d}^{-1}(g) = \varepsilon_d \circ Fg$, which is (64.2).

Step 3: Mutual inverseness. Because $\Phi_{c,d}$ is a bijection with inverse $\Phi_{c,d}^{-1}$, the two assignments (64.1) and (64.2) are mutually inverse by construction. This can also be checked directly from the triangle identities established in theorem 64.1.5, and the two verifications agree, completing the proof.

Formulas (64.1) and (64.2) are how one computes with an adjunction in practice: to transpose a map out of Fc, apply G and precompose with the unit; to transpose back, apply F and postcompose with the counit. Since the two are inverse, feeding one into the other must return the original morphism, and unwinding what that requires of η and ε alone gives a characterization of adjunctions with no mention of hom-sets. That characterization is the equivalence theorem.

The theorem collects three descriptions of the same situation. The first is the hom-set isomorphism of definition 64.1.1. The second replaces it by the unit and counit subject to two equations, the *triangle identities*, which require only that transposing a map and transposing it back be the identity. The third is the object-by-object universal-arrow condition, tying the chapter back to definition 63.1.4. Their equivalence is what lets one build, recognize, and use adjunctions from whichever description is at hand.

Theorem 64.1.5: Equivalent Formulations of an Adjunction

Let $F\colon C \to D$ and $G\colon D \to C$ be functors. The following data are equivalent, each determining the others.

1. A natural isomorphism $\Phi\colon \mathrm{Hom}_D(F-,-) \cong \mathrm{Hom}_C(-,G-)$, that is, an adjunction $F \dashv G$.
2. Natural transformations $\eta\colon \mathrm{id}_C \Rightarrow GF$ and $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ satisfying the *triangle identities*
$$(G\varepsilon)(\eta G) = \mathrm{id}_G, \qquad (\varepsilon F)(F\eta) = \mathrm{id}_F \tag{64.3}$$
as natural transformations $G \Rightarrow G$ and $F \Rightarrow F$.
3. A natural transformation $\eta\colon \mathrm{id}_C \Rightarrow GF$ whose component $\eta_c\colon c \to GFc$ is a universal arrow from c to G for every object c of C (definition 63.1.4).

***Proof*:**

We prove (1) $\Rightarrow$ (2) $\Rightarrow$ (3) $\Rightarrow$ (1).

Step 1: From the hom-set isomorphism to the triangle identities. Assume (1), and define η and ε as in definition 64.1.3. They are natural transformations, as noted after that definition. The triangle identities are the componentwise statements

$$G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}, \qquad \varepsilon_{Fc} \circ F\eta_c = \mathrm{id}_{Fc} \tag{64.4}$$

for all c and d. For the first, apply (64.1) of proposition 64.1.4 to the morphism $\varepsilon_d\colon FGd \to d$ with source object Gd: its transpose is $\Phi_{Gd,d}(\varepsilon_d) = G\varepsilon_d \circ \eta_{Gd}$. But $\varepsilon_d = \Phi^{-1}_{Gd,d}(\mathrm{id}_{Gd})$ by definition 64.1.3, so $\Phi_{Gd,d}(\varepsilon_d) = \mathrm{id}_{Gd}$, giving $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$. For the second, apply (64.2) to $\eta_c\colon c \to GFc$ with target object Fc: its transpose is $\Phi^{-1}_{c,Fc}(\eta_c) = \varepsilon_{Fc} \circ F\eta_c$, and $\eta_c = \Phi_{c,Fc}(\mathrm{id}_{Fc})$, so this transpose is id_{Fc}. Thus (64.4) holds, which is (64.3).

Step 2: From the triangle identities to universal arrows. Assume (2). Fix an object c; we show $\eta_c\colon c \to GFc$ is a universal arrow from c to G. Given any object d of D and any morphism $g\colon c \to Gd$ in C, we must produce a unique $f\colon Fc \to d$ with $Gf \circ \eta_c = g$.

Existence. Set $f = \varepsilon_d \circ Fg\colon Fc \to d$. Then

$$Gf \circ \eta_c = G\varepsilon_d \circ GFg \circ \eta_c$$

Naturality of η applied to $g\colon c \to Gd$ gives $GFg \circ \eta_c = \eta_{Gd} \circ g$, so

$$Gf \circ \eta_c = G\varepsilon_d \circ \eta_{Gd} \circ g = (G\varepsilon_d \circ \eta_{Gd}) \circ g = \mathrm{id}_{Gd} \circ g = g$$

using the first triangle identity in (64.4). This f solves the factorization problem.

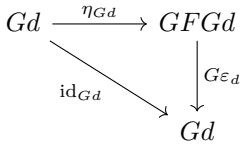
Uniqueness. Suppose $f'\colon Fc \to d$ also satisfies $Gf' \circ \eta_c = g$. Then

$$\varepsilon_d \circ F(Gf' \circ \eta_c) = \varepsilon_d \circ Fg$$

The left side equals $\varepsilon_d \circ FGf' \circ F\eta_c$. Naturality of ε applied to $f'\colon Fc \to d$ gives $\varepsilon_d \circ FGf' = f' \circ \varepsilon_{Fc}$, so the left side is $f' \circ \varepsilon_{Fc} \circ F\eta_c = f' \circ \mathrm{id}_{Fc} = f'$ by the second triangle identity. The right side is our chosen f. Hence $f' = f$, and the universal arrow is unique. Since c was arbitrary, η_c is universal for every c, which is (3).

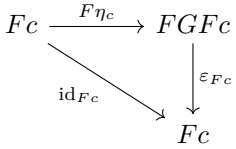
Step 3: From universal arrows to the hom-set isomorphism. Assume (3): $\eta\colon \mathrm{id}_C \Rightarrow GF$ is a natural transformation whose every component $\eta_c\colon c \to GFc$ is a universal arrow from c to G. Fix c and d and define

$$\Phi_{c,d}\colon \mathrm{Hom}_D(Fc, d) \to \mathrm{Hom}_C(c, Gd), \qquad \Phi_{c,d}(f) = Gf \circ \eta_c$$



The universal property of η_c says exactly that for each $g\colon c \to Gd$ there is a unique $f\colon Fc \to d$ with $Gf \circ \eta_c = g$, that is, $\Phi_{c,d}$ is a bijection. It remains to check naturality in c and d. For $v\colon d \to d'$, both $\Phi_{c,d'}(v \circ f)$ and $Gv \circ \Phi_{c,d}(f)$ equal $Gv \circ Gf \circ \eta_c$, since G is a functor; this is naturality in d. For $u\colon c' \to c$, naturality of η gives $GFu \circ \eta_{c'} = \eta_c \circ u$, whence

$$\Phi_{c',d}(f \circ Fu) = G(f \circ Fu) \circ \eta_{c'} = Gf \circ GFu \circ \eta_{c'} = Gf \circ \eta_c \circ u = \Phi_{c,d}(f) \circ u$$



which is naturality in c. Thus Φ is a natural isomorphism and $F \dashv G$, returning to (1) and closing the cycle, completing the proof.

The theorem is the working definition of an adjunction: one verifies whichever of the three is easiest and gains the other two. Presentation (1) is the cleanest to state and the one that makes symmetry between F and G visible. Presentation (2) is the most convenient in proofs, since the triangle identities are two equations to check rather than a family of bijections, and it survives into contexts where hom-sets are not available. Presentation (3) is the bridge from the last chapter: an adjunction is precisely a functorial choice of universal arrow, one at each object, so the free monoid, abelianization, and the initial ring of section 63.1 were adjunctions seen one object at a time. There is a symmetric fourth form, dual to (3), asking that each counit component $\varepsilon_d\colon FGd \to d$ be a universal arrow from F to d; it follows by applying the theorem in the opposite categories, since $F \dashv G$ in C, D is $G^{\mathrm{op}} \dashv F^{\mathrm{op}}$ in $D^{\mathrm{op}}, C^{\mathrm{op}}$ (box 61.3.3).

The name "triangle identity" comes from the diagrams the equations in (64.4) assert commute. The first says the outer path in

is the identity, and the second says the same of

Read aloud, they say that inserting generators into Gd and then evaluating, or building the free object on Fc and then collapsing it, returns where one started. In example 64.1.2 the first identity says: take a set of generators inside a monoid M (the map η_{UM}), form the free monoid on them, multiply each word out (ε_M), and the underlying-set effect is the identity on UM. The equations look slight, but by theorem 64.1.5 they carry the entire adjunction.

64.2 Examples of Adjunctions

The definition and its three forms are in place; the work of this section is to show how much of the mathematics already met is an adjunction in disguise. Four families cover most of the recurring instances: free constructions adjoint to forgetful functors, tensoring adjoint to hom, colimits and limits adjoint to the diagonal, and Galois connections between posets. Each is presented as a hom-set bijection $\mathrm{Hom}_D(Fc, d) \cong \mathrm{Hom}_C(c, Gd)$ (definition 64.1.1), natural in both variables, with the naturality left to the one-line check it always reduces to. The through-line stated at the definition returns here in its standard form: left adjoints are free constructions.

The first family is the one the definition was built to capture. A forgetful functor discards structure; its left adjoint builds the freest structure on the bare data it was handed. The universal property of a free construction is exactly a hom-set bijection, so each free-forgetful pair is an adjunction with no extra argument to make.

Example 64.2.1: Free and Forgetful Adjunctions
Across the standing cast, each free construction is left adjoint to the forgetful functor it inverts.

1. *Free group $\dashv$ forgetful.* Let $U\colon \mathbf{Grp} \to \mathbf{Set}$ be the forgetful functor (example 61.4.2) and $F\colon \mathbf{Set} \to \mathbf{Grp}$ the free-group functor. The universal property of the free group FX says that a set function $X \to UG$ extends uniquely to a homomorphism $FX \to G$, and every homomorphism $FX \to G$ restricts to such a function on generators ([21, Universal Property Of Free Groups]). These two operations are mutually inverse, giving a bijection

$$\mathrm{Hom}_{\mathbf{Grp}}(FX, G) \cong \mathrm{Hom}_{\mathbf{Set}}(X, UG)$$

   so $F \dashv U$. Naturality in X and in G is the statement that restriction to generators commutes with precomposing a function on the left and postcomposing a homomorphism on the right, which holds because both sides are "evaluate on generators, then extend."

2. *Free R-module $\dashv$ forgetful.* For a ring R, let $U\colon \mathbf{Mod}_R \to \mathbf{Set}$ forget the module structure and F send a set X to the free module $R^{(X)}$ on X. The universal property of the free module ([21, Universal Property of Free Modules]) gives, for every module M,

$$\mathrm{Hom}_{\mathbf{Mod}_R}(R^{(X)}, M) \cong \mathrm{Hom}_{\mathbf{Set}}(X, UM)$$

   a function $X \to UM$ extending uniquely to an R-linear map on the basis X, so $F \dashv U$. The same check applies with $\mathbf{Vect}_k$ in place of $\mathbf{Mod}_R$: every vector space is free, so the left adjoint here sends a set to the space with that basis.

3. *Abelianization $\dashv$ inclusion.* Let $\iota\colon \mathbf{Ab} \to \mathbf{Grp}$ be the inclusion of abelian groups among all groups and $\mathrm{ab}\colon \mathbf{Grp} \to \mathbf{Ab}$ send G to its abelianization $G^{\mathrm{ab}} = G/[G, G]$. A homomorphism from G to an abelian group A kills every commutator, hence factors uniquely through the quotient $G \to G^{\mathrm{ab}}$ ([21, Commutator Subgroup Properties]), which is the bijection

$$\mathrm{Hom}_{\mathbf{Ab}}(G^{\mathrm{ab}}, A) \cong \mathrm{Hom}_{\mathbf{Grp}}(G, \iota A)$$

   so $\mathrm{ab} \dashv \iota$. Here the "structure" the right adjoint remembers is commutativity, and the left adjoint imposes it as freely as possible, by quotienting out only what commutativity forces.

4. *Discrete ⊣ forgetful ⊣ indiscrete.* Let $U\colon \mathbf{Top} \to \mathbf{Set}$ forget the topology. It has adjoints on both sides. The *discrete* functor $\mathrm{disc}\colon \mathbf{Set} \to \mathbf{Top}$ equips a set with its discrete topology, in which every subset is open; the *indiscrete* functor indisc equips it with the indiscrete topology, whose only opens are $\varnothing$ and the whole set. Every function out of a discrete space is continuous and every function into an indiscrete space is continuous, so

$$\mathrm{Hom}_{\mathbf{Top}}(\mathrm{disc}\, X, Y) \cong \mathrm{Hom}_{\mathbf{Set}}(X, UY), \qquad \mathrm{Hom}_{\mathbf{Set}}(UY, X) \cong \mathrm{Hom}_{\mathbf{Top}}(Y, \mathrm{indisc}\, X)$$

The first bijection makes $\mathrm{disc} \dashv U$; the second makes $U \dashv \mathrm{indisc}$. Thus U is at once a right adjoint and a left adjoint, so it preserves both limits and colimits, a fact the next section will read off directly.

The first three items instantiate one pattern: the forgetful functor is a right adjoint and its left adjoint is the free construction, which is why free objects are recovered by the recipe "the value of the left adjoint on a set." The last item is different. A forgetful functor need not sit on only one side of an adjunction; when the structure being forgotten can be added in a freest and a cofreest way, it acquires adjoints on both. The point to carry forward is that a left adjoint is a free construction and a right adjoint is a forgetful or cofree one, with the hom-set bijection the precise content of "free."

The second family trades one bifunctor for two others. Fixing one input of a product and asking to map out of it is the same as mapping into a function object; this is currying, and in its module form it is the tensor-hom adjunction that pervades homological algebra. The prototype is in **Set**, where the function object is a plain set of functions.

Example 64.2.2: The Tensor-Hom Adjunction

Fix a set B. Currying converts a function of two variables into a function valued in functions: a map $A \times B \to C$ is the same as a map $A \to C^B$ sending a to the function $b \mapsto f(a, b)$, where $C^B = \mathrm{Hom}_{\mathbf{Set}}(B, C)$ is the set of functions $B \to C$. This assignment is a bijection, natural in A and C,

$$\mathrm{Hom}_{\mathbf{Set}}(A \times B, C) \cong \mathrm{Hom}_{\mathbf{Set}}(A, C^B)$$

so the functor $(-) \times B$ is left adjoint to $(-)^B = \mathrm{Hom}_{\mathbf{Set}}(B, -)$. This is the *cartesian closure* of **Set**: each product functor has the corresponding function-object functor as a right adjoint.

The module version replaces the product by the tensor product. Let R be a commutative ring and fix an R-module B. The defining property of the tensor product ([21, Universal Property Of Tensor Product (Over Commutative Rings)]) is that R-bilinear maps $A \times B \to C$ correspond to R-linear maps $A \otimes_R B \to C$; currying the second variable identifies a bilinear map with an R-linear map $A \to \mathrm{Hom}_R(B, C)$, giving the bijection

$$\mathrm{Hom}_R(A \otimes_R B, C) \cong \mathrm{Hom}_R(A, \mathrm{Hom}_R(B, C))$$

natural in A and C. Thus $(-) \otimes_R B$ is left adjoint to $\mathrm{Hom}_R(B, -)$.

The tensor-hom adjunction is why tensoring and hom behave as complementary halves of the same structure: the left adjoint $(-) \otimes_R B$ and the right adjoint $\mathrm{Hom}_R(B, -)$ are tied by a natural bijection, and the preservation theorem of the next section will explain from this alone why tensoring is right exact and hom left exact. The **Set** prototype is the same phenomenon with $\times$ for $\otimes$ and the bare function set for the internal hom; a category carrying such an adjunction for each fixed object is called closed, a notion the monoidal chapter returns to.

The third family exhibits limits and colimits themselves as adjoints. A single diagram-valued functor, the diagonal, has the limit on one side and the colimit on the other, so the two constructions of the previous chapter are the two adjoints of one functor.

Recall the diagonal functor $\Delta\colon \mathbf{C} \to [J, \mathbf{C}]$ sending an object X to the constant diagram at X, the diagram taking every object of J to X and every morphism to 1_X (section 63.2). A natural transformation $\Delta X \Rightarrow D$ is exactly a cone over D with apex X, and a natural transformation $D \Rightarrow \Delta X$ is exactly a cocone under D with nadir X. This identification turns the universal properties of the limit and the colimit into hom-set bijections.

Example 64.2.3: Limits and Colimits as Adjoints to the Diagonal
Let J be a small category and suppose $\mathbf{C}$ has all limits and all colimits of shape J, so that $\lim\colon [J, \mathbf{C}] \to \mathbf{C}$ and $\operatorname{colim}\colon [J, \mathbf{C}] \to \mathbf{C}$ are defined. Then

$$\operatorname{colim} \dashv \Delta \dashv \lim$$

the colimit is left adjoint to the diagonal and the limit is right adjoint to it.

The two adjunctions are dual, and each is immediate once the naturality bijection is unwound. Only the $\Delta \dashv \lim$ side is proved; the $\operatorname{colim} \dashv \Delta$ side is the same argument in $\mathbf{C}^{\mathrm{op}}$ by the duality principle (box 61.3.3), since a colimit in $\mathbf{C}$ is a limit in $\mathbf{C}^{\mathrm{op}}$ (proposition 63.3.2) and Δ is self-opposite.

***Proof*:**
Fix an object X of $\mathbf{C}$ and a diagram D in $[J, \mathbf{C}]$. A morphism in the functor category $\mathrm{Hom}_{[J,\mathbf{C}]}(\Delta X, D)$ is a natural transformation $\alpha\colon \Delta X \Rightarrow D$ (definition 61.5.4): a family of components $\alpha_j\colon X \to Dj$, one for each object j of J, such that for every morphism $u\colon j \to j'$ of J the naturality square commutes. Since ΔX sends u to 1_X, that square reads $Du \circ \alpha_j = \alpha_{j'} \circ 1_X = \alpha_{j'}$, which is exactly the cone condition (definition 63.2.1). A natural transformation $\Delta X \Rightarrow D$ is therefore the same data as a cone over D with apex X.

By the universal property of the limit, a cone over D with apex X corresponds to a unique morphism $X \to \lim D$ commuting with the projections, and every morphism $X \to \lim D$ arises this way by composing with the limit cone. This correspondence is a bijection

$$\mathrm{Hom}_{\mathbf{C}}(X, \lim D) \cong \mathrm{Hom}_{[J,\mathbf{C}]}(\Delta X, D)$$

It is natural in X: precomposing a morphism $X' \to X$ transports a cone with apex X to one with apex X' by the same precomposition on each component, and the induced map to $\lim D$ transforms accordingly. It is natural in D: a morphism of diagrams $D \Rightarrow D'$ postcomposes each cone component and the induced maps to the limits commute by the universal property. The bijection, natural in both variables, is the defining data of an adjunction (definition 64.1.1), so $\Delta \dashv \lim$. The dual identity $\operatorname{colim} \dashv \Delta$ follows by applying this to $\mathbf{C}^{\mathrm{op}}$, completing the proof.

This recovers the limits and colimits of the previous chapter as the two adjoints of a single functor, and it explains a fact used repeatedly downstream: the limit functor is a right adjoint, so it preserves limits. The general preservation theorem is deferred to the next section, but the shape of the consequence can already be stated, that a limit of limits may be computed in either order because the outer limit is a right adjoint. Dually the colimit functor is a left adjoint and preserves colimits. The diagonal, sitting between its two adjoints, is the categorical device that makes "take the limit" and "take the colimit" into functors with formal properties rather than case-by-case constructions.

The last family lives one dimension down, where the categories are posets and a functor is a monotone map. An adjunction between two posets is a pair of monotone maps tied by the single inequality that a hom-set, being either empty or a point, can express.

A poset $(P, \leq)$ is a category with one morphism $p \to q$ when $p \leq q$ and none otherwise (example 61.4.2 treats such thin categories). A functor between posets is a monotone map, and a hom-set $P(p, q)$ has at most one element, present exactly when $p \leq q$. The hom-set bijection defining an adjunction therefore collapses to a biconditional between inequalities.

Definition 64.2.4: Galois Connection

Let P and Q be posets, viewed as categories. A *(monotone) Galois connection* between P and Q is an adjunction $f \dashv g$ between them: a pair of monotone maps $f\colon P \to Q$ and $g\colon Q \to P$ such that for all $p \in P$ and $q \in Q$,

$$f(p) \leq q \quad \Longleftrightarrow \quad p \leq g(q)$$

The map f is the *left adjoint* (or lower adjoint) and g the *right adjoint* (or upper adjoint).

The biconditional is the poset case of the natural bijection $\mathrm{Hom}_Q(fp, q) \cong \mathrm{Hom}_P(p, gq)$: each hom-set is either empty or a single point, so the bijection between them is precisely the equivalence of the two inequalities, and naturality is automatic because there is nothing to compare beyond presence or absence of a morphism. A Galois connection is an adjunction with the analytic content stripped away, leaving the order-theoretic skeleton visible.

A single monotone connection already produces a closure operator, and the classical Galois correspondence is the archetype once one factor is passed to its opposite.

Example 64.2.5: The Galois Correspondence

Let L/k be a finite Galois extension with Galois group $G = \mathrm{Gal}(L/k)$. Write $\mathcal{S}$ for the poset of subgroups of G ordered by inclusion and $\mathcal{F}$ for the poset of intermediate fields $k \subseteq E \subseteq L$ ordered by inclusion. The two maps

$$\mathrm{Fix}\colon \mathcal{S} \to \mathcal{F}, \quad H \mapsto L^H, \qquad \mathrm{Gal}\colon \mathcal{F} \to \mathcal{S}, \quad E \mapsto \mathrm{Gal}(L/E)$$

each reverse inclusions: a larger subgroup fixes a smaller field, and a larger field is fixed by a smaller subgroup ([21, Galois Correspondence]). They satisfy

$$H \subseteq \mathrm{Gal}(L/E) \quad \Longleftrightarrow \quad E \subseteq L^H$$

both sides asserting that every element of H fixes every element of E. Because each map reverses order, the pair is an *antitone* Galois connection, which is a monotone one after replacing $\mathcal{F}$ by its opposite $\mathcal{F}^{\mathrm{op}}$: then $\mathrm{Fix}\colon \mathcal{S} \to \mathcal{F}^{\mathrm{op}}$ and $\mathrm{Gal}\colon \mathcal{F}^{\mathrm{op}} \to \mathcal{S}$ are monotone and the biconditional above is definition 64.2.4. The fundamental theorem of Galois theory ([21, Fundamental Theorem of Galois Theory I]) states that here both composites are the identity, so the connection is an order-reversing bijection between subgroups and intermediate fields.

The example carries two lessons about Galois connections in general. First, an antitone connection is an adjunction only after an opposite category is introduced; the raw pair of order-reversing maps becomes a genuine $f \dashv g$ once one side is flipped, which is the categorical account of why order-reversing correspondences are as natural as order-preserving ones. Second, even when the composites

are not the identity, a Galois connection $f \dashv g$ always yields a *closure operator* $gf\colon P \to P$: it is monotone, satisfies $p \leq gf(p)$, and is idempotent, $gfgf = gf$. The Galois correspondence is the degenerate case where the closure is trivial because gf is the identity; in a general connection the closure operator gf records the "saturation" a subset acquires, exactly as the double annihilator $(-)^{\perp\perp}$ closes a subspace W to $W^{\perp\perp}$. Every adjunction produces such a monad on the domain of its left adjoint, of which the closure operator is the poset instance, a thread the chapter on monads develops.

64.3 Units, Counits, and Preservation

The three formulations of an adjunction are on the table (theorem 64.1.5), and the examples of the previous section show how often one is in play. This section pays off the unit/counit formulation. The unit and counit are tied together by two equations, the triangle identities, and those equations are exactly the data that lets one reconstruct the hom-set bijection. Once the identities are in hand, two structural facts follow with almost no work: an adjoint, when it exists, is determined up to a unique natural isomorphism, and a right adjoint carries every limit that exists to a limit. The second of these, right adjoints preserve limits, explains at one stroke why so many limits in algebra and topology are computed on underlying sets.

Throughout, $F \dashv G$ is an adjunction with $F\colon \mathbf{C} \to \mathbf{D}$ and $G\colon \mathbf{D} \to \mathbf{C}$, unit $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow GF$ and counit $\varepsilon\colon FG \Rightarrow \mathrm{id}_{\mathbf{D}}$, in the notation of definition 64.1.3.

Proposition 64.1.4 computes the hom-set bijection from the unit and counit: the transpose of $g\colon Fc \to d$ is $Gg \circ \eta_c$, and the transpose of $f\colon c \to Gd$ is $\varepsilon_d \circ Ff$. By theorem 64.1.5, the unit and counit of an adjunction satisfy the triangle identities (64.3), which say that the two whiskered composites

$$G \xRightarrow{\eta G} GFG \xRightarrow{G\varepsilon} G, \qquad F \xRightarrow{F\eta} FGF \xRightarrow{\varepsilon F} F$$

are the identity natural transformations of G and of F. Conversely, natural transformations $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow GF$ and $\varepsilon\colon FG \Rightarrow \mathrm{id}_{\mathbf{D}}$ satisfying the triangle identities present an adjunction $F \dashv G$, through the bijection $g \mapsto Gg \circ \eta_c$.

The two equations (64.3) are named for the shape of the diagrams that express them. Reading the whiskered composites ηG, $G\varepsilon$ and $F\eta$, εF as edges, each identity says that a triangle commutes:

$$\begin{array}{ccc} G & \xRightarrow{\eta G} & GFG \\ & {\scriptstyle \mathrm{id}_G} \searrow & \Big\Downarrow {\scriptstyle G\varepsilon} \\ & & G \end{array} \qquad\qquad \begin{array}{ccc} F & \xRightarrow{F\eta} & FGF \\ & {\scriptstyle \mathrm{id}_F} \searrow & \Big\Downarrow {\scriptstyle \varepsilon F} \\ & & F \end{array}$$

Componentwise at objects $d \in \mathbf{D}$ and $c \in \mathbf{C}$, these read $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$ and $\varepsilon_{Fc} \circ F\eta_c = \mathrm{id}_{Fc}$.

The identities encode a single fact about the two transpose operations: they are inverse. Everything about how F and G interact through the adjunction, including the naturality of the correspondence, is compressed into these two equations. This makes the unit/counit formulation the computational one, since checking an adjunction reduces to producing η, ε and verifying two triangle equations, with no bijection to construct by hand.

Example 64.3.1: The Free Group Triangle Identities

Let $F\colon \mathbf{Set} \to \mathbf{Grp}$ be the free-group functor and $U\colon \mathbf{Grp} \to \mathbf{Set}$ the forgetful functor, $F \dashv U$ (example 64.1.2). The unit $\eta_S\colon S \to UFS$ includes a set S as the generators of the free group FS. The counit $\varepsilon_G\colon FUG \to G$ is the homomorphism from the free group on the underlying set of G that sends each generator g to the element $g \in G$; it evaluates a formal word in the elements of G as an actual product in G.

The first identity $(U\varepsilon)(\eta U) = \mathrm{id}_U$ reads, at a group G, as follows. Start with an element $g \in UG$. The unit η_{UG} views g as a generator of the free group FUG, that is, as the length-one word g. Then $U\varepsilon_G$ evaluates that word in G, returning the element g. The composite is the identity on UG, as the identity requires.

The second identity $(\varepsilon F)(F\eta) = \mathrm{id}_F$ reads, at a set S, as follows. A reduced word $w = s_1^{\pm 1} \cdots s_n^{\pm 1}$ in FS is sent by $F\eta_S$ to the same formal word, now regarded as living in $FUFS$ (each generator s_i first viewed as a generator of FS, then as an element of UFS, then as a generator of $FUFS$). Applying ε_{FS} evaluates that word back in FS, recovering w. The composite is the identity on FS. The two identities are the two ways "generator" and "evaluate" cancel.

An adjunction determines its right adjoint completely: if a functor has a left adjoint at all, the resulting right adjoint is fixed up to a unique natural isomorphism. This is what justifies the article "the" in "the right adjoint". The proof is a direct application of the Yoneda embedding (definition 62.3.1): a functor value Gd is pinned down by the functor it represents, $\mathrm{Hom}_{\mathbf{C}}(-, Gd)$, and the adjunction identifies that representable with one built from F alone.

Proposition 64.3.2: Uniqueness of Adjoints

Let $F\colon \mathbf{C} \to \mathbf{D}$. If $F \dashv G$ and $F \dashv G'$, then there is a unique natural isomorphism $\theta\colon G \Rightarrow G'$ compatible with the adjunctions, in the sense that it identifies the two transpose bijections. Dually, if $G \dashv F$ and $G' \dashv F$, the two left adjoints G, G' are isomorphic by a unique such natural isomorphism.

***Proof*:**

Fix $d \in \mathbf{D}$. The two adjunctions give, for every $c \in \mathbf{C}$, bijections

$$\mathrm{Hom}_{\mathbf{C}}(c, Gd) \cong \mathrm{Hom}_{\mathbf{D}}(Fc, d) \cong \mathrm{Hom}_{\mathbf{C}}(c, G'd)$$

natural in c, the first from $F \dashv G$ and the second from $F \dashv G'$. Their composite is a natural isomorphism

$$\mathrm{Hom}_{\mathbf{C}}(-, Gd) \cong \mathrm{Hom}_{\mathbf{C}}(-, G'd)$$

of functors $\mathbf{C}^{\mathrm{op}} \to \mathbf{Set}$. The Yoneda embedding $\mathbf{y}\colon \mathbf{C} \to \mathbf{PSh}(\mathbf{C})$ is fully faithful (definition 62.3.1), so this isomorphism of representables is $\mathbf{y}(\theta_d)$ for a unique isomorphism $\theta_d\colon Gd \to G'd$ in $\mathbf{C}$.

It remains to see that the θ_d assemble into a natural transformation $\theta\colon G \Rightarrow G'$. Let $k\colon d \to d'$ in $\mathbf{D}$. Both composite bijections are natural in d as well as in c, since the transpose correspondences

are natural in both variables (definition 64.1.1); consequently the square of representables

$$\begin{array}{ccc} \mathrm{Hom}_{\mathbf{C}}(-, Gd) & \xrightarrow{\cong} & \mathrm{Hom}_{\mathbf{C}}(-, G'd) \\ {\scriptstyle \mathrm{Hom}(-,Gk)}\downarrow & & \downarrow{\scriptstyle \mathrm{Hom}(-,G'k)} \\ \mathrm{Hom}_{\mathbf{C}}(-, Gd') & \xrightarrow{\cong} & \mathrm{Hom}_{\mathbf{C}}(-, G'd') \end{array}$$

commutes. Applying full faithfulness of $\mathbf{y}$ to this commuting square of representables yields $\theta_{d'} \circ Gk = G'k \circ \theta_d$, which is naturality of θ. Uniqueness of each θ_d, hence of θ, is the injectivity of $\mathbf{y}$ on morphisms. The compatibility with the transpose bijections holds by construction, since θ was read off from them.

For the dual statement, if $G \dashv F$ and $G' \dashv F$, then for every c the bijections $\mathrm{Hom}_{\mathbf{D}}(Gc, -) \cong \mathrm{Hom}_{\mathbf{C}}(c, F-) \cong \mathrm{Hom}_{\mathbf{D}}(G'c, -)$ are natural, so the covariant representables $\mathrm{Hom}_{\mathbf{D}}(Gc, -)$ and $\mathrm{Hom}_{\mathbf{D}}(G'c, -)$ are isomorphic; the covariant Yoneda embedding (definition 62.3.1, applied in $\mathbf{D}^{\mathrm{op}}$) delivers a unique natural isomorphism $Gc \cong G'c$ by the same argument, as we sought to show.

Two constructions each solving the same universal problem cannot differ in any observable way, and the isomorphism between them is forced rather than chosen. This is the categorical form of a phenomenon seen repeatedly in chapter 64: the free group on a set, the tensor product of two modules, the coproduct of a family of objects are each unique up to unique isomorphism, and here the reason is uniform, since all three are adjoint (or universal) constructions and Yoneda pins down what an adjoint represents. From now on we speak of *the* left adjoint and *the* right adjoint of a functor, when one exists.

The structural payoff of the section is that right adjoints preserve limits. The mechanism is the same Yoneda argument, now run against a diagram: a right adjoint commutes with a limit because its defining bijection turns the limit-detecting property of Gd into the limit-detecting property inherited through F from representables, which already preserve limits (proposition 63.4.7). The abbreviation RAPL, "right adjoints preserve limits", is standard.

Recall from definition 63.4.6 what preservation means: a functor $G\colon \mathbf{D} \to \mathbf{C}$ *preserves* the limit of $D\colon \mathbf{J} \to \mathbf{D}$ if, whenever $\lim D$ exists with limit cone $(\lambda_j\colon \lim D \to Dj)_j$, the image cone $(G\lambda_j\colon G(\lim D) \to G(Dj))_j$ is a limit cone for $G \circ D$, so that $G(\lim D) \cong \lim(G \circ D)$ canonically.

Theorem 64.3.3: Right Adjoints Preserve Limits

Let $F \dashv G$ with $G\colon \mathbf{D} \to \mathbf{C}$, and let $D\colon \mathbf{J} \to \mathbf{D}$ be a diagram whose limit $\lim D$ exists in $\mathbf{D}$. Then G preserves this limit: the canonical comparison morphism $G(\lim D) \to \lim(G \circ D)$ is an isomorphism, so

$$G(\lim D) \cong \lim_{j \in \mathbf{J}} G(Dj)$$

Dually, a left adjoint preserves all colimits that exist in its domain.

***Proof*:**
Write $L = \lim D$ in $\mathbf{D}$. The claim is that GL, with the cone $(G\lambda_j)_j$, is a limit of $G \circ D$ in $\mathbf{C}$. By the universal property of a limit (definition 63.2.1) this is equivalent to the statement that

for every $c \in \mathbf{C}$ the map

$$\mathrm{Hom}_{\mathbf{C}}(c, GL) \to \lim_j \mathrm{Hom}_{\mathbf{C}}(c, G(Dj)), \qquad f \mapsto (G\lambda_j \circ f)_j$$

is a bijection, where the limit on the right is the limit in **Set** of the diagram $j \mapsto \mathrm{Hom}_{\mathbf{C}}(c, G(Dj))$, that is, the set of cones over $G \circ D$ with apex c. Fix c and compute this hom-set through a chain of bijections, each natural in c.

Step 1: Cross the adjunction. The adjunction $F \dashv G$ gives

$$\mathrm{Hom}_{\mathbf{C}}(c, GL) \cong \mathrm{Hom}_{\mathbf{D}}(Fc, L)$$

natural in c (definition 64.1.1).

Step 2: Use that representables preserve limits. Since $L = \lim D$ in $\mathbf{D}$, the representable $\mathrm{Hom}_{\mathbf{D}}(Fc, -)$ preserves it (proposition 63.4.7):

$$\mathrm{Hom}_{\mathbf{D}}(Fc, L) \cong \lim_j \mathrm{Hom}_{\mathbf{D}}(Fc, Dj)$$

This is the step where the hypothesis that $\lim D$ exists is used: the limit-preservation of G is pulled back from the limit-preservation of a representable.

Step 3: Cross the adjunction back, inside the limit. Applying $F \dashv G$ objectwise in j, and using that these bijections are natural in j so they assemble into an isomorphism of the diagrams whose limits are being taken,

$$\lim_j \mathrm{Hom}_{\mathbf{D}}(Fc, Dj) \cong \lim_j \mathrm{Hom}_{\mathbf{C}}(c, G(Dj))$$

Step 4: Reassemble. Composing the three bijections gives an isomorphism

$$\mathrm{Hom}_{\mathbf{C}}(c, GL) \cong \lim_j \mathrm{Hom}_{\mathbf{C}}(c, G(Dj))$$

natural in c. Tracing an element through the chain shows the composite is $f \mapsto (G\lambda_j \circ f)_j$, the comparison map above. By the Yoneda embedding (definition 62.3.1) a natural isomorphism of the representables $\mathrm{Hom}_{\mathbf{C}}(-, GL)$ and $\mathrm{Hom}_{\mathbf{C}}(-, \lim(G \circ D))$ comes from a unique isomorphism $GL \cong \lim(G \circ D)$, and by naturality this isomorphism is the comparison morphism. Hence G preserves the limit.

The dual statement follows from the duality principle (box 61.3.3): a left adjoint $F \colon \mathbf{C} \to \mathbf{D}$ is $F \dashv G$, so $F^{\mathrm{op}} \colon \mathbf{C}^{\mathrm{op}} \to \mathbf{D}^{\mathrm{op}}$ is a right adjoint (its left adjoint is G^{op}, as one checks by dualizing the hom-set bijection), and a colimit in $\mathbf{C}$ is a limit in $\mathbf{C}^{\mathrm{op}}$. The result just proved, applied to F^{op}, says F^{op} preserves limits in $\mathbf{C}^{\mathrm{op}}$, which is exactly the statement that F preserves colimits in $\mathbf{C}$, completing the proof.

RAPL is a source of both computations and obstructions. On the computational side it says a right adjoint may be evaluated on a limit by evaluating it factorwise: G commutes with products, pullbacks, equalizers, and all other limits. On the obstruction side it gives a fast way to prove a functor is *not* a right adjoint, by exhibiting one limit it fails to preserve. The tensor product $M \otimes_R -$ does not preserve limits (it fails to preserve infinite products in general), so it cannot be a right adjoint; and indeed it is a left adjoint, adjoint to $\mathrm{Hom}_R(M, -)$, and preserves colimits instead (example 64.2.2). A functor that preserves neither all limits nor all colimits can be neither a left nor a right adjoint,

which is one reason adjointness is a strong condition.

The corollary the reader has already met is that a forgetful functor which happens to be a right adjoint computes limits on underlying sets.

Corollary 64.3.4: Limits on Underlying Sets

Let $U\colon \mathbf{D} \to \mathbf{Set}$ be a forgetful functor that has a left adjoint (a free functor $F \dashv U$). Then U preserves all limits that exist in $\mathbf{D}$: the underlying set of a limit in $\mathbf{D}$ is the corresponding limit of underlying sets, with its structure determined by that of the diagram.

***Proof*:**
Immediate from theorem 64.3.3 applied to $F \dashv U$, since U is the right adjoint, as required.

This recovers, and now explains, the pattern computed directly when limits were introduced (definition 63.2.1): the underlying set of a product of groups is the product of the underlying sets with coordinatewise multiplication, the underlying set of an equalizer is the equalizer of underlying sets, and the limit of a diagram of modules is computed on underlying sets. Each forgetful functor in question, from **Grp**, **Ab**, **Ring**, $\mathbf{Mod}_R$, or **Top** to **Set**, is a right adjoint (example 64.2.1), so RAPL forces its compatibility with limits, in the sense of preservation from definition 63.4.6.

Example 64.3.5: Products and Kernels of Abelian Groups
The forgetful functor $U\colon \mathbf{Ab} \to \mathbf{Set}$ has the free-abelian-group functor as left adjoint, so U preserves limits. Two instances show this.

A product $\prod_i A_i$ in **Ab** has underlying set $\prod_i UA_i$, the cartesian product of the underlying sets, because U preserves the product. The group structure is coordinatewise, which is precisely the structure the limit universal property forces once the underlying set is fixed as the product.

An equalizer of two homomorphisms $f, g\colon A \to B$ is the subgroup $\{a \in A \big| f(a) = g(a)\}$; its underlying set is $\{x \in UA \big| Uf(x) = Ug(x)\}$, the equalizer of Uf, Ug in **Set**, again because U preserves the equalizer. Taking $g = 0$ specializes this to the kernel, whose underlying set is $\{a \in UA \big| Uf(a) = 0\}$. Both computations are consequences of RAPL, not separate verifications.

64.4 Adjoint Functor Theorems

The RAPL theorem (theorem 64.3.3) makes limit-preservation a necessary condition for a functor $G\colon \mathbf{D} \to \mathbf{C}$ to be a right adjoint. The adjoint functor theorems address the converse: when a limit-preserving G is guaranteed to have a left adjoint. Preservation of limits alone is not enough, because a proper class of candidate arrows can obstruct the construction. The extra ingredient is a smallness hypothesis. The General Adjoint Functor Theorem asks for a set of arrows that jointly dominates every arrow out of a fixed object, the solution-set condition; the Special Adjoint Functor Theorem replaces that condition with a global structural hypothesis on $\mathbf{C}$. We prove the general theorem in full and record the special one with its key ideas.

The whole chapter turns on one reformulation, established in section 64.1: a left adjoint to G is the same data as a universal arrow $\eta_c\colon c \to Gd_c$ from each object c of $\mathbf{C}$ to G. A universal arrow from c to G (definition 63.1.4) is exactly an initial object of the comma category (c/G), whose objects

are pairs (d, f) with $f\colon c \to Gd$ and whose morphisms $(d, f) \to (d', f')$ are arrows $h\colon d \to d'$ in $\mathbf{D}$ with $Gh \circ f = f'$. Constructing a left adjoint therefore reduces to producing an initial object in each (c/G). The solution-set condition is precisely the smallness input that lets a completeness argument produce one.

Definition 64.4.1: Solution-Set Condition

Let $G\colon \mathbf{D} \to \mathbf{C}$ be a functor and c an object of $\mathbf{C}$. Then G satisfies the *solution-set condition* at c if there is a *set* of morphisms

$$\{\, f_i\colon c \to Gd_i \,\}_{i \in I}$$

such that every morphism $f\colon c \to Gd$ factors as $f = Gh \circ f_i$ for some index i and some morphism $h\colon d_i \to d$ in $\mathbf{D}$. The functor G *satisfies the solution-set condition* if it does so at every object c of $\mathbf{C}$.

In the language of the comma category, the condition says the objects (d_i, f_i) form a set that is *weakly initial* in (c/G): every object receives at least one morphism from a member of the set. The word "weakly" marks that the arrow witnessing the factorization is neither required to be unique nor to come from a single chosen source. The force of the definition is entirely its smallness. In a locally small $\mathbf{D}$ the objects (d, f) of (c/G) already form a proper class, and there is no reason a class-sized family should admit a set-sized dominating subfamily; the solution-set condition asserts that one exists. That is the gap the theorem fills between the necessary condition (RAPL) and sufficiency.

Example 64.4.2: The Solution Set for Free Groups

Let $G\colon \mathbf{Grp} \to \mathbf{Set}$ be the forgetful functor and c a set. A single arrow already works: take the free group Fc on c with its insertion of generators $\eta_c\colon c \to G(Fc)$, and let $\{f_i\}$ be the one-element family $\{\eta_c\}$. Every function $f\colon c \to G(H)$ into the underlying set of a group H extends uniquely to a homomorphism $\bar{f}\colon Fc \to H$ with $G(\bar{f}) \circ \eta_c = f$, so $f = G(\bar{f}) \circ \eta_c$ exhibits the required factorization. Here the solution set has one element because a genuine universal arrow already exists; the theorem below runs the implication in the other direction, manufacturing such a universal arrow from any solution set, however large.

The example makes the shape of the argument visible. When a left adjoint is present, the singleton solution set is the universal arrow itself. The content of the General Adjoint Functor Theorem is that a solution set of *any* size, together with completeness of $\mathbf{D}$ and preservation of limits by G, suffices to assemble a universal arrow that was not given in advance. The assembly is a completeness argument inside the comma category, and its engine is a lemma about initial objects, isolated first.

The lemma is where a set-sized weakly initial family is compressed to a single genuine initial object. In a complete category one can form the product of the family; the product receives an arrow to every object, so it is again weakly initial, and now it is a single object. Passing from weakly initial to initial then requires killing the ambiguity in those arrows, which is what an equalizer of endomorphisms does.

Lemma 64.4.3: Initial Object from a Weakly Initial Set

Let $\mathbf{A}$ be a complete, locally small category. Suppose $\mathbf{A}$ has a *weakly initial set*: a set $\{a_i\}_{i\in I}$ of objects such that every object of $\mathbf{A}$ admits at least one morphism from some a_i. Then $\mathbf{A}$ has an initial object.

***Proof*:**

Step 1: Form a weakly initial object. Since I is a set and $\mathbf{A}$ is complete, the product $P = \prod_{i\in I} a_i$ exists, with projections $\pi_i \colon P \to a_i$. Given any object a, weak initiality gives some i and a morphism $g \colon a_i \to a$; then $g \circ \pi_i \colon P \to a$ is a morphism from P to a. Thus P is a weakly initial *object*: every object receives at least one morphism from P.

Step 2: Equalize the endomorphisms of P. Local smallness makes $\mathbf{A}(P,P)$ a set, so the family of all endomorphisms of P is a set of parallel arrows $P \rightrightarrows P$. Completeness gives their equalizer

$$e \colon E \to P$$

the joint equalizer of $\{\, u \colon P \to P \,\}$, characterized by $u \circ e = e$ for every endomorphism u of P, and universal among arrows into P with this property. We claim E is initial.

Step 3: Existence of a morphism from E. For any object a, weak initiality of P gives a morphism $P \to a$, and precomposing with e yields a morphism $E \to a$. So E admits at least one morphism to every object.

Step 4: Uniqueness. Let $s, t \colon E \to a$ be two morphisms to a common object a; we must show $s = t$. Form the equalizer $k \colon K \to E$ of s and t, so $s \circ k = t \circ k$ and k is universal with this property. Since P is weakly initial there is a morphism $g \colon P \to K$, and composing produces an endomorphism

$$v = e \circ k \circ g \colon P \to P$$

Now e is the joint equalizer of all endomorphisms of P, and v is one such endomorphism, so $v \circ e = e$, that is $e \circ k \circ g \circ e = e$. The morphism e is a monomorphism, being an equalizer, so it is left-cancellable: from $e \circ (k \circ g \circ e) = e = e \circ \mathrm{id}_P$ we cancel e to get

$$k \circ (g \circ e) = \mathrm{id}_E$$

Thus k is a split epimorphism, with section $g \circ e$. But k is also a monomorphism, being an equalizer, and a split epimorphism that is monic is an isomorphism: composing $k \circ (g \circ e) = \mathrm{id}_E$ with k on the right gives $k \circ (g \circ e) \circ k = k = k \circ \mathrm{id}_K$, and cancelling the monic k on the left yields $(g \circ e) \circ k = \mathrm{id}_K$, so $g \circ e$ is a two-sided inverse of k. Since $s \circ k = t \circ k$ and k is an isomorphism, right-cancelling k gives $s = t$.

Combining Steps 3 and 4, every object of $\mathbf{A}$ admits exactly one morphism from E, so E is initial, completing the proof.

The lemma is the whole mechanism in miniature. The product collapses a set of objects into one weakly initial object; the equalizer of its endomorphisms then removes the freedom in the arrows out of it, leaving a single arrow to each target. The two hypotheses do disjoint work: completeness gives the product and the equalizers, local smallness guarantees that the endomorphisms of P form a set so that their equalizer exists. Drop either and the argument fails. With the lemma in hand the theorem is a matter of transporting it into the comma category (c/G), which is where the smallness

of the solution set becomes the weakly initial set the lemma requires.

The remaining input is that (c/G) inherits completeness from $\mathbf{D}$. This is exactly where the hypothesis that G preserves limits is spent: limits in (c/G) are computed in $\mathbf{D}$, and the cone over c that makes the limit an object of the comma category exists precisely because G carries the $\mathbf{D}$-limit to the corresponding $\mathbf{C}$-limit.

Theorem 64.4.4: General Adjoint Functor Theorem

Let $\mathbf{D}$ be a locally small, complete category and $G\colon \mathbf{D} \to \mathbf{C}$ a functor that preserves all small limits. Then G has a left adjoint if and only if G satisfies the solution-set condition (definition 64.4.1).

***Proof*:**

Necessity. Suppose G has a left adjoint $F \dashv G$, with unit η. For each object c of $\mathbf{C}$, the component $\eta_c\colon c \to G(Fc)$ is a universal arrow from c to G (theorem 64.1.5): every $f\colon c \to Gd$ factors as $f = Gh \circ \eta_c$ for a unique $h\colon Fc \to d$. The singleton family $\{\eta_c\}$ is then a solution set at c, so G satisfies the solution-set condition.

Sufficiency. Assume G preserves small limits and satisfies the solution-set condition. By theorem 64.1.5 it suffices to produce, for each object c of $\mathbf{C}$, a universal arrow from c to G, equivalently an initial object of the comma category (c/G) (definition 63.1.4). Fix c; we produce that initial object by applying lemma 64.4.3 to $\mathbf{A} = (c/G)$, which requires that (c/G) be locally small and complete and possess a weakly initial set.

Step 1: (c/G) is locally small. A morphism $(d, f) \to (d', f')$ in (c/G) is a morphism $h\colon d \to d'$ in $\mathbf{D}$ subject to the equation $Gh \circ f = f'$. Thus the hom-set of (c/G) is a subset of $\mathbf{D}(d, d')$, which is a set because $\mathbf{D}$ is locally small. So (c/G) is locally small.

Step 2: (c/G) is complete, using preservation of limits. Let $D\colon \mathbf{J} \to (c/G)$ be a small diagram, writing $D(j) = (d_j, f_j)$ with structure arrows $f_j\colon c \to Gd_j$; a morphism $j \to j'$ in $\mathbf{J}$ gives $\alpha_{jj'}\colon d_j \to d_{j'}$ with $G\alpha_{jj'} \circ f_j = f_{j'}$. The projection to $\mathbf{D}$ sends D to the diagram $j \mapsto d_j$, which has a limit $L = \lim_{\mathbf{J}} d_j$ in $\mathbf{D}$ by completeness, with limit cone $\lambda_j\colon L \to d_j$.

Because G preserves this limit, $G(L)$ with the cone $G\lambda_j\colon G(L) \to Gd_j$ is a limit of $j \mapsto Gd_j$ in $\mathbf{C}$. The arrows $f_j\colon c \to Gd_j$ form a cone over $j \mapsto Gd_j$ with apex c: for a morphism $j \to j'$ one has $G\alpha_{jj'} \circ f_j = f_{j'}$, which is exactly the compatibility condition for a cone. By the universal property of the limit $G(L)$, this cone factors through a unique morphism

$$f_L\colon c \to G(L)$$

satisfying $G\lambda_j \circ f_L = f_j$ for every j. The pair (L, f_L) is then an object of (c/G), and each $\lambda_j\colon L \to d_j$ satisfies $G\lambda_j \circ f_L = f_j$, so λ_j is a morphism $(L, f_L) \to (d_j, f_j)$ in (c/G); these assemble into a cone over D.

This cone is a limit cone in (c/G). Given any cone over D with apex (d, f), its legs are morphisms $\mu_j\colon (d, f) \to (d_j, f_j)$, hence morphisms $\mu_j\colon d \to d_j$ in $\mathbf{D}$ forming a cone over $j \mapsto d_j$; the limit L in $\mathbf{D}$ yields a unique $u\colon d \to L$ with $\lambda_j \circ u = \mu_j$. It remains to check u is a morphism $(d, f) \to (L, f_L)$, that is $Gu \circ f = f_L$. Both sides are morphisms $c \to G(L)$ into the limit $G(L)$; they agree after composing with each projection $G\lambda_j$, since $G\lambda_j \circ Gu \circ f = G(\lambda_j u) \circ f = G\mu_j \circ f = f_j$ and $G\lambda_j \circ f_L = f_j$. By the uniqueness clause of the limit $G(L)$, $Gu \circ f = f_L$. So u is the unique factorization in (c/G), and (L, f_L) is a limit of D. Hence (c/G) has all small limits: it is

complete.

Step 3: the solution set is a weakly initial set for (c/G). By hypothesis G satisfies the solution-set condition at c: there is a set $\{f_i \colon c \to Gd_i\}_{i \in I}$ such that every $f \colon c \to Gd$ factors as $f = Gh \circ f_i$ for some i and some $h \colon d_i \to d$. Read in (c/G), the objects $\{(d_i, f_i)\}_{i \in I}$ form a set, and the factorization $f = Gh \circ f_i$ says exactly that $h \colon (d_i, f_i) \to (d, f)$ is a morphism of (c/G). So every object (d, f) receives a morphism from some (d_i, f_i): the set $\{(d_i, f_i)\}$ is weakly initial.

Step 4: apply the lemma. By Steps 1-3 the comma category (c/G) is locally small, complete, and has a weakly initial set. Lemma 64.4.3 produces an initial object (d_c, η_c) of (c/G). An initial object of (c/G) is a universal arrow $\eta_c \colon c \to Gd_c$ from c to G (definition 63.1.4). This holds for every c, so by theorem 64.1.5 the assignment $c \mapsto d_c$ extends to a left adjoint $F \dashv G$, completing the proof.

The theorem isolates the two obstructions to being a right adjoint and names both. The soft obstruction is failure to preserve limits, ruled out by RAPL and assumed away here. The hard obstruction is size: a limit-preserving functor between well-behaved categories can still fail to have a left adjoint if the comma categories are too large to admit an initial object, and the solution-set condition is exactly the hypothesis that excludes this. When one has a candidate construction in hand, the theorem is often applied by exhibiting an explicit small solution set (frequently a single arrow, as in example 64.4.2) rather than by verifying an abstract smallness principle.

A recurring difficulty in practice is that verifying the solution-set condition can be as much work as constructing the adjoint by hand. The Special Adjoint Functor Theorem removes this burden under stronger global hypotheses on $\mathbf{C}$: a small cogenerating set does the work of every solution set at once. The cost is machinery, well-poweredness and cogenerators phrased through subobject lattices, that this book does not develop, so the theorem is stated with its key ideas rather than proved in full.

Theorem 64.4.5: Special Adjoint Functor Theorem

Let $\mathbf{D}$ be a locally small, complete, well-powered category with a small cogenerating set, and let $G \colon \mathbf{D} \to \mathbf{C}$ be a functor between locally small categories that preserves all small limits. Then G has a left adjoint.

***Proof Key ideas*:**
The full argument requires two notions this book does not develop: a category is *well-powered* when every object has only a set of subobjects (its subobjects form a set rather than a proper class), and a set $\{s_k\}$ of objects is *cogenerating* when any two distinct parallel morphisms $u \neq v \colon d \rightrightarrows d'$ are separated by some morphism $d' \to s_k$ that distinguishes them. These are hypotheses on the lattice of subobjects, whose systematic development belongs to a treatment of well-powered categories and their factorization systems; see Mac Lane, *Categories for the Working Mathematician*, Chapter V.8.

Granting them, the shape of the proof matches the general theorem, with the cogenerating set replacing the solution-set condition. Fix an object c of $\mathbf{C}$ and form, inside $\mathbf{D}$, the product $\prod_k s_k^{\mathbf{C}(c, Gs_k)}$ indexed by the cogenerating set and, for each factor, by the set of morphisms $c \to G(s_k)$. The candidate universal object is the smallest subobject of this product through which the canonical arrow from c factors; well-poweredness guarantees a smallest such subobject exists, since the subobjects form a set closed under the intersections that completeness provides, and the cogenerating property forces the resulting arrow to be universal. Preservation of limits

by G is used, as before, to place the construction in the comma category (c/G). The upshot is that a small cogenerating set functions as a uniform solution set: it gives, in one stroke, the smallness input that the general theorem requires separately at each object, completing the sketch.

The two theorems are the standard existence criteria for left adjoints, and their hypotheses trade off against each other. The general theorem requires little of the target categories but requires a solution set verified case by case; the special theorem front-loads strong structural hypotheses on $\mathbf{D}$, a small cogenerating set and well-poweredness, and then asks nothing further of the individual objects. Many categories of everyday interest, $\mathbf{Set}$, $\mathbf{Grp}$, $\mathbf{Ab}$, $\mathbf{Top}$, and $\mathbf{Mod}_R$, are complete and well-powered with a small cogenerating set, so the special theorem applies to limit-preserving functors out of them without any per-object verification.

A final application of the general theorem recurs across the series: producing a reflection onto a subcategory.

Example 64.4.6: A Reflective Subcategory via GAFT

Let $\mathbf{D}$ be a locally small, complete category and $\mathbf{C} \subseteq \mathbf{D}$ a full subcategory that is closed under small limits, meaning the inclusion $G\colon \mathbf{C} \hookrightarrow \mathbf{D}$ preserves and reflects small limits and every $\mathbf{D}$-limit of a diagram in $\mathbf{C}$ again lies in $\mathbf{C}$. Suppose in addition that $\mathbf{C}$ is complete and that G satisfies the solution-set condition: for each object d of $\mathbf{D}$ there is a set of morphisms $\{d \to c_i\}$ with c_i in $\mathbf{C}$ through which every morphism $d \to c$ into an object of $\mathbf{C}$ factors. Then theorem 64.4.4, applied to $G\colon \mathbf{C} \to \mathbf{D}$, produces a left adjoint $L \dashv G$: a *reflection* of $\mathbf{D}$ onto $\mathbf{C}$.

Concretely, take $\mathbf{D} = \mathbf{Grp}$ and $\mathbf{C} = \mathbf{Ab}$ the full subcategory of abelian groups, with $G\colon \mathbf{Ab} \hookrightarrow \mathbf{Grp}$ the inclusion. A limit of abelian groups computed in $\mathbf{Grp}$ is again abelian, so G preserves limits and $\mathbf{Ab}$ is closed under them; $\mathbf{Ab}$ is complete. For the solution-set condition at a group H, a single arrow suffices: the quotient map $q_H\colon H \to H^{\mathrm{ab}} = H/[H,H]$ onto the abelianization. Any homomorphism $H \to A$ into an abelian group A kills the commutator subgroup $[H,H]$, so it factors uniquely as $\bar{\varphi} \circ q_H$ with $\bar{\varphi}\colon H^{\mathrm{ab}} \to A$. The general theorem then returns the left adjoint $H \mapsto H^{\mathrm{ab}}$, recovering abelianization as the reflection of $\mathbf{Grp}$ onto $\mathbf{Ab}$. As with example 64.4.2, the singleton solution set is present because the universal arrow already exists; the value of the theorem is that a solution set of any size would have sufficed.

65

Monads and their Algebras

A monad is the algebraic structure an adjunction leaves on one side: from $F \dashv G$ the composite GF inherits a unit and a multiplication, and this structure alone suffices to rebuild a category of algebras. This chapter defines *monads*, constructs the two canonical adjunctions that realize any monad, the Eilenberg-Moore and Kleisli categories, and asks the converse, *monadicity*: when is a forgetful functor the forgetful functor of a monad? Beck's theorem answers it, and explains why the algebraic categories over **Set** are exactly the monadic ones.

65.1 Monads from Adjunctions

Every adjunction $F \dashv G$ leaves a trace on the category where its two functors meet: the composite GF is an endofunctor, the unit is a natural transformation $\mathrm{id} \Rightarrow GF$, and the counit gives a second natural transformation $GFGF \Rightarrow GF$. This section isolates that trace as a structure in its own right, the *monad*, defines it by the two laws it must obey, and shows that every adjunction produces one. The free-monoid, powerset, and error monads run alongside as the guiding examples.

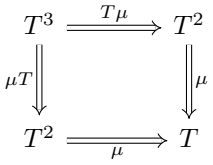
Definition 65.1.1: Monad

A *monad* on a category C is an endofunctor $T\colon C \to C$ together with two natural transformations, the *unit*

$$\eta\colon \mathrm{id}_C \Rightarrow T$$

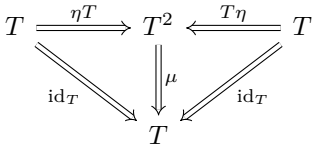
and the *multiplication*

$$\mu\colon T^2 \Rightarrow T$$



where T^2 denotes the composite TT, subject to two laws. The *associativity law* is the equality of natural transformations $T^3 \Rightarrow T$

$$\mu \circ T\mu = \mu \circ \mu T \tag{65.1}$$



and the *unit laws* are the equalities of natural transformations $T \Rightarrow T$

$$\mu \circ T\eta = \mathrm{id}_T = \mu \circ \eta T \tag{65.2}$$

Here $T\mu$ and μT are the whiskered composites: $T\mu$ has component $T(\mu_c)\colon T^3 c \to T^2 c$ at c, and μT has component $\mu_{Tc}\colon T^3 c \to T^2 c$; similarly $T\eta$ and ηT have components $T(\eta_c)$ and η_{Tc}. The two laws are the commutativity of the associativity square

and the two unit triangles

The pattern is that of a monoid: μ plays the role of a multiplication and η the role of a unit element, with (65.1) the associativity of the multiplication and (65.2) its two-sided unit law. The slogan is that a monad is a monoid in the category of endofunctors of C under composition, with the functor category $[C, C]$ (definition 61.5.4) giving the ambient category and functor composition giving the tensor product. The definition is the monoid axioms transported into that setting, with vertical composition of natural transformations for equality of maps and horizontal composition (whiskering) for the two ways of associating T^3.

The endofunctor alone carries no content; the unit and multiplication are what make a monad an algebraic object. Before the examples, the source of every such structure is an adjunction.

The chapter opening framed a monad as the structure an adjunction leaves on one side. That statement is now a proposition: the composite GF of an adjunction, equipped with the adjunction unit and the multiplication built from the counit, satisfies definition 65.1.1. The verification is a diagram chase in which every square commutes by naturality of the counit or by a triangle identity.

Proposition 65.1.2: The Monad of an Adjunction

Let $F\colon C \to D$ and $G\colon D \to C$ be functors with $F \dashv G$, unit $\eta\colon \mathrm{id}_C \Rightarrow GF$ and counit $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ (definition 64.1.1, definition 64.1.3). Then

$$T = GF\colon C \to C, \qquad \eta\colon \mathrm{id}_C \Rightarrow T, \qquad \mu = G\varepsilon F\colon T^2 \Rightarrow T$$

is a monad on C, where μ is the whiskered natural transformation with component $\mu_c = G\varepsilon_{Fc}\colon GFGFc \to GFc$ at c.

***Proof*:**
The unit of the monad is the adjunction unit, already a natural transformation $\mathrm{id}_C \Rightarrow GF = T$ (definition 64.1.3). The multiplication $\mu = G\varepsilon F$ is the whiskering of the natural transformation $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ by G on the left and F on the right, hence a natural transformation $GFGF \Rightarrow GF$, that is, $T^2 \Rightarrow T$. It remains to check the associativity law and the two unit laws.

Step 1: Associativity. Both $\mu \circ T\mu$ and $\mu \circ \mu T$ are natural transformations $T^3 = GFGFGF \Rightarrow GF = T$; the claim is that their components agree at every c. Writing out the components,

$$(\mu \circ T\mu)_c = G\varepsilon_{Fc} \circ GF(G\varepsilon_{Fc}) = G\varepsilon_{Fc} \circ GFG\varepsilon_{Fc}$$

and

$$(\mu \circ \mu T)_c = G\varepsilon_{Fc} \circ G\varepsilon_{FGFc}$$

Applying the functor G to the naturality square of ε reduces both to a common expression. Naturality of $\varepsilon\colon FG \Rightarrow \mathrm{id}_D$ at the morphism $\varepsilon_{Fc}\colon FGFc \to Fc$ in D gives the commuting square

$$\begin{array}{ccc} FGFGFc & \xrightarrow{\varepsilon_{FGFc}} & FGFc \\ {\scriptstyle FG\varepsilon_{Fc}}\downarrow & & \downarrow{\scriptstyle \varepsilon_{Fc}} \\ FGFc & \xrightarrow[\varepsilon_{Fc}]{} & Fc \end{array}$$

that is, $\varepsilon_{Fc} \circ FG\varepsilon_{Fc} = \varepsilon_{Fc} \circ \varepsilon_{FGFc}$ in D. Applying G to this equation yields $G\varepsilon_{Fc} \circ GFG\varepsilon_{Fc} = G\varepsilon_{Fc} \circ G\varepsilon_{FGFc}$, which is precisely $(\mu \circ T\mu)_c = (\mu \circ \mu T)_c$. As c was arbitrary, (65.1) holds. Associativity of the monad is thus the naturality of the counit, pushed through G.

Step 2: The unit laws. The component of $\mu \circ T\eta$ at c is

$$(\mu \circ T\eta)_c = G\varepsilon_{Fc} \circ GF(\eta_c) = G\varepsilon_{Fc} \circ GF\eta_c = G(\varepsilon_{Fc} \circ F\eta_c)$$

using that G is a functor. By the second triangle identity (theorem 64.1.5), $\varepsilon_{Fc} \circ F\eta_c = \mathrm{id}_{Fc}$, so the component is $G(\mathrm{id}_{Fc}) = \mathrm{id}_{GFc} = (\mathrm{id}_T)_c$. Hence $\mu \circ T\eta = \mathrm{id}_T$. For the other unit law, the component of $\mu \circ \eta T$ at c is

$$(\mu \circ \eta T)_c = G\varepsilon_{Fc} \circ \eta_{GFc}$$

the composite $GFc \to GFGFc \to GFc$. This is exactly the first triangle identity (theorem 64.1.5) evaluated at the object Fc of D, namely $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$ with $d = Fc$, giving $G\varepsilon_{Fc} \circ \eta_{GFc} = \mathrm{id}_{GFc}$. Hence $\mu \circ \eta T = \mathrm{id}_T$, and both equalities in (65.2) hold, completing the proof.

The proof shows the two monad laws are repackaged adjunction data: associativity is the naturality

of the counit, and each unit law is one of the two triangle identities. This is the origin of every monad met in practice. A monad is not usually written down axiomatically and then studied; it arises as GF for a free-forgetful adjunction, and its multiplication is the counit describing how a free object built on a free object collapses. The examples show this, and each recovers a familiar operation.

Example 65.1.3: The Free-Monoid, Powerset, and Error Monads
Three monads on **Set**, each the monad of a free-forgetful adjunction (proposition 65.1.2) or checked directly against definition 65.1.1.

1. *The free-monoid monad.* Let TX be the set of finite words $(x_1, \dots, x_n)$, $n \geq 0$, in the alphabet X, including the empty word; for $f\colon X \to Y$, Tf applies f letterwise. This is GF for the free-monoid adjunction $F \dashv G$ with $G\colon \mathbf{Mon} \to \mathbf{Set}$ the underlying-set functor and F the free-monoid functor ([21]). The unit $\eta_X\colon X \to TX$ sends x to the length-one word (x). The multiplication $\mu_X\colon T^2X \to TX$ takes a word of words and concatenates: a length-one word of words $\big((x_1, \dots, x_k)\big)$ flattens to $(x_1, \dots, x_k)$, and in general

$$\mu_X\big((w_1, \dots, w_m)\big) = w_1 \cdot w_2 \cdots w_m$$

   the concatenation of the constituent words $w_i \in TX$. Associativity (65.1) is the associativity of concatenation: flattening a triple-nested word by first concatenating the inner groupings or first concatenating the outer groupings gives the same word. The unit laws (65.2) say that turning each letter into a length-one word and then flattening, or wrapping a whole word into a length-one word of words and then flattening, both return the original word.

2. *The powerset monad.* Let $T = P$ be the covariant powerset functor: PX is the set of subsets of X, and $Pf(S) = f(S)$ is the image of $S \subseteq X$ under $f\colon X \to Y$. The unit $\eta_X\colon X \to PX$ is the singleton map $x \mapsto \{x\}$. The multiplication $\mu_X\colon P^2X \to PX$ is the union: for a set $\mathcal{S}$ of subsets of X,

$$\mu_X(\mathcal{S}) = \bigcup_{S \in \mathcal{S}} S$$

   Associativity is the equality of the two ways to flatten a set of sets of sets by union, which both give the union of all the innermost members. The unit laws read $\bigcup_{x \in S}\{x\} = S$ (union of the singletons of the elements of S) and $\bigcup\{S\} = S$ (union of the one-element family $\{S\}$). This is the monad of the adjunction between **Set** and the category of complete sup-lattices, whose algebras are taken up in the next section.

3. *The error monad.* Fix a one-point set $\{*\}$ and let $TX = X \sqcup \{*\}$, the disjoint union adjoining a single point $*$ read as an error value; for $f\colon X \to Y$, Tf acts as f on X and fixes $*$. The unit $\eta_X\colon X \to X \sqcup \{*\}$ is the inclusion of X. The multiplication $\mu_X\colon T^2X \to TX$, where $T^2X = X \sqcup \{*_1\} \sqcup \{*_2\}$ carries two error points ($*_1$ from the inner T, $*_2$ from the outer), acts as the identity on X and sends both $*_1$ and $*_2$ to the single $*$, merging the two error points. Associativity holds because on the X-part every map in sight is the identity and on the error part every composite lands on $*$; the unit laws hold because η adjoins an error point that μ immediately absorbs. This is the monad GF for the free-pointed-set adjunction, F adjoining a basepoint and G forgetting it.

The three examples share a shape: TX is a syntax of "X-terms" (words, subsets, values-or-error), the unit embeds each element as a trivial term, and the multiplication evaluates a term of terms

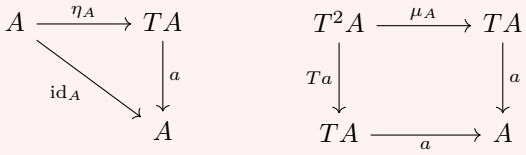
into a single term. A monad is thus a theory of substitution, with μ the operation that carries out one round of it, and the two laws are exactly what make repeated substitution unambiguous. This reading anticipates the theory of algebras for a monad, developed in the next section, where an algebra gives the missing evaluation of a term into an actual element.

Reversing every arrow in definition 65.1.1 produces the dual notion, obtained by applying the definition in the opposite category. A comonad packages the trace an adjunction casts on the *other* side, the composite FG with counit and comultiplication, and is the structure whose coalgebras encode "co-substitution" in the same way a monad's algebras encode substitution.

Definition 65.1.4: Comonad

A *comonad* on a category C is a monad on C^{op}: an endofunctor $T\colon C \to C$ with a *counit* $\varepsilon\colon T \Rightarrow \mathrm{id}_C$ and a *comultiplication* $\delta\colon T \Rightarrow T^2$ satisfying the coassociativity law $T\delta \circ \delta = \delta T \circ \delta$ and the counit laws $\varepsilon T \circ \delta = \mathrm{id}_T = T\varepsilon \circ \delta$, the diagrams of definition 65.1.1 with every arrow reversed. Dually to proposition 65.1.2, an adjunction $F \dashv G$ induces a comonad FG on D with counit ε and comultiplication $F\eta G$ (box 61.3.3).

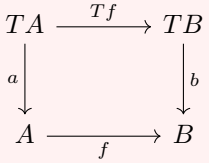
Everything proved for monads holds for comonads by the duality principle, with the roles of unit and multiplication interchanged and arrows reversed. The comonad and its coalgebras are the opposite-category translation of the monad theory developed here and in the sections that follow, and are not pursued further.



65.2 Algebras for a Monad

Proposition 65.1.2 produced a monad from every adjunction. This section runs the construction the other way. Given a monad (T, η, μ) on $\mathbf{C}$ (definition 65.1.1), an *algebra* for it is an object equipped with an action of T compatible with η and μ; the algebras assemble into a category, the Eilenberg-Moore category $\mathbf{C}^T$, and the free-algebra construction gives an adjunction whose induced monad is the original T. A monad thus records an algebraic theory, and $\mathbf{C}^T$ is its category of models.

The definition is the categorical distillation of what it means to be an algebra for an operation. If T is the free-monoid endofunctor on $\mathbf{Set}$, then TA is the set of finite words in A; an action $a\colon TA \to A$ that respects the unit and multiplication is precisely a rule multiplying words, that is, a monoid structure. The two laws below are exactly associativity and unitality of that multiplication, transcribed into the language of T.



Definition 65.2.1: Algebra for a Monad

Let (T, η, μ) be a monad on a category $\mathbf{C}$. A *T-algebra* is a pair (A, a) consisting of an object A of $\mathbf{C}$ and a morphism $a\colon TA \to A$, called the *structure map*, making the two diagrams

commute, that is, $a \circ \eta_A = \mathrm{id}_A$ (the *unit law*) and $a \circ \mu_A = a \circ Ta$ (the *associativity law*).

A *morphism of T-algebras* $(A, a) \to (B, b)$ is a morphism $f\colon A \to B$ in $\mathbf{C}$ commuting with the structure maps, that is, making

commute: $f \circ a = b \circ Tf$.

The unit law forces the structure map to restore an element inserted by η_A without altering it: the free elements act as they must. The associativity law compares the two ways of collapsing a doubly-applied T down to A (first collapse the outer layer with μ_A, then act by a; or first act by a inside the outer T, then act again) and requires they agree. For the free-monoid monad these are the associativity and unit axioms of a monoid, as the next passage makes precise; the definition abstracts that pattern away from any one theory.

Example 65.2.2: The Trivial Algebra and the Free Algebra

Two algebras exist for every monad. First, (TA, μ_A) is a T-algebra for each object A: the unit law $\mu_A \circ \eta_{TA} = \mathrm{id}_{TA}$ is one of the monad unit laws, and the associativity law $\mu_A \circ \mu_{TA} = \mu_A \circ T\mu_A$ is the monad associativity law (definition 65.1.1). This is the *free T-algebra* on A. Second, for any algebra (A, a) the associativity law read as a commuting square makes the structure map $a\colon (TA, \mu_A) \to (A, a)$ itself a morphism of T-algebras.

The algebras and their morphisms form a category, and the underlying-object assignment forgets back to $\mathbf{C}$.

Definition 65.2.3: Eilenberg-Moore Category

Let (T, η, μ) be a monad on $\mathbf{C}$. The *Eilenberg-Moore category* $\mathbf{C}^T$ has T-algebras as objects and morphisms of T-algebras as arrows, with composition and identities computed in $\mathbf{C}$. The *forgetful functor*

$$U^T \colon \mathbf{C}^T \to \mathbf{C}, \qquad (A, a) \mapsto A, \qquad (f \colon (A, a) \to (B, b)) \mapsto (f \colon A \to B)$$

sends an algebra to its underlying object and an algebra morphism to its underlying morphism.

Composition is well-defined because a composite of algebra morphisms is again one: stacking the two commuting squares of definition 65.2.1 for $f \colon (A, a) \to (B, b)$ and $g \colon (B, b) \to (C, c)$ gives the square for gf, using $T(gf) = Tg \circ Tf$. The identity of $\mathbf{C}$ on A is an algebra endomorphism of (A, a). So $\mathbf{C}^T$ is a genuine category and U^T a functor; the content lies not in these formalities but in what U^T admits as a partner. The free-algebra assignment $A \mapsto (TA, \mu_A)$ of example 65.2.2 is the object part of its left adjoint.

The motivation for the adjunction is the recovery program. Proposition 65.1.2 showed an adjunction breeds a monad; the reverse question is whether every monad comes from an adjunction, and if so from which one. The Eilenberg-Moore construction answers yes and produces a canonical such adjunction, built entirely out of T itself.

Theorem 65.2.4: The Eilenberg-Moore Adjunction

Let (T, η, μ) be a monad on $\mathbf{C}$. The assignment

$$F^T \colon \mathbf{C} \to \mathbf{C}^T, \qquad c \mapsto (Tc, \mu_c), \qquad (g \colon c \to c') \mapsto (Tg \colon (Tc, \mu_c) \to (Tc', \mu_{c'}))$$

is a functor, the *free T-algebra functor*, and it is left adjoint to the forgetful functor U^T. The adjunction $F^T \dashv U^T$ induces (via proposition 65.1.2) the original monad (T, η, μ).

***Proof*:**

Step 1: F^T is a functor. On objects $F^T c = (Tc, \mu_c)$ is a T-algebra by example 65.2.2. On a morphism $g \colon c \to c'$, the arrow $Tg \colon Tc \to Tc'$ is an algebra morphism $(Tc, \mu_c) \to (Tc', \mu_{c'})$: the required square $Tg \circ \mu_c = \mu_{c'} \circ T(Tg)$ is naturality of $\mu \colon T^2 \Rightarrow T$ applied to g. Functoriality of F^T then follows from functoriality of T, since F^T acts as T on morphisms.

Step 2: The transposition bijection. Fix an object c of $\mathbf{C}$ and a T-algebra (A, a). Define

$$\Phi \colon \mathrm{Hom}_{\mathbf{C}^T}\big((Tc, \mu_c), (A, a)\big) \longrightarrow \mathrm{Hom}_{\mathbf{C}}(c, A), \qquad \Phi(f) = f \circ \eta_c$$

which precomposes an algebra map out of the free algebra with the unit component $\eta_c \colon c \to Tc$; this is a morphism of $\mathbf{C}$ because $U^T f = f$ and η_c live there. In the other direction define

$$\Psi \colon \mathrm{Hom}_{\mathbf{C}}(c, A) \longrightarrow \mathrm{Hom}_{\mathbf{C}^T}\big((Tc, \mu_c), (A, a)\big), \qquad \Psi(g) = a \circ Tg$$

Two claims must be checked: that $\Psi(g)$ is an algebra morphism, and that Φ and Ψ are mutually inverse.

Step 3: $\Psi(g)$ is an algebra morphism. Write $h = a \circ Tg \colon Tc \to A$. The algebra-morphism square

for $h\colon (Tc, \mu_c) \to (A, a)$ requires $h \circ \mu_c = a \circ Th$. Compute the right-hand side:

$$a \circ Th = a \circ T(a \circ Tg) = a \circ Ta \circ T^2 g$$

Apply the associativity law $a \circ Ta = a \circ \mu_A$ of (A, a):

$$a \circ Ta \circ T^2 g = a \circ \mu_A \circ T^2 g$$

Naturality of $\mu\colon T^2 \Rightarrow T$ applied to g gives $\mu_A \circ T^2 g = Tg \circ \mu_c$, so

$$a \circ \mu_A \circ T^2 g = a \circ Tg \circ \mu_c = h \circ \mu_c$$

which is the identity required. Hence $\Psi(g)$ is a morphism $(Tc, \mu_c) \to (A, a)$ of T-algebras.

Step 4: Φ and Ψ are inverse. For $g\colon c \to A$,

$$\Phi(\Psi(g)) = (a \circ Tg) \circ \eta_c = a \circ Tg \circ \eta_c = a \circ \eta_A \circ g = g$$

where the third equality is naturality of $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow T$ applied to g (namely $Tg \circ \eta_c = \eta_A \circ g$) and the fourth is the unit law $a \circ \eta_A = \mathrm{id}_A$ of (A, a). Conversely, for an algebra morphism $f\colon (Tc, \mu_c) \to (A, a)$,

$$\Psi(\Phi(f)) = a \circ T(f \circ \eta_c) = a \circ Tf \circ T\eta_c$$

Because f is an algebra morphism, $a \circ Tf = f \circ \mu_c$, so

$$a \circ Tf \circ T\eta_c = f \circ \mu_c \circ T\eta_c = f \circ \mathrm{id}_{Tc} = f$$

the middle step using the monad unit law $\mu_c \circ T\eta_c = \mathrm{id}_{Tc}$ (definition 65.1.1). Thus Φ and Ψ are mutually inverse bijections.

Step 5: Naturality. The bijection must be natural in c and in (A, a), so that it is an adjunction (definition 64.1.1). For naturality in the algebra variable, let $\varphi\colon (A, a) \to (B, b)$ be an algebra morphism. Postcomposition by φ acts on the left-hand hom-set (in $\mathbf{C}^T$) and by $U^T\varphi = \varphi$ on the right (in $\mathbf{C}$); for $f\colon (Tc, \mu_c) \to (A, a)$,

$$\Phi(\varphi \circ f) = \varphi \circ f \circ \eta_c = \varphi \circ \Phi(f)$$

which is the naturality square for the target variable. For naturality in c, let $k\colon c' \to c$ be a morphism of $\mathbf{C}$. Precomposition acts by k on the right-hand hom-set and by $F^T k = Tk$ on the left; for $f\colon (Tc, \mu_c) \to (A, a)$,

$$\Phi(f \circ Tk) = f \circ Tk \circ \eta_{c'} = f \circ \eta_c \circ k = \Phi(f) \circ k$$

using naturality of η applied to k (namely $Tk \circ \eta_{c'} = \eta_c \circ k$). Both squares commute, so Φ is a natural isomorphism and $F^T \dashv U^T$.

Step 6: The induced monad is T. By proposition 65.1.2, the monad induced by $F^T \dashv U^T$ has endofunctor $U^T F^T$, unit the adjunction unit, and multiplication $U^T \varepsilon^T F^T$, where ε^T is the counit of $F^T \dashv U^T$. On objects, $U^T F^T c = U^T(Tc, \mu_c) = Tc$, and on morphisms $U^T F^T g = Tg$, so $U^T F^T = T$ as endofunctors. The adjunction unit is the transpose of the identity on $F^T c = (Tc, \mu_c)$, which by Step 2 is $\Phi(\mathrm{id}) = \mathrm{id}_{Tc} \circ \eta_c = \eta_c$; the induced unit is η. The counit component at (A, a) is the transpose of id_A under $F^T \dashv U^T$, that is $\varepsilon^T_{(A,a)} = \Psi(\mathrm{id}_A) = a \circ T\mathrm{id}_A = a$, the structure map itself. Hence the induced multiplication at c is $U^T \varepsilon^T_{F^T c} = \varepsilon^T_{(Tc, \mu_c)} = \mu_c$. Endofunctor, unit, and multiplication all agree with (T, η, μ), completing the proof.

The counit computation in Step 6 isolates a useful fact: the counit of $F^T \dashv U^T$ at an algebra (A, a) is its own structure map a, viewed as the algebra morphism $(TA, \mu_A) \to (A, a)$. This recovers the second observation of example 65.2.2 as the counit of the adjunction, and it says that every algebra is a canonical quotient of a free one, namely the free algebra on its underlying object, acted on by a. The theorem thus does two things at once: it realizes an arbitrary monad by an adjunction, closing the loop opened in section 65.1, and it does so through a category $\mathbf{C}^T$ assembled purely from T, with no auxiliary data.

The examples make the slogan "a monad is an algebraic theory, and $\mathbf{C}^T$ is its category of models" concrete. Each monad from example 65.1.3 has an Eilenberg-Moore category that is, up to equivalence, a familiar category of structured sets.

Example 65.2.5: Eilenberg-Moore Categories of Standard Monads

1. *The free-monoid monad.* Let T be the free-monoid monad on **Set**, so TA is the set of finite words $(a_1, \dots, a_n)$ in A, with $\eta_A(a) = (a)$ the length-one word and μ_A concatenating a word of words. A T-algebra (A, a) has a structure map $a\colon TA \to A$ assigning an element to each word. Write $a_1 \cdots a_n$ for $a(a_1, \dots, a_n)$. The unit law $a \circ \eta_A = \mathrm{id}_A$ says $a(a) = a$: single letters are unchanged. The associativity law $a \circ \mu_A = a \circ Ta$ says that evaluating a word of words either by first concatenating (via μ_A) or by first evaluating each inner word (via Ta) gives the same answer; taking the empty outer word gives a distinguished element $e = a()$ and taking a two-word split gives $(a_1 \cdots a_i)(a_{i+1} \cdots a_n) = a_1 \cdots a_n$. These are exactly the associativity and unit axioms of a monoid with unit e and product $xy = a(x, y)$. A morphism of T-algebras is a map preserving the product and unit, that is, a monoid homomorphism ([21]). Hence $\mathbf{Set}^T$ is equivalent to **Mon**, the category of monoids.

2. *The powerset monad.* Let $T = P$ be the covariant powerset monad on **Set**, with $\eta_A(a) = \{a\}$ and μ_A taking a union of a set of subsets. A P-algebra is a map $a\colon PA \to A$ sending each subset $S \subseteq A$ to an element $\bigvee S := a(S)$. The unit law $a(\{x\}) = x$ pins the singletons. Setting $x \leq y$ iff $\bigvee\{x, y\} = y$ defines a partial order on A, and the associativity law $a \circ \mu_A = a \circ Pa$ forces $a(S)$ to be the least upper bound of S for every subset S, including the empty set (whose supremum is the bottom element $a(\varnothing)$). An algebra structure on A is thus a rule assigning a supremum to *every* subset, which is exactly a complete sup-lattice; a P-algebra morphism is a map preserving arbitrary suprema. So $\mathbf{Set}^P$ is the category of complete sup-lattices and sup-preserving maps.

3. *The maybe monad.* For the maybe monad $MA = A \sqcup \{*\}$ (example 65.1.3), an M-algebra $a\colon A \sqcup \{*\} \to A$ is determined by its value $a(*)$ together with the unit law fixing A; the associativity law imposes nothing further, so an M-algebra is a set with a chosen basepoint $a(*)$, and $\mathbf{Set}^M$ is the category of pointed sets.

In each case the structure map is the operation of the theory: word-multiplication for monoids, supremum for sup-lattices, basepoint choice for pointed sets. This is the sense in which a monad on **Set** encodes an algebraic theory whose operations are "T-many arguments in, one out", and $\mathbf{C}^T$ is its category of models with the theory-preserving maps. The converse question, which categories over **Set** arise this way, is the subject of the monadicity theorem later in the chapter.

One interpretive point closes the section. Theorem 65.2.4 realizes a given monad by an adjunction, but it is not the only such realization: $\mathbf{C}^T$ is the *terminal* one. Among all adjunctions $F \dashv U$ inducing the given monad, the Eilenberg-Moore adjunction receives a unique comparison functor from every

other, making it the largest category of T-algebras compatible with the monad. The next section constructs the initial realization, the Kleisli category, together with the comparison functor between them; the two together bound every adjunction that induces T.

65.3 The Kleisli Category

Where the Eilenberg-Moore category $\mathbf{C}^T$ (section 65.2) realizes T from *every* T-algebra, this section builds the opposite extreme from the smallest possible family, the free ones. The construction packages the free algebras into a category $\mathbf{C}_T$ using only η and μ, exhibits it as a second adjunction that induces T, and locates it against $\mathbf{C}^T$: $\mathbf{C}_T$ is initial and $\mathbf{C}^T$ terminal among all adjunctions inducing T.

The idea is to read a morphism $c \to Tc'$ not as a map landing in Tc' but as a map from c to c' that carries a T-shaped effect: a function returning a formal word, a subset, or a possibly-undefined value rather than a single element. Composing two such effectful maps requires flattening the doubled effect, and μ is exactly the flattening.

Definition 65.3.1: Kleisli Category

Let (T, η, μ) be a monad on a category $\mathbf{C}$ (definition 65.1.1). The *Kleisli category* $\mathbf{C}_T$ has the same objects as $\mathbf{C}$. A morphism $c \to c'$ in $\mathbf{C}_T$ is a $\mathbf{C}$-morphism $f\colon c \to Tc'$, called a *Kleisli arrow*. The identity on c is the unit component

$$\eta_c\colon c \to Tc$$

and the composite of $f\colon c \to Tc'$ with $g\colon c' \to Tc''$ (in that order, g after f) is the Kleisli arrow

$$g \odot f \;=\; \mu_{c''} \circ Tg \circ f \;:\; c \to Tc'' \tag{65.3}$$

where $\odot$ denotes composition in $\mathbf{C}_T$ to distinguish it from composition $\circ$ in $\mathbf{C}$.

The formula (65.3) reads left to right through the effect: apply f to reach Tc', apply Tg to push each intermediate value through g and land in TTc'', then apply $\mu_{c''}$ to collapse the doubled effect down to Tc''. That $\mathbf{C}_T$ is a category is not automatic; it is exactly the monad laws in disguise, and the verification shows why associativity and unitality of μ and η are the right axioms to impose.

Proposition 65.3.2: The Kleisli Category is a Category

With the composition and identities of definition 65.3.1, $\mathbf{C}_T$ is a category.

***Proof*:**
Write $\odot$ for Kleisli composition and $\circ$ for composition in $\mathbf{C}$; naturality of η and μ and the monad laws (definition 65.1.1) are used throughout.

Step 1: Left unit. Let $f\colon c \to Tc'$ be a Kleisli arrow, so its target identity is $\eta_{c'}\colon c' \to Tc'$. Then

$$\eta_{c'} \odot f = \mu_{c'} \circ T\eta_{c'} \circ f = (\mu_{c'} \circ T\eta_{c'}) \circ f = \mathrm{id}_{Tc'} \circ f = f$$

using the right unit law $\mu \circ T\eta = \mathrm{id}_T$ of the monad.

Step 2: Right unit. With $\eta_c \colon c \to Tc$ the identity on the source,

$$f \odot \eta_c = \mu_{c'} \circ Tf \circ \eta_c$$

Naturality of $\eta \colon \mathrm{id}_{\mathbf{C}} \Rightarrow T$ applied to $f \colon c \to Tc'$ gives $Tf \circ \eta_c = \eta_{Tc'} \circ f$, so

$$f \odot \eta_c = \mu_{c'} \circ \eta_{Tc'} \circ f = (\mu_{c'} \circ \eta_{Tc'}) \circ f = \mathrm{id}_{Tc'} \circ f = f$$

now using the left unit law $\mu \circ \eta T = \mathrm{id}_T$.

Step 3: Associativity. Let $f \colon c \to Tc'$, $g \colon c' \to Tc''$, and $h \colon c'' \to Tc'''$. Expanding the two bracketings,

$$h \odot (g \odot f) = \mu_{c'''} \circ Th \circ (\mu_{c''} \circ Tg \circ f) \tag{65.4}$$

$$(h \odot g) \odot f = \mu_{c'''} \circ T(\mu_{c'''} \circ Th \circ g) \circ f \tag{65.5}$$

In (65.5), functoriality of T splits $T(h \odot g) = T\mu_{c'''} \circ TTh \circ Tg$, so the right side becomes $\mu_{c'''} \circ T\mu_{c'''} \circ TTh \circ Tg \circ f$. In (65.4), naturality of $\mu \colon TT \Rightarrow T$ applied to $h \colon c'' \to Tc'''$ gives $Th \circ \mu_{c''} = \mu_{Tc'''} \circ TTh$, so the left side becomes $\mu_{c'''} \circ \mu_{Tc'''} \circ TTh \circ Tg \circ f$. The two agree once $\mu_{c'''} \circ T\mu_{c'''} = \mu_{c'''} \circ \mu_{Tc'''}$, which is precisely the associativity law $\mu \circ T\mu = \mu \circ \mu T$ of the monad, evaluated at c'''. Hence (65.4) and (65.5) coincide, and Kleisli composition is associative, completing the proof.

The proof is the monad laws read backward: the two unit laws become the two identity axioms, and the single associativity square becomes associativity of composition. A monad is thus exactly the data needed to make Kleisli arrows compose, which is one sense in which a monad is an "algebraic theory" presented by its effects. A concrete instance makes the effects visible.

Example 65.3.3: The Kleisli Category of the Powerset Monad

Let $P \colon \mathbf{Set} \to \mathbf{Set}$ be the covariant powerset monad (example 65.1.3), with unit $\eta_X \colon X \to PX$ sending x to the singleton $\{x\}$ and multiplication $\mu_X \colon PPX \to PX$ sending a set of subsets to its union. A Kleisli arrow $f \colon X \to PY$ is a function assigning to each $x \in X$ a subset $f(x) \subseteq Y$, that is, a *relation* between X and Y. The Kleisli identity η_X is the diagonal relation $x \mapsto \{x\}$. Given $f \colon X \to PY$ and $g \colon Y \to PZ$, the Kleisli composite is

$$(g \odot f)(x) = \mu_Z\big((Pg)(f(x))\big) = \bigcup_{y \in f(x)} g(y)$$

which is exactly the composite relation: x is related to z if and only if some y has $x\ f\ y$ and $y\ g\ z$. Thus $\mathbf{Set}_P$ is the category $\mathbf{Rel}$ of sets and relations, with relational composition read off the monad structure. The maybe monad $X \mapsto X + 1$ (add a disjoint basepoint) gives instead the category of partial functions, and the free-monoid monad gives functions returning formal words.

Every Kleisli category comes with a canonical adjunction, and it induces the monad one started from. The left adjoint reinterprets an ordinary map as a pure Kleisli arrow, one with trivial effect, and the right adjoint sends an object to the free algebra Tc.

Theorem 65.3.4: The Kleisli Adjunction

Let (T, η, μ) be a monad on $\mathbf{C}$ with Kleisli category $\mathbf{C}_T$. Define functors

$$F_T \colon \mathbf{C} \to \mathbf{C}_T, \qquad U_T \colon \mathbf{C}_T \to \mathbf{C}$$

as follows. The functor F_T is the identity on objects, and sends $f \colon c \to c'$ in $\mathbf{C}$ to the Kleisli arrow $\eta_{c'} \circ f \colon c \to Tc'$. The functor U_T sends an object c to Tc, and a Kleisli arrow $f \colon c \to Tc'$ to the $\mathbf{C}$-morphism $\mu_{c'} \circ Tf \colon Tc \to Tc'$. Then $F_T \dashv U_T$, and the monad induced by this adjunction (proposition 65.1.2) is (T, η, μ).

***Proof*:**

Step 1: F_T and U_T are functors. For F_T: the identity on c in $\mathbf{C}$ goes to $\eta_c \circ \mathrm{id}_c = \eta_c$, the Kleisli identity. For composability, given $f \colon c \to c'$ and $g \colon c' \to c''$ in $\mathbf{C}$, the Kleisli composite of their images is

$$(\eta_{c''} \circ g) \odot (\eta_{c'} \circ f) = \mu_{c''} \circ T(\eta_{c''} \circ g) \circ \eta_{c'} \circ f$$

Naturality of $\eta \colon \mathrm{id}_{\mathbf{C}} \Rightarrow T$ at the morphism $\eta_{c''} \circ g \colon c' \to Tc''$ gives $T(\eta_{c''} \circ g) \circ \eta_{c'} = \eta_{Tc''} \circ \eta_{c''} \circ g$, whence

$$(\eta_{c''} \circ g) \odot (\eta_{c'} \circ f) = \mu_{c''} \circ \eta_{Tc''} \circ \eta_{c''} \circ g \circ f = \eta_{c''} \circ (g \circ f)$$

using $\mu_{c''} \circ \eta_{Tc''} = \mathrm{id}_{Tc''}$ (left unit law). This is $F_T(g \circ f)$, so F_T is a functor. For U_T: the identity η_c goes to $\mu_c \circ T\eta_c = \mathrm{id}_{Tc}$ (right unit law); and U_T preserves composition because, for $f \colon c \to Tc'$ and $g \colon c' \to Tc''$,

$$U_T(g \odot f) = \mu_{c''} \circ T(\mu_{c''} \circ Tg \circ f) = \mu_{c''} \circ T\mu_{c''} \circ TTg \circ Tf$$

while $U_T(g) \circ U_T(f) = \mu_{c''} \circ Tg \circ \mu_{c'} \circ Tf$. Naturality of μ at g gives $Tg \circ \mu_{c'} = \mu_{Tc''} \circ TTg$, and associativity $\mu_{c''} \circ \mu_{Tc''} = \mu_{c''} \circ T\mu_{c''}$ turns the second expression into the first. Thus U_T is a functor.

Step 2: The hom-set bijection. By construction, for objects c of $\mathbf{C}$ and c' of $\mathbf{C}_T$,

$$\mathrm{Hom}_{\mathbf{C}_T}(F_T c, c') = \mathrm{Hom}_{\mathbf{C}_T}(c, c') = \mathrm{Hom}_{\mathbf{C}}(c, Tc') = \mathrm{Hom}_{\mathbf{C}}(c, U_T c') \tag{65.6}$$

the middle equality being the definition of a Kleisli arrow and the last the definition of U_T on objects. Take $\Phi_{c,c'}$ to be this identification.

Step 3: Naturality of the bijection. Naturality in c requires that for $u \colon c_0 \to c$ in $\mathbf{C}$ and a Kleisli arrow $k \colon c \to c'$, precomposing in $\mathbf{C}_T$ with $F_T u$ matches precomposing in $\mathbf{C}$ with u under (65.6). The left side is $k \odot (\eta_c \circ u) = \mu_{c'} \circ Tk \circ \eta_c \circ u$; naturality of η at k gives $Tk \circ \eta_c = \eta_{Tc'} \circ k$, so this is $\mu_{c'} \circ \eta_{Tc'} \circ k \circ u = k \circ u$, the right side. Naturality in c' requires that for a Kleisli arrow $v \colon c' \to c''$, postcomposing in $\mathbf{C}_T$ with v matches postcomposing in $\mathbf{C}$ with $U_T v = \mu_{c''} \circ Tv$. The left side is $v \odot k = \mu_{c''} \circ Tv \circ k = (U_T v) \circ k$, the right side. Thus Φ is natural and $F_T \dashv U_T$.

Step 4: The induced monad is T. The composite $U_T F_T$ sends an object c to $U_T c = Tc$ and a morphism $f \colon c \to c'$ to $U_T(\eta_{c'} \circ f) = \mu_{c'} \circ T(\eta_{c'} \circ f) = \mu_{c'} \circ T\eta_{c'} \circ Tf = Tf$, using the right unit law. Hence $U_T F_T = T$ as an endofunctor. The unit of the adjunction is the transpose of the identity Kleisli arrow on $F_T c$: under (65.6) the identity $\mathrm{id}_{F_T c} = \eta_c \in \mathrm{Hom}_{\mathbf{C}_T}(c, c)$ corresponds to $\eta_c \in \mathrm{Hom}_{\mathbf{C}}(c, Tc)$, so the induced unit is η. The induced multiplication is $U_T \varepsilon F_T$ (proposition 65.1.2), where the counit $\varepsilon_{c'} \colon F_T U_T c' \to c'$ is the transpose of $\mathrm{id}_{U_T c'} = \mathrm{id}_{Tc'}$; under (65.6) at object Tc' this is the Kleisli arrow $\mathrm{id}_{Tc'} \colon Tc' \to Tc'$. Then $U_T \varepsilon_{c'} = \mu_{c'} \circ T\mathrm{id}_{Tc'} = \mu_{c'}$, so the induced multiplication at c' is $\mu_{c'}$. The induced monad is (T, η, μ), as we sought to show.

Together with theorem 65.2.4, the Kleisli adjunction proves the converse promised in section 65.1: every monad arises from an adjunction, and now from at least two. The left adjoint F_T names each object by its free algebra and each map by its pure lift; the counit at c is the identity Kleisli arrow on Tc, which under U_T is μ_c, so the counit *is* the multiplication seen through the underlying category. Two adjunctions inducing the same T raises the question of how they relate, and the answer places $\mathbf{C}_T$ inside $\mathbf{C}^T$.

The bridge is the comparison functor. Every free T-algebra (Tc, μ_c) lives in $\mathbf{C}^T$, and a Kleisli arrow induces a canonical map between free algebras; assembling these identifies $\mathbf{C}_T$ with the free-algebra part of $\mathbf{C}^T$.

Theorem 65.3.5: Kleisli as the Free Algebras

Let (T, η, μ) be a monad on $\mathbf{C}$. The assignment

$$K \colon \mathbf{C}_T \to \mathbf{C}^T$$

sending an object c to the free T-algebra (Tc, μ_c) and a Kleisli arrow $f \colon c \to Tc'$ to the $\mathbf{C}$-morphism $\mu_{c'} \circ Tf \colon Tc \to Tc'$ is a fully faithful functor. Its image is the full subcategory of $\mathbf{C}^T$ on the free algebras, so K identifies $\mathbf{C}_T$ with that subcategory. Moreover, among all adjunctions inducing T, the Kleisli adjunction is initial and the Eilenberg-Moore adjunction (theorem 65.2.4) is terminal.

***Proof*:**

Step 1: K lands in $\mathbf{C}^T$ and is a functor. That (Tc, μ_c) is a T-algebra (definition 65.2.1) is the content of the free-algebra construction: the unit law $\mu_c \circ \eta_{Tc} = \mathrm{id}_{Tc}$ and the associativity law $\mu_c \circ \mu_{Tc} = \mu_c \circ T\mu_c$ are two of the monad laws. For a Kleisli arrow $f \colon c \to Tc'$, the morphism $Kf = \mu_{c'} \circ Tf$ is an algebra map $(Tc, \mu_c) \to (Tc', \mu_{c'})$: the required square $Kf \circ \mu_c = \mu_{c'} \circ T(Kf)$ reads $\mu_{c'} \circ Tf \circ \mu_c = \mu_{c'} \circ T(\mu_{c'} \circ Tf)$, and both sides equal $\mu_{c'} \circ \mu_{Tc'} \circ TTf$ by naturality of μ at f (left) and functoriality of T together with associativity of μ (right). On objects and morphisms K agrees with U_T followed by the free-algebra data, so it preserves identities and composition exactly as U_T does (theorem 65.3.4, Step 1). Thus K is a functor.

Step 2: K is faithful. A Kleisli arrow $f \colon c \to Tc'$ can be recovered from $Kf = \mu_{c'} \circ Tf$ by precomposing with the unit:

$$Kf \circ \eta_c = \mu_{c'} \circ Tf \circ \eta_c = \mu_{c'} \circ \eta_{Tc'} \circ f = f$$

using naturality of η at f and the left unit law $\mu \circ \eta T = \mathrm{id}$. Hence $Kf = Kg$ forces $f = Kf \circ \eta_c = Kg \circ \eta_c = g$, so K is injective on each hom-set.

Step 3: K is full. Let $h \colon (Tc, \mu_c) \to (Tc', \mu_{c'})$ be any algebra map, so $h \circ \mu_c = \mu_{c'} \circ Th$. Set $f = h \circ \eta_c \colon c \to Tc'$, a Kleisli arrow. Then

$$Kf = \mu_{c'} \circ Tf = \mu_{c'} \circ T(h \circ \eta_c) = \mu_{c'} \circ Th \circ T\eta_c$$

The algebra-map condition rewrites $\mu_{c'} \circ Th = h \circ \mu_c$, so

$$Kf = h \circ \mu_c \circ T\eta_c = h \circ \mathrm{id}_{Tc} = h$$

using the right unit law $\mu \circ T\eta = \mathrm{id}$. Thus every algebra map between free algebras is Kf for some Kleisli arrow f, and combined with Step 2, K is fully faithful.

Step 4: The image and the identification. By Steps 2 and 3, K is injective on objects up to the free-algebra assignment and a bijection on each hom-set $\mathrm{Hom}_{\mathbf{C}_T}(c,c') \to \mathrm{Hom}_{\mathbf{C}^T}\big((Tc,\mu_c),(Tc',\mu_{c'})\big)$. Its objects are exactly the free algebras (Tc,μ_c), and fullness says every $\mathbf{C}^T$-morphism between two free algebras lies in the image. Hence K is an isomorphism of $\mathbf{C}_T$ onto the full subcategory of $\mathbf{C}^T$ spanned by the free algebras.

Step 5: Initial and terminal placement. Fix the monad T and let $\mathbf{Adj}(T)$ be the category whose objects are adjunctions inducing T: a category $\mathbf{D}$ with $F \dashv G$, $F\colon \mathbf{C} \to \mathbf{D}$ and $G\colon \mathbf{D} \to \mathbf{C}$, such that $GF = T$ and the induced unit and multiplication (proposition 65.1.2) are η and μ. A morphism from $(\mathbf{D},F,G)$ to $(\mathbf{D}',F',G')$ is a functor $R\colon \mathbf{D} \to \mathbf{D}'$ with $RF = F'$ and $G'R = G$.

Step 5a: The Kleisli adjunction is initial. Fix a target $(\mathbf{D}',F',G')$ with counit ε'; write $\Phi\colon \mathbf{D}'(F'c,F'c') \to \mathbf{C}(c,G'F'c')$ for the adjunction bijection of $F' \dashv G'$, which sends g to $G'g \circ \eta_c$ (definition 64.1.1), using that the induced unit of $F' \dashv G'$ is the monad unit η. A morphism $R\colon \mathbf{C}_T \to \mathbf{D}'$ must satisfy $RF_T = F'$ and $G'R = U_T$. Since F_T is the identity on objects, $Rc = RF_Tc = F'c$ on objects. For a Kleisli arrow $f\colon c \to Tc'$, note $Tc' = G'F'c'$, so f lies in $\mathbf{C}(c,G'F'c')$; the constraint $G'(Rf) = U_Tf = \mu_{c'} \circ Tf$ determines the transpose of Rf, because

$$\Phi(Rf) = G'(Rf) \circ \eta_c = \mu_{c'} \circ Tf \circ \eta_c = \mu_{c'} \circ \eta_{Tc'} \circ f = f$$

using naturality of η at f and the left unit law $\mu \circ \eta T = \mathrm{id}$. As Φ is a bijection, Rf is forced to be $\Phi^{-1}(f) = \varepsilon'_{F'c'} \circ F'f\colon F'c \to F'c'$. Both the object and the morphism assignment are thus determined, so at most one R exists.

This assignment is a morphism of adjunctions. It is a functor: the Kleisli identity η_c goes to $\varepsilon'_{F'c} \circ F'\eta_c = \mathrm{id}_{F'c}$ by the triangle identity $\varepsilon'F' \circ F'\eta = \mathrm{id}_{F'}$, and for Kleisli arrows $f\colon c \to Tc'$, $g\colon c' \to Tc''$ the two morphisms $R(g \odot f)$ and $Rg \circ Rf$ have the same transpose under Φ: the computation above gives $\Phi(R(g \odot f)) = g \odot f$, while

$$\Phi(Rg \circ Rf) = G'(Rg) \circ G'(Rf) \circ \eta_c = U_Tg \circ (U_Tf \circ \eta_c) = U_Tg \circ f = \mu_{c''} \circ Tg \circ f = g \odot f$$

where $U_Tf \circ \eta_c = \mu_{c'} \circ Tf \circ \eta_c = f$ as before, so $R(g \odot f) = Rg \circ Rf$. The constraint $G'R = U_T$ holds by construction: $G'(Rf) = G'\varepsilon'_{F'c'} \circ G'F'f = \mu_{c'} \circ Tf = U_Tf$, using that the induced multiplication is $\mu = G'\varepsilon'F'$, so $\mu_{c'} = G'\varepsilon'_{F'c'}$. Finally $RF_T = F'$: on a $\mathbf{C}$-morphism $f\colon c \to c'$, the image $F_Tf = \eta_{c'} \circ f$ has $R(F_Tf) = \varepsilon'_{F'c'} \circ F'\eta_{c'} \circ F'f = F'f$ by the same triangle identity. Hence R exists and is unique, and $\mathbf{C}_T$ is initial.

Step 5b: The Eilenberg-Moore adjunction is terminal. Fix a source $(\mathbf{D},F,G)$ with counit ε. Define $K^{\mathbf{D}}\colon \mathbf{D} \to \mathbf{C}^T$ on an object d by $K^{\mathbf{D}}d = (Gd, G\varepsilon_d)$ and on a morphism $p\colon d \to d'$ by $K^{\mathbf{D}}p = Gp$. That $(Gd,G\varepsilon_d)$ is a T-algebra (definition 65.2.1) uses the two adjunction facts. Its unit law $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$ is the triangle identity $G\varepsilon \circ \eta G = \mathrm{id}_G$ at d. Its associativity law reads $G\varepsilon_d \circ \mu_{Gd} = G\varepsilon_d \circ T(G\varepsilon_d)$; since $\mu_{Gd} = G\varepsilon_{FGd}$ and $T(G\varepsilon_d) = GFG\varepsilon_d$, both sides are G applied to $\varepsilon_d \circ \varepsilon_{FGd}$ and $\varepsilon_d \circ FG\varepsilon_d$ respectively, equal by naturality of $\varepsilon\colon FG \Rightarrow \mathrm{id}$ at ε_d. For $p\colon d \to d'$, the morphism Gp is an algebra map $(Gd,G\varepsilon_d) \to (Gd',G\varepsilon_{d'})$: the condition $Gp \circ G\varepsilon_d = G\varepsilon_{d'} \circ T(Gp)$ is G applied to $p \circ \varepsilon_d = \varepsilon_{d'} \circ FGp$, again naturality of ε at p. Being G on morphisms, $K^{\mathbf{D}}$ preserves identities and composition, so it is a functor.

It is a morphism of adjunctions. On objects $U^TK^{\mathbf{D}}d = Gd$ and on morphisms $U^TK^{\mathbf{D}}p = Gp$, so $U^TK^{\mathbf{D}} = G$. For F: on an object c, $K^{\mathbf{D}}(Fc) = (GFc, G\varepsilon_{Fc}) = (Tc,\mu_c) = F^Tc$, using $\mu_c = G\varepsilon_{Fc}$; on a morphism f, $K^{\mathbf{D}}(Ff) = GFf = Tf = F^Tf$, so $K^{\mathbf{D}}F = F^T$.

For uniqueness, let $S\colon \mathbf{D} \to \mathbf{C}^T$ be any morphism of adjunctions, so $SF = F^T$ and $U^TS = G$. The second constraint forces the underlying object of Sd to be $U^T(Sd) = Gd$, so $Sd = (Gd, x_d)$

for some structure map $x_d \colon TGd \to Gd$; only x_d remains to be pinned. Apply S to the counit $\varepsilon_d \colon FGd \to d$: since $SF = F^T$, the source is $SFGd = F^T(Gd) = (TGd, \mu_{Gd})$, so $S\varepsilon_d$ is an algebra map $(TGd, \mu_{Gd}) \to (Gd, x_d)$ whose underlying $\mathbf{C}$-morphism is $U^T(S\varepsilon_d) = G\varepsilon_d$. Under the free-forgetful bijection of theorem 65.2.4, an algebra map out of the free algebra (TGd, μ_{Gd}) equals $x_d \circ T(-)$ applied to its restriction along η_{Gd}; that restriction is $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$ by the triangle identity, so

$$G\varepsilon_d = x_d \circ T(\mathrm{id}_{Gd}) = x_d$$

Hence $x_d = G\varepsilon_d$ and $Sd = (Gd, G\varepsilon_d) = K^{\mathbf{D}}d$ on objects. On a morphism p, $U^T(Sp) = Gp = U^T(K^{\mathbf{D}}p)$, and U^T is faithful (a $\mathbf{C}^T$-morphism is determined by its underlying $\mathbf{C}$-morphism, definition 65.2.3), so $Sp = K^{\mathbf{D}}p$. Thus $S = K^{\mathbf{D}}$, and $\mathbf{C}^T$ is terminal.

Composing the two extremes, every $(\mathbf{D}, F, G)$ inducing T receives the unique morphism $R \colon \mathbf{C}_T \to \mathbf{D}$ from $\mathbf{C}_T$ and admits the unique morphism $K^{\mathbf{D}} \colon \mathbf{D} \to \mathbf{C}^T$ to $\mathbf{C}^T$, so the comparison factors as $\mathbf{C}_T \to \mathbf{D} \to \mathbf{C}^T$. Taking $\mathbf{D} = \mathbf{C}^T$ shows the composite $K^{\mathbf{C}^T} \circ R \colon \mathbf{C}_T \to \mathbf{C}^T$ is the unique morphism $\mathbf{C}_T \to \mathbf{C}^T$, which is the K of Steps 1 to 4. This establishes the initial and terminal placement, completing the proof.

The theorem exhibits $\mathbf{C}_T$ and $\mathbf{C}^T$ as the two ends of a spectrum. Every construction of T from an adjunction factors as $\mathbf{C}_T \to \mathbf{D} \to \mathbf{C}^T$: the Kleisli category adjoins nothing beyond the free algebras, the Eilenberg-Moore category adjoins every algebra, and any other realization sits between. When T is the free-monoid monad, $\mathbf{C}_T$ is the category whose objects are sets and whose maps $X \to Y$ are functions $X \to (\text{words in } Y)$, while $\mathbf{C}^T = \mathbf{Mon}$; the inclusion $\mathbf{C}_T \hookrightarrow \mathbf{Mon}$ is the free monoids sitting inside all monoids. Fullness on the free part is what makes $\mathbf{C}_T$ an object of study rather than a bookkeeping device: a Kleisli arrow and the algebra map it induces carry the same information, so one may compute with whichever is convenient. When the comparison functor $\mathbf{D} \to \mathbf{C}^T$ is not just unique but an equivalence, the category $\mathbf{D}$ is $\mathbf{C}^T$ up to equivalence, so the adjunction recovers the full algebraic content of T; whether a given forgetful functor has this property is the question of *monadicity*.

65.4 Monadicity

The previous sections travel one direction: every monad T on $\mathbf{C}$ produces a category of algebras $\mathbf{C}^T$, and the forgetful functor $U^T \colon \mathbf{C}^T \to \mathbf{C}$ carries the monad back (definition 65.2.3, theorem 65.2.4). This section runs the converse. Given a functor $G \colon \mathbf{D} \to \mathbf{C}$ with a left adjoint, G remembers a monad $T = GF$ on $\mathbf{C}$; the question is whether $\mathbf{D}$ is nothing more than the algebras for that monad. When it is, G is *monadic*: the objects of $\mathbf{D}$ are algebraic structures on their images, and G forgets exactly the operations that a T-algebra structure records. Beck's theorem gives the exact test.

Fix an adjunction $F \dashv G$ with $F \colon \mathbf{C} \to \mathbf{D}$, $G \colon \mathbf{D} \to \mathbf{C}$, unit η, and counit ε. By proposition 65.1.2 this induces the monad $T = GF$ on $\mathbf{C}$, with unit $\eta \colon \mathrm{id}_C \Rightarrow T$ and multiplication $\mu = G\varepsilon F$. Every object d of $\mathbf{D}$ then carries a canonical T-algebra structure on its image Gd: the counit component $\varepsilon_d \colon FGd \to d$ has image $G\varepsilon_d \colon TGd = GFGd \to Gd$, and the triangle identities and naturality of the counit make $(Gd, G\varepsilon_d)$ a T-algebra. This assignment is functorial, and it is the object of study.

Definition 65.4.1: Monadic Functor

Let $G\colon \mathbf{D} \to \mathbf{C}$ have a left adjoint $F \dashv G$, and let $T = GF$ be the induced monad on $\mathbf{C}$. The *comparison functor* is

$$K\colon \mathbf{D} \to \mathbf{C}^T, \qquad K(d) = (Gd,\, G\varepsilon_d), \qquad K(h\colon d \to d') = Gh$$

into the Eilenberg-Moore category of T. The functor G is *monadic* if it has a left adjoint and the comparison functor K is an equivalence of categories.

The comparison functor always exists and always commutes with the forgetful functors: $U^T K = G$, since $U^T(Gd, G\varepsilon_d) = Gd$. So K factors G through the algebras, presenting $\mathbf{D}$ as sitting over $\mathbf{C}^T$. Monadicity is the requirement that this factorization lose nothing, that K be an equivalence. When it is, $\mathbf{D}$ is, up to equivalence, precisely $\mathbf{C}^T$: every object of $\mathbf{D}$ is a T-algebra, every T-algebra comes from an object of $\mathbf{D}$, and morphisms match. The functor G is then a bona fide forgetful functor, and T is the complete record of the structure it forgets.

Before stating Beck's test, it helps to see why a naive expectation fails. One might hope that any G with a left adjoint is monadic. It is not: the free-forgetful adjunction between **Set** and **Top** has $GF = \mathrm{id}_{\mathbf{Set}}$ (the free topology on a set is discrete, whose underlying set is the set again), so T is the identity monad, $\mathbf{Set}^T \cong \mathbf{Set}$, and $K\colon \mathbf{Top} \to \mathbf{Set}$ is the forgetful functor, which is not an equivalence. A topology is not encoded by any operations on the underlying set. Beck's theorem isolates the exact structure whose presence certifies monadicity.

The certifying structure is a condition on how G interacts with certain coequalizers (definition 63.3.5). A parallel pair $f, g\colon d \rightrightarrows d'$ in $\mathbf{D}$ is a *G-split pair* if its image $Gf, Gg\colon Gd \rightrightarrows Gd'$ admits a split coequalizer in $\mathbf{C}$: a coequalizer $q\colon Gd' \to c$ together with sections $s\colon c \to Gd'$ and $t\colon Gd' \to Gd$ satisfying $qs = \mathrm{id}_c$, $Gf\,t = \mathrm{id}_{Gd'}$, and $Gg\,t = sq$. A split coequalizer is preserved by every functor, because the equations defining it are equational: applying any functor to q, s, t produces the split coequalizer of the image pair. This is the property that makes the condition usable, and it is why the coequalizers Beck asks for are exactly the G-split ones.

Theorem 65.4.2: Beck's Monadicity Theorem

A functor $G\colon \mathbf{D} \to \mathbf{C}$ is monadic if and only if

1. G has a left adjoint, and
2. G creates coequalizers of G-split pairs (definition 63.4.6): for every G-split pair $f, g\colon d \rightrightarrows d'$ in $\mathbf{D}$, the coequalizer cocone of Gf, Gg in $\mathbf{C}$ has a unique lift along G to a cocone on f, g in $\mathbf{D}$, and that lifted cocone is a coequalizer.

***Proof Key ideas*:**
The full proof is a long diagram bookkeeping (the *precise* and *crude* monadicity theorems in the literature); it is deferred to Mac Lane's *Categories for the Working Mathematician* (VI.7) and Riehl's *Category Theory in Context* (5.5), which is why only the ideas are recorded here (BOOK.md §6 sanctions this deferral). Three points carry the argument.

The canonical presentation of a T-algebra. Every T-algebra (A, a) is a coequalizer of free algebras.

The free algebras (T^2A, μ_{TA}) and (TA, μ_A) sit in a parallel pair

$$(T^2A,\ \mu_{TA}) \rightrightarrows (TA,\ \mu_A)$$

with legs μ_A and Ta, and (A, a) is its coequalizer in $\mathbf{C}^T$. Applying U^T gives the pair $\mu_A, Ta\colon T^2A \rightrightarrows TA$ in $\mathbf{C}$, which is split by η_{TA} and η_A: the algebra axioms $a \circ \eta_A = \mathrm{id}_A$ and $a \circ \mu_A = a \circ Ta$ give the section and coequalizing equations, the remaining splitting data coming from the monad unit laws and the naturality of η. So every T-algebra is a U^T-split pair's coequalizer, and it is its own free presentation.

Constructing the inverse to K. The comparison functor K has a left adjoint $L\colon \mathbf{C}^T \to \mathbf{D}$ built by forming these coequalizers in $\mathbf{D}$. Given (A, a), transport its free presentation $\mu_A, Ta\colon T^2A \rightrightarrows TA$ through F to the parallel pair $FTA \rightrightarrows FA$ in $\mathbf{D}$ (the legs are $F\mu_A$ and the composite FTa followed by ε_{FA}, the transported free presentation); this pair is G-split, its splitting descending from the split coequalizer of μ_A, Ta established above. Condition (2) creates the coequalizer of this pair in $\mathbf{D}$, and $L(A, a)$ is defined to be that coequalizer. Creation makes L well-defined and functorial.

Why the G-split condition forces an equivalence. The unit and counit of $L \dashv K$ are the comparison maps between an object and the coequalizer of its canonical presentation. On the algebra side, $KL(A, a) \cong (A, a)$ because K preserves the created coequalizer (split coequalizers are absolute, preserved by every functor) and (A, a) is the coequalizer of its own presentation. On the $\mathbf{D}$ side, $LK(d) \cong d$ because d is the coequalizer of the G-split pair $\varepsilon_{FGd}, FG\varepsilon_d\colon FGFGd \rightrightarrows FGd$ (the presentation of d), and creation delivers exactly that object. Thus K and L are mutually inverse up to isomorphism, so K is an equivalence and G is monadic. Conversely, if G is monadic then G inherits condition (2) from U^T, which creates these coequalizers by the free-presentation computation above, completing the proof.

The theorem trades the global requirement "K is an equivalence" for a local, checkable one: create the coequalizers of G-split pairs. The mechanism is the canonical presentation. Every algebra is the coequalizer of free algebras built from it, and G knows the free objects because it has a left adjoint; the only thing G needs to give on its own is these coequalizers, lifted uniquely from $\mathbf{C}$. Where G can build them, $\mathbf{D}$ reassembles from the free part exactly as the algebras do, and the two categories coincide. This is why the condition is about coequalizers and not general colimits: the presentation of an algebra is a single reflexive coequalizer, so that one shape suffices.

The payoff is that the standard forgetful functors of algebra pass the test, and this is the precise content of the slogan that groups, rings, and modules are algebraic structures.

Example 65.4.3: Groups, Rings, and Modules are Monadic over Set
The forgetful functors

$$U\colon \mathbf{Grp} \to \mathbf{Set}, \qquad U\colon \mathbf{Ring} \to \mathbf{Set}, \qquad U\colon \mathbf{Mod}_R \to \mathbf{Set}$$

are each monadic. Take $U\colon \mathbf{Grp} \to \mathbf{Set}$; the other two are identical in form.

The left adjoint is the free-group functor F, so condition (1) holds by the free-forgetful adjunction ([21, Universal Property Of Free Groups]). The induced monad $T = UF$ sends a set X to the underlying set of the free group on X, and its algebras are groups: a T-algebra structure on a set is precisely a choice of multiplication, inverse, and identity satisfying the group axioms, recovered from the operations that the free-group monad encodes ([21, Universal Property Of Free Groups, Group] for the free group and the group axioms). So the comparison functor $K\colon \mathbf{Grp} \to \mathbf{Set}^T$ is

already the identification of groups with T-algebras.

For condition (2), let $f, g\colon G \rightrightarrows H$ be group homomorphisms whose underlying maps Uf, Ug admit a split coequalizer of sets. The coequalizer of Uf, Ug in **Set** is the quotient of UH by the equivalence relation generated by $Uf(x) \sim Ug(x)$. The split hypothesis is what guarantees this set-level quotient is compatible with the operations, so a group structure descends onto it: under that hypothesis the set-level quotient coincides with UH modulo the normal subgroup generated by $\{f(x)g(x)^{-1}\}$, which is the coequalizer of f, g in **Grp**. So the quotient carries a unique group structure making q a homomorphism, and with that structure it is the coequalizer in **Grp**. The lift exists, is unique, and is a coequalizer, so U creates the coequalizer. Both conditions hold, and Beck's theorem gives monadicity. The rings and modules cases run the same way, with the relevant quotient (by an ideal, by a submodule) descending along the split coequalizer. This is what "algebraic over **Set**" means: the category is the algebras for a monad on **Set** that its forgetful functor remembers.

By contrast, $U\colon \mathbf{Top} \to \mathbf{Set}$ is not monadic. As noted above, the free topology on a set is the discrete one, whose underlying set is the original set, so the induced monad is the identity and $\mathbf{Set}^T \cong \mathbf{Set}$; the comparison functor is U itself, sending a space to its point-set and collapsing all topologies on a fixed set to one object. No monad on **Set** has topological spaces as its algebras, because a topology is not a system of finitary operations on the underlying set. Beck's theorem locates the failure precisely in condition (2): U does *not* create coequalizers of U-split pairs. Given a U-split pair with set-coequalizer $q\colon UY \to Q$, the lift is not unique. The final topology on Q (the quotient topology) does make q a coequalizer in **Top**, but every topology on Q coarser than the final one also makes q continuous, so the coequalizer cocone admits many lifts along U, only one of which is a coequalizer. Creation requires a *unique* lift, and uniqueness fails. This is the same multiplicity-of-topologies phenomenon that also breaks conservativity: U does not reflect isomorphisms, because a continuous bijection from a finer to a coarser topology has underlying map a set-isomorphism yet is not a homeomorphism, and a monadic functor is conservative. Both failures trace to one fact: many topologies sit over a single set, and U cannot tell them apart. The dividing line Beck's theorem draws is exactly the line between structure recorded by operations and structure, like a topology, that is not.

66

Kan Extensions

Given a functor $F\colon \mathbf{C} \to \mathbf{E}$ and a functor $K\colon \mathbf{C} \to \mathbf{D}$, a *Kan extension* extends F along K universally, in a left and a right variant. This is the last construction the book needs: limits, colimits, adjunctions, and the Yoneda lemma are all Kan extensions. This chapter defines the two Kan extensions as adjoints to restriction, computes them by a pointwise (co)limit formula, derives that slogan, and closes with the calculus of ends and coends and the density theorem, which writes every presheaf as a colimit of the representables the Yoneda embedding produced.

66.1 Left and Right Kan Extensions

A functor $F\colon \mathbf{C} \to \mathbf{E}$ records data indexed by the objects and morphisms of $\mathbf{C}$. Given a second functor $K\colon \mathbf{C} \to \mathbf{D}$, one may ask to transport that data along K: to produce a functor on $\mathbf{D}$ that agrees with F on the image of K, and does so in the best possible way. When K is an inclusion this is a genuine extension of F from a subcategory to the whole of $\mathbf{D}$; in general K need not be injective on objects, so the word "extension" is optimistic, but the universal formulation survives intact. Two such best approximations exist, one approximating F from the left and one from the right, and each is characterized by a universal property. This section defines them and shows that the two universal properties are precisely the two halves of a chain of adjunctions with restriction along K.

Throughout, fix $K\colon \mathbf{C} \to \mathbf{D}$. Restriction along K is the functor

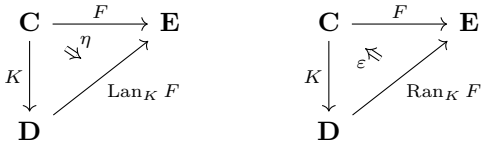
$$K^*\colon [\mathbf{D}, \mathbf{E}] \to [\mathbf{C}, \mathbf{E}], \qquad H \mapsto HK$$

sending a functor $H\colon \mathbf{D} \to \mathbf{E}$ to the composite $HK\colon \mathbf{C} \to \mathbf{E}$ and a natural transformation $\theta\colon H \Rightarrow H'$ to its whiskering θK (the natural transformation with component θ_{Kc} at c). Left and right Kan extension will turn out to be the two adjoints of K^*.

Definition 66.1.1: Left and Right Kan Extension

Let $K\colon \mathbf{C} \to \mathbf{D}$ and $F\colon \mathbf{C} \to \mathbf{E}$ be functors. A *left Kan extension* of F along K is a functor

$$\mathrm{Lan}_K F\colon \mathbf{D} \to \mathbf{E}$$



together with a natural transformation $\eta\colon F \Rightarrow (\mathrm{Lan}_K F)K$, the *unit*, that is universal from F to K^*: for every functor $G\colon \mathbf{D} \to \mathbf{E}$ and every natural transformation $\alpha\colon F \Rightarrow GK$, there is a unique natural transformation $\beta\colon \mathrm{Lan}_K F \Rightarrow G$ with

$$(\beta K) \circ \eta = \alpha$$

where βK is the whiskering of β by K.

Dually, a *right Kan extension* of F along K is a functor $\mathrm{Ran}_K F\colon \mathbf{D} \to \mathbf{E}$ with a natural transformation $\varepsilon\colon (\mathrm{Ran}_K F)K \Rightarrow F$, the *counit*, universal to F from K^*: for every $G\colon \mathbf{D} \to \mathbf{E}$ and every $\alpha\colon GK \Rightarrow F$, there is a unique $\beta\colon G \Rightarrow \mathrm{Ran}_K F$ with $\varepsilon \circ (\beta K) = \alpha$.

The two triangles record the same shape with the 2-cell pointing opposite ways. For the left Kan extension the unit fills the extension triangle

and the universal property says every competing pair (G, α) factors through $(\mathrm{Lan}_K F, \eta)$ by a unique 2-cell β. This is the defining shape of a universal arrow from F into the functor K^*, and universal objects are unique up to unique isomorphism. Applied here: if $(\mathrm{Lan}_K F, \eta)$ and (L', η') both left-Kan-extend F along K, the universal property of each produces a comparison, and the uniqueness clause forces the two comparisons to be mutually inverse. So the left Kan extension, when it exists, is determined up to a unique natural isomorphism compatible with the units; likewise the right Kan extension.

Existence, on the other hand, is not automatic: for a fixed K and F there may be no functor on $\mathbf{D}$ carrying a universal unit, and whether one exists depends on $\mathbf{E}$ having enough (co)limits. That question is settled in section 66.2, which constructs the extensions explicitly as (co)limits and pins down exactly when they exist. The present section treats the extensions where they do exist and extracts the structural consequence: the universal property of definition 66.1.1 is an adjunction.

Before the adjunction, one worked example, to see that "extension" is sometimes literal. It also isolates the mechanism, a coproduct that copies Fc once for each arrow $Kc \to d$, that section 66.2 will generalize into the pointwise formula.

Example 66.1.2: Extension Along a Coproduct Inclusion

Let $\mathbf{C}$ be the discrete category on one object $*$, so a functor $F\colon \mathbf{C} \to \mathbf{E}$ is the choice of a single object $e = F*$ of $\mathbf{E}$. Let $\mathbf{D}$ be the discrete category on a two-element set $\{0, 1\}$, and let $K\colon \mathbf{C} \to \mathbf{D}$ pick out the object 0. Assume $\mathbf{E}$ has an initial object and binary coproducts.

A functor $G\colon \mathbf{D} \to \mathbf{E}$ is a pair of objects $(G0, G1)$, and GK is the single object $G0$; a natural

transformation $F \Rightarrow GK$ is a single morphism $e \to G0$. The left Kan extension is

$$(\mathrm{Lan}_K F)(0) = e, \qquad (\mathrm{Lan}_K F)(1) = 0_{\mathbf{E}}$$

where $0_{\mathbf{E}}$ is the initial object, with unit $\eta\colon e \to e$ the identity. Given $\alpha\colon e \to G0$, the unique $\beta\colon \mathrm{Lan}_K F \Rightarrow G$ satisfying $(\beta K) \circ \eta = \alpha$ has component $\beta_0 = \alpha$ at 0, forced by the equation, and component $\beta_1\colon 0_{\mathbf{E}} \to G1$ the unique map out of the initial object. So the extension copies F where K lands and fills the rest with the initial object, the "empty" value that imposes no constraint. The right Kan extension is the mirror image: $(\mathrm{Ran}_K F)(0) = e$ and $(\mathrm{Ran}_K F)(1) = 1_{\mathbf{E}}$, the terminal object.

The mechanism sharpens when K is not injective. Take $\mathbf{C}$ discrete on $\{a, b\}$ and $\mathbf{D} = \mathbf{1}$ the terminal category, so K sends both objects to the single object $*$. A functor F is a pair (Fa, Fb) of objects of $\mathbf{E}$; a natural transformation $F \Rightarrow GK$ is a pair of maps $Fa \to G*$, $Fb \to G*$ into the one object $G*$. Such a pair is exactly a map out of the coproduct $Fa \sqcup Fb$, so

$$(\mathrm{Lan}_K F)(*) = Fa \sqcup Fb$$

with unit the two coprojections. This is the colimit of F, computed by hand. That a left Kan extension along the functor to $\mathbf{1}$ is a colimit is the first of the identifications developed in section 66.3.

The example shows the universal property doing local work; the following theorem shows it is global. Read across all F at once, the correspondence $\alpha \leftrightarrow \beta$ of definition 66.1.1 is exactly the defining bijection of an adjunction between Lan_K and K^*.

Theorem 66.1.3: Kan Extensions as Adjoints to Restriction

Fix $K\colon \mathbf{C} \to \mathbf{D}$ and a category $\mathbf{E}$. Suppose the left Kan extension $\mathrm{Lan}_K F$ exists for every $F\colon \mathbf{C} \to \mathbf{E}$. Then $F \mapsto \mathrm{Lan}_K F$ is the object part of a functor $\mathrm{Lan}_K\colon [\mathbf{C}, \mathbf{E}] \to [\mathbf{D}, \mathbf{E}]$ that is left adjoint to restriction,

$$\mathrm{Lan}_K \dashv K^*$$

Dually, if $\mathrm{Ran}_K F$ exists for every F, then Ran_K is right adjoint to K^*, so that

$$\mathrm{Lan}_K \dashv K^* \dashv \mathrm{Ran}_K$$

The unit η of definition 66.1.1 is the unit of the first adjunction, and the counit ε is the counit of the second.

***Proof*:**
The two claims are dual (box 61.3.3): a right Kan extension of F along K is a left Kan extension of F^{op} along K^{op} into $\mathbf{E}^{\mathrm{op}}$, and $\mathrm{Ran}_K \dashv$-ness for $\mathbf{E}$ is $\mathrm{Lan}_{K^{\mathrm{op}}} \dashv$-ness for $\mathbf{E}^{\mathrm{op}}$. We prove the left case; the right case follows by replacing every category by its opposite and reversing every 2-cell.

Step 1: the hom-set bijection. Fix $F\colon \mathbf{C} \to \mathbf{E}$ and let $(\mathrm{Lan}_K F, \eta_F)$ be its left Kan extension. For any $G\colon \mathbf{D} \to \mathbf{E}$, the universal property of definition 66.1.1 states that the assignment

$$[\mathbf{D}, \mathbf{E}](\mathrm{Lan}_K F, G) \longrightarrow [\mathbf{C}, \mathbf{E}](F, K^*G), \qquad \beta \longmapsto (\beta K) \circ \eta_F \tag{66.1}$$

is a bijection: existence of a unique β for each α on the right is exactly the statement that

this map is bijective, with inverse sending α to the induced β. Here $[\mathbf{D}, \mathbf{E}]$ and $[\mathbf{C}, \mathbf{E}]$ are the functor categories of definition 61.5.4 and the elements are natural transformations in the sense of definition 61.5.2.

Step 2: Lan_K is a functor. Given $\varphi\colon F \Rightarrow F'$ in $[\mathbf{C}, \mathbf{E}]$, define $\mathrm{Lan}_K \varphi\colon \mathrm{Lan}_K F \Rightarrow \mathrm{Lan}_K F'$ to be the unique natural transformation β obtained by applying the universal property of $(\mathrm{Lan}_K F, \eta_F)$ to the competitor

$$F \xRightarrow{\varphi} F' \xRightarrow{\eta_{F'}} (\mathrm{Lan}_K F')K$$

that is, $\mathrm{Lan}_K \varphi$ is the unique 2-cell with $((\mathrm{Lan}_K \varphi)\, K) \circ \eta_F = \eta_{F'} \circ \varphi$. Uniqueness in the universal property gives functoriality directly: for $\varphi = \mathrm{id}_F$ the transformation $\mathrm{id}_{\mathrm{Lan}_K F}$ satisfies the defining equation, so $\mathrm{Lan}_K \mathrm{id}_F = \mathrm{id}$; and for $F \xRightarrow{\varphi} F' \xRightarrow{\psi} F''$ both $\mathrm{Lan}_K(\psi \circ \varphi)$ and $(\mathrm{Lan}_K \psi) \circ (\mathrm{Lan}_K \varphi)$ solve the universal problem for $\eta_{F''} \circ \psi \circ \varphi$, hence coincide.

Step 3: naturality of the bijection. An adjunction is a bijection (66.1) natural in both variables (definition 64.1.1). Naturality in G: for $\gamma\colon G \Rightarrow G'$ in $[\mathbf{D}, \mathbf{E}]$ and $\beta\colon \mathrm{Lan}_K F \Rightarrow G$, post-composing then restricting gives $((\gamma \circ \beta)K) \circ \eta_F = (\gamma K) \circ (\beta K) \circ \eta_F$, since whiskering by K preserves vertical composition; this is exactly $K^*\gamma$ applied to the image of β, so the square commutes. Naturality in F: for $\varphi\colon F' \Rightarrow F$ and $\beta\colon \mathrm{Lan}_K F \Rightarrow G$, one must check

$$\big((\beta \circ \mathrm{Lan}_K \varphi)\, K\big) \circ \eta_{F'} = \big((\beta K) \circ \eta_F\big) \circ \varphi$$

The left side is $(\beta K) \circ \big((\mathrm{Lan}_K \varphi)\, K\big) \circ \eta_{F'}$, and by the defining equation of $\mathrm{Lan}_K \varphi$ from Step 2 the tail $\big((\mathrm{Lan}_K \varphi)\, K\big) \circ \eta_{F'}$ equals $\eta_F \circ \varphi$; substituting gives $(\beta K) \circ \eta_F \circ \varphi$, the right side. So (66.1) is natural in both variables, and $\mathrm{Lan}_K \dashv K^*$.

Step 4: the unit. Under the correspondence of definition 64.1.3, the unit of $\mathrm{Lan}_K \dashv K^*$ at F is the image of $\mathrm{id}_{\mathrm{Lan}_K F}$ under (66.1), namely $(\mathrm{id}\, K) \circ \eta_F = \eta_F$. So the unit of the adjunction is the unit η of definition 66.1.1, as claimed. Dualizing, the counit of $K^* \dashv \mathrm{Ran}_K$ is the counit ε, completing the proof.

The theorem reorganizes the definition rather than adding to it: the phrase "universal among functors restricting to something receiving F" is the phrase "left adjoint to restriction", once one reads the universal property as a natural hom-set bijection. This is the productive form of the definition. Adjoints are unique when they exist, which re-derives the uniqueness noted after definition 66.1.1; a right adjoint preserves limits (theorem 64.3.3) and, dually, a left adjoint preserves colimits, so Lan_K and Ran_K inherit exactness properties for free; and composites of Kan extensions along composable functors become composites of adjoints. The hypothesis, that the extension exist for *every* F, is what upgrades the object-level universal property into a functor and hence an adjunction. When only some F admit an extension there is no global adjoint, only the pointwise universal arrows of definition 66.1.1.

66.2 The Pointwise Formula

The adjoint characterization of theorem 66.1.3 shows that Kan extensions exist, but it does not say what they are: knowing that Lan_K is left adjoint to restriction gives no recipe for the value $(\mathrm{Lan}_K F)(d)$ at a particular object d of $\mathbf{D}$. This section gives the recipe. When the target category $\mathbf{E}$

has enough colimits, the left Kan extension is computed one object at a time as a colimit, and dually the right Kan extension as a limit. The indexing shape of that colimit is a comma category, so the formula reduces the abstract extension to a concrete diagram assembled out of the values of F.

Fix functors $K\colon \mathbf{C} \to \mathbf{D}$ and $F\colon \mathbf{C} \to \mathbf{E}$. For an object d of $\mathbf{D}$, the relevant indexing category is the comma category $(K \downarrow d)$ of definition 63.1.6: its objects are pairs (c, φ) with c an object of $\mathbf{C}$ and $\varphi\colon Kc \to d$ a morphism of $\mathbf{D}$, and a morphism $(c, \varphi) \to (c', \varphi')$ is a morphism $f\colon c \to c'$ of $\mathbf{C}$ with $\varphi' \circ Kf = \varphi$. Projecting to the first coordinate gives a functor

$$\Pi_d\colon (K \downarrow d) \to \mathbf{C}, \qquad (c, \varphi) \mapsto c, \quad f \mapsto f$$

and composing with F gives the diagram $F \circ \Pi_d\colon (K \downarrow d) \to \mathbf{E}$ whose colimit will be the value at d. The dual indexing category $(d \downarrow K)$ has objects $(c, \psi\colon d \to Kc)$ with the projection $\Pi^d\colon (d \downarrow K) \to \mathbf{C}$ defined the same way.

The colimit of $F \circ \Pi_d$ carries more structure than its value at a single d: as d varies it assembles into a functor, and that functor is the Kan extension. The next theorem proves this, and in doing so exhibits the universal 2-cell of definition 66.1.1 directly from the colimit injections.

Theorem 66.2.1: The Pointwise Formula for Kan Extensions

Let $K\colon \mathbf{C} \to \mathbf{D}$ and $F\colon \mathbf{C} \to \mathbf{E}$ be functors, and suppose that for every object d of $\mathbf{D}$ the colimit of $F \circ \Pi_d\colon (K \downarrow d) \to \mathbf{E}$ exists. Then the left Kan extension $\mathrm{Lan}_K F$ exists and is computed pointwise by

$$(\mathrm{Lan}_K F)(d) \cong \mathrm{colim}_{(K \downarrow d)}\, F \circ \Pi_d$$

Dually, if for every d the limit of $F \circ \Pi^d\colon (d \downarrow K) \to \mathbf{E}$ exists, then the right Kan extension $\mathrm{Ran}_K F$ exists and is computed pointwise by

$$(\mathrm{Ran}_K F)(d) \cong \lim_{(d \downarrow K)} F \circ \Pi^d$$

***Proof*:**

The right Kan extension case follows from the left by duality (box 61.3.3), so the proof concentrates on $\mathrm{Lan}_K F$. The argument has four steps: define the object function on $\mathbf{D}$, extend it to a functor $L\colon \mathbf{D} \to \mathbf{E}$, build a natural transformation $\eta\colon F \Rightarrow L \circ K$, and verify that (L, η) satisfies the universal property of the left Kan extension.

Step 1: The value at each object. For each object d of $\mathbf{D}$, write

$$Ld = \mathrm{colim}_{(K \downarrow d)}\, F \circ \Pi_d$$

which exists by hypothesis. The colimit comes with injection morphisms

$$\iota^d_{(c,\varphi)}\colon Fc \to Ld$$

one for each object (c, φ) of $(K \downarrow d)$, and these form a cocone: for a morphism $f\colon (c, \varphi) \to (c', \varphi')$ in $(K \downarrow d)$ one has $\iota^d_{(c',\varphi')} \circ Ff = \iota^d_{(c,\varphi)}$. The colimit is universal among such cocones: a family of morphisms $\lambda_{(c,\varphi)}\colon Fc \to X$ compatible with all the Ff factors uniquely through a single morphism $Ld \to X$.

Step 2: Functoriality in d. A morphism $g\colon d \to d'$ in $\mathbf{D}$ induces a functor

$$g_*\colon (K \downarrow d) \to (K \downarrow d'), \qquad (c, \varphi) \mapsto (c, g \circ \varphi)$$

which acts as the identity on the underlying morphisms of $\mathbf{C}$, so that $\Pi_{d'} \circ g_* = \Pi_d$ and hence $F \circ \Pi_{d'} \circ g_* = F \circ \Pi_d$. The injections for d' therefore restrict along g_* to a cocone on $F \circ \Pi_d$ with vertex Ld', whose leg at (c, φ) is $\iota^{d'}_{(c, g\circ\varphi)} \colon Fc \to Ld'$. By the universal property of Ld this cocone factors through a unique morphism

$$Lg \colon Ld \to Ld'$$

characterized by $Lg \circ \iota^{d}_{(c,\varphi)} = \iota^{d'}_{(c,g\circ\varphi)}$ for every (c, φ). Functoriality is now a uniqueness argument: both $L(\mathrm{id}_d)$ and id_{Ld} satisfy the defining equation for $g = \mathrm{id}_d$, so they agree, and for composable $g \colon d \to d'$, $h \colon d' \to d''$ both $L(h \circ g)$ and $Lh \circ Lg$ send $\iota^{d}_{(c,\varphi)}$ to $\iota^{d''}_{(c,(h\circ g)\circ\varphi)}$, so they agree by the uniqueness clause of the universal property. Thus $L \colon \mathbf{D} \to \mathbf{E}$ is a functor.

Step 3: The universal 2-cell. An object c of $\mathbf{C}$ gives a canonical object (c, id_{Kc}) of $(K \downarrow Kc)$, and the injection there defines a morphism

$$\eta_c = \iota^{Kc}_{(c,\mathrm{id}_{Kc})} \colon Fc \longrightarrow L(Kc)$$

To see that $\eta \colon F \Rightarrow L \circ K$ is natural, let $f \colon c \to c'$ be a morphism of $\mathbf{C}$. The map f is a morphism $(c, Kf) \to (c', \mathrm{id}_{Kc'})$ in $(K \downarrow Kc')$, since $\mathrm{id}_{Kc'} \circ Kf = Kf$, so the cocone condition for $L(Kc')$ gives

$$\iota^{Kc'}_{(c',\mathrm{id}_{Kc'})} \circ Ff = \iota^{Kc'}_{(c,Kf)}$$

On the other hand $Kf \colon Kc \to Kc'$ acts by Step 2 with $(Kf)_*(c, \mathrm{id}_{Kc}) = (c, Kf)$, so

$$L(Kf) \circ \eta_c = L(Kf) \circ \iota^{Kc}_{(c,\mathrm{id}_{Kc})} = \iota^{Kc'}_{(c,Kf)}$$

Comparing the two displays, $L(Kf) \circ \eta_c = \eta_{c'} \circ Ff$, which is exactly the naturality square for η.

Step 4: The universal property. It remains to show that (L, η) is initial among pairs (G, γ) consisting of a functor $G \colon \mathbf{D} \to \mathbf{E}$ and a natural transformation $\gamma \colon F \Rightarrow G \circ K$; this is the universal property of definition 66.1.1. Given such a pair, a natural transformation $\alpha \colon L \Rightarrow G$ satisfies $(\alpha K) \circ \eta = \gamma$ if and only if, for every c,

$$\alpha_{Kc} \circ \eta_c = \gamma_c$$

The claim is that there is exactly one such α. Fix an object d of $\mathbf{D}$. For each object (c, φ) of $(K \downarrow d)$ the morphism $\varphi \colon Kc \to d$ gives, by naturality of the candidate α against φ and the required equation at c, the composite

$$Gd \xleftarrow{G\varphi} G(Kc) \xleftarrow{\gamma_c} Fc$$

and the family $\{G\varphi \circ \gamma_c\}_{(c,\varphi)}$ is a cocone on $F \circ \Pi_d$ with vertex Gd: for a morphism $f \colon (c, \varphi) \to (c', \varphi')$ one has $\varphi' \circ Kf = \varphi$, so naturality of γ gives

$$(G\varphi' \circ \gamma_{c'}) \circ Ff = G\varphi' \circ G(Kf) \circ \gamma_c = G(\varphi' \circ Kf) \circ \gamma_c = G\varphi \circ \gamma_c$$

which is the cocone compatibility condition. By the universal property of the colimit Ld there is a unique morphism

$$\alpha_d \colon Ld \to Gd, \qquad \alpha_d \circ \iota^{d}_{(c,\varphi)} = G\varphi \circ \gamma_c$$

Taking $d = Kc$ and $(c, \varphi) = (c, \mathrm{id}_{Kc})$ recovers $\alpha_{Kc} \circ \eta_c = G(\mathrm{id}_{Kc}) \circ \gamma_c = \gamma_c$, so any α with components so defined satisfies the required equation; and conversely, for any such α, naturality against φ and the equation at c force

$$\alpha_d \circ \iota^{d}_{(c,\varphi)} = \alpha_d \circ L\varphi \circ \iota^{Kc}_{(c,\mathrm{id}_{Kc})} = G\varphi \circ \alpha_{Kc} \circ \iota^{Kc}_{(c,\mathrm{id}_{Kc})} = G\varphi \circ \gamma_c$$

which is exactly the defining equation, so α_d is the only possibility. Naturality of α against a morphism $g\colon d \to d'$ is checked on injections: using the defining equations for $\alpha_{d'}$, Lg, and α_d,

$$\alpha_{d'} \circ Lg \circ \iota^{d}_{(c,\varphi)} = \alpha_{d'} \circ \iota^{d'}_{(c,g\circ\varphi)} = G(g \circ \varphi) \circ \gamma_c = Gg \circ G\varphi \circ \gamma_c = Gg \circ \alpha_d \circ \iota^{d}_{(c,\varphi)}$$

Since the $\iota^{d}_{(c,\varphi)}$ are jointly epic (a colimit cocone is), $\alpha_{d'} \circ Lg = Gg \circ \alpha_d$, so α is natural. This exhibits (L, η) as initial in the category of pairs (G, γ), hence as the left Kan extension $\mathrm{Lan}_K F$ with universal 2-cell η, completing the proof.

The comma-category colimit deserves a plain reading. An object (c, φ) of $(K \downarrow d)$ is a way of mapping the image Kc into d; the value $(\mathrm{Lan}_K F)(d)$ glues together all the values Fc over all such approaches to d, identifying Fc with Fc' whenever a morphism of $\mathbf{C}$ carries one approach to another. The extension therefore builds the value at d out of "everything $\mathbf{C}$ knows about d through K", and does so in the most efficient way, which is what a colimit is. When K is the inclusion of a full subcategory and $\varphi = \mathrm{id}$ is available (that is, when $d = Kc$ lies in the image of K), the object (c, id_{Kc}) is terminal in $(K \downarrow d)$, the colimit collapses to Fc, and the extension extends F; the general formula measures how far the Kan extension must interpolate when no such terminal approach exists.

The hypothesis of theorem 66.2.1 is the existence of colimits indexed by the categories $(K \downarrow d)$. When $\mathbf{C}$ is small these indexing categories are small, so a cocomplete target guarantees every required colimit at once.

Corollary 66.2.2: Existence of Kan Extensions

Let $K\colon \mathbf{C} \to \mathbf{D}$ be a functor with $\mathbf{C}$ small. If $\mathbf{E}$ is cocomplete, then $\mathrm{Lan}_K F$ exists for every functor $F\colon \mathbf{C} \to \mathbf{E}$; if $\mathbf{E}$ is complete, then $\mathrm{Ran}_K F$ exists for every F. In either case the extension along K is defined for all functors simultaneously, so restriction $K^*\colon [\mathbf{D}, \mathbf{E}] \to [\mathbf{C}, \mathbf{E}]$ acquires the adjoints $\mathrm{Lan}_K \dashv K^* \dashv \mathrm{Ran}_K$ of theorem 66.1.3.

***Proof*:**
For each object d of $\mathbf{D}$ the comma category $(K \downarrow d)$ is small: its objects are pairs (c, φ) with c ranging over the small object collection of $\mathbf{C}$ and φ over the set $\mathbf{D}(Kc, d)$ (a set since $\mathbf{D}$ is locally small, as throughout), and its morphisms form a set for the same reason. A cocomplete category has a colimit for every functor out of a small category (definition 63.4.1), so $F \circ \Pi_d$ has a colimit for every d, and theorem 66.2.1 produces $\mathrm{Lan}_K F$. Since this holds for every F, restriction has a left adjoint on all of $[\mathbf{C}, \mathbf{E}]$, which is the content of the left half of theorem 66.1.3. The complete case is dual (box 61.3.3): $(d \downarrow K)$ is small by the same count, a complete $\mathbf{E}$ gives the limits, and restriction gains its right adjoint Ran_K, completing the proof.

Most target categories met so far are cocomplete and complete: $\mathbf{Set}$, $\mathbf{Grp}$, $\mathbf{Ab}$, $\mathbf{Ring}$, $\mathbf{Mod}_R$, and $\mathbf{Top}$ all have all small limits and colimits, so along any functor out of a small category the Kan extensions into these categories always exist. The pointwise formula is thus not an existence caveat in practice but a computation: it turns the question "what is $\mathrm{Lan}_K F$" into the question "what is this colimit", which the concrete structure of $\mathbf{E}$ answers. The following example runs that computation to the end.

Example 66.2.3: Left Kan Extension along an Inclusion of Ordinals

Let $\mathbf{C}$ be the two-object discrete category $\{0, 1\}$ (no morphisms beyond identities), let $\mathbf{D}$ be the poset $\{0 < 1 < 2\}$ regarded as a category, and let $K\colon \mathbf{C} \to \mathbf{D}$ send $0 \mapsto 0$ and $1 \mapsto 1$. Take $\mathbf{E} = \mathbf{Set}$ and let $F\colon \mathbf{C} \to \mathbf{Set}$ pick out two sets, $F0 = A$ and $F1 = B$. Since $\mathbf{C}$ is small and $\mathbf{Set}$ is cocomplete, corollary 66.2.2 guarantees $\mathrm{Lan}_K F$ exists, and theorem 66.2.1 computes it object by object.

Compute each comma category $(K \downarrow d)$. Its objects are pairs $(c, \varphi\colon Kc \to d)$, and in a poset there is at most one morphism between any two objects, so φ exists precisely when $Kc \leq d$.

- For $d = 0$: the only c with $Kc \leq 0$ is $c = 0$ (since $K0 = 0 \leq 0$ but $K1 = 1 \not\leq 0$), and φ is the unique arrow $0 \leq 0$. So $(K \downarrow 0)$ has a single object $(0, \varphi)$, and the colimit of $F \circ \Pi_0$ is just $F0 = A$.
- For $d = 1$: both $K0 = 0 \leq 1$ and $K1 = 1 \leq 1$, giving two objects $(0, \varphi_0)$ and $(1, \varphi_1)$. There are no morphisms between them ($\mathbf{C}$ is discrete), so $(K \downarrow 1)$ is the discrete two-object category and the colimit is the coproduct $F0 \coprod F1 = A \coprod B$, the disjoint union.
- For $d = 2$: again both $K0 = 0 \leq 2$ and $K1 = 1 \leq 2$, so $(K \downarrow 2)$ is discrete on two objects and the colimit is $A \coprod B$.

The value function is therefore $(\mathrm{Lan}_K F)(0) = A$ and $(\mathrm{Lan}_K F)(1) = (\mathrm{Lan}_K F)(2) = A \coprod B$. The functor structure is read off Step 2 of the proof of theorem 66.2.1: the morphism $0 \leq 1$ of $\mathbf{D}$ induces the coprojection $A \hookrightarrow A \coprod B$ into the first summand, while the morphism $h\colon 1 \leq 2$ induces the identity $A \coprod B \to A \coprod B$, since the functor $h_*\colon (K \downarrow 1) \to (K \downarrow 2)$ sends $(c, \varphi) \mapsto (c, h \circ \varphi)$, matching the two objects of each comma category by their $\mathbf{C}$-component, so the induced map on colimits carries each coprojection to itself. The unit $\eta\colon F \Rightarrow (\mathrm{Lan}_K F) \circ K$ is read off the colimit injections at the identity approaches $(0, \mathrm{id})$ and $(1, \mathrm{id})$: $\eta_0\colon A \to (\mathrm{Lan}_K F)(0) = A$ is the identity, an isomorphism, while $\eta_1\colon B \to (\mathrm{Lan}_K F)(1) = A \coprod B$ is the coprojection into the second summand, which is monic but not an isomorphism unless $A = \emptyset$; there $\eta_1\colon B \to \emptyset \coprod B$ is itself an isomorphism. So η is not invertible. This is consistent with the general principle that runs in one direction: when K is fully faithful the pointwise unit η is a natural isomorphism, so F is recovered on the nose. Here K is not full, since $\mathbf{C}(0, 1) = \emptyset$ while $\mathbf{D}(K0, K1) = \{0 \leq 1\}$ is nonempty, and the direct computation shows η fails to be invertible. The converse fails in general: fullness is sufficient but not necessary for η to be an isomorphism, as the case $A = \emptyset$ of this same example shows, where η is a natural isomorphism while K remains non-full. The extension therefore fails to restrict back to F on the nose.

The picture matches the interpretive reading above. At objects in the image of K (namely 0 and 1) the extension records the data F prescribes, assembled by coproduct where K maps two objects below the same d; at the new object 2, which lies above both 0 and 1 but is not in the image of K, the extension is forced by the colimit to be the coproduct $A \coprod B$, the freest set receiving compatible maps from A and B. A left Kan extension fills in unseen values as freely as the diagram permits, which is the precise sense in which it is the left, rather than the right, adjoint to restriction.

66.3 All Concepts are Kan Extensions

The machinery of the previous two sections was built for one payoff: to show that the central constructions of this book are Kan extensions in disguise. Limits and colimits, adjoints, and the Yoneda lemma each reappear here as an instance of Lan or Ran, computed by the universal property of definition 66.1.1 or the pointwise formula of theorem 66.2.1. The identifications are short, so the section is a sequence of corollaries rather than a development of new theory.

The first identification is the cleanest. A functor $F\colon \mathbf{J} \to \mathbf{E}$ out of a small category has a colimit exactly when a certain Kan extension exists, and the two objects agree. The trick is to extend F not along an inclusion but along the collapse $\mathbf{J} \to \mathbf{1}$ to the terminal category, the category with one object $*$ and only its identity arrow.

Proposition 66.3.1: Limits and Colimits as Kan Extensions

Let $\mathbf{J}$ be a small category and $!\colon \mathbf{J} \to \mathbf{1}$ the unique functor to the terminal category. For $F\colon \mathbf{J} \to \mathbf{E}$:

1. the colimit of F exists if and only if $\mathrm{Lan}_! F$ exists, and then $(\mathrm{Lan}_! F)(*) \cong \operatorname{colim} F$;
2. the limit of F exists if and only if $\mathrm{Ran}_! F$ exists, and then $(\mathrm{Ran}_! F)(*) \cong \lim F$.

***Proof*:**
We prove (1); part (2) follows by the duality principle (box 61.3.3), reading the statement in $\mathbf{E}^{\mathrm{op}}$.

A functor $\mathbf{1} \to \mathbf{E}$ is the same datum as an object of $\mathbf{E}$: it picks out the image $G(*)$ of the unique object, and its action on the sole arrow is forced to be id. Write $e = G(*)$. Precomposition with $!$ sends such a functor to the constant functor $\Delta e\colon \mathbf{J} \to \mathbf{E}$ at e, since every object of $\mathbf{J}$ maps to $*$ and thence to e, and every arrow to id_e. A natural transformation $F \Rightarrow (\Delta e)$ assigns to each object j of $\mathbf{J}$ a map $\lambda_j\colon Fj \to e$, naturally in j: for every arrow $u\colon j \to j'$ the square

$$\begin{array}{ccc} Fj & \xrightarrow{Fu} & Fj' \\ & {\scriptstyle\lambda_j}\searrow & \downarrow{\scriptstyle\lambda_{j'}} \\ & & e \end{array}$$

commutes, that is, $\lambda_{j'} \circ Fu = \lambda_j$. This is precisely the data of a cocone under F with summit e (definition 63.3.1). So a natural transformation $F \Rightarrow (\Delta e) = G \circ !$ is the same thing as a cocone under F with summit e.

Now unwind definition 66.1.1. The left Kan extension $\mathrm{Lan}_! F$ is a functor $\mathbf{1} \to \mathbf{E}$, hence an object $L = (\mathrm{Lan}_! F)(*)$, equipped with a universal natural transformation $\eta\colon F \Rightarrow (\mathrm{Lan}_! F) \circ ! = \Delta L$. By the previous paragraph η is a cocone under F with summit L. Universality of η says: every natural transformation $F \Rightarrow G \circ !$, equivalently every cocone (λ_j) under F with some summit e, factors uniquely as η followed by a natural transformation $(\mathrm{Lan}_! F) \Rightarrow G$; the latter is a single map $L \to e$ in $\mathbf{E}$. Uniqueness of the factoring map is exactly the statement that (L, η) is initial among cocones under F, which is the universal property of the colimit (definition 63.3.1, definition 63.1.1). Hence $L \cong \operatorname{colim} F$, and the objects exist together, completing the proof.

This is the pointwise formula (theorem 66.2.1) at the single object $*$. The comma category $(! \downarrow *)$ has an object of $\mathbf{J}$ for each way of mapping $!\,j = *$ to $*$ in $\mathbf{1}$, of which there is exactly one, so $(! \downarrow *) \cong \mathbf{J}$ and the projection to $\mathbf{J}$ is the identity; the colimit formula $(\mathrm{Lan}_! F)(*) \cong \mathrm{colim}_{(!\downarrow *)} F\pi$ collapses to $\mathrm{colim}_{\mathbf{J}} F$. The proposition says a (co)limit is the universal way to compress a diagram to a single object, and Kan extension along $\mathbf{J} \to \mathbf{1}$ is the universal compression. Every general Kan extension is then, by the pointwise formula, a (co)limit computed one object of the target at a time.

The second identification places adjunctions inside the same frame. An adjoint is determined by a universal property, and a universal property is what a Kan extension records; the content of the next result is that a right adjoint is literally the Kan extension of the identity along its left adjoint.

Proposition 66.3.2: Adjoints as Kan Extensions

Let $F\colon \mathbf{C} \to \mathbf{D}$ be left adjoint to $G\colon \mathbf{D} \to \mathbf{C}$, with unit $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow G \circ F$ and counit $\varepsilon\colon F \circ G \Rightarrow \mathrm{id}_{\mathbf{D}}$. Then G is the left Kan extension of $\mathrm{id}_{\mathbf{C}}$ along F,

$$G \cong \mathrm{Lan}_F \mathrm{id}_{\mathbf{C}}$$

with the unit $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow G \circ F$ serving as the universal cell. Dually, F is the right Kan extension of $\mathrm{id}_{\mathbf{D}}$ along G, $F \cong \mathrm{Ran}_G \mathrm{id}_{\mathbf{D}}$, with the counit as its universal cell.

***Proof*:**

We prove the first statement; the second is its dual under box 61.3.3, read in the opposite categories, exchanging the left and right adjoints. By definition 66.1.1, exhibiting G as $\mathrm{Lan}_F \mathrm{id}_{\mathbf{C}}$ means producing a natural transformation $u\colon \mathrm{id}_{\mathbf{C}} \Rightarrow G \circ F$ such that for every functor $H\colon \mathbf{D} \to \mathbf{C}$ the map

$$\Phi_H\colon [\mathbf{D}, \mathbf{C}](G, H) \longrightarrow [\mathbf{C}, \mathbf{C}](\mathrm{id}_{\mathbf{C}}, H \circ F), \qquad \theta \longmapsto (\theta F) \circ u$$

is a bijection natural in H, where $(\theta F) \circ u$ has components $\theta_{Fc} \circ u_c\colon c \to GFc \to HFc$. We take $u = \eta$, the unit, and produce an inverse to Φ_H from the adjunction $F \dashv G$ (definition 64.1.1).

Step 1: the inverse. Given $\beta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow H \circ F$ with components $\beta_c\colon c \to HFc$, define

$$\Psi_H(\beta)_d \;=\; H\varepsilon_d \circ \beta_{Gd}\colon\; Gd \xrightarrow{\beta_{Gd}} HFGd \xrightarrow{H\varepsilon_d} Hd$$

for each object d of $\mathbf{D}$, using the counit $\varepsilon_d\colon FGd \to d$. Naturality of β and of ε makes $\Psi_H(\beta)\colon G \Rightarrow H$ a natural transformation: for $g\colon d \to d'$ the square for $\Psi_H(\beta)$ commutes because β is natural at Gg and ε is natural at g. This defines a map Ψ_H in the reverse direction.

Step 2: Ψ_H inverts Φ_H. Take $\theta\colon G \Rightarrow H$ and compute $\Psi_H(\Phi_H(\theta))$. Its component at d is

$$H\varepsilon_d \circ (\Phi_H \theta)_{Gd} \;=\; H\varepsilon_d \circ \theta_{FGd} \circ \eta_{Gd}$$

Naturality of θ at $\varepsilon_d\colon FGd \to d$ gives $H\varepsilon_d \circ \theta_{FGd} = \theta_d \circ G\varepsilon_d$, so the component equals $\theta_d \circ G\varepsilon_d \circ \eta_{Gd}$. The triangle identity $G\varepsilon_d \circ \eta_{Gd} = \mathrm{id}_{Gd}$ (definition 64.1.3) collapses this to θ_d. Hence $\Psi_H \circ \Phi_H = \mathrm{id}$.

Conversely take $\beta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow HF$ and compute $\Phi_H(\Psi_H(\beta))$. Its component at c is

$$(\Psi_H \beta)_{Fc} \circ \eta_c \;=\; H\varepsilon_{Fc} \circ \beta_{GFc} \circ \eta_c$$

Naturality of β at $\eta_c\colon c \to GFc$ gives $\beta_{GFc} \circ \eta_c = HF\eta_c \circ \beta_c$, so the component equals $H\varepsilon_{Fc} \circ HF\eta_c \circ \beta_c = H(\varepsilon_{Fc} \circ F\eta_c) \circ \beta_c$. The other triangle identity $\varepsilon_{Fc} \circ F\eta_c = \mathrm{id}_{Fc}$ (definition 64.1.3) collapses this to β_c. Hence $\Phi_H \circ \Psi_H = \mathrm{id}$.

So Φ_H is a bijection, and it is natural in H because it is given by postcomposition with the fixed cell η. By definition 66.1.1 this exhibits (G, η) as the left Kan extension $\mathrm{Lan}_F \mathrm{id}_{\mathbf{C}}$, completing the proof.

An adjoint is a Kan extension. The unit $\eta\colon \mathrm{id}_{\mathbf{C}} \Rightarrow GF$, which one meets first as the insertion of generators of the free construction, is exactly the universal cell exhibiting the right adjoint G as $\mathrm{Lan}_F \mathrm{id}_{\mathbf{C}}$; the right Kan extension $\mathrm{Ran}_G \mathrm{id}_{\mathbf{D}} \cong F$ recovers the left adjoint dually, with the counit as its universal cell. The converse holds only under an extra hypothesis: if $\mathrm{Lan}_F \mathrm{id}_{\mathbf{C}}$ exists and is *preserved* by F, it is right adjoint to F; without the preservation clause a Kan extension of the identity need not arise from an adjunction.

The last identification returns to the Yoneda lemma. The Yoneda embedding $\mathbf{y}\colon \mathbf{C} \to \mathbf{PSh}(\mathbf{C})$ (definition 62.3.1) is fully faithful (theorem 62.2.1), so restricting a functor along $\mathbf{y}$ loses nothing that the functor does on representables. The precise statement is that a functor out of the presheaf category which respects colimits is recovered as the left Kan extension of its restriction to representables.

Proposition 66.3.3: Yoneda via Kan Extension

Let $\mathbf{C}$ be small and $L\colon \mathbf{PSh}(\mathbf{C}) \to \mathbf{E}$ a colimit-preserving functor into a cocomplete category. Then L is the left Kan extension along $\mathbf{y}$ of its restriction to representables:

$$L \cong \mathrm{Lan}_{\mathbf{y}}(L \circ \mathbf{y})$$

In particular L is determined up to canonical isomorphism by the composite $L \circ \mathbf{y}\colon \mathbf{C} \to \mathbf{E}$.

***Proof*:**
Every presheaf is canonically a colimit of representables: for $P \in \mathbf{PSh}(\mathbf{C})$ there is a natural isomorphism $P \cong \mathrm{colim}_{(\mathbf{y}\downarrow P)} \mathbf{y}\pi$, the colimit of the representables mapping into P. This is the density theorem, proved in the next section; grant it here. Because L preserves colimits,

$$L(P) \cong L\big(\mathrm{colim}_{(\mathbf{y}\downarrow P)} \mathbf{y}\pi\big) \cong \mathrm{colim}_{(\mathbf{y}\downarrow P)} (L \circ \mathbf{y})\pi$$

The right-hand side is the pointwise colimit formula (theorem 66.2.1) for the left Kan extension of $L \circ \mathbf{y}$ along $\mathbf{y}$, evaluated at P. Hence $L(P) \cong (\mathrm{Lan}_{\mathbf{y}}(L \circ \mathbf{y}))(P)$, naturally in P, so $L \cong \mathrm{Lan}_{\mathbf{y}}(L \circ \mathbf{y})$. The composite $L \circ \mathbf{y}$ therefore determines L, as we sought to show.

The presheaf category is the free cocompletion of $\mathbf{C}$: a colimit-preserving functor out of $\mathbf{PSh}(\mathbf{C})$ is no more and no less than an arbitrary functor out of $\mathbf{C}$, extended by the universal formula. This is the sense in which the Yoneda lemma is a Kan extension. The density theorem that gives the canonical presentation $P \cong \mathrm{colim}\, \mathbf{y}\pi$ is the subject of the next section, where the co-Yoneda identity $P \cong \int^{c} Pc \cdot \mathbf{y}(c)$ makes the same statement in the language of coends.

66.4 Ends, Coends, and Density

The pointwise formula (theorem 66.2.1) writes a Kan extension as a colimit over a comma category. That comma-category colimit has a more compact description once one has a piece of notation for integrating a functor of two variables that is contravariant in one and covariant in the other. This section develops that notation, the calculus of ends and coends, and applies it to presheaves. The

results are the *density* theorem, which recovers every presheaf as a colimit of representables, and a one-line coend formula for the left Kan extension.

A functor $T\colon \mathbf{C}^{\mathrm{op}} \times \mathbf{C} \to \mathbf{E}$ pairs each object c with itself along the diagonal, giving objects $T(c,c)$, but a morphism $f\colon c \to c'$ acts on T in two clashing directions: covariantly in the second slot, $T(c,f)\colon T(c,c) \to T(c,c')$, and contravariantly in the first, $T(f,c')\colon T(c',c') \to T(c,c')$. A single object of $\mathbf{E}$ that sees all the $T(c,c)$ at once must reconcile these two actions. The device that does so is a wedge.

Definition 66.4.1: End and Coend

Let $T\colon \mathbf{C}^{\mathrm{op}} \times \mathbf{C} \to \mathbf{E}$ be a functor, with $\mathbf{C}$ small. A *wedge* from an object $e \in \mathbf{E}$ to T is a family of morphisms $w_c\colon e \to T(c,c)$, one for each object c, that is *dinatural*: for every morphism $f\colon c \to c'$ the square

$$\begin{array}{ccc} e & \xrightarrow{w_{c'}} & T(c',c') \\ {\scriptstyle w_c}\downarrow & & \downarrow{\scriptstyle T(f,c')} \\ T(c,c) & \xrightarrow[T(c,f)]{} & T(c,c') \end{array}$$

commutes, that is $T(c,f) \circ w_c = T(f,c') \circ w_{c'}$. The *end* of T, written $\int_c T(c,c)$, is a universal wedge: an object $\int_c T(c,c)$ with a wedge $\pi_c\colon \int_c T(c,c) \to T(c,c)$ such that every wedge $w_c\colon e \to T(c,c)$ factors as $w_c = \pi_c \circ u$ through a unique $u\colon e \to \int_c T(c,c)$.

Dually, a *cowedge* from T to an object e is a dinatural family $\iota_c\colon T(c,c) \to e$, meaning $\iota_c \circ T(f,c) = \iota_{c'} \circ T(c',f)$ for every $f\colon c \to c'$. The *coend* of T, written $\int^c T(c,c)$, is a universal cowedge: an object $\int^c T(c,c)$ with a cowedge $\iota_c\colon T(c,c) \to \int^c T(c,c)$ through which every cowedge factors uniquely.

The universal property is the abstract characterization; the computational handle is a (co)equalizer. A wedge $w_c\colon e \to T(c,c)$ is exactly a map $e \to \prod_c T(c,c)$ whose two composites into $\prod_{f\colon c\to c'} T(c,c')$ agree, one composite applying $T(c,f)$ in the codomain and the other $T(f,c')$. The end is therefore the equalizer

$$\int_c T(c,c) \longrightarrow \prod_c T(c,c) \rightrightarrows \prod_{f\colon c\to c'} T(c,c') \tag{66.2}$$

of these two maps (definition 63.2.4), so an end exists whenever $\mathbf{E}$ has the products indexed by the objects and the morphisms of $\mathbf{C}$ together with equalizers. Dualizing every arrow, the coend is the coequalizer

$$\coprod_{f\colon c\to c'} T(c',c) \rightrightarrows \coprod_c T(c,c) \longrightarrow \int^c T(c,c) \tag{66.3}$$

of the two maps sending the f-summand $T(c',c)$ into $T(c,c)$ by $T(f,c)$ and into $T(c',c')$ by $T(c',f)$ (definition 63.3.5). A coend is thus $\coprod_c T(c,c)$ with the two ways of moving along a morphism identified. This is the description used in every computation below.

Two pieces of notation package the copies of an object indexed by a set. For a set S and an object $e \in \mathbf{E}$, the *copower* $S \cdot e$ is the S-indexed coproduct $\coprod_S e$, and the *power* e^S is the S-indexed product $\prod_S e$. When $\mathbf{E} = \mathbf{Set}$ the copower $S \cdot e = S \times e$ and the power e^S is the set of functions $S \to e$.

These appear the moment a coend involves a hom-set: a coend $\int^c \mathbf{C}(c', c) \cdot Fc$ has each summand $\mathbf{C}(c', c) \cdot Fc$ a copower of Fc by a hom-set.

The end over a Hom-valued functor is the object that justifies the notation: it is the set of natural transformations.

Example 66.4.2: Natural Transformations as an End

Let $F, G \colon \mathbf{C} \to \mathbf{Set}$ be functors on a small category $\mathbf{C}$. The assignment $(c', c) \mapsto \mathbf{Set}(Fc', Gc)$ is a functor $\mathbf{C}^{\mathrm{op}} \times \mathbf{C} \to \mathbf{Set}$, contravariant in c' (precompose with Ff) and covariant in c (postcompose with Gf). A wedge from a one-point set to this functor is a choice, for each c, of an element $\alpha_c \in \mathbf{Set}(Fc, Gc)$, that is a map $\alpha_c \colon Fc \to Gc$; dinaturality at $f \colon c \to c'$ reads

$$Gf \circ \alpha_c = \alpha_{c'} \circ Ff$$

which is exactly the naturality square of α. By (66.2) the end is the equalizer of

$$\prod_c \mathbf{Set}(Fc, Gc) \rightrightarrows \prod_{f \colon c \to c'} \mathbf{Set}(Fc, Gc')$$

whose elements are the families (α_c) satisfying every naturality square, so

$$\int_c \mathbf{Set}(Fc, Gc) \;\cong\; \mathrm{Nat}(F, G)$$

The set of natural transformations is an end. This is the identity that makes the Yoneda lemma, and the density theorem below, coend computations rather than ad hoc arguments.

The dual computation is a coend that identifies elements rather than selecting them. For a functor $M \colon \mathbf{C}^{\mathrm{op}} \to \mathbf{Set}$ and a functor $N \colon \mathbf{C} \to \mathbf{Set}$ on a small category $\mathbf{C}$, the coend $\int^c Mc \times Nc$ is the set of pairs $(x \in Mc,\, y \in Nc)$ modulo the relation identifying $(x \cdot f, y)$ with $(x, f \cdot y)$ for $f \colon c \to c'$ and $x \in Mc'$, by (66.3) with $T(c', c) = Mc' \times Nc$. This is the tensor product of the two functors over $\mathbf{C}$: the same coequalizer shape, taken over a one-object category enriched in abelian groups (a ring R) with $\otimes$ in place of $\times$, produces the module tensor product $M \otimes_R N$ by identifying (xf, y) with (x, fy). The coend is the categorical tensor product, which is why the copower notation borrows the multiplicative sign.

That tensor reading underlies the density theorem. Every presheaf decomposes as a coend of representables, and the coend is a colimit, so every presheaf is a colimit of representables: a presheaf is assembled from the representables $\mathbf{y}(c) = \mathbf{C}(-, c)$ by gluing along $\mathbf{C}$'s own morphisms.

Theorem 66.4.3: Density (Co-Yoneda)

Let $\mathbf{C}$ be small and $F \colon \mathbf{C}^{\mathrm{op}} \to \mathbf{Set}$ a presheaf (definition 62.1.3). Then there is a canonical isomorphism

$$F \;\cong\; \int^c Fc \cdot \mathbf{y}(c) \tag{66.4}$$

in $\mathbf{PSh}(\mathbf{C})$, where $\mathbf{y}(c) = \mathbf{C}(-, c)$ is the representable presheaf (definition 62.1.1) under the Yoneda embedding $\mathbf{y}$ (definition 62.3.1) and $Fc \cdot \mathbf{y}(c)$ is the copower. Consequently every presheaf is a colimit of representables, and the Yoneda embedding $\mathbf{y} \colon \mathbf{C} \to \mathbf{PSh}(\mathbf{C})$ is dense.

***Proof*:**
The integrand $(c', c) \mapsto Fc' \cdot \mathbf{y}(c) = Fc' \times \mathbf{C}(-, c)$ is a functor $\mathbf{C}^{\mathrm{op}} \times \mathbf{C} \to \mathbf{PSh}(\mathbf{C})$, contravariant in the first slot through F and covariant in the second through $\mathbf{y}$; its coend is computed in $\mathbf{PSh}(\mathbf{C})$, where colimits are formed objectwise (definition 63.3.1). It suffices to produce, for each presheaf G, a bijection

$$\mathbf{PSh}(\mathbf{C})\Big(\int^{c} Fc \cdot \mathbf{y}(c),\, G\Big) \;\cong\; \mathbf{PSh}(\mathbf{C})(F, G)$$

natural in G: two objects of $\mathbf{PSh}(\mathbf{C})$ whose covariant hom-functors are naturally isomorphic are themselves isomorphic, this being the Yoneda lemma (theorem 62.2.1) applied in the opposite category $\mathbf{PSh}(\mathbf{C})^{\mathrm{op}}$, where the covariant hom-functors become the representables.

Step 1: Unwind the left-hand side to a wedge. By the universal property of the coend, a map $\int^c Fc \cdot \mathbf{y}(c) \to G$ is a cowedge, a dinatural family of maps $Fc \cdot \mathbf{y}(c) \to G$. A map out of a copower $Fc \cdot \mathbf{y}(c) = \coprod_{x \in Fc} \mathbf{y}(c)$ is a choice, for each $x \in Fc$, of a map $\mathbf{y}(c) \to G$ in $\mathbf{PSh}(\mathbf{C})$. Thus

$$\mathbf{PSh}(\mathbf{C})\big(Fc \cdot \mathbf{y}(c),\, G\big) \;\cong\; \prod_{x \in Fc} \mathbf{PSh}(\mathbf{C})\big(\mathbf{y}(c), G\big) \;\cong\; \mathbf{Set}\big(Fc,\; \mathbf{PSh}(\mathbf{C})(\mathbf{y}(c), G)\big)$$

Step 2: Apply Yoneda. The Yoneda lemma (theorem 62.2.1) gives a bijection $\mathbf{PSh}(\mathbf{C})(\mathbf{y}(c), G) \cong Gc$, natural in c. Substituting,

$$\mathbf{PSh}(\mathbf{C})\big(Fc \cdot \mathbf{y}(c),\, G\big) \;\cong\; \mathbf{Set}(Fc, Gc)$$

and a cowedge into G becomes a wedge from the one-point set to the functor $(c', c) \mapsto \mathbf{Set}(Fc', Gc)$, the dinaturality conditions matching under the Yoneda bijection because that bijection is natural in c.

Step 3: Recognize the end. By example 66.4.2 the wedges from a point to $(c', c) \mapsto \mathbf{Set}(Fc', Gc)$ are exactly the natural transformations $F \Rightarrow G$:

$$\int_{c} \mathbf{Set}(Fc, Gc) \;\cong\; \mathrm{Nat}(F, G) = \mathbf{PSh}(\mathbf{C})(F, G)$$

Composing the three bijections gives $\mathbf{PSh}(\mathbf{C})\big(\int^c Fc \cdot \mathbf{y}(c), G\big) \cong \mathbf{PSh}(\mathbf{C})(F, G)$, natural in G. By the Yoneda lemma applied in $\mathbf{PSh}(\mathbf{C})$, the two presheaves are isomorphic, and the isomorphism is the canonical one sending $x \in Fc$ to the pair (x, id_c) in the copower, as we sought to show.

For the final clause, the coend (66.4) is the coequalizer (66.3), hence a colimit, of a diagram of representables. So F is a colimit of representables, and since F was arbitrary the representables generate $\mathbf{PSh}(\mathbf{C})$ under colimits, which is the statement that $\mathbf{y}$ is dense, completing the proof.

The density theorem is the promised converse to the Yoneda embedding. Yoneda embeds $\mathbf{C}$ fully faithfully into $\mathbf{PSh}(\mathbf{C})$; density says the image is not lost inside a larger category but generates it, every presheaf being reachable from the representables by colimits. Together they identify $\mathbf{PSh}(\mathbf{C})$ as the *free cocompletion* of $\mathbf{C}$: freely adjoining colimits to $\mathbf{C}$ produces exactly the presheaf category, with $\mathbf{y}$ the universal inclusion. The isomorphism (66.4) shows this: a presheaf F is rebuilt from the sets Fc of its elements and the representables that receive them.

The concrete content is a formula for the elements of a presheaf and how they patch, seen most on a poset.

Example 66.4.4: Density over a Poset

Let $\mathbf{C}$ be a poset, viewed as a category with a single arrow $c \to c'$ when $c \leq c'$, and let $F\colon \mathbf{C}^{\mathrm{op}} \to \mathbf{Set}$ be a presheaf (an order-reversing assignment of sets with restriction maps $Fc' \to Fc$ for $c \leq c'$). The representable $\mathbf{y}(c) = \mathbf{C}(-, c)$ sends b to the one-point set if $b \leq c$ and to the empty set otherwise, so $\mathbf{y}(c)$ is the presheaf represented by the down-set of c. The coend (66.4) identifies, for each $x \in Fc$ and each $b \leq c$, the "germ" of x at b with the actual restriction $x|_b \in Fb$: the copower $Fc \cdot \mathbf{y}(c)$ contributes one copy of the down-set of c for every section $x \in Fc$, and the coequalizer glues the copy attached to x to the copy attached to $x|_b$ along b. The result reassembles F from its sections and their restrictions, the poset analogue of recovering a sheaf from its stalks, that is from its local data together with the compatibilities that let the pieces be glued.

The same coend calculus rewrites the pointwise formula. The colimit over the comma category $(K \downarrow d)$ in theorem 66.2.1 is a coend once the comma category is unwound, and the coend form is the one that composes with the density theorem and generalizes to the enriched setting.

Proposition 66.4.5: Coend Formula for Kan Extensions

Let $K\colon \mathbf{C} \to \mathbf{D}$ with $\mathbf{C}$ small, $F\colon \mathbf{C} \to \mathbf{E}$, and suppose the relevant (co)limits exist in $\mathbf{E}$. Then the left Kan extension is the coend

$$(\mathrm{Lan}_K F)(d) \;\cong\; \int^{c} \mathbf{D}(Kc, d) \cdot Fc \tag{66.5}$$

and the right Kan extension is the end

$$(\mathrm{Ran}_K F)(d) \;\cong\; \int_{c} Fc^{\mathbf{D}(d, Kc)} \tag{66.6}$$

where $\mathbf{D}(Kc, d) \cdot Fc$ is the copower and $Fc^{\mathbf{D}(d,Kc)}$ the power.

***Proof*:**

Fix $d \in \mathbf{D}$. By theorem 66.2.1 the value $(\mathrm{Lan}_K F)(d)$ is the colimit of the composite $(K \downarrow d) \xrightarrow{\pi} \mathbf{C} \xrightarrow{F} \mathbf{E}$, where the comma category $(K \downarrow d)$ has objects the pairs (c, g) with $g\colon Kc \to d$ and morphisms $(c, g) \to (c', g')$ the maps $h\colon c \to c'$ with $g' \circ Kh = g$. The claim is that this colimit is computed by the coequalizer (66.3) for the integrand $T(c', c) = \mathbf{D}(Kc', d) \cdot Fc$.

Step 1: Match the coproducts. The coproduct $\coprod_c T(c, c) = \coprod_c \mathbf{D}(Kc, d) \cdot Fc$ is $\coprod_c \coprod_{g\colon Kc \to d} Fc$, one copy of Fc for each pair (c, g), that is one copy of Fc for each object of $(K \downarrow d)$. This is the coproduct over the objects of $(K \downarrow d)$ of $F\pi$, the vertex coproduct in the coequalizer presentation of the colimit $\mathrm{colim}_{(K\downarrow d)} F\pi$ (definition 63.3.1).

Step 2: Match the relations. The parallel pair in (66.3) identifies, for each $h\colon c \to c'$ in $\mathbf{C}$, the summand $T(c', c) = \mathbf{D}(Kc', d) \cdot Fc$ under the two maps $T(h, c)$ and $T(c', h)$. Concretely a summand indexed by $h\colon c \to c'$ and $g'\colon Kc' \to d$ is sent, on one side, to the copy of Fc at $(c, g' \circ Kh)$ acting by the identity on Fc, and on the other to the copy of Fc' at (c', g') acting by $Fh\colon Fc \to Fc'$. This is exactly the relation imposed in the colimit of $F\pi$: a morphism

$h\colon (c, g' \circ Kh) \to (c', g')$ of $(K \downarrow d)$ identifies the image of Fc in the vertex with the image of Fc' precomposed by Fh. The two coequalizers therefore present the same quotient, giving (66.5).

Step 2 (dual): the right extension. Applying the duality principle (box 61.3.3) to the argument just given, $(\mathrm{Ran}_K F)(d)$ is the limit over $(d \downarrow K)$ of $F\pi$, presented by the equalizer (66.2) for the integrand $(c', c) \mapsto Fc^{\mathbf{D}(d, Kc')}$. The vertex product $\prod_c Fc^{\mathbf{D}(d,Kc)}$ is one copy of Fc for each map $d \to Kc$, that is one copy for each object of $(d \downarrow K)$, and the equalizer imposes the morphisms of $(d \downarrow K)$ exactly as in the left case with all arrows reversed. This gives (66.6), completing the proof.

Read against density, the coend formula (66.5) says the left Kan extension along K is what one gets by resolving F into representables and then relabeling their indices along K: the coend integrates Fc against the hom-set $\mathbf{D}(Kc, d)$, the copower weighting each Fc by the ways Kc maps to d. Taking $K = \mathbf{y}$ the Yoneda embedding and $F = \mathbf{y}$ itself, (66.5) computes $(\mathrm{Lan}_{\mathbf{y}}\, \mathbf{y})(G) \cong \int^c \mathbf{PSh}(\mathbf{C})(\mathbf{y}(c), G) \cdot \mathbf{y}(c) \cong \int^c Gc \cdot \mathbf{y}(c)$ at a presheaf G, using $\mathbf{PSh}(\mathbf{C})(\mathbf{y}(c), G) \cong Gc$; this is the density isomorphism (66.4) for G. Density is the case of the coend formula where the extension is along Yoneda. The end and coend are thus not a separate topic appended to Kan extensions but the notation in which the pointwise formula, the Yoneda lemma, and density are one computation.

67

Monoidal Categories

A *monoidal category* carries a tensor product $\otimes$, a binary operation on objects that is associative and unital up to coherent isomorphism. It is the structure behind every tensor product in mathematics, and behind a category acting on itself. This chapter defines monoidal categories and the coherence theorem that tames their associativity isomorphisms, adds the symmetry and closedness most examples carry, and identifies the monoids that live inside a monoidal category, whose instance among endofunctors is the monad of chapter 65.

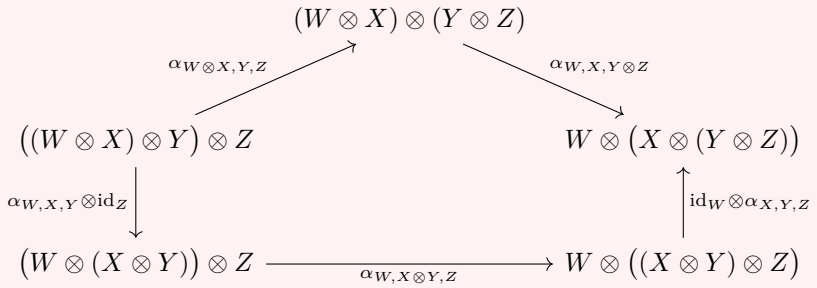
67.1 Monoidal Categories and Coherence

A tensor product multiplies objects. On R-modules it is $\otimes_R$; on sets it is the cartesian product; on the endofunctors of a category it is composition. Each is associative and unital, but only up to a natural isomorphism, and those isomorphisms are themselves data that must fit together. This section isolates that data as the notion of a monoidal category, states the two axioms (pentagon and triangle) that control it, and proves the coherence theorem, which shows the axioms suffice to make every reassociation unambiguous. We write $\otimes$ for the tensor product and I for the unit object throughout.

The associativity isomorphism $(X \otimes Y) \otimes Z \cong X \otimes (Y \otimes Z)$ is called the *associator*, and the isomorphisms $I \otimes X \cong X$ and $X \otimes I \cong X$ the *left* and *right unitors*. Requiring these to be natural in their arguments is the first constraint; the pentagon and triangle axioms are the second, and they are what distinguishes a coherent choice of associativity from an arbitrary one.

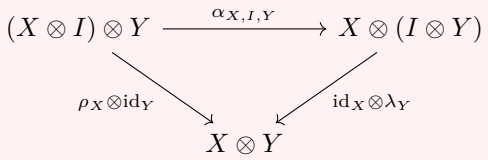
Definition 67.1.1: Monoidal Category

A *monoidal category* is a category C equipped with



- a functor $\otimes\colon C \times C \to C$, the *tensor product*;
- an object I of C, the *unit object*;
- a natural isomorphism α, the *associator*, with components

$$\alpha_{X,Y,Z}\colon (X \otimes Y) \otimes Z \to X \otimes (Y \otimes Z)$$



- natural isomorphisms λ and ρ, the *left* and *right unitors*, with components

$$\lambda_X\colon I \otimes X \to X, \qquad \rho_X\colon X \otimes I \to X$$

subject to two axioms. The *pentagon axiom* requires that the diagram

commutes for all objects W, X, Y, Z, and the *triangle axiom* requires that the diagram

commutes for all objects X, Y.

The pentagon governs a fourfold tensor product. There are five ways to fully parenthesize $W \otimes X \otimes Y \otimes Z$, and the associator gives an isomorphism between adjacent parenthesizations; the pentagon says the two paths around its perimeter, from $\big((W \otimes X) \otimes Y\big) \otimes Z$ to $W \otimes \big(X \otimes (Y \otimes Z)\big)$, agree. The triangle relates the associator to the unitors, forcing the two ways of cancelling a unit factor wedged between X and Y to coincide. These two small diagrams are the entire input; the coherence theorem below shows they already force every larger diagram of associators and unitors to commute.

When the associator and unitors are not just coherent but are identity morphisms, the tensor product is strictly associative and strictly unital, and the bookkeeping vanishes.

Definition 67.1.2: Strict Monoidal Category

A monoidal category is *strict* if the associator α and the unitors λ, ρ are all identity morphisms, so that $(X \otimes Y) \otimes Z = X \otimes (Y \otimes Z)$, $I \otimes X = X$, and $X \otimes I = X$ on the nose.

In a strict monoidal category the pentagon and triangle axioms hold trivially, being equalities of identity morphisms, and one may write iterated tensor products $X_1 \otimes \cdots \otimes X_n$ without parentheses. Most monoidal categories arising from a tensor construction are not strict, since $(X \otimes Y) \otimes Z$ and $X \otimes (Y \otimes Z)$ are built by different constructions, isomorphic but not equal. The endofunctor example below is a case where strictness does hold.

The unit object is determined by the structure. It is not extra data to be pinned down by a further choice, but is fixed up to a unique compatible isomorphism, in the same way a terminal object is (definition 63.1.1).

Proposition 67.1.3: Uniqueness of the Unit Object

Let $(C, \otimes, I, \alpha, \lambda, \rho)$ be a monoidal category, and suppose I' is another object admitting isomorphisms $\lambda'_X \colon I' \otimes X \to X$ and $\rho'_X \colon X \otimes I' \to X$ natural in X and satisfying the triangle axiom with α. Then there is a unique isomorphism $u \colon I \to I'$ satisfying $u \circ \lambda_I = \lambda'_{I'} \circ (u \otimes u)$; it is the canonical comparison of the two unit structures.

The compatibility condition packages the two units into a single square: it says u intertwines the multiplication $\lambda_I \colon I \otimes I \to I$ that the unit induces on itself with the corresponding multiplication $\lambda'_{I'} \colon I' \otimes I' \to I'$ on I'. Three standard facts about the unitors drive the proof. Two are recorded once and for all in Mac Lane, *Categories for the Working Mathematician*, Chapter VII: the left and right unitors agree at the unit, $\lambda_I = \rho_I$ (and likewise $\lambda'_{I'} = \rho'_{I'}$), so the induced multiplication is unambiguous; and the two unit structures are compared by the left-unit coherence identity $\lambda'_X \circ (u \otimes \mathrm{id}_X) = \lambda_X$, a consequence of the pentagon and triangle axioms. The third is elementary: tensoring by an object whose unitors are isomorphisms is an equivalence, hence *faithful*, which lets one cancel a factor $(-) \otimes \mathrm{id}_I$ from an equation.

***Proof Key ideas*:**
Write $v = \lambda_I = \rho_I \colon I \otimes I \to I$ and $v' = \lambda'_{I'} = \rho'_{I'} \colon I' \otimes I' \to I'$ for the two induced multiplications, using $\lambda_I = \rho_I$ (and its primed analogue) cited above.

Existence. Set

$$u = \rho_{I'} \circ (\lambda'_I)^{-1} \colon I \to I' \otimes I \to I',$$

an isomorphism as a composite of isomorphisms. The compatibility square $u \circ v = v' \circ (u \otimes u)$ reduces to a single unitor identity. Indeed, write $u \otimes u = (u \otimes \mathrm{id}_{I'}) \circ (\mathrm{id}_I \otimes u)$; naturality of λ at $u \colon I \to I'$ gives $u \circ \lambda_I = \lambda_{I'} \circ (\mathrm{id}_I \otimes u)$, so $u \circ v = u \circ \lambda_I$ and $v' \circ (u \otimes u) = \lambda'_{I'} \circ (u \otimes \mathrm{id}_{I'}) \circ (\mathrm{id}_I \otimes u)$ agree if and only if, after cancelling the isomorphism $\mathrm{id}_I \otimes u$,

$$\lambda'_{I'} \circ (u \otimes \mathrm{id}_{I'}) = \lambda_{I'}$$

This is the instance at $X = I'$ of the left-unit coherence identity $\lambda'_X \circ (u \otimes \mathrm{id}_X) = \lambda_X$, which relates the two unit structures through α and holds in any monoidal category by the pentagon and triangle axioms; it is a companion to the coherence theorem (theorem 67.1.5), deferred with it to Mac Lane, Chapter VII, which is why the existence half is given in outline. Granting it, the square commutes and u is a compatible comparison.

Uniqueness. Suppose $f\colon I \to I'$ is another isomorphism with $f \circ \upsilon = \upsilon' \circ (f \otimes f)$. Both u and f are then isomorphisms $I \to I'$ of the two multiplications υ, υ', so $g = u^{-1} \circ f\colon I \to I$ is an isomorphism satisfying $g \circ \upsilon = \upsilon \circ (g \otimes g)$, an automorphism of the multiplication υ. Naturality of λ at g gives $g \circ \lambda_I = \lambda_I \circ (\mathrm{id}_I \otimes g)$, that is $g \circ \upsilon = \upsilon \circ (\mathrm{id}_I \otimes g)$; comparing with $g \circ \upsilon = \upsilon \circ (g \otimes g)$ and cancelling the isomorphism υ yields $g \otimes g = \mathrm{id}_I \otimes g$. By functoriality of $\otimes$, $g \otimes g = (g \otimes \mathrm{id}_I) \circ (\mathrm{id}_I \otimes g)$, so the equation reads $(g \otimes \mathrm{id}_I) \circ (\mathrm{id}_I \otimes g) = \mathrm{id}_I \otimes g$; precomposing with the inverse of the isomorphism $\mathrm{id}_I \otimes g$ gives $g \otimes \mathrm{id}_I = \mathrm{id}_{I \otimes I} = \mathrm{id}_I \otimes \mathrm{id}_I$, whence $g = \mathrm{id}_I$ by faithfulness of $(-) \otimes I$. Thus $f = u$, and the unit object is unique up to a unique compatible isomorphism, as we sought to show.

The proposition is the reason one speaks of *the* unit object: any two choices are canonically identified, so the ambiguity carries no content. This is the monoidal analogue of the uniqueness of a terminal object (definition 63.1.1), and it is what allows I to be treated as a fixed piece of the structure rather than a variable one.

The standing cast gives the primary examples. Each is a category already in use, now viewed as carrying a tensor product.

Example 67.1.4: Monoidal Structures on the Standing Cast
Four monoidal categories, each read against the data and axioms of definition 67.1.1.

1. *Sets under cartesian product.* The category **Set** is monoidal with $\otimes = \times$ the cartesian product (definition 63.2.3) and $I = 1$ any singleton, terminal in **Set** (definition 63.1.1). The associator $\alpha_{X,Y,Z}\colon (X \times Y) \times Z \to X \times (Y \times Z)$ sends $((x, y), z)$ to $(x, (y, z))$, and the unitors $\lambda_X\colon 1 \times X \to X$, $\rho_X\colon X \times 1 \to X$ delete the singleton coordinate. These are bijections, natural in their arguments, and the pentagon and triangle are the evident equalities of tuple regroupings. This is not strict: $(X \times Y) \times Z$ is a set of pairs whose first entry is a pair, not equal to $X \times (Y \times Z)$.

2. *Vector spaces under tensor product.* The category $\mathbf{Vect}_k$ of vector spaces over a field k is monoidal with $\otimes = \otimes_k$ the tensor product over k ([21, Tensor Product]) and $I = k$ the ground field as a one-dimensional space. The associator is the canonical isomorphism $(U \otimes V) \otimes W \to U \otimes (V \otimes W)$ sending $(u \otimes v) \otimes w$ to $u \otimes (v \otimes w)$, and the unitors $k \otimes V \to V$, $V \otimes k \to V$ send $c \otimes v$ and $v \otimes c$ to cv. The pentagon and triangle hold because both sides of each act identically on the generating simple tensors. Again not strict.

3. *Modules under tensor product.* The same construction gives a monoidal structure on $\mathbf{Mod}_R$ for a commutative ring R, with $\otimes = \otimes_R$ and $I = R$ ([21, Tensor Product]). The associator and unitors are the standard isomorphisms of module tensor products, and $\mathbf{Vect}_k$ is the special case $R = k$.

4. *Endofunctors under composition.* For any category C, the functor category $[C, C]$ (definition 61.5.4) of endofunctors is monoidal with $\otimes = \circ$ functor composition and $I = \mathrm{id}_C$ the identity functor. Composition of functors is associative on the nose, $(F \circ G) \circ H = F \circ (G \circ H)$, and the identity functor is a strict two-sided unit, $\mathrm{id}_C \circ F = F = F \circ \mathrm{id}_C$, so the associator and unitors are identity natural transformations. Thus $([C, C], \circ, \mathrm{id}_C)$ is a *strict* monoidal category (definition 67.1.2).

The endofunctor example is the one to keep in mind. It is where strictness appears without contrivance, composition being an operation that is equal, not just isomorphic, when reassociated, and it is the

setting in which the monad (T, η, μ) met earlier will reappear as a monoid object. The strictification argument in the coherence proof is modelled on exactly this category, replacing each object by its translation endofunctor. The first three examples, by contrast, are the reason coherence is needed at all: their associators and unitors are nontrivial isomorphisms, and without the pentagon and triangle there would be no guarantee that a long chain of reassociations returns an unambiguous answer.

More generally, any category with finite products is monoidal under $(\times, 1)$, with $\times$ the binary product (definition 63.2.3) and 1 a terminal object (definition 63.1.1) as unit; the first example is the case $C = \mathbf{Set}$. This is the *cartesian monoidal* structure, and it is available on **Grp**, **Top**, **Cat**, and every other member of the standing cast with finite products.

The pentagon and triangle are two small diagrams. It is not obvious that they suffice: a diagram built from a dozen associators and unitors offers many paths between its corners, and nothing so far forces those paths to agree. Mac Lane's coherence theorem is the guarantee that they do. It has two equivalent formulations, one internal (every formal diagram commutes) and one structural (every monoidal category is equivalent to a strict one), and the second is the route to proving the first.

Theorem 67.1.5: Mac Lane's Coherence Theorem

Let C be a monoidal category. Then:

1. *Coherence.* Every diagram in C whose edges are built by tensoring identities, associators $\alpha^{\pm 1}$, and unitors $\lambda^{\pm 1}$, $\rho^{\pm 1}$ commutes. Any two morphisms between the same pair of iterated tensor products built from these constituents are equal.
2. *Strictification.* There is a strict monoidal category C^{st} and a monoidal equivalence $C \simeq C^{\mathrm{st}}$.

The full proof of part (1) is a combinatorial argument about a word problem: one shows that any two formal composites of associators and unitors with the same source and target are provably equal from the pentagon and triangle, and the complete verification is long. It is given in Mac Lane, *Categories for the Working Mathematician*, Chapter VII. What follows establishes part (2) in full and shows how it yields part (1), which is the conceptual content.

***Proof Key ideas*:**
The strictification construction is given in full; the word-problem proof of part (1) from part (2) is sketched, with the complete combinatorial argument cited to Mac Lane, Chapter VII, as noted above.

Step 1: The strict category of lists. Let C^{st} be the category whose objects are finite lists $\underline{X} = (X_1, \dots, X_n)$ of objects of C (including the empty list, of length 0), and whose morphisms

$$C^{\mathrm{st}}(\underline{X}, \underline{Y}) = \mathrm{Hom}_C\big(\overline{\underline{X}}, \overline{\underline{Y}}\big)$$

are the C-morphisms between the tensorings $\overline{\underline{X}} = ((X_1 \otimes X_2) \otimes \cdots) \otimes X_n$ associated to the left in a fixed order (the empty list tensoring to I), with composition and identities taken in C. Concatenation of lists, $\underline{X} \otimes \underline{Y} = (X_1, \dots, X_n, Y_1, \dots, Y_m)$, is an associative operation on objects with strict unit the empty list, and on morphisms it is defined by transporting the tensor of the underlying C-morphisms across the associators that compare $\overline{\underline{X} \otimes \underline{Y}}$ with $\overline{\underline{X}} \otimes \overline{\underline{Y}}$; the pentagon axiom makes this transport well-defined and functorial. Thus C^{st} is a *strict* monoidal category (definition 67.1.2): concatenation is associative and unital on the nose. This is the list model of the endofunctor picture, where a length-one list (X) plays the role of the translation $X \otimes -$

and concatenation the role of composition, but built so that the bookkeeping isomorphisms live inside the definition of the tensor rather than obstructing strictness.

Step 2: L is a monoidal equivalence. Define $L\colon C \to C^{\mathrm{st}}$ on objects by $L(\underline{X}) = (X)$, the length-one list, and on morphisms by $L(f) = f$, viewing $f\colon X \to Y$ as a morphism $\overline{(X)} = X \to Y = \overline{(Y)}$ in C. Because $C^{\mathrm{st}}((X),(Y)) = \mathrm{Hom}_C(X,Y)$ by definition, L is *fully faithful* with no further argument, its action on each hom-set being the identity map of $\mathrm{Hom}_C(X,Y)$. It is essentially surjective: every list $\underline{X}$ is isomorphic in C^{st} to the length-one list $(\overline{X})$, the isomorphism being the identity of $\overline{X}$ regarded as a morphism $\underline{X} \to (\overline{X})$. A functor that is fully faithful and essentially surjective is an equivalence (proposition 61.5.6), so L is an equivalence of categories. Finally L is *strong monoidal*: the structure isomorphism $L(\underline{X}) \otimes L(\underline{Y}) = (X,Y) \to (X \otimes Y) = L(X \otimes Y)$ is the identity of $X \otimes Y$ regarded as a morphism $\overline{(X,Y)} = X \otimes Y \to X \otimes Y$, and the unit comparison $I_{C^{\mathrm{st}}} = () \to (I)$ is id_I, since both $\overline{()}$ and $\overline{(I)}$ equal I; the pentagon and triangle axioms of C are exactly the coherence identities these comparisons must satisfy. Hence L is a monoidal equivalence $C \simeq C^{\mathrm{st}}$ with strict target, proving part (2).

Step 3: Coherence from strictification. Given a formal diagram in C built from associators and unitors, apply the equivalence $L\colon C \simeq C^{\mathrm{st}}$. Since L is *strong* (not strict) monoidal, it does not send an associator to an identity; rather, the strong-monoidal coherence axioms and the strictness of the target force $L(\alpha_{X,Y,Z})$ to equal a fixed composite of the structure isomorphisms $\varphi_{A,B}\colon L(A)\otimes L(B) \cong L(A\otimes B)$ of Step 2 (each of which, in the list model, is an identity morphism of C regarded across a change of tensoring), and likewise $L(\lambda_X)$, $L(\rho_X)$ to fixed composites of the $\varphi_{A,B}$ and the unit comparison. Because concatenation in C^{st} is strictly associative and unital, these image composites depend only on the source and target parenthesizations, not on the path taken: any two formal composites of associators and unitors sharing a source and target map under L to the *same* morphism of C^{st}. As L is faithful, they are already equal in C, so the formal diagram commutes. The content that Step 3 defers is exactly the path-independence just used: that the structure isomorphisms assemble into a well-defined map depending only on the endpoints is the word-problem statement, that the free monoidal category on the objects involved has at most one morphism between any two parenthesizations. This is the combinatorial argument deferred to Mac Lane, Chapter VII; granting it, every formal diagram of associators and unitors commutes, completing the proof of part (1).

Coherence permits a controlled sloppiness. Because every formal diagram of associators and unitors commutes, one may drop parentheses from iterated tensor products and suppress the unit isomorphisms entirely, writing $X \otimes Y \otimes Z$ and $I \otimes X = X$ as though the category were strict. No ambiguity results: whichever way a suppressed reassociation is reinstated, part (1) guarantees the same morphism. In practice one works in a monoidal category as if it were strict, invoking coherence to justify the omitted brackets, and the strictification of part (2) is what makes this rigorous rather than convenient. Every monoidal category met later in this chapter is handled this way.

67.2 Braided and Symmetric Monoidal Categories

A monoidal structure (definition 67.1.1) relates $X \otimes Y$ and $Y \otimes X$ by nothing at all; in $(\mathbf{Vect}_k, \otimes, k)$ they are visibly isomorphic by the swap $x \otimes y \mapsto y \otimes x$, coherently with the tensor. This section isolates that extra datum. A *braiding* is a natural isomorphism $\beta_{X,Y}\colon X \otimes Y \to Y \otimes X$ compatible with the associator, and a braiding is *symmetric* when swapping twice returns to the start. The compatibility is governed not by one axiom but by two hexagons, one for each way of moving a factor

past a tensor product.

The compatibility a braiding must satisfy is forced by coherence. Given three objects, $X \otimes (Y \otimes Z)$ can be rewritten as $(Y \otimes Z) \otimes X$ in two ways: apply the braiding to the whole factor $Y \otimes Z$ at once, or slide X past Y and then past Z one factor at a time, reassociating as needed. A braiding is required to make these two routes agree. Each route is a hexagon of associators and braidings, and there are two of them because X may be moved to the right (past $Y \otimes Z$) or an object may be moved to the left (past $X \otimes Y$); the second hexagon is the analogue of the first for the reverse braiding.

Definition 67.2.1: Braided Monoidal Category

A *braided monoidal category* is a monoidal category $(\mathbf{C}, \otimes, I, \alpha, \lambda, \rho)$ (definition 67.1.1) equipped with a natural isomorphism

$$\beta_{X,Y} \colon X \otimes Y \to Y \otimes X$$

called the *braiding*, natural in X and Y (definition 61.5.2), such that the two hexagon diagrams commute for all objects X, Y, Z. The first hexagon

$$\begin{array}{ccccc} & & (X \otimes Y) \otimes Z & \xrightarrow{\beta_{X,Y} \otimes \mathrm{id}_Z} & (Y \otimes X) \otimes Z \\ & \overset{\alpha^{-1}}{\nearrow} & & & \searrow^{\alpha} \\ X \otimes (Y \otimes Z) & & & & Y \otimes (X \otimes Z) \\ & \underset{\beta_{X,Y \otimes Z}}{\searrow} & & & \underset{\mathrm{id}_Y \otimes \beta_{X,Z}}{\swarrow} \\ & & (Y \otimes Z) \otimes X & \xrightarrow[\alpha]{} & Y \otimes (Z \otimes X) \end{array}$$

expresses the compatibility of β with α when the object X is braided past the tensor product $Y \otimes Z$. The second hexagon

$$\begin{array}{ccccc} & & X \otimes (Y \otimes Z) & \xrightarrow{\mathrm{id}_X \otimes \beta_{Y,Z}} & X \otimes (Z \otimes Y) \\ & \overset{\alpha}{\nearrow} & & & \searrow^{\alpha^{-1}} \\ (X \otimes Y) \otimes Z & & & & (X \otimes Z) \otimes Y \\ & \underset{\beta_{X \otimes Y,Z}}{\searrow} & & & \underset{\beta_{X,Z} \otimes \mathrm{id}_Y}{\swarrow} \\ & & Z \otimes (X \otimes Y) & \xrightarrow[\alpha^{-1}]{} & (Z \otimes X) \otimes Y \end{array}$$

expresses the same compatibility when Z is braided past $X \otimes Y$.

Naturality of β means that for morphisms $f \colon X \to X'$ and $g \colon Y \to Y'$, the square

$$\begin{array}{ccc} X \otimes Y & \xrightarrow{\beta_{X,Y}} & Y \otimes X \\ {\scriptstyle f \otimes g}\downarrow & & \downarrow{\scriptstyle g \otimes f} \\ X' \otimes Y' & \xrightarrow[\beta_{X',Y'}]{} & Y' \otimes X' \end{array}$$

commutes: braiding and then acting by $g \otimes f$ agrees with acting by $f \otimes g$ and then braiding. The two hexagons are the coherence conditions for the braiding against the associator; together with Mac

Lane's coherence theorem (theorem 67.1.5) for the underlying monoidal structure, they guarantee that every diagram built from associators, unitors, and braidings that one might expect to commute does commute, provided its two sides braid the factors into the same permutation by isotopic routes. The proviso is the point: unlike the associator and unitors, the braiding is not forced to be its own inverse, so the order in which factors are braided can matter.

In a strict monoidal category (definition 67.1.2) the associators are identities and each hexagon collapses to a triangle. The first becomes

$$\beta_{X,Y\otimes Z} = (\mathrm{id}_Y \otimes \beta_{X,Z}) \circ (\beta_{X,Y} \otimes \mathrm{id}_Z)$$

and the second becomes

$$\beta_{X\otimes Y,Z} = (\beta_{X,Z} \otimes \mathrm{id}_Y) \circ (\mathrm{id}_X \otimes \beta_{Y,Z})$$

so that a braiding past a tensor product is determined by braiding past each factor in turn. These are the relations one draws as strands crossing: $\beta_{X,Y}$ is the strand carrying X passing over the strand carrying Y, and the hexagons say that a strand passing over two others equals its passing over them one at a time.

The extra condition that makes a braiding into a symmetry is the one the swap map satisfies: undoing the crossing recovers the identity.

Definition 67.2.2: Symmetric Monoidal Category

A braided monoidal category (definition 67.2.1) is *symmetric* if its braiding satisfies

$$\beta_{Y,X} \circ \beta_{X,Y} = \mathrm{id}_{X\otimes Y}$$

for all objects X and Y. A braiding with this property is called a *symmetry*.

For a symmetry, $\beta_{Y,X} = \beta_{X,Y}^{-1}$, so the two hexagons of definition 67.2.1 become equivalent: each is obtained from the other by inverting the braidings, and symmetry identifies a braiding with its inverse. A symmetric monoidal category therefore carries a single hexagon axiom, and the strand carrying X over the strand carrying Y is indistinguishable from X under Y. The distinction between over and under crossings is what a general braiding retains and a symmetry discards.

The condition $\beta_{Y,X}\beta_{X,Y} = \mathrm{id}$ is the categorical form of a familiar identity: it says the swap is an involution. Symmetry is the monoidal counterpart of commutativity. Just as a commutative operation lets a product $a_1 a_2 \cdots a_n$ be formed without regard to the order of its factors, a symmetric braiding lets a tensor $X_1 \otimes \cdots \otimes X_n$ be reindexed by any permutation, with any two reindexings related by a canonical isomorphism independent of how the permutation is factored into transpositions. This is coherence for the symmetric group: the symmetric group S_n acts on the n-fold tensor, and the action is well-defined precisely because $\beta_{Y,X}\beta_{X,Y} = \mathrm{id}$ makes a transposition square to the identity. In a braided category that is not symmetric the braid group B_n acts in place of S_n, and B_n is infinite, so the order of braiding is remembered.

Example 67.2.3: The Standing Cast as Symmetric Monoidal Categories

The commutative examples of example 67.1.4, $(\mathbf{Vect}_k, \otimes, k)$ and $(\mathbf{Set}, \times, 1)$, each carry a symmetry; the third example there, the endofunctor category $([\mathbf{C},\mathbf{C}], \circ, \mathrm{id})$, is deliberately excluded, since functor composition is non-commutative ($F \circ G$ is not naturally isomorphic to $G \circ F$ in general) and so admits no braiding, a point that returns when a monad is identified as a monoid object in that category. The vector-space case extends to modules over any commutative ring.

1. In $(\mathbf{Vect}_k, \otimes, k)$ the braiding is the swap

$$\beta_{V,W} : V \otimes W \to W \otimes V, \qquad v \otimes w \mapsto w \otimes v$$

extended k-bilinearly. This is a well-defined linear isomorphism because $(v, w) \mapsto w \otimes v$ is k-bilinear, and its inverse is $\beta_{W,V}$. Applying it twice returns $v \otimes w \mapsto w \otimes v \mapsto v \otimes w$, so $\beta_{W,V}\beta_{V,W} = \mathrm{id}_{V\otimes W}$ and the structure is symmetric. The hexagon axioms hold because both routes send $u \otimes v \otimes w$ (with the associators identifying the two bracketings) to the same reordered pure tensor.

2. For a commutative ring R, the category $(\mathbf{Mod}_R, \otimes_R, R)$ is symmetric with the same swap $m \otimes n \mapsto n \otimes m$. Well-definedness uses commutativity of R: for $r \in R$ the assignment must respect $rm \otimes n = m \otimes rn$, and the target $n \otimes rm = rn \otimes m$ agrees only because r is central, which it is. The tensor product itself is the tensor product of R-modules cited from [21, Tensor Product]; here it is repackaged as a symmetric monoidal structure. The case $R = k$ a field recovers the previous item.

3. In $(\mathbf{Set}, \times, 1)$ the braiding is the swap of ordered pairs

$$\beta_{A,B} : A \times B \to B \times A, \qquad (a, b) \mapsto (b, a)$$

which is its own inverse: applying it twice returns $(a, b) \mapsto (b, a) \mapsto (a, b)$, so it is a symmetry. Every category with finite products carries this symmetry on its cartesian monoidal structure $(\mathbf{C}, \times, 1)$ (the structure of definition 63.2.3): the braiding $\beta_{X,Y} : X \times Y \to Y \times X$ is the unique map whose projections to Y and X are the projections of $X \times Y$ in the other order, and its square is the identity because both maps have the same projections. A cartesian monoidal category is thus symmetric with no further choice.

Braidings that are not symmetric exist. The category of finite-dimensional representations of a quantum group $U_q(\mathfrak{g})$ carries a braiding, built from the R-matrix solving the Yang-Baxter equation, for which $\beta_{Y,X}\beta_{X,Y} \neq \mathrm{id}$: braiding past twice is a nontrivial automorphism, and the braid group B_n acts faithfully on tensor powers. This is the source of the quantum knot invariants, the Jones polynomial among them, where an over-crossing and an under-crossing of strands must be assigned different operators precisely because β and β^{-1} differ. These braided-not-symmetric categories are the natural home of that theory and are developed in the literature on quantum groups; the present book stays with the symmetric case, where the standing cast lives.

The three examples share a mechanism. In each, the braiding is a swap of coordinates, its square is the identity, and the hexagons hold because reassociating and swapping commute on pure tensors or pairs. The symmetry is not an added structure to be checked case by case so much as a reflection of the fact that the underlying product, of vector spaces, of modules, of sets, is commutative up to canonical isomorphism. Symmetric monoidal categories are the ambient setting in which the algebra of tensor products behaves like the algebra of a commutative operation.

67.3 Closed Monoidal Categories

The tensor product $\otimes$ combines two objects into one. A closed structure gives the inverse move: an object $[X, Y]$ inside the category whose maps out of any A are exactly the maps $A \otimes X \to Y$. This section makes that require precise as an adjunction (definition 64.1.1), identifies the two canonical

maps it carries, and reads off the closure of the two examples the adjunction chapter already met in another guise.

The condition to impose is that tensoring with a fixed object have a right adjoint. Naming that right adjoint $[X, -]$ turns the informal "object of maps $X \to Y$" into a functor internal to the category.

Definition 67.3.1: Closed Monoidal Category

A monoidal category $(\mathbf{C}, \otimes, I)$ (definition 67.1.1) is *closed* if for every object X the functor

$$- \otimes X \colon \mathbf{C} \to \mathbf{C}$$

has a right adjoint (definition 64.1.1), written $[X, -] \colon \mathbf{C} \to \mathbf{C}$ and called the *internal hom*. Explicitly, for each X there is a bijection

$$\mathbf{C}(A \otimes X, Y) \;\cong\; \mathbf{C}(A, [X, Y]) \tag{67.1}$$

natural in A and in Y. The object $[X, Y]$ is the *internal hom* from X to Y.

The word "closed" names the fact that the hom-set $\mathbf{C}(X, Y)$, an object of **Set** external to $\mathbf{C}$, has been promoted to an object $[X, Y]$ of $\mathbf{C}$ itself: the category is closed under forming its own hom-objects. (67.1) is the defining feature. It says a map from A into the internal hom $[X, Y]$ is the same datum as a map from $A \otimes X$ to Y, so $[X, Y]$ represents the functor $A \mapsto \mathbf{C}(A \otimes X, Y)$. The external hom is recovered by taking $A = I$: since $I \otimes X \cong X$ through the left unitor, (67.1) gives $\mathbf{C}(X, Y) \cong \mathbf{C}(I, [X, Y])$, so the ordinary maps $X \to Y$ are the "points" $I \to [X, Y]$ of the internal hom.

The definition asks $- \otimes X$ to have a right adjoint, tensoring on the right. In a symmetric monoidal category (definition 67.2.2) the braiding gives a natural isomorphism $A \otimes X \cong X \otimes A$, so a right adjoint to $- \otimes X$ is at once a right adjoint to $X \otimes -$: left and right closedness coincide, and one speaks simply of a closed symmetric monoidal category.[1]

The adjunction packaged by (67.1) carries a unit and a counit (definition 64.1.3). Named and unwound in the present notation, they are the two structural maps a closed category always provides: an evaluation and a currying map.

[1] Without symmetry the two conditions may differ, and a category can be right closed without being left closed. Every example below is symmetric, so the distinction does not arise.

Theorem 67.3.2: The Tensor-Hom Adjunction

Let $(\mathbf{C}, \otimes, I)$ be a closed monoidal category (definition 67.3.1), and fix an object X. The adjunction $- \otimes X \dashv [X, -]$ has:

1. counit the *evaluation* morphism, natural in Y,
$$\mathrm{ev}_{X,Y} \colon [X, Y] \otimes X \to Y$$
the transpose of $\mathrm{id}_{[X,Y]}$;
2. unit the *coevaluation* (or *currying*) morphism, natural in A,
$$\mathrm{coev}_{A,X} \colon A \to [X, A \otimes X]$$
the transpose of $\mathrm{id}_{A \otimes X}$.

The bijection (67.1) sends $f \colon A \otimes X \to Y$ to $[X, f] \circ \mathrm{coev}_{A,X} \colon A \to [X, Y]$, and is natural in A and in Y.

***Proof*:**
By definition 67.3.1 the functors $- \otimes X$ and $[X, -]$ are adjoint, so the general theory of section 64.1 applies with $F = - \otimes X$ and $G = [X, -]$; the content of the theorem is to name the unit and counit in this setting and confirm the transpose formula.

Step 1: The counit is evaluation. By definition 64.1.3 the counit of $- \otimes X \dashv [X, -]$ has component at Y the transpose of $\mathrm{id}_{[X,Y]}$ under the inverse of (67.1). Setting $A = [X, Y]$, that bijection reads $\mathbf{C}([X, Y] \otimes X, Y) \cong \mathbf{C}([X, Y], [X, Y])$, and the transpose of $\mathrm{id}_{[X,Y]}$ is a morphism
$$\mathrm{ev}_{X,Y} \colon [X, Y] \otimes X \to Y$$
which is the counit, hence natural in Y. It evaluates the internal hom: for $\mathbf{C} = \mathbf{Set}$ with $[X, Y] = \mathbf{Set}(X, Y)$, ev is the map $(g, x) \mapsto g(x)$.

Step 2: The unit is coevaluation. Dually, the unit has component at A the transpose of $\mathrm{id}_{A \otimes X}$ under (67.1) with $Y = A \otimes X$: the bijection $\mathbf{C}(A \otimes X, A \otimes X) \cong \mathbf{C}(A, [X, A \otimes X])$ sends $\mathrm{id}_{A \otimes X}$ to a morphism
$$\mathrm{coev}_{A,X} \colon A \to [X, A \otimes X]$$
the unit, natural in A. In $\mathbf{Set}$ it sends a to the function $x \mapsto (a, x)$, the map that curries the second coordinate.

Step 3: The transpose formula. Proposition 64.1.4 computes the transpose of a morphism through the unit and counit: for $F \dashv G$ with unit η, the transpose of $f \colon FA \to Y$ is $Gf \circ \eta_A$. With $F = - \otimes X$, $G = [X, -]$, $\eta_A = \mathrm{coev}_{A,X}$, and $Gf = [X, f]$, the transpose of $f \colon A \otimes X \to Y$ is
$$A \xrightarrow{\mathrm{coev}_{A,X}} [X, A \otimes X] \xrightarrow{[X,f]} [X, Y] \tag{67.2}$$
which is the asserted formula: curry the identity, then apply the internal hom to f.

Step 4: Naturality. Naturality of (67.1) in A and Y is naturality of the adjunction isomorphism $\Phi \colon \mathbf{C}(F-, -) \cong \mathbf{C}(-, G-)$ of definition 64.1.1, which holds by the definition of an adjunction. Concretely, for $u \colon A' \to A$ the square relating $\Phi_{A,Y}$ and $\Phi_{A',Y}$ commutes because (67.2) is built

from the natural transformation coev and the functor $[X, -]$; the Y-variable is dual, using ev. Thus the bijection is natural in both variables, completing the proof.

The evaluation and coevaluation maps are the internal forms of two operations on ordinary functions. Evaluation $[X,Y] \otimes X \to Y$ applies a map to an argument; coevaluation $A \to [X, A \otimes X]$ holds an element of A and waits for an argument in X, producing the pair. The triangle identities of theorem 64.1.5 record that currying and then evaluating returns the original map, which is the content of (67.2) run forward and back. This is the tensor-hom adjunction of example 64.2.2, now read as structure carried by a single category rather than a bijection between two external hom-sets: the module Hom-tensor identity $\mathrm{Hom}_R(A \otimes_R X, Y) \cong \mathrm{Hom}_R(A, \mathrm{Hom}_R(X,Y))$ and the currying isomorphism $\mathbf{Set}(A \times X, Y) \cong \mathbf{Set}(A, Y^X)$ are exactly (67.1) for $\mathbf{Mod}_R$ and for $\mathbf{Set}$. What the adjunction chapter presented as two adjoint functors, the closed structure presents as the category's ability to internalize its own hom.

When the monoidal structure is the cartesian one built from finite products (definition 63.2.3), closedness has a classical name and the internal hom is the exponential object.

Definition 67.3.3: Cartesian Closed Category

A category $\mathbf{C}$ with finite products is *cartesian closed* if its cartesian monoidal structure $(\mathbf{C}, \times, 1)$ is closed (definition 67.3.1): for every object X the functor $- \times X$ has a right adjoint $(-)^X \colon \mathbf{C} \to \mathbf{C}$, the *exponential*. The object $Y^X = [X,Y]$ is the *exponential object*, and the adjunction reads

$$\mathbf{C}(A \times X, Y) \;\cong\; \mathbf{C}(A, Y^X) \tag{67.3}$$

natural in A and Y.

Cartesian closedness is the special case where the tensor is the product and the unit is the terminal object 1. The bijection (67.3) is currying in its familiar form: a map of two variables $A \times X \to Y$ is the same as a map $A \to Y^X$ into the object of maps $X \to Y$. The evaluation counit $Y^X \times X \to Y$ applies a function to an argument, and taking $A = 1$ recovers the global elements of Y^X as the maps $X \to Y$, so the exponential is a genuine internal object of functions.

Example 67.3.4: Set and Vect as Closed Categories

1. **Set** *is cartesian closed.* The cartesian monoidal structure is $(\mathbf{Set}, \times, 1)$ with 1 a one-point set. For sets X and Y the exponential is the set of all functions,

$$Y^X = \mathbf{Set}(X, Y)$$

and currying is the bijection

$$\mathbf{Set}(A \times X, Y) \;\cong\; \mathbf{Set}(A, Y^X)$$

sending $f \colon A \times X \to Y$ to $a \mapsto (x \mapsto f(a,x))$. This is a bijection because a function of two arguments is determined by, and determines, its curried form; it is natural in A and Y because currying commutes with precomposition on A and postcomposition on Y. Thus $- \times X \dashv (-)^X$, and the evaluation counit $Y^X \times X \to Y$ is $(g,x) \mapsto g(x)$.

2. $\mathbf{Vect}_k$ *is closed monoidal, not cartesian.* The relevant monoidal structure on vector spaces over k is $(\mathbf{Vect}_k, \otimes_k, k)$, the tensor product with unit the ground field k, not the cartesian

product. It is closed with internal hom the space of linear maps,

$$[X, Y] = \mathrm{Hom}_k(X, Y)$$

itself a k-vector space. The bijection

$$\mathrm{Hom}_k(A \otimes_k X, Y) \;\cong\; \mathrm{Hom}_k(A, \mathrm{Hom}_k(X, Y))$$

is the tensor-hom adjunction over k (example 64.2.2): a bilinear map $A \times X \to Y$ corresponds to a linear map $A \otimes_k X \to Y$ and, curried, to a linear map $A \to \mathrm{Hom}_k(X, Y)$. The evaluation counit $\mathrm{Hom}_k(X, Y) \otimes_k X \to Y$ is $g \otimes x \mapsto g(x)$. The cartesian product $X \times Y$ (the direct sum, since finite products and coproducts coincide here) does *not* make $\mathbf{Vect}_k$ cartesian closed: the exponential would need $\mathbf{Vect}_k(A \times X, Y) \cong \mathbf{Vect}_k(A, Y^X)$, but the left side is not additive in A while the representable right side is. Since $A \times X = A \oplus X$, the left side is $\mathbf{Vect}_k(A \oplus X, Y) \cong \mathbf{Vect}_k(A, Y) \times \mathbf{Vect}_k(X, Y)$, which carries the constant summand $\mathbf{Vect}_k(X, Y)$: at $A = 0$ it returns $\mathbf{Vect}_k(X, Y)$, not a one-point set, so with $X = Y = k$ it fails to send the zero space to a terminal set. A representable functor $\mathbf{Vect}_k(-, Y^X)$ does send 0 to a point, so the two cannot be naturally isomorphic and no cartesian exponential exists. Closedness here is a feature of $\otimes_k$, not of $\times$.

The two examples separate the cartesian case from the general one. In **Set** the tensor is the product, so the internal hom is the exponential and the category is cartesian closed. In $\mathbf{Vect}_k$ the closure lives on the tensor product, and the cartesian product carries no matching exponential; the category is closed monoidal but not cartesian closed. The pattern recurs: the tensor-hom adjunction of example 64.2.2 for $\mathbf{Mod}_R$ makes each module category closed monoidal under $\otimes_R$, while a topos such as **Set** or a presheaf category is cartesian closed under $\times$.

Cartesian closed categories are the categorical semantics of the typed lambda calculus: types are objects, terms are morphisms, the product $\times$ interprets pairing, the exponential Y^X interprets the function type $X \to Y$, and the evaluation and currying maps interpret function application and lambda abstraction, with the adjunction (67.3) the statement that a function of two arguments and its curried form are interchangeable.[2]

67.4 Monoids, Comonoids, and Duality

The definition of a monoid transcribes verbatim into any monoidal category once the product is a functor $\otimes$ rather than a set-theoretic multiplication, and the reward is that the same three axioms name at once monoids, rings, algebras, and, in the endofunctor category of example 67.1.4, monads. This section makes that transcription, dualizes it to comonoids, and closes with a taste of the finiteness condition, dualizability, that lets an object have a linear dual.

Fix a monoidal category $(\mathbf{C}, \otimes, I)$ with associator α and unitors λ, ρ (definition 67.1.1). A monoid in **Set** is a set M together with a multiplication $M \times M \to M$ and a chosen unit element, which is the same as a map $1 \to M$ from the terminal set. Replacing $\times$ by $\otimes$ and the terminal set by the monoidal unit I gives the general definition.

[2]This correspondence, that cartesian closed categories model simply typed lambda calculus, is due to Lambek; a standard reference is Lambek and Scott, *Introduction to Higher Order Categorical Logic*.

Definition 67.4.1: Monoid Object

A *monoid object* in a monoidal category $(\mathbf{C}, \otimes, I)$ is an object M of $\mathbf{C}$ together with two morphisms

$$\mu\colon M \otimes M \to M \qquad \text{and} \qquad \eta\colon I \to M$$

the *multiplication* and the *unit*, such that the associativity diagram

$$\begin{array}{ccccc} (M \otimes M) \otimes M & \xrightarrow{\alpha_{M,M,M}} & M \otimes (M \otimes M) & \xrightarrow{\mathrm{id}_M \otimes \mu} & M \otimes M \\ \downarrow{\scriptstyle \mu \otimes \mathrm{id}_M} & & & & \downarrow{\scriptstyle \mu} \\ M \otimes M & & \xrightarrow[\mu]{\qquad\qquad\qquad\qquad} & & M \end{array}$$

and the two unit diagrams

$$\begin{array}{ccccc} I \otimes M & \xrightarrow{\eta \otimes \mathrm{id}_M} & M \otimes M & \xleftarrow{\mathrm{id}_M \otimes \eta} & M \otimes I \\ & {\scriptstyle \lambda_M} \searrow & \downarrow{\scriptstyle \mu} & \swarrow {\scriptstyle \rho_M} & \\ & & M & & \end{array}$$

commute.

The associativity square says the two ways of multiplying a triple $M \otimes M \otimes M$ agree once the parenthesization is corrected by the associator, and the two triangles say that inserting the unit on either side and multiplying is the same as forgetting the unit factor via λ or ρ. When $\mathbf{C}$ is strict the associator and unitors are identities and the diagrams reduce to the familiar equations $\mu(\mu \otimes \mathrm{id}) = \mu(\mathrm{id} \otimes \mu)$, $\mu(\eta \otimes \mathrm{id}) = \mathrm{id} = \mu(\mathrm{id} \otimes \eta)$; theorem 67.1.5 guarantees no generality is lost by picturing the strict case. A morphism of monoid objects $(M, \mu, \eta) \to (M', \mu', \eta')$ is a map $f\colon M \to M'$ with $f\mu = \mu'(f \otimes f)$ and $f\eta = \eta'$; monoid objects and their morphisms form a category $\mathrm{Mon}(\mathbf{C})$.

Reversing every arrow gives the dual notion. Rather than a multiplication that fuses two copies of M into one, a comonoid carries a comultiplication that splits one copy into two, and in place of a unit picking out an element it has a counit that measures an element against the ground object I.

Definition 67.4.2: Comonoid Object

A *comonoid object* in $(\mathbf{C}, \otimes, I)$ is a monoid object in the opposite monoidal category $(\mathbf{C}^{\mathrm{op}}, \otimes, I)$: an object C with a *comultiplication* $\delta\colon C \to C \otimes C$ and a *counit* $\varepsilon\colon C \to I$ making the coassociativity diagram

$$\begin{array}{ccc} C & \xrightarrow{\ \delta\ } & C \otimes C \\ {\scriptstyle\delta}\downarrow & & \downarrow{\scriptstyle \mathrm{id}_C \otimes \delta} \\ C \otimes C & \xrightarrow[\ \delta \otimes \mathrm{id}_C\ ]{} & C \otimes C \otimes C \end{array}$$

and the two counit diagrams

$$\begin{array}{ccccc} & & C & & \\ & {\scriptstyle\lambda_C^{-1}}\swarrow & \downarrow{\scriptstyle\delta} & \searrow{\scriptstyle\rho_C^{-1}} & \\ I \otimes C & \xleftarrow[\ \varepsilon \otimes \mathrm{id}_C\ ]{} & C \otimes C & \xrightarrow[\ \mathrm{id}_C \otimes \varepsilon\ ]{} & C \otimes I \end{array}$$

commute (associators suppressed in the strict picture).

By the duality principle (box 61.3.3), every statement about monoid objects has a mirror statement about comonoid objects, obtained by reversing the arrows in $\mathbf{C}$; there is nothing to prove separately. Comonoids are the less familiar of the pair only because the everyday examples, sets and modules, carry no interesting comultiplication under $\times$ or $\otimes$: the diagonal $C \to C \otimes C$ is forced. They become substantial in categories where $\otimes$ is genuinely non-cartesian, where a comonoid is the categorical form of a coalgebra, the structure dual to an algebra that organizes, for instance, the representation theory of a group through its group algebra.

The point of the definition is that a single set of axioms, read in different monoidal categories, returns structures that look unrelated on their face. The following example collects the payoff.

Example 67.4.3: Monoids, Rings, Algebras, and Monads

A monoid object is a monoid, a ring, an algebra, or a monad according to where it is read.

1. *In* $(\mathbf{Set}, \times, 1)$. A monoid object is exactly a monoid in the ordinary sense. The map $\mu\colon M \times M \to M$ is a binary operation, $\eta\colon 1 \to M$ picks out an element $e = \eta(*)$, the associativity square is $\mu(\mu(a,b),c) = \mu(a,\mu(b,c))$, and the unit triangles say $ea = a = ae$. The cartesian structure $(\mathbf{C}, \times, 1)$ of definition 63.2.3 is what makes this the definition of a monoid; the same reading in **Top** or **Grp** gives topological monoids and monoids internal to **Grp**.

2. *In* $(\mathbf{Ab}, \otimes_{\mathbb{Z}}, \mathbb{Z})$. A monoid object is exactly a ring. An abelian group R with a $\mathbb{Z}$-bilinear multiplication $\mu\colon R \otimes_{\mathbb{Z}} R \to R$ and a unit $\eta\colon \mathbb{Z} \to R$, $\eta(1) = 1_R$, is precisely a ring: bilinearity is built into the tensor product, associativity and unitality are the two diagrams. Replacing $\mathbb{Z}$ by a commutative ring k and **Ab** by $(\mathbf{Mod}_k, \otimes_k, k)$ gives a k-algebra (the multiplication and unit of k-modules cited to [21, Tensor Product, Universal Property Of Tensor Product (Over Commutative Rings)]). Thus rings and algebras are monoid objects, one monoidal category up from monoids.

3. *In* $([\mathbf{C}, \mathbf{C}], \circ, \mathrm{id})$. A monoid object in the strict monoidal category of endofunctors of $\mathbf{C}$, with $\otimes$ the composition of functors and unit object the identity functor (example 67.1.4,

> definition 61.5.4), is exactly a monad on $\mathbf{C}$. An object of $[\mathbf{C},\mathbf{C}]$ is an endofunctor T; the multiplication $\mu\colon T\circ T\to T$ and unit $\eta\colon \mathrm{id}\to T$ are natural transformations; and the associativity and unit diagrams of definition 67.4.1 are, symbol for symbol, the associativity and unit laws of a monad (T,η,μ) from definition 65.1.1. This is the identity
>
> *a monad is a monoid in the category of endofunctors*
>
> stated as the theorem it is: the two definitions are not analogous, they are the same definition read in two monoidal categories.

The third reading is the reason the notion of monoid object is worth isolating. Chapter 5 built monads by hand, checking the associativity and unit squares of natural transformations directly; definition 67.4.1 now shows those squares were never special to endofunctors. Any construction valid for monoids in an arbitrary monoidal category applies at once to monads: the category of monoid objects, the free monoid on an object, morphisms of monoids. A monad morphism, for instance, is nothing but a morphism of monoid objects in $[\mathbf{C},\mathbf{C}]$.

A monoid in $(\mathbf{Set},\times,1)$ becomes a group exactly when every element has an inverse, and the inverse is itself a morphism $i\colon G\to G$ subject to a diagram. This upgrades the monoid-object definition in a cartesian monoidal category to a group object, the notion that lets "group" be interpreted inside geometry.

Example 67.4.4: Group Objects

Let $(\mathbf{C},\times,1)$ be a category with finite products (definition 63.2.3), regarded as a cartesian monoidal category. A *group object* is a monoid object (G,μ,η) together with an *inverse* morphism $i\colon G\to G$ such that

$$\begin{array}{ccccc} G & \xrightarrow{(\mathrm{id}_G,i)} & G\times G & \xleftarrow{(i,\mathrm{id}_G)} & G \\ {\scriptstyle e}\downarrow & & \downarrow{\scriptstyle \mu} & & \downarrow{\scriptstyle e} \\ 1 & \xrightarrow[\eta]{} & G & \xleftarrow[\eta]{} & 1 \end{array}$$

commutes, where $e\colon G\to 1$ is the unique map to the terminal object and (id_G,i), (i,id_G) are the maps into the product with the indicated components. The two squares say $\mu(g,i(g))=\eta e(g)=\mu(i(g),g)$: multiplying an element by its inverse on either side returns the unit. In $(\mathbf{Set},\times,1)$ a group object is a group. In $(\mathbf{Top},\times,1)$ it is a topological group, a group whose multiplication and inversion are continuous; in the category $\mathbf{Man}$ of smooth manifolds with the product, it is a Lie group, a group whose operations are smooth, the central object of the differential-geometric theory in [97].

Group objects show that "group" is not a set-theoretic notion but a diagrammatic one: the same diagrams, interpreted in $\mathbf{Top}$ or $\mathbf{Man}$, define topological and Lie groups without a word changing. Comultiplication reverses the picture once more, and a group object with a compatible comonoid structure in a symmetric monoidal category (definition 67.2.2) is a Hopf algebra, the structure underlying quantum groups; the symmetry is what lets the compatibility between μ and δ be stated.

The remaining topic is a finiteness property of the object itself, orthogonal to the algebraic structure above. In $\mathbf{Vect}_k$ a finite-dimensional space V has a dual V^*, and the pairing $V^*\otimes V\to k$ together with the "identity element" $k\to V\otimes V^*$ obey two triangle identities that reconstruct V from V^* and conversely. Abstracting those two identities gives dualizability.

Definition 67.4.5: Dualizable Object

An object X of a monoidal category $(\mathbf{C}, \otimes, I)$ is *(left) dualizable* if there is an object $X^\vee$, the *dual*, together with morphisms

$$\mathrm{ev}\colon X^\vee \otimes X \to I \qquad \text{and} \qquad \mathrm{coev}\colon I \to X \otimes X^\vee$$

the *evaluation* and *coevaluation*, such that the two *zigzag identities*

$$\begin{array}{ccc} X & \xrightarrow{\mathrm{coev}\otimes \mathrm{id}_X} & X \otimes X^\vee \otimes X \\ & \searrow^{\mathrm{id}_X} & \downarrow{\scriptstyle \mathrm{id}_X \otimes \mathrm{ev}} \\ & & X \end{array} \qquad \begin{array}{ccc} X^\vee & \xrightarrow{\mathrm{id}\otimes \mathrm{coev}} & X^\vee \otimes X \otimes X^\vee \\ & \searrow^{\mathrm{id}} & \downarrow{\scriptstyle \mathrm{ev}\otimes \mathrm{id}} \\ & & X^\vee \end{array}$$

commute (associators and unitors suppressed in the strict picture). A monoidal category in which every object is dualizable is called *rigid*.

The two triangles are the categorical form of the linear-algebra identity that expresses id_V through a basis and its dual basis. Reading them in $\mathbf{Vect}_k$ shows the abstraction, and pins down exactly which spaces qualify.

Example 67.4.6: Dualizable Vector Spaces

In $(\mathbf{Vect}_k, \otimes_k, k)$ a vector space V is dualizable if and only if it is finite-dimensional, with dual $V^\vee = V^* = \mathrm{Hom}_k(V, k)$. The evaluation is the pairing $\mathrm{ev}(\varphi \otimes v) = \varphi(v)$, and the coevaluation is

$$\mathrm{coev}\colon k \to V \otimes V^*, \qquad 1 \mapsto \sum_i e_i \otimes e_i^*$$

for a basis (e_i) with dual basis (e_i^*); the element $\sum_i e_i \otimes e_i^*$ is independent of the basis, being the image of id_V under the isomorphism $\mathrm{End}_k(V) \cong V \otimes V^*$ that holds precisely when V is finite-dimensional. The first zigzag sends $v \mapsto \sum_i e_i \otimes e_i^* \otimes v \mapsto \sum_i e_i\, e_i^*(v) = v$, so it is id_V; the second is the symmetric computation. When V is infinite-dimensional no coevaluation exists: a map $k \to V \otimes V^*$ has image an element of $V \otimes V^*$, necessarily a finite sum of simple tensors, and no such finite sum can satisfy the first zigzag for every v. Thus dualizability is exactly the finiteness that makes $V \cong V^{**}$ canonically.

Dualizable objects are where the linear-algebraic notion of trace survives into a symmetric monoidal category (definition 67.2.2): for an endomorphism $f\colon X \to X$ of a dualizable object one forms the composite $I \xrightarrow{\mathrm{coev}} X \otimes X^\vee \xrightarrow{f\otimes \mathrm{id}} X \otimes X^\vee \xrightarrow{\beta_{X,X^\vee}} X^\vee \otimes X \xrightarrow{\mathrm{ev}} I$, an endomorphism of I that specializes to the ordinary trace in $\mathbf{Vect}_k$. The symmetry β is what gives the swap $X \otimes X^\vee \to X^\vee \otimes X$; in a bare monoidal category no such canonical map exists, so the trace needs at least a braiding. Rigid symmetric monoidal categories, in which every object is dualizable, are the setting for Tannakian duality, which reconstructs a group from its rigid tensor category of representations; both developments belong to the next stage of the theory and are not pursued here.

68

Enriched and 2-Categories

Two facts about the previous chapters were left unremarked. The hom-*sets* of a category are objects of **Set**, but nothing forced that choice; and **Cat** carried natural transformations, a second layer of morphism an ordinary category lacks. This chapter follows both threads. *Enriched category theory* replaces hom-sets by objects of a monoidal category, recovering additive, topological, and simplicial categories as the base varies. *Two-category theory* takes the morphisms between morphisms seriously, with **Cat** as the guiding example, and recovers adjunctions and monads as statements internal to a 2-category.

The two threads are developed to different depths. The enriched theory is built in full through section 68.3: tensors and cotensors, the enriched functor category, the enriched Yoneda lemma with its proof, and weighted limits, which subsume ordinary limits and both of the first two. The 2-categorical theory is developed only as far as the enriched theory already carries it, since a strict 2-category is the **Cat**-enriched case of definition 68.1.1 and the structures whose coherence is genuine, rather than provable, are the subject of the sequel. The chapter, and the book, close at the edge of the subject, where the strict equalities weaken to coherent isomorphism, pointing beyond it to higher category theory.

68.1 Enriched Categories

The hom-set of a category is a set, and nothing more. Yet the standing cast carries hom-sets with extra structure that the plain definition discards: the morphisms between two abelian groups form an abelian group under pointwise addition, the maps between two topological spaces form a topological space, and between two categories the functors form a category (with natural transformations as its own morphisms). *Enriched category theory* takes this extra structure seriously. It replaces the hom-*set* $\mathbf{C}(x, y)$ by a hom-*object* living in a fixed monoidal category $\mathbf{V}$ (definition 67.1.1), whose tensor product gives the composition and whose unit gives the identities. The one requirement is

that $\mathbf{V}$ be monoidal: composition pairs two hom-objects, and $\otimes$ is exactly the operation for pairing objects of $\mathbf{V}$.

Definition 68.1.1: Enriched Category

Let $(\mathbf{V}, \otimes, I)$ be a monoidal category. A *category enriched over* $\mathbf{V}$, or a $\mathbf{V}$*-category*, $\mathbf{C}$ consists of

- a collection of *objects* $\mathrm{Ob}(\mathbf{C})$;
- for each ordered pair (x, y) of objects, a *hom-object* $\mathbf{C}(x, y)$ of $\mathbf{V}$;
- for each ordered triple (x, y, z), a *composition* morphism of $\mathbf{V}$

$$\circ_{xyz} \colon \mathbf{C}(y, z) \otimes \mathbf{C}(x, y) \to \mathbf{C}(x, z)$$

- for each object x, an *identity* morphism of $\mathbf{V}$

$$j_x \colon I \to \mathbf{C}(x, x)$$

subject to the associativity and unit laws, which are the following diagrams in $\mathbf{V}$. Associativity is the commuting square (writing α for the associator of $\mathbf{V}$)

$$\begin{array}{ccc} \big(\mathbf{C}(z,w) \otimes \mathbf{C}(y,z)\big) \otimes \mathbf{C}(x,y) & \xrightarrow{\ \alpha\ } & \mathbf{C}(z,w) \otimes \big(\mathbf{C}(y,z) \otimes \mathbf{C}(x,y)\big) \\ \downarrow{\scriptstyle \circ\otimes\mathrm{id}} & & \downarrow{\scriptstyle \mathrm{id}\otimes\circ} \\ \mathbf{C}(y,w) \otimes \mathbf{C}(x,y) & & \mathbf{C}(z,w) \otimes \mathbf{C}(x,z) \\ \downarrow{\scriptstyle \circ} & & \downarrow{\scriptstyle \circ} \\ \mathbf{C}(x,w) & = & \mathbf{C}(x,w) \end{array}$$

and the two unit laws are the commuting triangles (writing λ, ρ for the left and right unitors of $\mathbf{V}$)

$$\begin{array}{ccccc} I \otimes \mathbf{C}(x,y) & \xrightarrow{j_y \otimes \mathrm{id}} & \mathbf{C}(y,y) \otimes \mathbf{C}(x,y) & \xleftarrow{\mathrm{id} \otimes j_x} & \mathbf{C}(x,y) \otimes I \\ & {\scriptstyle \lambda} \searrow & \downarrow{\scriptstyle \circ} & \swarrow {\scriptstyle \rho} & \\ & & \mathbf{C}(x,y) & & \end{array}$$

The two diagrams are the ordinary associativity and unit laws with every equation of *elements* replaced by a commuting diagram of *morphisms in* $\mathbf{V}$, and every reassociation or unit-insertion routed through the coherence isomorphisms α, λ, ρ that a monoidal category gives for exactly this purpose. Nowhere does the definition speak of an element of $\mathbf{C}(x, y)$: $\mathbf{C}(x, y)$ is an object of $\mathbf{V}$, and $\mathbf{V}$ need not be a category of structured sets. Composition is not a function applied to a pair of morphisms but a single arrow out of a tensor product, and the identity at x is not a chosen element but an arrow $I \to \mathbf{C}(x, x)$ selecting it in whatever sense $\mathbf{V}$ allows. This is the shift the definition forces: from *elements and functions* to *objects and morphisms of* $\mathbf{V}$.

An ordinary category is the special case $\mathbf{V} = (\mathbf{Set}, \times, 1)$. Then $\mathbf{C}(x, y)$ is a hom-set, the composition arrow $\mathbf{C}(y, z) \times \mathbf{C}(x, y) \to \mathbf{C}(x, z)$ is the usual composition function $(g, f) \mapsto gf$, and the identity

arrow $j_x \colon 1 \to \mathbf{C}(x,x)$ from the one-point set picks out id_x. The associativity and unit diagrams reduce to $h(gf) = (hg)f$ and $f\,\mathrm{id}_x = f = \mathrm{id}_y f$. Enrichment loses nothing and is a genuine generalization: it remembers structure on the hom-objects that the passage to underlying sets throws away.

That passage is itself a construction. Given a $\mathbf{V}$-category, one recovers an ordinary category by asking $\mathbf{V}$ for the elements of each hom-object, where "element" means a morphism out of the monoidal unit.

Definition 68.1.2: Underlying Ordinary Category

Let $\mathbf{C}$ be a $\mathbf{V}$-category. Its *underlying ordinary category* $\mathbf{C}_0$ has the same objects as $\mathbf{C}$, and hom-sets

$$\mathrm{Hom}_{\mathbf{C}_0}(x,y) = \mathbf{V}\big(I, \mathbf{C}(x,y)\big)$$

the set of $\mathbf{V}$-morphisms from the unit I to the hom-object $\mathbf{C}(x,y)$. The identity of x in $\mathbf{C}_0$ is the enriched identity $j_x \colon I \to \mathbf{C}(x,x)$. The composite in $\mathbf{C}_0$ of $f \colon I \to \mathbf{C}(x,y)$ and $g \colon I \to \mathbf{C}(y,z)$ is

$$I \xrightarrow{\lambda^{-1}} I \otimes I \xrightarrow{g \otimes f} \mathbf{C}(y,z) \otimes \mathbf{C}(x,y) \xrightarrow{\circ} \mathbf{C}(x,z)$$

where $\lambda^{-1} \colon I \to I \otimes I$ is the inverse left unitor.

The associativity and unit laws of $\mathbf{C}_0$ are not assumed; they are *consequences* of the enriched laws of definition 68.1.1. Composing three elements in $\mathbf{C}_0$ produces two bracketings of the same triple tensor, and the enriched associativity square, together with the coherence (theorem 67.1.5) that makes all instances of α, λ, ρ agree, identifies them; the enriched unit triangles give the identity laws in $\mathbf{C}_0$. The underlying category is what the $\mathbf{V}$-category induces on $\mathbf{Set}$ by probing each hom-object with the unit. When $\mathbf{V} = \mathbf{Set}$ it changes nothing, since $\mathbf{Set}(1,S) \cong S$: an ordinary category is its own underlying category. The interesting cases are those where $\mathbf{C}_0$ forgets real structure, and the enriched data is strictly richer than the ordinary category it sits over.

Example 68.1.3: Enrichment over the Standing Cast

Each choice of monoidal base $\mathbf{V}$ names a familiar species of category.

1. $\mathbf{Set}$*-enriched categories are ordinary categories.* With $\mathbf{V} = (\mathbf{Set}, \times, 1)$ the data of definition 68.1.1 is precisely objects, hom-sets, a composition function, and chosen identities obeying associativity and unit laws. This is the definition of a locally small category, and the underlying category $\mathbf{C}_0$ is $\mathbf{C}$ itself.

2. $\mathbf{Ab}$*-enriched categories are preadditive categories.* Take $\mathbf{V} = (\mathbf{Ab}, \otimes_{\mathbb{Z}}, \mathbb{Z})$, the tensor product of abelian groups with unit $\mathbb{Z}$. Each hom-object $\mathbf{C}(x,y)$ is then an abelian group, and composition is a morphism of abelian groups

   $$\mathbf{C}(y,z) \otimes_{\mathbb{Z}} \mathbf{C}(x,y) \to \mathbf{C}(x,z)$$

   which is exactly a $\mathbb{Z}$-bilinear map $\mathbf{C}(y,z) \times \mathbf{C}(x,y) \to \mathbf{C}(x,z)$, by the universal property of $\otimes_{\mathbb{Z}}$. Composition is therefore biadditive: $h(g+g') = hg + hg'$ and $(h+h')g = hg + h'g$. A category with abelian-group hom-sets and biadditive composition is a *preadditive category*, and the underlying category recovers the hom-set as $\mathbf{Ab}(\mathbb{Z}, \mathbf{C}(x,y)) \cong \mathbf{C}(x,y)$. This is the enrichment that homological algebra rests on: an additive category is a preadditive category

with a zero object and biproducts, and **Ab**-enrichment is the first axiom (see [21, Tensor Product] for the module-theoretic origin of $\otimes_{\mathbb{Z}}$).

3. **Top**-*enriched categories topologize their hom-sets.* With $\mathbf{V} = (\mathbf{Top}, \times, *)$ each $\mathbf{C}(x, y)$ is a topological space and composition $\mathbf{C}(y, z) \times \mathbf{C}(x, y) \to \mathbf{C}(x, z)$ is continuous. The identity $* \to \mathbf{C}(x, x)$ from the one-point space picks out id_x. The underlying category has hom-sets $\mathbf{Top}(*, \mathbf{C}(x, y)) \cong \mathbf{C}(x, y)$ as sets, discarding the topology; the enriched structure remembers, for instance, when two maps are homotopic through a continuous path of morphisms.

4. **Cat**-*enriched categories are strict* 2-*categories.* Take $\mathbf{V} = (\mathbf{Cat}, \times, \mathbf{1})$, categories under product with the terminal category $\mathbf{1}$ as unit. Each hom-object $\mathbf{C}(x, y)$ is now a *category*: its objects are the morphisms $x \to y$, and its own morphisms are a second layer of structure between them. Composition is a functor $\mathbf{C}(y, z) \times \mathbf{C}(x, y) \to \mathbf{C}(x, z)$. This is exactly a strict 2-category, the subject of section 68.4: the prototype is **Cat** itself, whose hom-categories are the functor categories $[\mathbf{C}, \mathbf{D}]$ (definition 61.5.4) with natural transformations as the second layer.

5. *Lawvere metric spaces.* Let $\mathbf{V} = ([0, \infty], +, 0)$ be the extended nonnegative reals, viewed as a category by the order $\geq$ (an arrow $a \to b$ exactly when $a \geq b$), monoidal under addition with unit 0. A category enriched over this $\mathbf{V}$ has objects, and for each pair a number $\mathbf{C}(x, y) \in [0, \infty]$ to be read as a *distance*. The composition arrow $\mathbf{C}(y, z) + \mathbf{C}(x, y) \to \mathbf{C}(x, z)$ is, in this order category, precisely the inequality

$$\mathbf{C}(x, z) \leq \mathbf{C}(y, z) + \mathbf{C}(x, y)$$

the triangle inequality, and the identity $0 \to \mathbf{C}(x, x)$ is the inequality $\mathbf{C}(x, x) \leq 0$, forcing $\mathbf{C}(x, x) = 0$. Such a structure is a *Lawvere metric space*: a metric space that drops symmetry and the separation axiom (distinct points may sit at distance 0) and permits ∞. Composition of morphisms and the triangle inequality are the same axiom seen through two monoidal bases.

The five bases run from the trivial to the exotic and read off five theories at a stroke. **Set** recovers the ordinary notion; **Ab** recovers the preadditive categories of homological algebra; **Cat** recovers strict 2-categories; and the order category $[0, \infty]$ shows that enrichment need not be over structured sets at all, turning the triangle inequality into an instance of composition. The last example is the sharpest test of the definition, since $[0, \infty]$ has no underlying sets in the naive sense: what matters is only that it is monoidal, and that alone is enough to carry categorical composition. The lesson is that "category" is not tied to **Set**; it is tied to whatever monoidal $\mathbf{V}$ one composes in.

68.2 Enriched Functors and Naturality

A $\mathbf{V}$-category (definition 68.1.1) carries its structure in $\mathbf{V}$: a functor between two such categories must act on hom-objects by morphisms of $\mathbf{V}$, and a natural transformation must have components that live in $\mathbf{V}$ rather than in Hom-sets. This section installs the two notions, shows how a monoidal functor transports the whole theory from one base to another, and records the enriched form of the Yoneda lemma.

An ordinary functor sends each hom-set $\mathrm{Hom}(x, y)$ to $\mathrm{Hom}(Fx, Fy)$ by post- and pre-composition, and the two functoriality axioms say this map respects composition and identities. The enriched

version replaces those set functions with $\mathbf{V}$-morphisms and rewrites the two axioms as commuting diagrams in $\mathbf{V}$.

Definition 68.2.1: Enriched Functor

Let $\mathbf{V}$ be a monoidal category and let $\mathbf{C}$, $\mathbf{D}$ be $\mathbf{V}$-categories. A $\mathbf{V}$-*functor* (or *enriched functor*) $F\colon \mathbf{C} \to \mathbf{D}$ consists of

- a map $x \mapsto Fx$ on objects, and
- for each pair of objects x, y of $\mathbf{C}$, a $\mathbf{V}$-morphism

$$F_{x,y}\colon \mathbf{C}(x,y) \to \mathbf{D}(Fx, Fy)$$

such that the following two diagrams in $\mathbf{V}$ commute. Writing $\circ$ for the composition morphisms of $\mathbf{C}$ and $\mathbf{D}$ and $j_x\colon I \to \mathbf{C}(x,x)$ for the identity morphisms, compatibility with composition is the commutativity of

$$\begin{array}{ccc} \mathbf{C}(y,z) \otimes \mathbf{C}(x,y) & \xrightarrow{F_{y,z} \otimes F_{x,y}} & \mathbf{D}(Fy,Fz) \otimes \mathbf{D}(Fx,Fy) \\ \downarrow{\scriptstyle \circ} & & \downarrow{\scriptstyle \circ} \\ \mathbf{C}(x,z) & \xrightarrow[F_{x,z}]{} & \mathbf{D}(Fx,Fz) \end{array}$$

and compatibility with identities is the commutativity of

$$\begin{array}{ccc} I & \xrightarrow{j_x} & \mathbf{C}(x,x) \\ & \searrow^{j_{Fx}} & \downarrow{\scriptstyle F_{x,x}} \\ & & \mathbf{D}(Fx,Fx) \end{array}$$

Reading the squares in $\mathbf{V} = \mathbf{Set}$ recovers the ordinary axioms: the first says $F(g \circ f) = Fg \circ Ff$ and the second $F(\mathrm{id}_x) = \mathrm{id}_{Fx}$. The content is that these hold at the level of $\mathbf{V}$, so the functor is compatible with whatever extra structure the hom-objects carry.

Example 68.2.2: Additive Functors as Ab-Functors

Let $\mathbf{V} = \mathbf{Ab}$, so that $\mathbf{C}$ and $\mathbf{D}$ are preadditive categories (example 68.1.3): each Hom-set is an abelian group and composition is bilinear. An $\mathbf{Ab}$-functor $F\colon \mathbf{C} \to \mathbf{D}$ is an ordinary functor whose action on morphisms

$$F_{x,y}\colon \mathbf{C}(x,y) \to \mathbf{D}(Fx,Fy)$$

is a group homomorphism for every pair x, y, that is, $F(f+g) = Ff + Fg$. These are exactly the *additive functors*. The composition square is the statement that F is bilinear-compatible, and the identity triangle that $F(\mathrm{id}_x) = \mathrm{id}_{Fx}$; both are automatic for a functor once additivity on hom-groups is imposed. For $\mathbf{V} = \mathbf{Cat}$, an enriched functor is a strict 2-functor, sending objects, 1-cells, and 2-cells compatibly (this is developed in section 68.4).

An enriched functor moves objects and hom-objects; a natural transformation must compare two such functors at each object. In the unenriched setting a component is a morphism $\alpha_x\colon Fx \to Gx$, and morphisms out of x are elements of a hom-set. In $\mathbf{V}$ there are no elements; a "point" of the hom-object

$\mathbf{D}(Fx, Gx)$ is a $\mathbf{V}$-morphism $I \to \mathbf{D}(Fx, Gx)$ out of the unit, matching the underlying-category convention $\mathrm{Hom}(x, y) = \mathbf{V}(I, \mathbf{C}(x, y))$ from definition 68.1.2. A component is therefore such a morphism, and naturality becomes a single diagram in $\mathbf{V}$.

Definition 68.2.3: Enriched Natural Transformation

Let $F, G \colon \mathbf{C} \to \mathbf{D}$ be $\mathbf{V}$-functors. A $\mathbf{V}$-*natural transformation* (or *enriched natural transformation*) $\alpha \colon F \Rightarrow G$ assigns to each object x of $\mathbf{C}$ a $\mathbf{V}$-morphism

$$\alpha_x \colon I \to \mathbf{D}(Fx, Gx)$$

(the *component* at x) such that for every pair x, y the following diagram in $\mathbf{V}$ commutes:

$$\begin{array}{ccccc} \mathbf{C}(x,y) & \xrightarrow{\rho^{-1}} & \mathbf{C}(x,y) \otimes I & \xrightarrow{G_{x,y} \otimes \alpha_x} & \mathbf{D}(Gx,Gy) \otimes \mathbf{D}(Fx,Gx) \\ \downarrow{\scriptstyle \lambda^{-1}} & & & & \downarrow{\scriptstyle \circ} \\ I \otimes \mathbf{C}(x,y) & \xrightarrow[\alpha_y \otimes F_{x,y}]{} & \mathbf{D}(Fy,Gy) \otimes \mathbf{D}(Fx,Fy) & \xrightarrow[\circ]{} & \mathbf{D}(Fx,Gy) \end{array}$$

Here λ and ρ are the unitors of $\mathbf{V}$ (definition 67.1.1), inserting the unit I so that a component may be composed against a hom-object.

The two legs of the diagram are the enriched versions of the two paths around the ordinary naturality square. The top-right leg applies G to a morphism $f \colon x \to y$ and pre-composes with α_x, producing the path $Gf \cdot \alpha_x$; the bottom-left leg applies F and post-composes with α_y, producing $\alpha_y \cdot Ff$. Equality of the legs is precisely $\alpha_y \circ Ff = Gf \circ \alpha_x$ written internally to $\mathbf{V}$. In $\mathbf{V} = \mathbf{Set}$ each component $\alpha_x \colon I = \{*\} \to \mathbf{D}(Fx, Gx)$ names an element $\alpha_x \in \mathrm{Hom}(Fx, Gx)$, and the diagram collapses to the familiar commuting square.

Example 68.2.4: Additive Natural Transformations

For $\mathbf{V} = \mathbf{Ab}$, a component $\alpha_x \colon \mathbb{Z} \to \mathbf{D}(Fx, Gx)$ is a group homomorphism out of $\mathbb{Z}$, hence pinned down by the single element $\alpha_x(1) \in \mathrm{Hom}(Fx, Gx)$: an ordinary component morphism. The enriched naturality diagram then says nothing more than ordinary naturality, because both composition maps of $\mathbf{Ab}$ are $\mathbb{Z}$-bilinear and evaluating at $1 \otimes 1$ returns the set-level square. An $\mathbf{Ab}$-natural transformation between additive functors is thus an ordinary natural transformation, with no further condition to check.

The definitions of $\mathbf{V}$-category, $\mathbf{V}$-functor, and $\mathbf{V}$-natural transformation depend on $\mathbf{V}$ only through its monoidal structure. A functor between monoidal categories that preserves that structure should therefore transport enriched categories along it. The correct hypothesis is weaker than strict preservation of $\otimes$: it is enough that $\mathbf{V}$-tensors map to $\mathbf{W}$-tensors up to a coherent comparison morphism, which is exactly a lax monoidal functor. That comparison is what carries composition across the base.

Proposition 68.2.5: Change of Enriching Base

Let $(\Phi, \varphi, \varphi_0)\colon \mathbf{V} \to \mathbf{W}$ be a lax monoidal functor: Φ is a functor equipped with a natural comparison $\varphi_{a,b}\colon \Phi a \otimes \Phi b \to \Phi(a \otimes b)$ and a unit comparison $\varphi_0\colon I_{\mathbf{W}} \to \Phi(I_{\mathbf{V}})$, satisfying the associativity and unit coherence laws. Then Φ induces a functor

$$\Phi_*\colon \mathbf{V}\text{-}\mathbf{Cat} \to \mathbf{W}\text{-}\mathbf{Cat}$$

called *change of base*, sending a $\mathbf{V}$-category $\mathbf{C}$ to the $\mathbf{W}$-category $\Phi_*\mathbf{C}$ with the same objects and hom-objects $(\Phi_*\mathbf{C})(x, y) = \Phi\big(\mathbf{C}(x, y)\big)$.

***Proof*:**
Fix a lax monoidal functor $(\Phi, \varphi, \varphi_0)$. The construction proceeds in two stages: first the object $\Phi_*\mathbf{C}$, then the action of Φ_* on enriched functors, checking the axioms at each stage.

Step 1: The category $\Phi_*\mathbf{C}$. Take the objects of $\mathbf{C}$ and the hom-objects $\Phi(\mathbf{C}(x, y))$ in $\mathbf{W}$. The composition morphism of $\Phi_*\mathbf{C}$ is the composite

$$\Phi(\mathbf{C}(y, z)) \otimes \Phi(\mathbf{C}(x, y)) \xrightarrow{\varphi} \Phi\big(\mathbf{C}(y, z) \otimes \mathbf{C}(x, y)\big) \xrightarrow{\Phi(\circ)} \Phi(\mathbf{C}(x, z))$$

which first uses the comparison φ to gather the two hom-objects inside Φ and then applies Φ to the composition of $\mathbf{C}$. The identity morphism is

$$I_{\mathbf{W}} \xrightarrow{\varphi_0} \Phi(I_{\mathbf{V}}) \xrightarrow{\Phi(j_x)} \Phi(\mathbf{C}(x, x))$$

using the unit comparison followed by Φ applied to the identity of $\mathbf{C}$. Associativity of composition in $\Phi_*\mathbf{C}$ follows from associativity in $\mathbf{C}$ (apply Φ to its associativity square) glued to the associativity coherence of the lax structure φ; the two unit laws follow likewise from the unit laws in $\mathbf{C}$ glued to the unit coherence of φ_0. Each verification is a diagram in $\mathbf{W}$ built from a Φ-image of a $\mathbf{C}$-axiom and one lax-coherence cell sharing a common edge: the coherence cell rebrackets the φ-comparisons to expose Φ applied to the tensor of the hom-objects, and the Φ-image of the $\mathbf{C}$-axiom equates the two composites there, so the two cells paste along that edge into the required square. Thus $\Phi_*\mathbf{C}$ is a $\mathbf{W}$-category.

Step 2: The action on functors and naturality. Given a $\mathbf{V}$-functor $F\colon \mathbf{C} \to \mathbf{D}$, define Φ_*F to agree with F on objects and to act on hom-objects by

$$(\Phi_*F)_{x,y} = \Phi(F_{x,y})\colon \Phi(\mathbf{C}(x, y)) \to \Phi(\mathbf{D}(Fx, Fy))$$

Its composition square is Φ applied to the composition square of F, with the naturality of φ used to slide $\Phi(F_{y,z}) \otimes \Phi(F_{x,y})$ past the two copies of the comparison; the identity triangle is Φ applied to that of F, precomposed with φ_0. Both commute, so Φ_*F is a $\mathbf{W}$-functor. Functoriality of Φ_*, preservation of enriched composition and identities of functors, is immediate, since Φ_* acts as Φ on hom-objects and Φ is a functor. This gives the assignment on $\mathbf{V}$-$\mathbf{Cat}$, completing the proof.

Change of base is the mechanism by which enriched category theory specializes to ordinary category theory, and by which one kind of enrichment passes to another. The main instance takes $\mathbf{W} = \mathbf{Set}$.

Example 68.2.6: The Underlying Category as Change of Base
Let $\mathbf{V}$ be monoidal. The representable functor

$$\mathbf{V}(I,-)\colon \mathbf{V}\to\mathbf{Set},\qquad a\mapsto \mathbf{V}(I,a)$$

is lax monoidal: its comparison sends a pair $(u\colon I\to a,\ v\colon I\to b)$ to the composite $I\xrightarrow{\lambda^{-1}} I\otimes I\xrightarrow{u\otimes v} a\otimes b$, and its unit comparison $\{*\}\to\mathbf{V}(I,I)$ picks out id_I. Change of base along it,

$$\big(\mathbf{V}(I,-)\big)_*\colon \mathbf{V}\text{-}\mathbf{Cat}\to\mathbf{Set}\text{-}\mathbf{Cat}=\mathbf{Cat}$$

sends a $\mathbf{V}$-category $\mathbf{C}$ to a category with hom-sets $\mathbf{V}(I,\mathbf{C}(x,y))$, exactly the underlying category $\mathbf{C}_0$ of definition 68.1.2. The construction of $\mathbf{C}_0$ is thus not an ad hoc device but the $\mathbf{W}=\mathbf{Set}$ case of this proposition. Concretely, for $\mathbf{V}=\mathbf{Ab}$ the functor $\mathbf{Ab}(\mathbb{Z},-)$ is the forgetful functor $\mathbf{Ab}\to\mathbf{Set}$, and change of base along it strips a preadditive category down to its underlying ordinary category, forgetting the abelian-group structure on the hom-sets while keeping the same objects and morphisms.

A $\mathbf{V}$-natural transformation, as definition 68.2.3 defines it, is a family of morphisms, and families form a set. Every other hom in this chapter has been an object of $\mathbf{V}$, and the collection of $\mathbf{V}$-natural transformations ought to be one too. Constructing that object is the first task of section 68.3, and it is what the enriched Yoneda lemma needs before it can even be stated.

68.3 Enriched Functor Categories and Weighted Limits

Two constructions stand between the definitions of the previous section and a working enriched theory. The first is the *end*, a limit in $\mathbf{V}$ that cuts the product of the hom-objects $\mathbf{D}(Fc,Gc)$ down to the part respecting naturality; it is what promotes the $\mathbf{V}$-natural transformations from a set to an object of $\mathbf{V}$, and with it the $\mathbf{V}$-functors $\mathbf{C}\to\mathbf{D}$ become a $\mathbf{V}$-category $[\mathbf{C},\mathbf{D}]$. The second is the *tensor* and *cotensor*, by which an object of $\mathbf{V}$ acts on an object of a $\mathbf{V}$-category. Together they make the enriched Yoneda lemma provable, and they yield one definition, the weighted limit, that has ordinary limits, tensors and cotensors as three instances.

Throughout this section $\mathbf{V}$ is symmetric monoidal closed (definition 67.2.2, definition 67.3.1) with all small limits and colimits, and $\mathbf{C}$ is small. Closedness gives the internal hom $[a,b]$; symmetry is what allows $\mathbf{C}^{\mathrm{op}}$ to be formed as a $\mathbf{V}$-category and what orients the second of the two morphisms in definition 68.3.3; completeness gives the products and equalizers that the end is built from, and cocompleteness the coproducts and coequalizers its dual needs. The bracket $[a,b]$ for the internal hom and $[\mathbf{C},\mathbf{D}]$ for the functor category are distinguished by their arguments, objects in the first case and categories in the second.

Ordinary category theory copies an object along a set: the copower $S\cdot e$ of section 66.4 is S-many copies of e, characterized by $\mathrm{Hom}(S\cdot e,d)\cong\mathbf{Set}(S,\mathrm{Hom}(e,d))$. Enriched over $\mathbf{V}$ the indexing set becomes an object of $\mathbf{V}$ and the hom-sets become hom-objects, and the same two universal properties read in $\mathbf{V}$ define the two constructions below.

Definition 68.3.1: Tensor and Cotensor

Let $\mathbf{C}$ be a $\mathbf{V}$-category, c an object of $\mathbf{C}$, and v an object of $\mathbf{V}$. The *tensor* of c by v is an object $v \odot c$ of $\mathbf{C}$ together with an isomorphism

$$\mathbf{C}(v \odot c,\ d) \ \cong\ \big[v,\ \mathbf{C}(c, d)\big]$$

of objects of $\mathbf{V}$, natural in d. The *cotensor* of c by v is an object c^{v} of $\mathbf{C}$ together with an isomorphism

$$\mathbf{C}(d,\ c^{v}) \ \cong\ \big[v,\ \mathbf{C}(d, c)\big]$$

natural in d. The category $\mathbf{C}$ is *tensored* if $v \odot c$ exists for every v and c, and *cotensored* if c^{v} always exists.

Each is defined by a representing property, so each is unique up to a unique isomorphism compatible with the displayed natural isomorphism, by the argument of theorem 62.2.1 applied to the underlying category. The tensor is v-indexed copies of c and the cotensor is v-indexed families in c, with "v-indexed" interpreted by $\mathbf{V}$ rather than by a set. Note which variable each is natural in: the tensor represents a functor of the target and the cotensor a functor of the source, which is why the tensor is a colimit-like construction and the cotensor a limit-like one.

Example 68.3.2: Tensors and Cotensors over the Standing Bases

1. $\mathbf{V}$ *over itself.* The base $\mathbf{V}$ is a $\mathbf{V}$-category with hom-objects $[a, b]$. Its composition $[b, c] \otimes [a, b] \to [a, c]$ is the transpose under (67.1) of

$$\big([b, c] \otimes [a, b]\big) \otimes a \xrightarrow{\alpha} [b, c] \otimes \big([a, b] \otimes a\big) \xrightarrow{\mathrm{id} \otimes \mathrm{ev}_{a,b}} [b, c] \otimes b \xrightarrow{\mathrm{ev}_{b,c}} c$$

   with ev the evaluation of theorem 67.3.2, and its identity $I \to [a, a]$ is the transpose of $\lambda_a \colon I \otimes a \to a$. By construction $\mathrm{ev}_{a,c} \circ (\circ \otimes a)$ is the displayed composite of two evaluations, and $\mathrm{ev}_{a,a} \circ (j_a \otimes a) = \lambda_a$ for the identity j_a. Transpose both sides of each axiom of definition 68.1.1. For associativity, applying the first identity twice on each side, and moving associators past evaluations by naturality of α, turns both sides into the composite of the three evaluations out of $[c, d] \otimes [b, c] \otimes [a, b] \otimes a$, each preceded by a composite of associators. For the unit axioms, the second identity and naturality of λ, ρ and ev turn both sides into $\mathrm{ev}_{a,b}$ preceded by a composite of associators and unitors. In each case the two composites of structure isomorphisms agree by theorem 67.1.5(1), which covers the pentagon for associativity and the identity $\lambda_{X \otimes Y} \circ \alpha_{I,X,Y} = \lambda_X \otimes Y$ for the left unit, so the two sides are equal. For $g \colon a' \to a$, composition with the name $I \to [a', a]$ of g (the transpose of $g \circ \lambda_{a'}$) is the map $[a, b] \to [a', b]$ whose transpose is $\mathrm{ev}_{a,b} \circ (\mathrm{id} \otimes g) \colon [a, b] \otimes a' \to b$, by the same computation, with the triangle axiom $(\mathrm{id} \otimes \lambda_{a'}) \circ \alpha_{[a,b],I,a'} = \rho_{[a,b]} \otimes a'$ in place of theorem 67.1.5, so the functoriality of $[-, b]$ in this $\mathbf{V}$-category is the one for which (67.1) is natural in X as well as in A and Y. There $v \odot a = v \otimes a$ and $a^{v} = [v, a]$. The first is the internal form of (67.1): the required isomorphism $[v \otimes a, b] \cong [v, [a, b]]$ holds because, for every u, the adjunction gives $\mathbf{V}(u, [v \otimes a, b]) \cong \mathbf{V}(u \otimes v \otimes a, b) \cong \mathbf{V}(u, [v, [a, b]])$ naturally in u, and theorem 62.2.1 turns a natural isomorphism of representables into one of the representing objects. The second follows from the first by symmetry of $\otimes$.

2. $\mathbf{V} = \mathbf{Set}$. For an ordinary category $\mathbf{C}$ the defining isomorphism reads $\mathrm{Hom}(S \odot c, d) \cong \mathbf{Set}(S, \mathrm{Hom}(c, d))$, and an S-indexed family of maps $c \to d$ is a single map out of the

coproduct. So $S \odot c = \coprod_S c$ and, dually, $c^S = \prod_S c$: the tensor and cotensor are the copower and power of section 66.4, and a category is tensored and cotensored over **Set** exactly when it has all small coproducts and products.

3. $\mathbf{V} = \mathbf{Ab}$. For $\mathbf{C} = \mathbf{Ab}$ itself, $A \odot B = A \otimes_{\mathbb{Z}} B$ and $B^A = \mathrm{Hom}_{\mathbb{Z}}(A, B)$, by (1), since **Ab** is closed with internal hom $\mathrm{Hom}_{\mathbb{Z}}$. For $\mathbf{C}$ the R-modules, the tensor of a module M by an abelian group A is $A \otimes_{\mathbb{Z}} M$ with R acting through M, because a homomorphism $A \to \mathrm{Hom}_R(M, N)$ is the same as an R-linear map $A \otimes_{\mathbb{Z}} M \to N$.

The three bases show the pattern: over **Set** the tensor is a coproduct of copies, over **Ab** it is a tensor product, and over $\mathbf{V}$ itself it is $\otimes$. In every case the operation is the one that lets an object of the base act on an object of the enriched category, and that action is what definition 68.3.7 will weight a diagram by.

The second construction is the one the previous section stopped short of. A $\mathbf{V}$-natural transformation $F \Rightarrow G$ is a family of morphisms $I \to \mathbf{D}(Fc, Gc)$ satisfying the naturality condition of definition 68.2.3. Replacing "family of morphisms out of I" by "object of $\mathbf{V}$ mapping to each $\mathbf{D}(Fc, Gc)$", and imposing naturality as an equation between two morphisms into a product, turns that collection into a limit in $\mathbf{V}$.

Definition 68.3.3: The Object of Enriched Natural Transformations

Let $F, G \colon \mathbf{C} \to \mathbf{D}$ be $\mathbf{V}$-functors. The *object of* $\mathbf{V}$*-natural transformations* from F to G, also called the *end* of $c \mapsto \mathbf{D}(Fc, Gc)$ and written

$$[\mathbf{C}, \mathbf{D}](F, G) \;=\; \int_c \mathbf{D}(Fc, Gc)$$

is the equalizer in $\mathbf{V}$ (definition 63.2.4) of the two morphisms

$$\prod_c \mathbf{D}(Fc, Gc) \;\rightrightarrows\; \prod_{c,c'} \left[\, \mathbf{C}(c, c'),\ \mathbf{D}(Fc, Gc') \,\right]$$

whose components at a pair (c, c') are the transposes under (67.1) of

$$\textstyle\prod_b \mathbf{D}(Fb, Gb) \otimes \mathbf{C}(c, c') \xrightarrow{\pi_{c'} \otimes F_{c,c'}} \mathbf{D}(Fc', Gc') \otimes \mathbf{D}(Fc, Fc') \xrightarrow{\circ} \mathbf{D}(Fc, Gc')$$

and

$$\begin{aligned}\textstyle\prod_b \mathbf{D}(Fb, Gb) \otimes \mathbf{C}(c, c') &\xrightarrow{\pi_c \otimes G_{c,c'}} \mathbf{D}(Fc, Gc) \otimes \mathbf{D}(Gc, Gc') \\ &\xrightarrow{\sigma} \mathbf{D}(Gc, Gc') \otimes \mathbf{D}(Fc, Gc) \xrightarrow{\circ} \mathbf{D}(Fc, Gc')\end{aligned}$$

where π_c is a product projection and σ the symmetry of $\mathbf{V}$. The products are indexed by the objects and the ordered pairs of objects of the small category $\mathbf{C}$, and both they and the equalizer exist because $\mathbf{V}$ is complete.

The two morphisms are the two routes from a component at one object to a value at another: the first carries the component at c' backwards along F, the second carries the component at c forwards along G, and a family is natural exactly when the two agree. Writing α_c for a component, the first is $\alpha_{c'} \circ F(f)$ and the second $G(f) \circ \alpha_c$ in the notation of an ordinary category; the symmetry σ appears in the second because $\circ$ takes its arguments in the order (later, earlier) while the projection produces

them in the order (earlier, later).

Probing the equalizer with the unit recovers the unenriched notion. The functor $\mathbf{V}(I,-)$ is representable, hence preserves limits, so $\mathbf{V}\big(I,[\mathbf{C},\mathbf{D}](F,G)\big)$ is the equalizer of the corresponding pair of functions, which is precisely the set of families $\alpha_c\colon I\to\mathbf{D}(Fc,Gc)$ satisfying definition 68.2.3. The new object therefore refines the old set rather than replacing it.

Proposition 68.3.4: The Enriched Functor Category

Let $\mathbf{C}$ be a small $\mathbf{V}$-category and $\mathbf{D}$ a $\mathbf{V}$-category. The $\mathbf{V}$-functors $\mathbf{C}\to\mathbf{D}$ are the objects of a $\mathbf{V}$-category $[\mathbf{C},\mathbf{D}]$ whose hom-objects are those of definition 68.3.3. Its underlying ordinary category (definition 68.1.2) is the category of $\mathbf{V}$-functors and $\mathbf{V}$-natural transformations, and for $\mathbf{V}=\mathbf{Set}$ it is the functor category of definition 61.5.4.

***Proof*:**
Write $E(F,G)=[\mathbf{C},\mathbf{D}](F,G)$ and let $\pi_c\colon E(F,G)\to\mathbf{D}(Fc,Gc)$ denote the composite of the equalizer inclusion with the projection at c.

Step 1: Composition. The componentwise composites

$$E(G,H)\otimes E(F,G)\xrightarrow{\pi_c\otimes\pi_c}\mathbf{D}(Gc,Hc)\otimes\mathbf{D}(Fc,Gc)\xrightarrow{\circ}\mathbf{D}(Fc,Hc)$$

are the components of a morphism into $\prod_c\mathbf{D}(Fc,Hc)$. It factors through the equalizer $E(F,H)$, and this is the one point needing argument. Transposing, the claim is that the two routes from $E(G,H)\otimes E(F,G)\otimes\mathbf{C}(c,c')$ to $\mathbf{D}(Fc,Hc')$ agree. Take the route carrying the composite component at c' backwards along F. Since $E(G,H)$ and $E(F,G)$ are equalizers, their own defining equations apply: the β-factor may be moved from "at c', transported along G" to "at c, transported along G" and then the α-factor from "at c' along F" to "at c along H". Concretely, insert $\mathbf{C}(c,c')$ between the two factors using symmetry, apply the equalizer equation of $E(F,G)$ to replace $\alpha_{c'}\circ F$ by $G\circ\alpha_c$, then apply the equalizer equation of $E(G,H)$ to replace $\beta_{c'}\circ G$ by $H\circ\beta_c$. The two applications are along different tensor factors, so they commute, and associativity of $\circ$ in $\mathbf{D}$ closes the square onto the second route. Hence the composite lands in $E(F,H)$.

Step 2: Identities. The morphisms $j_{Fc}\colon I\to\mathbf{D}(Fc,Fc)$ assemble into $I\to\prod_c\mathbf{D}(Fc,Fc)$, and this factors through $E(F,F)$: the two routes out of $I\otimes\mathbf{C}(c,c')$ are $\mathrm{id}_{Fc'}\circ F(f)$ and $F(f)\circ\mathrm{id}_{Fc}$, equal by the unit laws of $\mathbf{D}$. This gives $j_F\colon I\to E(F,F)$.

Step 3: The axioms. Associativity and the unit laws for the composition of Step 1 are equations between morphisms into $E(F,K)$, and the projections π_c out of an equalizer of a product are jointly monic, so it suffices to check them after each π_c. There they read as associativity and the unit laws of $\mathbf{D}$ at the object Fc, which hold by definition 68.1.1. So $[\mathbf{C},\mathbf{D}]$ is a $\mathbf{V}$-category.

Step 4: The underlying category and the **Set** *case.* By definition 68.1.2 the underlying category has hom-sets $\mathbf{V}(I,E(F,G))$, identified above with the $\mathbf{V}$-natural transformations $F\Rightarrow G$, and Steps 1 and 2 restrict to their usual composition and identities. For $\mathbf{V}=\mathbf{Set}$ the internal hom is the hom-set, the product is the cartesian product and the equalizer the subset on which the two functions agree, so $E(F,G)$ is the set of natural transformations and $[\mathbf{C},\mathbf{D}]$ is definition 61.5.4.

The construction is the ordinary functor category with two substitutions: the product of hom-sets becomes a product in $\mathbf{V}$, and the naturality condition, stated in the ordinary case as an equation

holding at each morphism, becomes the equalizer that imposes it. Everything else, composition and identities, is inherited componentwise from $\mathbf{D}$, which is why Step 3 reduces to axioms already available.

One base shows both constructions at once.

Example 68.3.5: Modules over a Ring as an Enriched Functor Category

Let R be a ring and let $\mathbf{R}$ be the $\mathbf{Ab}$-category with a single object $*$ and hom-object $\mathbf{R}(*,*) = R$, its composition the multiplication of R and its identity $j_*\colon \mathbb{Z} \to R$ the map sending 1 to 1_R. This is definition 68.1.1 over $\mathbf{V} = (\mathbf{Ab}, \otimes_{\mathbb{Z}}, \mathbb{Z})$, and the associativity and unit diagrams are the ring axioms.

An $\mathbf{Ab}$-functor $F\colon \mathbf{R} \to \mathbf{Ab}$ is an abelian group $M = F(*)$ together with a homomorphism $R \to \mathrm{Hom}_{\mathbb{Z}}(M,M)$ respecting multiplication and the unit, which is exactly a left R-module.

For two such, $F \leftrightarrow M$ and $G \leftrightarrow N$, definition 68.3.3 has a single-factor product $\mathrm{Hom}_{\mathbb{Z}}(M,N)$ and equalizes the two maps $\mathrm{Hom}_{\mathbb{Z}}(M,N) \to \mathrm{Hom}_{\mathbb{Z}}\big(R, \mathrm{Hom}_{\mathbb{Z}}(M,N)\big)$ sending f to $r \mapsto f \circ (r \cdot -)$ and to $r \mapsto (r \cdot -) \circ f$. Their equalizer is the subgroup of f with $f(rm) = rf(m)$, so

$$[\mathbf{R}, \mathbf{Ab}](F,G) \;=\; \mathrm{Hom}_R(M,N)$$

and proposition 68.3.4 says the left R-modules form an $\mathbf{Ab}$-category whose hom-objects are the R-linear maps. The $\mathbf{Ab}$-enrichment of R-modules that homological algebra takes as given is thus an instance of the enriched functor category.

With $[\mathbf{C}, \mathbf{V}]$ available, the enriched Yoneda lemma can be stated and proved. The ordinary statement (theorem 62.2.1) identified the natural transformations out of a representable with the elements of Fx; the enriched one identifies an object of $\mathbf{V}$ with an object of $\mathbf{V}$, and the proof is the same evaluation-at-the-identity argument written in $\mathbf{V}$.

Theorem 68.3.6: Enriched Yoneda Lemma

Let $\mathbf{C}$ be a small $\mathbf{V}$-category and $F\colon \mathbf{C} \to \mathbf{V}$ a $\mathbf{V}$-functor into the base. For each object x of $\mathbf{C}$ there is an isomorphism

$$[\mathbf{C}, \mathbf{V}]\big(\mathbf{C}(x,-),\, F\big) \;\cong\; Fx$$

of objects of $\mathbf{V}$, natural in x and in F. For $\mathbf{V} = \mathbf{Set}$ it is the bijection $\mathrm{Nat}(\mathrm{Hom}(x,-), F) \cong Fx$ of theorem 62.2.1.

***Proof*:**

Write $E = [\mathbf{C}, \mathbf{V}]\big(\mathbf{C}(x,-), F\big) = \int_y \big[\mathbf{C}(x,y), Fy\big]$, with $\pi_y\colon E \to [\mathbf{C}(x,y), Fy]$ the map of definition 68.3.3. Two morphisms are constructed and shown to be mutually inverse.

Step 1: The map $\psi\colon E \to Fx$. Take the component at $y = x$ and evaluate at the identity. The identity $j_x\colon I \to \mathbf{C}(x,x)$ induces $[\,j_x, Fx\,]\colon [\mathbf{C}(x,x), Fx] \to [I, Fx]$, and $[I, Fx] \cong Fx$ since I is the unit. Set $\psi = \big([\,j_x, Fx\,] \circ \pi_x\big)$ followed by that isomorphism.

Step 2: The map $\varphi\colon Fx \to E$. The $\mathbf{V}$-functor F gives $F_{x,y}\colon \mathbf{C}(x,y) \to [Fx, Fy]$, whose transpose under (67.1) is an action $\mathbf{C}(x,y) \otimes Fx \to Fy$. Transposing that in the other variable gives $\varphi_y\colon Fx \to [\mathbf{C}(x,y), Fy]$ for each y. These form a wedge: the equalizer condition of definition 68.3.3 at (y,z) is, after transposition, the assertion that acting by a morphism of $\mathbf{C}(y,z)$ after acting by one of $\mathbf{C}(x,y)$ agrees with acting by their composite, which is the

composition axiom of the $\mathbf{V}$-functor F. So the φ_y factor through E, defining φ.

Step 3: $\psi\varphi = \mathrm{id}_{Fx}$. Composing, $\psi\varphi$ is the transpose of $\mathbf{C}(x,x) \otimes Fx \to Fx$ precomposed with $j_x \otimes \mathrm{id}$, that is, the action of the identity. The unit axiom of the $\mathbf{V}$-functor F says $F_{x,x} \circ j_x = j_{Fx}$, and j_{Fx} is the transpose of the left unitor, so the action of the identity is λ and $\psi\varphi = \mathrm{id}$.

Step 4: $\varphi\psi = \mathrm{id}_E$. The projections π_z are jointly monic, so it suffices that $\pi_z\varphi\psi = \pi_z$ for every z. Transpose to morphisms $E \otimes \mathbf{C}(x,z) \to Fz$. Now take the equalizer equation of definition 68.3.3 at the pair (x,z) and transpose it to an equation between morphisms $E \otimes \mathbf{C}(x,z) \otimes \mathbf{C}(x,x) \to Fz$: one side applies π_x and then acts by $\mathbf{C}(x,z)$, the other composes $\mathbf{C}(x,z) \otimes \mathbf{C}(x,x) \to \mathbf{C}(x,z)$ and then applies π_z. Precompose both with $\mathrm{id}_E \otimes \mathrm{id} \otimes j_x$ and use the unit law of $\mathbf{C}$. The left side becomes the transpose of $\pi_z\varphi\psi$, since ψ is exactly π_x followed by evaluation at j_x and φ is the action; the right side becomes the transpose of π_z. Hence $\pi_z\varphi\psi = \pi_z$ for all z, and $\varphi\psi = \mathrm{id}_E$.

Step 5: Naturality. Naturality in F holds because ψ was built from π_x and j_x, neither of which involves F, so a $\mathbf{V}$-natural transformation $F \Rightarrow F'$ commutes with it by construction. Naturality in x follows from Step 4 read for the two objects together with the composition axiom of $\mathbf{C}$, in the same way that Step 2 used the composition axiom of F.

Nothing in the argument is new relative to theorem 62.2.1: Step 1 is "evaluate at id_x", Step 2 is "transport along the action", and Steps 3 and 4 are the two round trips. What the enrichment changes is that each step is a morphism of $\mathbf{V}$ rather than a function on elements, and the naturality condition that was a family of equations is now the equalizer through which the maps must factor. Setting $\mathbf{V} = \mathbf{Set}$ collapses every internal object to a set and returns the original proof verbatim.

The last definition of the chapter's enriched material unifies the two constructions above. An ordinary limit is a universal cone, and a cone over F with vertex d is a natural transformation from the constant functor at a point into $\mathrm{Hom}(d, F-)$. Nothing requires the constant functor: any $\mathbf{V}$-functor W may take its place, and the resulting notion is strictly more general because W may assign different objects of $\mathbf{V}$ to different objects of $\mathbf{C}$.

Definition 68.3.7: Weighted Limit and Weighted Colimit

Let $\mathbf{C}$ be a small $\mathbf{V}$-category, $\mathbf{D}$ a $\mathbf{V}$-category and $F\colon \mathbf{C} \to \mathbf{D}$ a $\mathbf{V}$-functor. For a *weight* $W\colon \mathbf{C} \to \mathbf{V}$, the *limit of F weighted by W* is an object $\lim^W F$ of $\mathbf{D}$ with an isomorphism

$$\mathbf{D}\big(d,\ \lim^W F\big) \ \cong\ [\mathbf{C},\mathbf{V}]\big(W,\ \mathbf{D}(d, F-)\big)$$

of objects of $\mathbf{V}$, natural in d. For a weight $W\colon \mathbf{C}^{\mathrm{op}} \to \mathbf{V}$, the *colimit of F weighted by W*, written $W \star F$, is an object with

$$\mathbf{D}\big(W \star F,\ d\big) \ \cong\ [\mathbf{C}^{\mathrm{op}},\mathbf{V}]\big(W,\ \mathbf{D}(F-, d)\big)$$

natural in d. Here $\mathbf{C}^{\mathrm{op}}$ is the $\mathbf{V}$-category with the same objects, hom-objects $\mathbf{C}^{\mathrm{op}}(c,c') = \mathbf{C}(c',c)$, and composition that of $\mathbf{C}$ precomposed with the symmetry σ.

Both are representing objects, so both are unique up to canonical isomorphism when they exist. The weight is the diagram's shape data: where an ordinary cone offers one morphism $d \to Fc$ for each c, a W-weighted cone offers an object Wc worth of them, and the naturality built into $[\mathbf{C},\mathbf{V}]$ requires those to be compatible along the morphisms of $\mathbf{C}$. The definition of $\mathbf{C}^{\mathrm{op}}$ is where symmetry of $\mathbf{V}$ is needed, since reversing composition means feeding $\circ$ its two arguments in the opposite order.

Example 68.3.8: Three Weighted Limits

1. *Ordinary limits are the constant weight.* Take $\mathbf{V} = \mathbf{Set}$ and W the constant functor at the one-point set. Then $[\mathbf{C}, \mathbf{Set}]\big(W, \mathrm{Hom}(d, F-)\big)$ is the set of natural transformations from the constant functor into $\mathrm{Hom}(d, F-)$, which is the set of cones over F with vertex d. The defining isomorphism becomes $\mathrm{Hom}(d, \lim^W F) \cong \{\text{cones with vertex } d\}$, the universal property of the ordinary limit. Definition 63.2.1 is thus the special case in which every object of $\mathbf{C}$ carries the same one-point weight.

2. *Tensors and cotensors are weighted (co)limits.* Let $\mathbf{I}$ be the unit $\mathbf{V}$-category, one object $*$ with $\mathbf{I}(*,*) = I$. A $\mathbf{V}$-functor $F\colon \mathbf{I} \to \mathbf{D}$ is an object c of $\mathbf{D}$, and a weight $W\colon \mathbf{I} \to \mathbf{V}$ is an object v of $\mathbf{V}$. Unwinding definition 68.3.7, the products in definition 68.3.3 have one factor and the equalizer is trivial, so the defining isomorphism reads $\mathbf{D}(d, \lim^W F) \cong [v, \mathbf{D}(d,c)]$, which is definition 68.3.1: $\lim^W F = c^{\,v}$ and dually $W \star F = v \odot c$.

3. *Tensor product of modules.* In the setting of example 68.3.5, a weight $W\colon \mathbf{R}^{\mathrm{op}} \to \mathbf{Ab}$ is a right R-module and F a left R-module M. For an abelian group A, the group $\mathrm{Hom}_{\mathbb{Z}}(M, A)$ is a right R-module by $(f \cdot r)(m) = f(rm)$, and the defining isomorphism reads

$$\mathrm{Hom}_{\mathbb{Z}}(W \star F,\ A) \ \cong\ \mathrm{Hom}_{R^{\mathrm{op}}}\big(W,\ \mathrm{Hom}_{\mathbb{Z}}(M, A)\big)$$

   the right-hand side being the right R-module maps, by example 68.3.5 applied to $\mathbf{R}^{\mathrm{op}}$. That is the universal property of $W \otimes_R M$, so $W \star F = W \otimes_R M$: the tensor product over a ring is a weighted colimit.

Three constructions that arose separately, the limit of a diagram, the power of an object and the tensor product of two modules, are one construction read over three bases with three weights. The generality is used again once homotopy enters: a homotopy limit is a weighted limit whose weight is built from simplicial sets, and the two-sided bar construction computing it is a weighted colimit. Both are developed in *Higher Category Theory* [27], which takes definition 68.3.7 as given.

68.4 Strict 2-Categories

The enriching base of the preceding sections has been an arbitrary monoidal category $\mathbf{V}$. Take $\mathbf{V} = \mathbf{Cat}$, and a $\mathbf{V}$-category acquires an extra layer of morphisms: each hom-object is now itself a category, so between two arrows there sit arrows-of-arrows. This is the setting in which the natural transformation lives on the same footing as the functor, and in which the adjunction of definition 64.1.1 and the monad of definition 65.1.1 become structures one can name on any object at all. This section makes the extra layer explicit, gives it its own composition laws, and identifies it with the **Cat**-enriched case of definition 68.1.1.

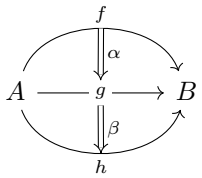
Definition 68.4.1: Strict 2-Category

A *strict 2-category* $\mathbf{K}$ consists of

- a class of 0-*cells* (or *objects*) $A, B, C, \ldots$;
- for each ordered pair A, B of 0-cells, a class of 1-*cells* $f\colon A \to B$;
- for each parallel pair $f, g\colon A \to B$ of 1-cells, a class of 2-*cells* $\alpha\colon f \Rightarrow g$,

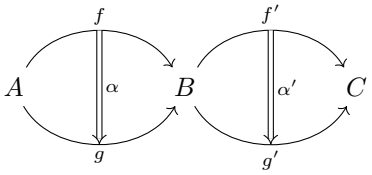
together with two ways of composing 2-cells. *Vertical composition* takes 2-cells sharing a 1-cell boundary,

$$\alpha\colon f \Rightarrow g, \qquad \beta\colon g \Rightarrow h,$$



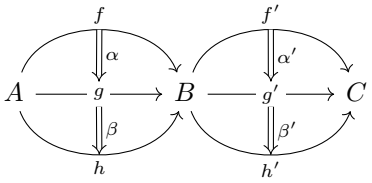
to a 2-cell $\beta \cdot \alpha\colon f \Rightarrow h$; *horizontal composition* takes 2-cells sharing a 0-cell boundary,

$$\alpha\colon f \Rightarrow g \ (A \to B), \qquad \alpha'\colon f' \Rightarrow g' \ (B \to C),$$



to a 2-cell $\alpha' \circ \alpha\colon f'f \Rightarrow g'g \ (A \to C)$. Both compositions are strictly associative and unital: vertical composition has, for each 1-cell f, an identity 2-cell $1_f\colon f \Rightarrow f$; horizontal composition has, for each 0-cell A, an identity 2-cell 1_{id_A} on the identity 1-cell id_A. The two compositions are compatible through the *interchange law*: whenever the composites are defined,

$$(\beta' \cdot \alpha') \circ (\beta \cdot \alpha) = (\beta' \circ \beta) \cdot (\alpha' \circ \alpha) \tag{68.1}$$



The two compositions are pictured most cleanly by drawing 1-cells as arrows and 2-cells as double arrows between them. Vertical composition stacks two 2-cells inside a single hom-class $\mathbf{K}(A, B)$:

Horizontal composition pastes two 2-cells along a shared 0-cell B:

The interchange law is the assertion that the four-fold pasting diagram

evaluates to a single 2-cell $f'f \Rightarrow h'h$, no matter whether one first composes vertically within each column and then horizontally across, or first composes horizontally within each row and then vertically down. Equation (68.1) says the two readings agree. This is the one axiom that couples the two operations; associativity and unitality govern each in isolation.

The definition looks like a bookkeeping exercise until one reads it through the lens of section 68.1. Assemble, for each pair A, B, the 1-cells $A \to B$ as objects and the 2-cells between them as morphisms; vertical composition makes this data a category $\mathbf{K}(A, B)$, its identities the 1_f. Horizontal composition of 1-cells and of 2-cells then assembles into functors $\mathbf{K}(B, C) \times \mathbf{K}(A, B) \to \mathbf{K}(A, C)$, and the interchange law is exactly the statement that horizontal composition respects the categorical structure of each factor, that is, that it is a functor on the product and not only a function on objects. This is the hinge of the section.

Proposition 68.4.2: 2-Categories are Cat-enriched Categories

A strict 2-category is exactly a category enriched over $(\mathbf{Cat}, \times, \mathbf{1})$ in the sense of definition 68.1.1: the hom-object $\mathbf{K}(A, B)$ is the category whose objects are the 1-cells $A \to B$ and whose morphisms are the 2-cells between them.

***Proof*:**
Fix the correspondence between the two packages of data and check that the axioms match term by term.

From a 2-category to enrichment. Given a strict 2-category $\mathbf{K}$, for each pair A, B let $\mathbf{K}(A, B)$ be the category with the 1-cells $A \to B$ as objects, the 2-cells as morphisms, and vertical composition as composition; associativity and unitality of vertical composition are precisely the category axioms, with 1_f the identity on f. Horizontal composition assigns to a pair of objects (f', f) the object $f'f$ and to a pair of 2-cells (α', α) the 2-cell $\alpha' \circ \alpha$. That this assignment is a functor

$$c_{A,B,C} \colon \mathbf{K}(B, C) \times \mathbf{K}(A, B) \to \mathbf{K}(A, C)$$

is the content of the interchange law (68.1): it sends the identity morphism $(1_{f'}, 1_f)$ to $1_{f'f}$, which is unitality of horizontal composition, and it respects composition of morphisms in the product category, where composition is componentwise vertical, so functoriality is the equation $(\beta' \cdot \alpha') \circ (\beta \cdot \alpha) = (\beta' \circ \beta) \cdot (\alpha' \circ \alpha)$ of (68.1). The identity 1-cell id_A together with 1_{id_A} is a functor $\mathbf{1} \to \mathbf{K}(A, A)$ from the terminal category, the unit map of the enrichment. Associativity and unitality of horizontal composition of 1-cells become the associativity and unit diagrams required of an enriched category.

From enrichment to a 2-category. Conversely, a $\mathbf{Cat}$-enriched category gives for each pair a category $\mathbf{K}(A, B)$: its objects are declared the 1-cells, its morphisms the 2-cells, its composition the vertical composition. The composition functors $c_{A,B,C}$ act on objects to give horizontal composition of 1-cells and on morphisms to give horizontal composition of 2-cells; functoriality of $c_{A,B,C}$ is the interchange law, and the enriched associativity and unit axioms are the associativity and unitality of horizontal composition. The two passages are mutually inverse, matching each datum and each axiom, so the two notions coincide, as we sought to show.

The proposition is the reason the tensor product $\times$ on $\mathbf{Cat}$ mattered. An ordinary category is enriched over $(\mathbf{Set}, \times)$; promoting the enriching base one level, from sets to categories, adds exactly one dimension of morphism and produces the strict 2-category. The interchange law is not an extra

decoration but the naturality already built into enrichment, read in the base **Cat**. Every general fact about **V**-categories from section 68.1 specializes: a 2-category has an underlying ordinary category $\mathbf{K}_0$ (definition 68.1.2), obtained by discarding the 2-cells and keeping only the 0-cells and 1-cells, since $\mathbf{Cat}(\mathbf{1}, \mathbf{K}(A,B))$ is the set of objects of $\mathbf{K}(A,B)$, namely the 1-cells $A \to B$.

The definition of a 2-category was abstracted from one example, in which all three layers of cell are already familiar and the two compositions of 2-cells have standing names.

Example 68.4.3: Cat as a 2-Category
Let **Cat** denote the 2-category whose

- 0-cells are (small) categories $\mathbf{C}, \mathbf{D}, \ldots$;
- 1-cells $F \colon \mathbf{C} \to \mathbf{D}$ are functors (definition 61.4.1);
- 2-cells $\alpha \colon F \Rightarrow G$ are natural transformations (definition 61.5.2) between parallel functors.

The hom-object $\mathbf{Cat}(\mathbf{C}, \mathbf{D})$ is the functor category $[\mathbf{C}, \mathbf{D}]$ (definition 61.5.4). Vertical composition is the composition of natural transformations: for $\alpha \colon F \Rightarrow G$ and $\beta \colon G \Rightarrow H$, the transformation $\beta \cdot \alpha$ has component $(\beta \cdot \alpha)_c = \beta_c \circ \alpha_c$ at each object c. Horizontal composition is the Godement product: for $\alpha \colon F \Rightarrow G$ between functors $\mathbf{C} \to \mathbf{D}$ and $\alpha' \colon F' \Rightarrow G'$ between functors $\mathbf{D} \to \mathbf{E}$, the component of $\alpha' \circ \alpha$ at $c \in \mathbf{C}$ is the common value of the two paths around the naturality square of α' at α_c:

$$(\alpha' \circ \alpha)_c = G'(\alpha_c) \circ \alpha'_{Fc} = \alpha'_{Gc} \circ F'(\alpha_c) \tag{68.2}$$

The interchange law is the middle-four exchange for natural transformations.

The two expressions in (68.2) are equal precisely because $\alpha' \colon F' \Rightarrow G'$ is natural: applied to the arrow $\alpha_c \colon Fc \to Gc$ of $\mathbf{D}$, naturality of α' is the commuting square

$$\begin{array}{ccc} F'Fc & \xrightarrow{\alpha'_{Fc}} & G'Fc \\ {\scriptstyle F'(\alpha_c)}\downarrow & & \downarrow{\scriptstyle G'(\alpha_c)} \\ F'Gc & \xrightarrow[\alpha'_{Gc}]{} & G'Gc \end{array}$$

whose two directed paths from $F'Fc$ to $G'Gc$ are the two formulas for $(\alpha' \circ \alpha)_c$. That **Cat** satisfies the axioms of definition 68.4.1 is the content of proposition 68.4.2 together with the fact that $[\mathbf{C}, \mathbf{D}]$ is a category (definition 61.5.4) and that these composites are natural. The interchange law $(\beta' \cdot \alpha') \circ (\beta \cdot \alpha) = (\beta' \circ \beta) \cdot (\alpha' \circ \alpha)$ is verified componentwise from (68.2) by a direct diagram chase; it is the classical middle-four exchange, so named because the four inner terms of the two sides pair off.

A frequent special case of horizontal composition fixes one of the two 2-cells to be an identity. This is common enough, and geometrically clean enough, to deserve its own name.

Definition 68.4.4: Whiskering

Let $\alpha\colon f \Rightarrow g$ be a 2-cell between 1-cells $f, g\colon A \to B$ in a 2-category $\mathbf{K}$. Given a 1-cell $h\colon B \to C$, the *left whiskering* of α by h is the horizontal composite of α with the identity 2-cell on h,

$$h * \alpha \coloneqq 1_h \circ \alpha\colon hf \Rightarrow hg,$$

a 2-cell between 1-cells $A \to C$. Given a 1-cell $k\colon Z \to A$, the *right whiskering* of α by k is

$$\alpha * k \coloneqq \alpha \circ 1_k\colon fk \Rightarrow gk,$$

a 2-cell between 1-cells $Z \to B$.

Pictorially, whiskering appends a 1-cell to one side of the 2-cell α without introducing a second nondegenerate 2-cell:

In **Cat**, where $\alpha\colon F \Rightarrow G$ is a natural transformation and H a functor, left whiskering $H * \alpha$ has component $(H * \alpha)_c = H(\alpha_c)$ at each object c, obtained by applying H to each component of α; right whiskering $\alpha * K$ has component $(\alpha * K)_z = \alpha_{Kz}$, obtained by reindexing α along K. Every horizontal composite factors through whiskering: for $\alpha\colon F \Rightarrow G$ and $\alpha'\colon F' \Rightarrow G'$ as in (68.2),

$$\alpha' \circ \alpha = (G' * \alpha) \cdot (\alpha' * F) = (\alpha' * G) \cdot (F' * \alpha),$$

the two factorizations being the two paths of the naturality square, so the two whiskerings together with vertical composition recover the full Godement product. Whiskering is therefore the elementary operation from which horizontal composition is built, and it is the notation in which the constructions below are cleanest.

With the two compositions and whiskering in hand, one can transcribe the central notions of the core theory into any 2-category, referring only to 0-, 1-, and 2-cells and never to elements. The payoff is that an adjunction (definition 64.1.1) and a monad (definition 65.1.1) become structures an object can carry in any $\mathbf{K}$, of which the definitions of the earlier chapters are the **Cat** case.

Proposition 68.4.5: Adjunctions and Monads in a 2-Category

Let $\mathbf{K}$ be a 2-category.

1. An *adjunction* in $\mathbf{K}$ consists of 1-cells $f\colon A \to B$ and $g\colon B \to A$ and 2-cells $\eta\colon \mathrm{id}_A \Rightarrow gf$ and $\varepsilon\colon fg \Rightarrow \mathrm{id}_B$ satisfying the triangle identities
$$(\varepsilon * f) \cdot (f * \eta) = 1_f, \qquad (g * \varepsilon) \cdot (\eta * g) = 1_g \tag{68.3}$$
2. A *monad* on an object A consists of a 1-cell $t\colon A \to A$ and 2-cells $\eta\colon \mathrm{id}_A \Rightarrow t$ and $\mu\colon tt \Rightarrow t$ satisfying the associativity and unit laws
$$\mu \cdot (\mu * t) = \mu \cdot (t * \mu), \qquad \mu \cdot (\eta * t) = 1_t = \mu \cdot (t * \eta) \tag{68.4}$$
3. Every adjunction in $\mathbf{K}$ induces a monad on A, with underlying 1-cell $t = gf$, unit the adjunction unit η, and multiplication $\mu = g * \varepsilon * f\colon gfgf \Rightarrow gf$.

In $\mathbf{K} = \mathbf{Cat}$, an adjunction is an adjunction of functors in the sense of definition 64.1.1 with unit and counit as in definition 64.1.3, a monad is a monad in the sense of definition 65.1.1, and the induced monad of part (3) is the monad an adjunction of functors induces on its source.

***Proof*:**
Parts (1) and (2) are definitions internal to $\mathbf{K}$; the content is part (3), that the data they package assemble into a monad, and that in $\mathbf{Cat}$ everything reduces to the earlier chapters.

Step 1: The induced multiplication and unit. From an adjunction $(f, g, \eta, \varepsilon)$ set $t = gf$. Left whiskering by g and right whiskering by f turn the counit $\varepsilon\colon fg \Rightarrow \mathrm{id}_B$ into a 2-cell
$$\mu = g * \varepsilon * f\colon gfgf \Rightarrow gf,$$
that is, $\mu\colon tt \Rightarrow t$, where $g*\varepsilon*f$ abbreviates the whiskering $g*(\varepsilon*f) = (g*\varepsilon)*f$ (associativity of horizontal composition makes the two readings equal). The unit of the monad is the adjunction unit $\eta\colon \mathrm{id}_A \Rightarrow t$.

Step 2: The unit laws. The two unit laws in (68.4) are the two triangle identities (68.3), whiskered into place. Whisker the first triangle identity $(\varepsilon * f) \cdot (f * \eta) = 1_f$ on the left by g: using functoriality of whiskering with respect to vertical composition,
$$(g * \varepsilon * f) \cdot (gf * \eta) = 1_{gf},$$
and since $t * \eta = gf * \eta$ and $\mu = g * \varepsilon * f$, this reads $\mu \cdot (t * \eta) = 1_t$. Whiskering the second triangle identity $(g * \varepsilon) \cdot (\eta * g) = 1_g$ on the right by f gives, by the same computation, $\mu \cdot (\eta * t) = 1_t$. Together these are the unit laws.

Step 3: Associativity. Both sides of $\mu \cdot (\mu * t) = \mu \cdot (t * \mu)$ are 2-cells $ttt \Rightarrow t$, that is, $gfgfgf \Rightarrow gf$. Expand using $\mu = g * \varepsilon * f$ and $t = gf$: the left side, $\mu \cdot (\mu * gf)$, whiskers the outer copy of ε over the inner one on the left, while the right side, $\mu \cdot (gf * \mu)$, whiskers on the right; the two inner whiskerings apply ε at the two different copies of the pair fg in $fgfg$. Both reduce to a single whiskered double application of the counit,
$$g * (\varepsilon \circ \varepsilon) * f\colon gfgfgf \Rightarrow gf,$$

where $\varepsilon \circ \varepsilon \colon fgfg \Rightarrow \mathrm{id}_B$ is the horizontal composite of ε with itself. That this horizontal composite is unambiguous, that whiskering the outer ε over the inner one on the left equals whiskering it on the right, is precisely the interchange law (68.1) applied to the two copies of ε: $(\varepsilon \circ 1_{\mathrm{id}_B}) \cdot (1_{fg} \circ \varepsilon) = (\varepsilon \circ \varepsilon) = (1_{\mathrm{id}_B} \circ \varepsilon) \cdot (\varepsilon \circ 1_{fg})$. Hence the two sides agree and (t, η, μ) satisfies (68.4), a monad on A.

Step 4: The **Cat** *case.* Take $\mathbf{K} = \mathbf{Cat}$. A 1-cell $f \colon A \to B$ is a functor, a 2-cell is a natural transformation, and the triangle identities (68.3), read componentwise via the whiskering formulas $(H * \alpha)_c = H(\alpha_c)$ and $(\alpha * K)_z = \alpha_{Kz}$ of definition 68.4.4, are exactly the triangle identities of definition 64.1.3: at an object a the first reads $\varepsilon_{fa} \circ f(\eta_a) = \mathrm{id}_{fa}$. So an adjunction in **Cat** is an adjunction of functors (definition 64.1.1). Likewise $t = gf$ is the composite endofunctor, and the multiplication $\mu = g * \varepsilon * f$ has component $\mu_a = g(\varepsilon_{fa})$ at $a \in A$, which is the multiplication of the monad an adjunction of functors induces (definition 65.1.1). The construction of part (3) used only 2-cells, whiskering, and the interchange law, which is why the derivation for **Cat** was, without saying so, purely 2-categorical. This completes the proof.

The proposition is the abstract residue of the monad theory of the core chapters. The construction of a monad from an adjunction (definition 65.1.1) never touched an element of an object; it composed the counit with functors on the left and right and invoked naturality, and those are exactly whiskering and the interchange law. Reread through proposition 68.4.5, that construction proved a fact about **Cat** that holds verbatim in any 2-category: the endomorphism gf of the source of any adjunction carries a canonical monad structure. The same transcription runs the other way for the Eilenberg-Moore and Kleisli constructions (section 65.2, section 65.3), which recover an adjunction from a monad by building new objects, and it is the systematic version of this dictionary, one layer of categorical structure at a time, that the sequel takes up.

68.5 Toward Weak and Higher Categories

A strict 2-category asks the composition of 1-cells to be strictly associative and strictly unital, exactly as in an ordinary category. In the archetype **Cat** this holds on the nose. But many of the 2-dimensional structures that arise in practice do not: composing 1-cells there produces objects that are associative and unital only *up to* a specified invertible 2-cell, and one cannot wish those 2-cells away without discarding the mathematics that forced them. The passage from the strict laws of definition 68.4.1 to laws-up-to-coherent-isomorphism is the last structural step this book takes, and it is the door to the sequel.

The relaxation is governed by exactly the coherence discipline of chapter 67. There the associator and unitors of a monoidal category were required to satisfy the pentagon and triangle axioms, and Mac Lane's coherence theorem (theorem 67.1.5) guaranteed that every formal diagram then commutes. A bicategory imports that discipline one dimension up: the associativity and unit *equalities* of 1-cell composition become invertible 2-cells subject to a pentagon and a triangle, and the same kind of coherence theorem results.

Definition 68.5.1: Bicategory

A *bicategory* $\mathbf{B}$ consists of

- a collection of *0-cells* (objects) $A, B, C, \dots$;
- for each ordered pair (A, B) a category $\mathbf{B}(A, B)$, whose objects are the *1-cells* $f\colon A \to B$ and whose morphisms are the *2-cells* $\alpha\colon f \Rightarrow g$ (composition within $\mathbf{B}(A, B)$ is *vertical* composition of 2-cells);
- for each triple (A, B, C) a *horizontal composition* functor
$$\circ\colon \mathbf{B}(B, C) \times \mathbf{B}(A, B) \to \mathbf{B}(A, C)$$
and for each A an identity 1-cell $\mathrm{id}_A \in \mathbf{B}(A, A)$;
- for all composable 1-cells f, g, h a natural *associator* 2-cell
$$a_{h,g,f}\colon (h \circ g) \circ f \;\Rightarrow\; h \circ (g \circ f)$$
and for each $f\colon A \to B$ natural *left* and *right unitor* 2-cells
$$\lambda_f\colon \mathrm{id}_B \circ f \Rightarrow f, \qquad \rho_f\colon f \circ \mathrm{id}_A \Rightarrow f$$
each of which is invertible,

subject to two coherence axioms: the *pentagon*, requiring that the two ways of reassociating a fourfold composite $((k \circ h) \circ g) \circ f$ to $k \circ (h \circ (g \circ f))$ agree, that is

$$(\mathrm{id}_k \circ a_{h,g,f}) \cdot a_{k,h\circ g,f} \cdot (a_{k,h,g} \circ \mathrm{id}_f) \;=\; a_{k,h,g\circ f} \cdot a_{k\circ h,g,f}$$

(where $\cdot$ is vertical composition and $\circ$ here denotes whiskering, definition 68.4.4); and the *triangle*, requiring for composable $g\colon B \to C$, $f\colon A \to B$ that

$$(\mathrm{id}_g \circ \lambda_f) \cdot a_{g,\mathrm{id}_B,f} \;=\; \rho_g \circ \mathrm{id}_f$$

A *strict 2-category* (definition 68.4.1) is the special case in which a, λ, and ρ are all identity 2-cells.

The two axioms are the pentagon and triangle of theorem 67.1.5, transplanted from the 1-cells of a monoidal category to the 1-cells of $\mathbf{B}$. This is not an analogy imposed after the fact: a bicategory with a single 0-cell is precisely a monoidal category, its one hom-category $\mathbf{B}(A, A)$ being the underlying category, horizontal composition the tensor, id_A the unit, and a, λ, ρ the monoidal associator and unitors. A bicategory is thus a monoidal category with many objects, and the coherence data is the same data seen one dimension higher.

The force of the pentagon and triangle is again a coherence theorem, which frees the working mathematician from tracking associators and unitors explicitly.

Theorem 68.5.2: Coherence for Bicategories

Every bicategory is biequivalent to a strict 2-category. Consequently, in any bicategory every diagram of 2-cells built from associators, unitors, their inverses, whiskerings, and identities commutes.

***Proof Key ideas*:**
The statement, and the notion of biequivalence it uses, belong to the weak 2-dimensional theory developed in the sequel; the full argument is beyond the light treatment here. The mechanism mirrors the strictification of a monoidal category behind theorem 67.1.5: one embeds $\mathbf{B}$ into a strict 2-category of $\mathbf{B}$-representations by a bicategorical Yoneda construction, sending each 0-cell to a strict object whose 1-cells compose on the nose, and checks the embedding is a biequivalence. A complete proof is given in the sequel ([27]) and in Mac Lane's and Bénabou's original treatments, to which the details are deferred.

Coherence has a practical consequence worth stating plainly: a bicategory may be manipulated as though it were strict. Parenthesization of a composite of 1-cells can be suppressed, and any two reassociations of the same string are identified by a canonical invertible 2-cell. The weakness is real, but coherence renders it invisible in computation, precisely as in the monoidal case.

The examples that make bicategories necessary are the ones where the associator fails to be an identity. Two are canonical.

Example 68.5.3: The Bicategory of Bimodules

Bimodules. Let **Bimod** have as 0-cells the (unital, associative) rings. A 1-cell $R \to S$ is an (S,R)-bimodule ${}_SM_R$, that is, an abelian group carrying commuting left S- and right R-actions ([21, (S,R)-Bimodule]). A 2-cell ${}_SM_R \Rightarrow {}_SN_R$ is a bimodule homomorphism. Vertical composition is composition of bimodule maps, so $\mathbf{Bimod}(R,S)$ is the category of (S,R)-bimodules.

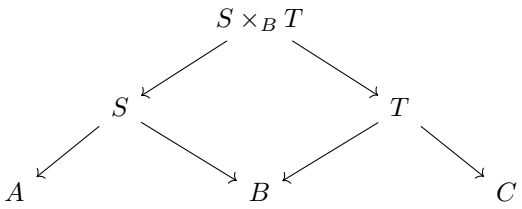
Horizontal composition is the tensor product over the middle ring: the composite of $R \xrightarrow{M} S$ and $S \xrightarrow{N} T$ is the (T,R)-bimodule

$$N \circ M \;=\; N \otimes_S M$$

The identity 1-cell on R is the bimodule ${}_RR_R$, since $R \otimes_R M \cong M$ and $M \otimes_R R \cong M$ naturally.

Here associativity is not an equality. For bimodules ${}_SM_R$, ${}_TN_S$, ${}_UP_T$ the two triple tensor products

$$(P \otimes_T N) \otimes_S M \qquad \text{and} \qquad P \otimes_T (N \otimes_S M)$$



are distinct abelian groups: their elements are cosets in different quotients of $P \otimes N \otimes M$. They are canonically isomorphic by $(p \otimes n) \otimes m \mapsto p \otimes (n \otimes m)$, and this isomorphism is the associator $a_{P,N,M}$; it is invertible but not the identity. The unitors are the canonical maps $R \otimes_R M \cong M$ and $M \otimes_R R \cong M$. That these satisfy the pentagon and triangle is the statement that the standard tensor-product isomorphisms cohere, which they do because each is built from the universal property of $\otimes$. Thus **Bimod** is a bicategory that is not a strict 2-category, and no reasonable change of definition makes it one: the tensor product of bimodules is associative up to canonical isomorphism and no more.

The second canonical example needs only a category with pullbacks, and it shows the same phenomenon geometrically rather than algebraically.

Example 68.5.4: The Bicategory of Spans

Let $\mathbf{C}$ be a category with pullbacks. A *span* from A to B is a diagram $A \leftarrow S \rightarrow B$, an object S with a leg to each of A and B; this is a 1-cell $A \to B$. A 2-cell between spans $A \leftarrow S \rightarrow B$ and $A \leftarrow S' \rightarrow B$ is a morphism $S \to S'$ commuting with both legs.

Horizontal composition composes spans by pullback. Given $A \leftarrow S \rightarrow B$ and $B \leftarrow T \rightarrow C$, form the pullback $S \times_B T$ of the two legs over B (definition 63.2.6):

The composite span $A \leftarrow S \times_B T \rightarrow C$ takes the outer legs. The identity 1-cell on A is the span $A \xleftarrow{\mathrm{id}} A \xrightarrow{\mathrm{id}} A$.

Associativity again holds only up to isomorphism. Composing three spans in the two possible orders forms two iterated pullbacks, $(S \times_B T) \times_C U$ and $S \times_B (T \times_C U)$; these are canonically isomorphic because both compute the limit of the same diagram, but the isomorphism is given by the universal property of the pullback and is not an identity. It is the associator, and the pentagon it satisfies is exactly the coherence of iterated pullback limits. So $\mathbf{Span}(\mathbf{C})$ is a bicategory, strict only in the degenerate cases where pullbacks can be chosen strictly functorially.

In both examples the weakness is not a defect of the definition to be engineered away but a feature of the mathematics: tensor product and pullback are operations defined by universal properties, and a universal property determines its output only up to canonical isomorphism. Any 2-dimensional structure organized by such operations is a bicategory and not, on the nose, a strict 2-category. The equalities of definition 68.4.1 were an idealization; the isomorphisms of definition 68.5.1 are what the objects satisfy.

This is where strictness gives way to coherence, and where the present book ends. Everything developed here has been strict 1-category theory. Composition of morphisms is strictly associative and strictly unital; a diagram commutes or it does not; two objects are the same when they are equal or, at the outermost, when they are isomorphic. Sameness has meant equality or isomorphism, and nothing weaker. The structured categories of the last two chapters have pushed against that boundary, introducing associators and unitors as data, but coherence has kept them tame: by theorem 67.1.5 and theorem 68.5.2 the strict theory recovers the weak one up to equivalence, and the strict picture remains adequate.

The subject changes character when equality weakens past this point. When the associativity of composition is asked to hold only up to a coherent *homotopy*, and that homotopy up to a further homotopy, and so on through every dimension, one is no longer doing strict 1-category theory but *higher category theory*. There the objects of study are model categories, quasi-categories, and ∞-categories, in which morphisms compose only up to coherent higher cells and the coherence data is infinite rather than a single pentagon. The theorems of this book do not disappear beyond it; they reappear in homotopy-coherent form. Limits and colimits become homotopy limits and colimits, taken up to coherent equivalence rather than on the nose. Adjunctions, monads, and the Yoneda lemma each have ∞-categorical statements that specialize back to the strict ones proved here. The

duality principle of box 61.3.3 survives verbatim, opposite ∞-categories and all.

The sequel is *Higher Category Theory* ([27]), which takes up simplicial sets and nerves, Quillen's model categories, the quasi-category model of ∞-categories after Joyal, Lurie, and Riehl, homotopy (co)limits, and the stable and derived structures that connect back to homological algebra. It is the natural continuation for a reader who now recognizes a universal property on sight and wants to see what becomes of these constructions when equality is replaced throughout by coherent equivalence. The strict theory built here is the ground from which that generalization is read.

Part XIII

Appendix

In the appendix, certain section will take liberties on how much the reader know's. In particular, the reader is expected to be comfortable with (some analysis or topology in certain appendicies, like category theory and geometric group theory).

A

Axiom of Choice

In mathematics, we are constantly making choices. We can make algorithmic choices (for example, if you're given the number n, choose the number $n+1$), or we make arbitrary choices (choose some natrual number n). The fact that we can make an arbitrary choice is uncontroversial in the axioms mathematicians used, that is ZF (short for Zermelo-Frankel axioms). So too is making a finite number of choices. These two "abilities" were also uncontroversial in other foundational formulations of mathematics, not just ZF. It might seem very natural then to be able to make an infinite, or more generally an arbitrary (including uncountably infinite or other cardinalities) amount of choices. However, making an arbitrary amount of choices turns out to have some very strange consequences. The German mathematician Ernst Zermelo axiomatically used the fact that you can make an arbitrary number of choices (which we will soon define what this means mathematically) to prove a very controversial conjecture called the *well-ordering Theorem* (which we shall cover later in this appendix), sparking a debate on whether mathematics should allow for arbitrary choice. One famous "counter-example" developed to "prove" that we shouldn't allow arbitray choice is a proof by Banach and Tarski that you can take a sphere, partition it into 6 subsets (which uses the axiom of choice), rotate them in certain ways, and recombine them to form 2 identical spheres! Importantly, we did *not* add any more points, yet we have somehow "doubled" the surface area of the points we've chosen [1]! This is called the *Banach-Tarski Paradox*.

Though this result is strange, as time went on, more and more mathematicians found that making an arbitrary number of choices produces some "natural" results. For example, the fact that every vector-space has a basis comes down to the ability of making an arbitrary number of choices. In 1963, a mathematician named Paul Cohen proved that the making an arbitrary number of choices is independent of the standard system of axioms ZF, meaning if we assume the we can do an arbitrary number of choices, it will not cause any more contradiction and ZF would already cause [2], and if we

[1] For those who have taken measure theory, the chosen subsets turn out to be *unmeasurable* sets, and so the concept of surface area does not apply to these sets which allows us to produce this strange result

[2] The careful wording here is because it has *not* been proven that the axioms of ZF don't contradict each other –

assume we can't make an arbitrary number of choices, it will *also* not cause any more contradiction than ZF would already cause. Through this result, most mathematicians now accept the axiom of choice as part of the standard model we use, which is represented as ZFC (ZF + the axiom of **C**hoice).

In Algebra, the axiom of choice most often appears in a special form called *Zorn's Lemma*. The aim of this chapter is to be able show that Zorn's lemma is equivalent to the axiom of choice.

A.1 Build-up

Definition A.1.1: Cartesian Product and Choice Function

Let $\{A_i\}_{i\in I}$ be any family of sets. Then the *Cartesian product* of this family, written $\prod_{i\in I} A_i$, is the set of all function $x : I \to \bigcup_{i\in I} A_i$, where $x(i) \in A_i$ for all $i \in I$ The function x is called a *choice function*.

Though we've defined what the cartesian product is, it does not mean that the function x exist! Naturally, if $I = \emptyset$ or if $A_i = \emptyset$ for some $i \in I$ (since then $\prod_{i\in I} A_i = \emptyset$), then this function exists. If $I \neq \emptyset$ or $A_i \neq \emptyset$, then it turns out the existence of this function is independent of the ZF axioms! Thus, the axiom of choice was formulated:

Axiom A.1.2: Axiom of Choice

The cartesian product of any non-empty family of non-empty sets is a non-empty set. In particular, if $\{A_i\}_{i\in I}$ is a family of sets such that $I \neq \emptyset$ and $A_i \neq \emptyset$ for each $i \in I$, then there exists at least one choice function for $\{A_i\}_{i\in I}$

Since the cartesian product exists (axiomatically), we will make some shorthand notation for it similar to that defined in chapter 5. If $\{A_i\}_{i\in I}$ is a family of sets, let $A^I = \prod_{i\in I} A_i$ where $A_i = A$ for each $i \in I$. If $|I|$ is finite, and so $|I| = n$ for some $n \in \mathbb{N}$, then we write A^n instead. If $|I|$ is countable, we sometimes use the A^∞ or $A^{\mathbb{N}}$ notation. the elements of A^n can be represented as n-tuples, that is

$$A^n = \{(a_1, a_2, ..., a_n \mid a_i \in A\}$$

and the elements of $A^{\mathbb{N}}$ can be represents as sequences

$$A^{\mathbb{N}} = \{(a_1, a_2, ..., a_n, ...) \mid a_i \in A\}$$

Example A.1.3: Cartesian Products

1. An example we've already encountered is $\mathbb{R}^n$ and $\mathbb{R}^{\mathbb{N}}$. This caretsian product is called *Euclidan Space*
2. Let $A = \{0, 1\}$. Then $A^{\mathbb{N}}$ is the set of all sequences with either 0 or 1 in each component. If we change notation a bit and let $A = \mathbb{Z}/2\mathbb{Z}$, and define addition point-wise, then this would be a group

this remains an open problem in mathematics

Definition A.1.4: Partially Ordered Sets

1. Let P be a non-mepty set. A *partial order* on P is a relation $\leq$ ($\leq \subseteq P \times P$) on P such that

   (a) **(reflective)** $x \leq x$ for all $x \in A$

   (b) **(antisymmetric)** if $x \leq y$ and $y \leq x$, then $x = y$

   (c) **(transitive)** if $x \leq y$ and $y \leq z$ then $x \leq z$

   Where we usually say P is a partiallly ordered set under the orering $\leq$ or that A is partially ordered by $\leq$.

   If $\leq$ also satisfies

   (d) **(trichotomy)** If $x, y \in P$, then $x \leq y$ or $y \leq x$,

   then $\leq$ is called a *total* (or linear, simple, complete) ordering on P. If further

   (e) **(Well-Ordering)**For all $\emptyset \neq A \subseteq P$, there exists an element $a \in A$ such that $a \leq x$ for all $x \in A$

   then we say that $\leq$ is a *well-ordering* of P, or that P is well-ordered by $\leq$

2. Let $(P, \leq)$ be a partially ordered set and let $A \subseteq P$. An element $u \in P$ is called an *upper bound* for A if for all $x \in A$, $x \leq u$. Similarly, $l \in P$ is called a *lower bound* if for all $x \in A$, $l \leq x$.

3. Let $(P, \leq)$ be a partially oredered set and let $A \subseteq P$. An element $m \in P$ is called a *maximal element* of P if whenever $m \leq x$ with $x \in P$, then $m = x$. Similarly, an element $m \in P$ is called a *minimal element* if whenever $x \leq m$ for $x \in P$, then $x = m$.

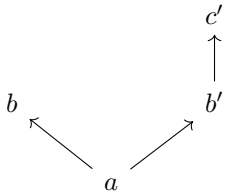
4. Let $(P, \leq)$ be a partially ordered set. Then a subset $C \subseteq P$ is called a *chain* in P if C is totally ordered under the order relation of $\leq$, that is, if $x, y \in C$, then either $x \leq y$ or $y \leq x$.

Note that it's called a *partial* order because becaue not all elements *necessarily* need to to have a relation between them: if $x, y \in P$ and $\leq$ is a parital order on P, then it need not be the case that $x \leq y$ or $y \leq x$. If this were the case, we would call $\leq$ a *total order*.

In the following examples we'll show the difference between being maximal and being an upper bound. Importantly, it is possible that *not all* $x \in P$ have the relation $x \leq m$ (i.e. m is not necessarily the "*largest*" or "*maximum*" element)

Example A.1.5: Partially Ordered Sets

1. Let S be an arbitrary set, and $P(S)$ be it's powerset. Then $(P(S), \subseteq)$ forms a partially ordered set. This set is *only* a partial order (it is not a total order) if $|S| > 1$: for two distinct elements $x, y \in S$ $\{x\} \not\subseteq \{y\}$ and $\{y\} \not\subseteq \{x\}$. A chain in $(P(S), \subseteq)$ would look like:



$$S_1 \subseteq S_2 \subseteq S_3 \subseteq S_4 \subseteq \cdots$$

If $T \subseteq S$, then then T has an upperbound U:

$$U = \bigcup_{x \in T} \{x\}$$

Furthermore, S is also the maximal element of $P(S)$.

2. Let $S = \{a, b, b', c'\}$ be the set, and $\leq$ be the relation visualized by the graph:

Then both b and c' are maximal elements. S has no upper bound, but it has a as a lower bound.

3. Let S be the collection of *proper subsets* of $\mathbb{N}$ ordered by $\subseteq$. Notice that the chain

$$\{1\} \subseteq \{1, 2\}\, \{1, 2, 3\} \subseteq \cdots$$

does not have an upper bound. However, S *does* have maximal elements. $(\mathbb{N} - \{n\}) \in S$ for any $n \in \mathbb{N}$ is a maximal element of S

4. Let $S = \mathbb{R}$ with the usual order $\leq$. Notice that $\leq$ is a *total order* in this case. some sets of $\mathbb{R}$ have upper bound (ex. $[0, 1]$ or $\{0, 1, 2, 3\}$), while other's don't $(\mathbb{Z}, (0, \infty), (0, 1))$. $\mathbb{R}$ does not have maximal elements in this order.

When we say we give a partial order to an arbitrary set S, we will assume that this is the partial order on the power set given by $\subseteq$.

Next, we will build-up some facts to bootstrap the result

Definition A.1.6: Finite Character

Let $\mathcal{F}$ be a family of sets. Then $\mathcal{F}$ is said to be a *family of finite character* if for any set S, $S \in \mathcal{F}$ if and only if each finite subset of S is in $\mathcal{F}$.

Lemma A.1.7: Finite Character and Chains

Let $\mathcal{F}$ be a family of finite character and let $\mathcal{B}$ be a chain in $\mathcal{F}$. Then $\cup\mathcal{B} \in \mathcal{F}$

***Proof*:**
Since $\mathcal{F}$ is of finite character, if we show that every finite subset of $\mathcal{B}$ is an element of $\mathcal{F}$. Let $\{x_1, x_2, ..., x_n\} = F \subseteq \cup\mathcal{B}$. Then there must exists sts $\mathcal{B}_1, ...\mathcal{B}_n \in \mathcal{B}$ such that $x_i \in \mathcal{B}_i$. Since $\mathcal{B}$ is a chain, there exists a $1 \leq j \leq n$ such that $B_i \subseteq B_j$, for all $i \in \{1, 2, ...n\}$. But then, $F \subseteq B_j \in \mathcal{F}$. Since $\mathcal{F}$ is of finite character, and $\mathcal{B}_j \in \mathcal{F}$, $F \in \mathcal{F}$. Since F was arbitrary, then this holds true for any finite subset of $\cup\mathcal{B}$, and so $\cup\mathcal{B} \in \mathcal{F}$, as we sought to show.

A.2 Axiom of Choice Equivalences

Note that terms like "lemma" or "theorem" for the following names are due to historical precedents rather than actually representing a lemma or theorem, since all of the following will be equivalent to the axiom of choice.

Theorem A.2.1: Tukey's Lemma

Every nomepty family of finite character has a maximal member

Theorem A.2.2: Hausdorff Maximality Principle

Every nonempty partially ordered set contains a maximal chain, i.e., every totally ordered subset is contained in a maximally totaly ordered subset

Maximally totally ordered here means that if it is enlraged in any way, it does not remained totally ordered

Theorem A.2.3: Zorn's Lemma

Every nonemtpy partially ordered set in which each chain has an upper bound has a maximal element

Theorem A.2.4: Well-Ordering Theorem

Every set can be well-orderd, i.e., if S is a set, then there exists some well-ordering $\leq$ on S

A well-ordering on a set S is a total order (i.e. a chain) on S with the additional property that every non-empty subset of S has a lower-bound. For example, given the usual orderings for the following examples, $\mathbb{N}$ is well-ordered (every subset has a lower-bound), while $\mathbb{Z}$ is not (namely, $\mathbb{Z}$ itself doens't have a lower-bound). A trickier example would be $\mathbb{R}$. The set (a, b) for $a, b \in \mathbb{R}$, $a \neq b$, does *not* have a minimal element, and so $\mathbb{R}$ is not well-ordered with the usual ordering.

Theorem A.2.5: Axiom of Choice Equivalences

The following are equivalent

1. The axiom of choice
2. Tukey's Lemma
3. The Hausdroff maximality principle
4. Zorn's Lemma
5. Well-ordering Theorem

***Proof*:**
The proof follows [62, (3.12)] and uses no transfinite induction.

(1) ⇒ (2) For the sake of contradiction, suppose Tukey's lemma was false: there exists a non-empty family of sets of finite character that has no maximal element. Let $\mathcal{F}$ be such a family. That means for every $A \in \mathcal{F}$, there exists a B such that $A \subsetneq B$. Let $\mathcal{O}_F = \{E \in \mathcal{F} \mid F \subsetneq E\}$. Then $\{\mathcal{O}_F \mid F \in \mathcal{F}\}$ is a set of sets indexed by $\mathcal{F}$. Thus, by the axiom of choice, there exists a choice function f defined on $\mathcal{F}$ such that $f(F) \in \mathcal{O}_F$ (i.e. $F \subsetneq f(F)$ for all F).

Using f, we'll define a new concept: a subfamily $\mathscr{F} \subseteq \mathcal{F}$ is f-inductive if:

(a) $\emptyset \in \mathscr{F}$
(b) if $A \in \mathscr{F}$ then $f(A) \in \mathscr{F}$
(c) if $\mathcal{C} \subseteq \mathscr{F}$ is a chain, then $\cup\mathcal{C} \in \mathscr{F}$

Notice that $\mathcal{F}$ is itself an f-inductive set since: $\mathcal{F}$ is non-empty (by assumption), so some $A \in \mathcal{F}$ exists, and $\emptyset \subseteq A$ is a finite set, and so $\emptyset \in \mathcal{F}$ since $\mathcal{F}$ has finite character, fulfilling the first condition. The second conditions holds true since the image of f is in $\mathcal{F}$, and the third condition holds by lemma A.1.7. Notice too that if the family $\mathscr{F}_i \subseteq \mathcal{F}$ is f-inductive (for some indexing set I), then so too is $\bigcap_i \mathscr{F}_i$. Thus, define the smallest f-inductive set of $\mathcal{F}$:

$$\mathscr{F}_0 = \{A \in \mathcal{F} \mid A \in \mathscr{F} \text{ for every } f\text{-inductive subset of } \mathcal{F}\}$$

The fact that $\mathscr{F}_0$ is the smallest f-inductive set will allow us to force certain properties on to it. Our goal is to show that $\mathscr{F}_0$ *must* be a chain, which we will use to arrive at a contradiction.

To show that $\mathscr{F}_0$ is a chain, we will have to go through some technical steps. First, let $\mathcal{H} = \{A \in \mathscr{F}_0 \mid \text{if } B \in \mathscr{F}_0 \text{ and } B \subsetneq A \text{ then } f(B) \subseteq A\}$. The set $\mathcal{H}$ is the set of all elements $A \in \mathscr{F}_0$ such that B element is an element of $\mathscr{F}_0$ and is properly contained in A, f of that elements is contained in or equal to A. However, some oddities occurs with this set too: note that $\mathcal{H}$ is non-empty since vacusously, $\emptyset \in \mathcal{H}$ (since (False ⇒ True) and (False ⇒ False) are both *true* statements!!) This oddity is necessary, since we are guaranteed that $\mathcal{H}$ is non-empty. Now, we'll show that if $A \in \mathcal{H}$ and $C \in \mathscr{F}_0$, then one of two relations *must* hold between A and C: either $C \subseteq A$ or $f(A) \subseteq C$. Notice we are forcing a subset relation between all elements of $\mathscr{F}_0$ and $\mathcal{H}$ – wel'l use this to create a total order later. First, let's prove the last assertion:

Proof. Define $\mathcal{G}_A = \{C \in \mathscr{F}_0 \mid C \subseteq A \text{ or } f(A) \subseteq C\}$. By definition, $\mathcal{G}_A \subseteq \mathscr{F}_0$. If we show that $\mathcal{G}_A$ is f-inductive, then $\mathscr{F}_0 \subseteq \mathcal{G}_A$, and since $\mathscr{F}_0$ is the smallest f-inductive subset, it must be that $\mathcal{G}_A = \mathscr{F}_0$ which will tell us that any element $C \in \mathscr{F}_0$ must be either contained in A or contain $f(A)$. For notational convinience, let's label the condition $C \subseteq A$ as [1] and condition $F(A) \subseteq C$ as [2]

(a) Since $\emptyset \in \mathscr{F}_0$, $\emptyset \subseteq A$, and so by [1] $\emptyset \in \mathcal{G}_A$
(b) Let $C \in \mathcal{G}_A$. We must show that $f(C) \in \mathcal{G}_A$. Since $C \in \mathcal{G}_A$, then we have 3 possibilites (we're splitting [1] into 2 seperate cases:
    i. $C \subsetneq A$: Since $C \subsetneq A$ and $A \in \mathcal{H}$, then $f(C) \subseteq A$, so by [1] $f(C) \in \mathcal{G}_A$

ii. $C = A$: Since $C = A$ then $f(C) = f(A)$. Which is equivalent to $f(C) \subseteq f(A)$ and $f(A) \subseteq f(C)$. For our purposes, we care that $f(A) \subseteq f(C)$. By condition [2], $f(C) \in \mathcal{G}_A$

iii. $f(A) \subseteq C$, then since $C \subsetneq f(C)$ by definition of f, $f(A) \subseteq f(C)$, and so by condition [2], $f(C) \in \mathcal{G}_A$

in all cases, $f(C) \in \mathcal{G}_A$

(c) Let $\mathcal{C} \subseteq \mathcal{G}_A$ be a chain in $\mathcal{G}_A$. We must show that $\cup\mathcal{C} \in \mathcal{G}_A$. Then, either for all $C \in \mathcal{C}$, $C \subseteq A$, in which case $\cup\mathcal{C} \subseteq A$, and so by [1] $\cup\mathcal{C} \in \mathcal{G}_A$, or there is some $C \in \mathcal{C}$ $f(A) \subseteq C \subseteq \cup\mathcal{C}$, in which case by [2] $\cup\mathcal{C} \in \mathcal{G}_A$. In both cases, the chain is in $\mathcal{G}_A$

Thus, $\mathcal{G}_A$ is indeed f-inductive for any A, and so $\mathscr{F}_0 = \mathcal{G}_A$

□

Using the previous result, we will force one more important result: $\mathcal{H} = \mathscr{F}_0$.

Proof. As before, it is already given that $\mathcal{H} \subseteq \mathscr{F}_0$. If we show $\mathcal{H}$ is f-inductive, we'll have that $\mathcal{H} = \mathscr{F}_0$:

(a) As mentioned before, $\emptyset$ has no proper subset, so $(F \Rightarrow T)$ is vacuously true, meaning $\emptyset \in \mathcal{H}$

(b) Let $A \in \mathcal{H}$. We must show $f(A) \in \mathcal{H}$, that is if $B \in \mathscr{F}_0$ and $B \subsetneq f(A)$ then $f(B) \subseteq f(A)$. Since $B \in \mathscr{F}_0 = \mathcal{G}_A$, then either $B \subseteq A$ or $f(A) \subseteq B$. Since $B \subsetneq f(A)$, it cannot be the latter, thus we must have that $B \subseteq A$. From here, we have two possibilities:

i. $B \subsetneq A$: If so, then since $A \in \mathcal{H}$, by definition $f(B) \subseteq A \subseteq f(A)$, where the last $\subseteq$ comes from the definition of f. Thus, $f(B) \subseteq f(A)$

ii. $B = A$: Then $f(A) = f(B)$, in particular $f(B) \subseteq f(A)$

in either case, we get $f(B) \subseteq f(A)$

(c) Let $\mathcal{C} \subseteq \mathcal{H}$ be a chain. To show $\cup\mathcal{C} \in \mathcal{H}$, it must be that for any $B \in \mathscr{F}_0$ where $B \subsetneq \cup\mathcal{C}$, then $f(B) \subseteq \cup\mathcal{C}$. We will do a sneaky trick for this proof using the law of excluded middle [a]: For each $C \in \mathcal{C}$, either "$C \subseteq A$ for some A", or "$A \subsetneq C$ for all A" (which is it's direct negation). If the latter was true then

$$B \subsetneq \cup\mathcal{C} \subseteq \cup\{f(A) \mid A \in \mathcal{C}\} \subseteq B$$

implying $B \subsetneq B$ – a contradiction. Thus, it must be that for some $A \in \mathcal{C}$, $B \subseteq A$. There are again two cases

i. $B \subsetneq A$: Since $A \in \mathcal{H}$, then $f(B) \subseteq A \subseteq \cup\mathcal{C}$, so $f(B) \subseteq \cup\mathcal{C}$

ii. $B = A$: Then we have $B \in \mathcal{H}$, so $\mathcal{G}_B$ is defined and $\mathscr{F}_0 = \mathcal{G}_B$. Since $\mathcal{G}_B$ is f-inductive, $\cup\mathcal{C} \in \mathcal{G}_B = \mathscr{F}_0$. Thus, either $\cup\mathcal{C} \subseteq B$ or $f(B) \subseteq \cup\mathcal{C}$, and since $\cup\mathcal{C} \subseteq B$ is not possible since $B \subsetneq \cup\mathcal{C}$, it must be that $f(B) \subseteq \cup\mathcal{C}$.

In either case, $f(B) \subseteq \cup\mathcal{C}$, showing that $\cup\mathcal{C} \in \mathcal{H}$, showing that $\mathcal{H}$ is f-inducitve

Thus, $\mathscr{F}_0 = \mathcal{H}$ as we sought to show □

Finally, we get to combine all these facts. If $A \in \mathscr{F}_0 = \mathcal{H}$ and $B \in \mathscr{F}_0 = \mathcal{G}_A$, then either $B \subseteq A$ or $A \subseteq f(A) \subseteq B$. We couldn't do this earlier since we didn't know that $\mathscr{F}_0 = \mathcal{H}$ and $\mathscr{F}_0 = \mathcal{G}_F$ for any $F \in \mathscr{F}_0$. Thus, we have that $A \subseteq B$

or $B \subseteq A$, showing that $\mathscr{F}_0$ is a chain. We can now define $M = \cup\mathscr{F}_0$. Since $\mathscr{F}_0$ is f-inductive, then by the 3rd condition $M \in \mathscr{F}_0$. By the 2nd condition:

$$\cup\mathscr{F}_0 = M \subsetneq f(M) \in \mathscr{F}_0$$

But $f(M) \subseteq \cup\mathscr{F}_0 = M$, so $M \subsetneq f(M) \subseteq M$ implying $M \subsetneq M$ – a contradiction. The source of the contradiction was assuming an f existed which let's as choose an ever bigger value, and so no such function can exist, meaning for some A, there does not exist a B such that $A \subsetneq B$, but then A is maximal. And so, we have that (1) ⇒ (2)

(2) ⇒ (3) Let $(P, \leq)$ be a non-empty partialy orderd set. We want to show that $(P, \leq)$ contains a maximal chain (i.e. a chain C that cannot be enlarged further without loosing its total order). Let $\mathcal{F}$ be the set of all chains in P, orderd by inclusion (so if $P = A \leq B$ is a chain and $Q = A \leq B \leq C$, then $P \leq Q$). This set is non-empty, since $\emptyset \in \mathcal{F}$ and $\{x\} \in \mathcal{F}$ for all $x \in P$. Furthermore, Since any finite subchain of any infinite chain in $\mathcal{F}$ would be in $\mathcal{F}$, $\mathcal{F}$ has finite character. Thus, by Tukey's Lemma, $\mathcal{F}$ has a maximal element, meaning P has a maximal chain.

(3) ⇒ (4) Let $(P, \leq)$ be a non-empty partially ordered set where each chain has an upper bound. Then by the Hausdroff Maximality Principle, there exists a maximal chain $M \subseteq P$. Since M is a chain, it has an upper-bound – let's say m. Then m is must be a maximal element of P: If there exists some $x \in P$ such that $m \leq x$ and $m \neq x$, then $M \cup \{x\}$ is a chain that properly contains M, but M is maximal, a contradiction. Thus, m is maximal in P

(4) ⇒ (5) Let S be any set, and let $\mathcal{L}$ be the family of all well-ordered set $(W, \leq)$ such that $W \subseteq S$. This set is non-empty, since for each $x \in S$, $(\{x\}, \{(x, x)\}) \in \mathcal{L}$. In the upcoming proof, we will give an ordering to $\mathcal{L}$ and use Zorns Lemma to show that the maximal element will be $(S, \leq)$ with appropriate $\leq$

Define $(W_1, \leq_1) \preceq (W_2, \leq_2)$ if either

(a) $W_1 = W_2$ and $\leq_1 = \leq_2$ or

(b) there exists a $a \in W_2$ such that $W_1 = \{x \in W_2 \mid x \leq_2 a,\ x \neq a\}$, and $\leq_2$ agrees with $\leq_1$ on W_1 ($\leq_1 \subseteq \leq_2$ [b]). In this case, W_2 is called a continuition of $(W_1, \leq_1)$

The relation $\preceq$ is a partial ordering on $\mathcal{L}$. Reflexivity is the first case. If $(W_1, \leq_1) \preceq (W_2, \leq_2)$ holds by the second case, then W_1 is a proper subset of W_2, since $a \in W_2 \setminus W_1$, so the second case cannot hold in both directions at once, which gives antisymmetry. For transitivity it suffices to treat two instances of the second case, $W_1 = \{x \in W_2 \mid x \leq_2 a,\ x \neq a\}$ and $W_2 = \{x \in W_3 \mid x \leq_3 b,\ x \neq b\}$, each order agreeing with the next on the smaller set. Since $a \in W_2$, $a \leq_3 b$ and $a \neq b$. If $x \in W_3$ satisfies $x \leq_3 a$ and $x \neq a$, then $x \leq_3 b$, and $x \neq b$ because $b \leq_3 a$ would force $a = b$, so $x \in W_2$ and $x \leq_2 a$, that is, $x \in W_1$. Conversely every $x \in W_1$ lies in W_3 with $x \leq_3 a$ and $x \neq a$, as $\leq_2$ agrees with $\leq_3$ on W_2. Hence $W_1 = \{x \in W_3 \mid x \leq_3 a,\ x \neq a\}$, and $\leq_3$ agrees with $\leq_2$, hence with $\leq_1$, on W_1. Note that it is not a total ordering: If W_i and W_j do not have the same minimal element, then $W_i \not\preceq W_j$ and $W_j \not\preceq W_i$. This means that any chain of elements will end up with the same minimal element. Now, let $\ell = \{(W_i, \leq_i)\}_{i \in I}$ be any non-empty chain

in $\mathcal{L}$ (relative to $\preceq$). We want to show it must have an upper-bound. Set $W = \bigcup_{i\in I} W_i$ and $\leq = \bigcup_{i\in I} \leq_i$ (see definition 0.1.12). Any two members of ℓ are comparable under $\preceq$, and $(W_i, \leq_i) \preceq (W_j, \leq_j)$ implies that $W_i \subseteq W_j$ and that $\leq_i$ consists of the pairs in $\leq_j$ with both entries in W_i. This has two consequences.

(a) Finitely many elements of W lie in a single W_k: each lies in some W_i, and among these finitely many members of the chain ℓ there is a largest one, which contains the others.

(b) For $x, y \in W_k$, $x \leq y$ holds exactly when $x \leq_k y$. One direction holds because $\leq_k \subseteq \leq$. Conversely, suppose $(x, y) \in \leq_m$. If $(W_m, \leq_m) \preceq (W_k, \leq_k)$, then $\leq_m \subseteq \leq_k$. If $(W_k, \leq_k) \preceq (W_m, \leq_m)$, then (x, y) is a pair in $\leq_m$ with both entries in W_k, hence lies in $\leq_k$.

So $(W, \leq)$ is a total order: each condition of definition A.1.4 involves at most three elements of W, these lie in one W_k by the first consequence, and on W_k the relation $\leq$ is the total order $\leq_k$ by the second. It is moreover a well-ordering. Let A be a non-empty subset of W. Since it's non-empty, there exists some $i \in I$ such that $A \cap W_i \neq \emptyset$. Since $(W_i, \leq_i)$ is well-ordered, there is an element $a \in A \cap W_i$ such that $a \leq_i x$ for all $x \in A \cap W_i$. Suppose now that there is an element $b \in A$ such that $b \leq a$, and say $b \in W_j$. Then $b \in W_i$. This holds if $(W_j, \leq_j) \preceq (W_i, \leq_i)$, because then $W_j \subseteq W_i$. Otherwise $(W_i, \leq_i) \preceq (W_j, \leq_j)$ with $W_i \neq W_j$, so $W_i = \{x \in W_j \mid x \leq_j c,\ x \neq c\}$ for some $c \in W_j$, and $b \leq_j a$ by the second consequence, while $a \leq_j c$ and $a \neq c$. So $b \leq_j c$, and $b \neq c$ because $c \leq_j a$ would force $a = c$. Now $b \leq_i a$ by the second consequence and $a \leq_i b$ by the choice of a, so $b = a$. As $\leq$ is total, every $x \in A$ satisfies $a \leq x$ or $x \leq a$, and the latter forces $x = a$. Thus, A has a smallest element a in $(W, \leq)$, meaning $(W, \leq) \in \mathcal{L}$.

Furthermore, $(W, \leq)$ is an upper-bound for ℓ. Fix $i \in I$. By the second consequence, $\leq_i$ consists of the pairs in $\leq$ with both entries in W_i, so if $W_i = W$, then $(W_i, \leq_i) = (W, \leq)$. Otherwise let c be the smallest element of $W \setminus W_i$, which exists since $(W, \leq)$ is well-ordered. Say $c \in W_j$. Then $(W_j, \leq_j) \not\preceq (W_i, \leq_i)$, since $c \notin W_i$, so $(W_i, \leq_i) \preceq (W_j, \leq_j)$ with $W_i \neq W_j$, that is, $W_i = \{x \in W_j \mid x \leq_j d,\ x \neq d\}$ for some $d \in W_j$, and $d \leq_j c$ because $c \notin W_i$ and $\leq_j$ is total. Every $x \in W_i$ satisfies $x \leq_j d \leq_j c$ and $x \neq c$, so $x \leq c$ and $x \neq c$. Conversely, every $x \in W$ with $x \leq c$ and $x \neq c$ lies in W_i by the minimality of c. Hence $W_i = \{x \in W \mid x \leq c,\ x \neq c\}$, and $(W_i, \leq_i) \preceq (W, \leq)$.

Thus, by Zorn's Lemma, $\mathcal{L}$ has a maximal element $(W_0, \leq_0)$. If $W_0 = S$, we are done, as $\leq_0$ is our well-ordering of S. If $W_0 \neq S$, let $z \in S \setminus W_0$. Define $(W_0 \cup \{z\}, \leq)$, where

$$\leq = \leq_0 \cup \{(x, z) \mid x \in W_0 \cup \{z\}\}$$

that is, place z after everything in W_0. Then $(W_0 \cup \{z\}, \leq) \in \mathcal{L}$, since a non-empty subset meeting W_0 has as smallest element the $\leq_0$-smallest element of its intersection with W_0, and the only other non-empty subset is $\{z\}$. Moreover $(W_0, \leq_0) \preceq (W_0 \cup \{z\}, \leq)$ and $(W_0 \cup \{z\}, \leq) \not\preceq (W_0, \leq_0)$. However, this contradicts the maximality of $(W_0, \leq_0)$, and so it must be that $W_0 = S$, showing that S does indeed have a well-ordering.

(5) ⇒ (1) Let $\{A_i\}_{i\in I}$ be any non-empty family of non-empty sets, and let $S = \cup_{i\in I} A_i$. By the well-ordering principle, there exists an $\leq$ that well-orders S. Now, for each $i \in I$, let $f(i)$ be the smallest element of A_i (relative to $\leq$). Then f is a chocie function on the family $\{A_i\}_{i\in I}$

[a]For every proposition P, either P is true or $\neg P$ is true. This is implied by ZF
[b]If these seems strange, review the technical definition of a relation in section 0.1.4

This textbook contains many cases where zorn's lemma must be used, for example:

1. All proper ideals in a ring [with identity] is contained in a maximal ideal
2. All vector-spaces have a basis

A.3 Zorn's Lemma

For the purposes of this textbook, the most important consequence of the Axiom of Choice is Zorn's lemma (theorem A.2.3), and the two applications listed above follow one pattern. The objects sought are maximal elements of a set P of partial objects, ordered by inclusion. An application of Zorn's lemma checks that P is non-empty and that every chain in P has an upper bound in P, usually its union. Zorn's lemma then provides a maximal element, and maximality forces it to be complete, because a partial object that is not complete can be enlarged inside P. For maximal ideals, P is the set of proper ideals containing a given proper ideal, as in proposition 9.4.18. For bases, it is the set of linearly independent subsets:

Proposition A.3.1: Every Vector Space Has A Basis

Let V be a vector space over a field k. Then V has a basis, that is, a linearly independent subset that spans V.

***Proof*:**
Let P be the set of linearly independent subsets of V, ordered by inclusion. It contains $\emptyset$. Let $\mathcal{C}$ be a chain in P, and put $S = \bigcup \mathcal{C}$, with $S = \emptyset$ when $\mathcal{C}$ is empty. A linear relation $c_1 s_1 + \cdots + c_n s_n = 0$ among distinct elements of S involves finitely many members of $\mathcal{C}$, the largest of which contains $s_1, \ldots, s_n$, so every c_i is 0. So $S \in P$ is an upper bound for $\mathcal{C}$, and theorem A.2.3 gives a maximal element B of P. Suppose some $v \in V$ is not in the span of B. In a relation $cv + c_1 b_1 + \cdots + c_n b_n = 0$ with distinct $b_i \in B$, the coefficient c is 0, since otherwise $v = -c^{-1}(c_1 b_1 + \cdots + c_n b_n)$ would lie in the span of B, and then every c_i is 0 because B is linearly independent. So $B \cup \{v\}$ is a linearly independent set properly containing B, contradicting the maximality of B. Hence B spans V.

A.4 The Schröder-Bernstein Theorem

Theorem A.4.1: Schröder-Bernstein Theorem

Let A and B be sets with injections $f : A \to B$ and $g : B \to A$. Then there is a bijection $h : A \to B$.

***Proof*:**

For $E \subseteq A$ put $\Phi(E) = A \setminus g\big(B \setminus f(E)\big)$. If $E \subseteq E'$, then $f(E) \subseteq f(E')$, so $B \setminus f(E) \supseteq B \setminus f(E')$, so $g(B \setminus f(E)) \supseteq g(B \setminus f(E'))$, and so $\Phi(E) \subseteq \Phi(E')$. Let C be the union of all sets $E \subseteq A$ with $E \subseteq \Phi(E)$. Each such E satisfies $E \subseteq C$, hence $E \subseteq \Phi(E) \subseteq \Phi(C)$, so $C \subseteq \Phi(C)$. Applying Φ gives $\Phi(C) \subseteq \Phi(\Phi(C))$, so $\Phi(C)$ is one of the sets E, and $\Phi(C) \subseteq C$. Hence $C = \Phi(C)$, which says

$$A \setminus C = g\big(B \setminus f(C)\big)$$

Define $h(a) = f(a)$ for $a \in C$, and for $a \in A \setminus C$ let $h(a)$ be the element $b \in B \setminus f(C)$ with $g(b) = a$, which exists by the display and is unique because g is injective. Then h maps C injectively onto $f(C)$, since f is injective. It maps $A \setminus C$ onto $B \setminus f(C)$, since each $b \in B \setminus f(C)$ equals $h(g(b))$, and injectively, since $g(h(a)) = a$. These two images are disjoint with union B, so h is a bijection.

No choice is made in this proof: the set C and the map h are defined outright, so the theorem holds without the axiom of choice.

B

Sub-Group of a Free Group is Free

In this book, the fact that a subgroup of a free-group is free doesn't come into play. It is interesting tangentially as an example of a property which is closed under taking subgroups, contrasting to how being finitely generated is is not a property closed under taking subgroups, or that a sub-module of a free module is not always free, but we don't use this fact anywhere else. However, some might be curious as to how we would prove this fact. The goal of this section is to do just that using only group-theoretical knowledge.

B.1 Using Cosets

There are in fact many proofs of this fact, including a famous one by Serre topological properties of trees (connected graphs with no cycles). Such a proof would be covered in geometric group theory.

Lemma B.1.1: Finite Index Subgroup Of Finitely Generated Subgroup

Let G be a finitely generated group, and let $H \leqslant G$ be a subgroup of finite index (i.e. $|G : H| = s$ for some $s \in \mathbb{N}$). Then H is finitely generated

***Proof*:**
Let $G = \langle x_1, x_2, ..., x_n \rangle$ be generated by the elements $X = \{x_1, x_2, ..., x_n\}$, $H \leqslant G$ so that $|G : H| = s$, and let $A = \{a_1 = 1, ..., a_s\}$ be a set of representative sfor the right cosets of H (also known as a transversal for H in G).

Let $x \in H$. Since $H \leqslant G$, then $x \in G$. Since G is finitely generated we have that

$$x = y_1 y_2 \cdots y_n$$

where y_i is either a generator or an inverse of a generator. Since $y_1, y_2, ..., y_n$ are not necessarily in H, this is not a finite representation of x. Instead, we'll show that from these we can create a representation with elements in H. Take the representative a_{i_1} which represents the coset Hy_1, so $a_{i_1} \in Hy_1$, meaning $a_{i_1} = h_1 y_1$ for some $h_1 \in H$. Then

$$x = y_1 a_{i_1}^{-1} a_{i_1} y_2 y_3 \cdots y_n$$

Next, let a_{i_2} be the represetnative for $Ha_{i_1} y_2$ so that $a_{i_2} = h_2 a_{i_1} y_2$. In particular, $h_2^{-1} = a_{i_1} y_2 a_{i_2}^{-1}$ so that this conjugation is part of H. Now, re-write

$$x = y_1 a_{i_1}^{-1} a_{i_1} y_2 a_{i_2}^{-1} a_{i_2} y_3 \cdots y_n$$

Similarly for a_{i_3}, picking a representative from $Ha_{i_2} y_3$. Going on in this fashion, we'll end up with an equation

$$x = y_1 a_{i_1}^{-1} a_{i_1} y_2 a_{i_2}^{-1} a_{i_2} y_3 a_{i_3}^{-1} a_{i_3} \cdots y_n a_{i_n}^{-1} a_{i_n} \tag{B.1}$$

Thus, every element $x \in H$ can be in written out as in equation (B.1). Put $a_{i_0} = a_1 = 1$. For each k, the representative a_{i_k} of $Ha_{i_{k-1}} y_k$ has the form $a_{i_k} = h_k a_{i_{k-1}} y_k$ with $h_k \in H$, so the triple $a_{i_{k-1}} y_k a_{i_k}^{-1} = h_k^{-1}$ lies in H. Grouping (B.1) into these triples gives

$$x = h a_{i_n} \qquad h = \left(a_{i_0} y_1 a_{i_1}^{-1}\right)\left(a_{i_1} y_2 a_{i_2}^{-1}\right) \cdots \left(a_{i_{n-1}} y_n a_{i_n}^{-1}\right) \in H$$

As x and h lie in H, so does $a_{i_n} = h^{-1} x$. The coset $Ha_{i_{n-1}} y_n$ that a_{i_n} represents contains a_{i_n}, and a right coset Hc containing a_{i_n} equals Ha_{i_n}, because $a_{i_n} = h'c$ with $h' \in H$ gives $Hc = Hh'^{-1} a_{i_n} = Ha_{i_n}$. Since $a_{i_n} \in H$, this coset is $Ha_{i_n} = H$, whose representative is $a_1 = 1$. Hence $a_{i_n} = 1$, and $x = h$ is a product of elements $a_j y a_l^{-1}$ in which $a_j \in A$, $y \in X \cup X^{-1}$ and a_l is the representative of $Ha_j y$. There are at most $2s|X|$ such elements, all of them lie in H, and $x \in H$ was arbitrary, so H is finitely generated.

This theorem is interesting in its own right as a partial result to when a subgroup of a finitely generated group is finitely generated[1]. It also has application in geometric group theory where we are interested in finding what is the growth type of the function $\mathfrak{g}(G)(n)$ (ex. polynomial growth, exponential growth) which represents the number of words which require n elements from the generators to represent it. In this case, what we found was if $m(H)$ represents the minimum number of generators for the group H, then $m(H) \leq 2m(G)|G : H|$. For more on growth, see [72, Growth types of groups].

Proposition B.1.2: The Commutator Subgroup Of F_2 Is Not Finitely Generated

Let F_2 be the free group on $\{a, b\}$, and let F_2' be its commutator subgroup, the subgroup generated by the commutators $[u, v] = u^{-1} v^{-1} uv$ with $u, v \in F_2$. Then F_2' is not finitely generated.

***Proof*:**

Let $D = \{c/2^n \mid c \in \mathbb{Z},\ n \geq 0\}$, a subgroup of $(\mathbb{R}, +)$ that is closed under multiplication by 2^k for every $k \in \mathbb{Z}$, and let T be the set of maps $\mathbb{R} \to \mathbb{R}$ of the form $t \mapsto 2^k t + r$ with $k \in \mathbb{Z}$ and

[1] Without the finite-index hypothesis the conclusion fails: the commutator subgroup of the free group on two generators is not finitely generated, proposition B.1.2 below.

$r \in D$. Composing two of them gives

$$(2^k t + r) \circ (2^l t + s) = 2^{k+l} t + (2^k s + r)$$

which is again in T. The inverse of $t \mapsto 2^k t + r$ is $t \mapsto 2^{-k} t - 2^{-k} r$, also in T, and the identity is in T, so T is a group under composition. The exponent k is determined by the map, as its slope is 2^k, and the displayed formula shows that $\delta(2^k t + r) = k$ defines a homomorphism $\delta : T \to (\mathbb{Z}, +)$. Its kernel is the group of translations $\tau_r(t) = t + r$ with $r \in D$, and $\tau_r \circ \tau_s = \tau_{r+s}$.

Put $\alpha = \tau_1$ and $\beta(t) = 2t$. By theorem 2.3.27 there is a homomorphism $\varphi : F_2 \to T$ with $\varphi(a) = \alpha$ and $\varphi(b) = \beta$. For $u, v \in F_2$, the homomorphism $\delta \circ \varphi$ into the abelian group $\mathbb{Z}$ gives

$$\delta\varphi([u, v]) = -\delta\varphi(u) - \delta\varphi(v) + \delta\varphi(u) + \delta\varphi(v) = 0$$

so the kernel of $\delta \circ \varphi$ is a subgroup containing every commutator, hence containing F_2'. So $\varphi(F_2') = \{\tau_r \mid r \in E\}$ for a subgroup E of D.

For $m \in \mathbb{Z}$, evaluating the composite from the right,

$$[\beta^m, \alpha](t) = \beta^{-m}\alpha^{-1}\beta^m\alpha(t) = 2^{-m}\big(2^m(t+1) - 1\big) = t + 1 - 2^{-m}$$

Since $[b^m, a] \in F_2'$ and $\varphi([b^m, a]) = [\beta^m, \alpha]$, this gives $1 - 2^{-m} \in E$ for every $m \in \mathbb{Z}$. Taking $m = -1$ gives $-1 \in E$, so $1 \in E$, and then $2^{-m} = 1 - (1 - 2^{-m}) \in E$ for every $m \geq 0$.

Suppose F_2' were generated by finitely many elements $w_1, \ldots, w_k$, and write $\varphi(w_i) = \tau_{r_i}$. Every element of F_2' is a product of the w_i and their inverses, and φ carries such a product to the translation by the corresponding sum of the $\pm r_i$, so every element of E has the form $\sum_i n_i r_i$ with $n_i \in \mathbb{Z}$. Choose $N \geq 0$ with $2^N r_i \in \mathbb{Z}$ for every i. Then $E \subseteq 2^{-N}\mathbb{Z}$, which does not contain $2^{-(N+1)}$, contradicting $2^{-(N+1)} \in E$.

The part that is more intriguing for us is the way we have constructed the elements of H. Though we have limited to $|G : H|$ being finite, we can still represent the elements of $H \leqslant G$ with the same trick! Using this fact, we will show that the elements of a subgroup of a free-group will have to be relation less:

Theorem B.1.3: Nielsen-Schreier's Theorem

Let G be a free group and $H \leqslant G$. Then H is a free group

***Proof*:**

Step 1: words and the ordering. Let X be a set and $F = F(X)$ the group of reduced words on X (proposition 2.3.26). A free group is isomorphic to such an F: if G is free on $X \subseteq G$ in the sense of definition 2.3.29, the homomorphisms $F \to G$ and $G \to F$ that restrict to the identity of X, given by the two universal properties, compose in either order to homomorphisms restricting to the identity of X, and these are identities by the uniqueness in the same universal properties (theorem 2.3.27). An isomorphism carries H onto an isomorphic subgroup, so it suffices to show that every subgroup H of F is free. Note that X need not be finite, or even countable. The elements of F are the reduced words in the letters $X \cup X^{-1}$, and $|g|$ denotes the length of $g \in F$. By the well-ordering theorem (theorem A.2.4), fix a well-ordering of the letters. Order the elements of F by length first and, among words of the same length, lexicographically, comparing two different words at the first position where they differ. This is a well-ordering of

F: in a non-empty set of words, the words of least length n have a least first letter, those among them with that first letter have a least second letter, and after n such choices one word remains, which is the least element of the set.

Step 2: a Schreier transversal. For $g \in F$ let $\overline{g}$ be the first element of the right coset Hg in this ordering, and let $A = \{\overline{g} \mid g \in F\}$, which contains exactly one element of each right coset of H. So $\overline{g} = \overline{g'}$ exactly when $Hg = Hg'$, and $\overline{a} = a$ for $a \in A$. The coset H contains the empty word, so $\overline{h} = 1$ for every $h \in H$. Every prefix of an element of A lies in A. Let $a \in A$ have reduced word uw, with u and w its first k and its last $|a| - k$ letters, and put $c = \overline{u}$, so that c does not come after u, and in particular $|c| \leq |u|$. The element cw lies in $Hcw = Huw = Ha$. If $|c| < |u|$, then $|cw| \leq |c| + |w| < |a|$. If $|c| = |u|$ and $c \neq u$, then either the word cw is not reduced, and $|cw| < |c| + |w| = |a|$, or it is reduced of length $|a|$ and comes before $uw = a$, since c comes before u and the two words first differ within their first k letters. In each case cw comes before a, which is impossible, as a is the first element of Ha. Hence $u = c \in A$.

Step 3: generators, for any index. For $a \in A$ and $x \in X$ put $\gamma(a, x) = ax\overline{ax}^{-1}$, which lies in H because $\overline{ax} \in Hax$. These elements generate H. Let $h \in H$ have reduced word $z_1 \cdots z_m$, with letters $z_k \in X \cup X^{-1}$, and put $u_k = \overline{z_1 \cdots z_k}$ for $0 \leq k \leq m$, so that $u_0 = 1$ and $u_m = \overline{h} = 1$. Then

$$h = \left(u_0 z_1 u_1^{-1}\right)\left(u_1 z_2 u_2^{-1}\right) \cdots \left(u_{m-1} z_m u_m^{-1}\right)$$

and $u_k = \overline{u_{k-1} z_k}$, since $H u_{k-1} z_k = H z_1 \cdots z_k$. If $z_k = x \in X$, the kth factor is $\gamma(u_{k-1}, x)$. If $z_k = x^{-1}$ with $x \in X$, then $H u_k x = H u_{k-1} x^{-1} x = H u_{k-1}$ gives $\overline{u_k x} = u_{k-1}$, so the kth factor $u_{k-1} x^{-1} u_k^{-1}$ is $\gamma(u_k, x)^{-1}$. The element $\gamma(a, x)$ is trivial exactly when $ax = \overline{ax}$, that is, when $ax \in A$. So, with

$$I = \{(a, x) \in A \times X \mid ax \notin A\}$$

the set $Y = \{\gamma(a, x) \mid (a, x) \in I\}$ of the nontrivial elements $\gamma(a, x)$ generates H.

Step 4: the generators as reduced words. Call a pair (p, z) with $p \in A$, $z \in X \cup X^{-1}$ and $pz \notin A$ *admissible*, and for it put $\gamma_{(p,z)} = pz\overline{pz}^{-1}$. The admissible pairs whose letter lies in X are exactly the elements of I, and $\gamma_{(a,x)} = \gamma(a, x)$ for them. Let (p, z) be admissible and $q = \overline{pz}$. The word obtained by writing the reduced words of p, z and q^{-1} side by side is reduced. A cancellation in it could only occur between the last letter of p and z, or between z and the first letter of q^{-1}, which is the inverse of the last letter of q. If $p = p'z^{-1}$ as reduced words, then $pz = p'$ is a prefix of p, so $pz \in A$ by Step 2. If $q = q'z$ as reduced words, then the prefix $q' = qz^{-1}$ of q lies in A, and since $Hqz^{-1} = Hpzz^{-1} = Hp$, it equals p, so $pz = q \in A$. Both contradict $pz \notin A$. So $\gamma_{(p,z)}$ is the non-empty reduced word $p\, z\, q^{-1}$, whose letter in position $|p| + 1$ is z.

For (p, z) admissible and $q = \overline{pz}$, put $(p, z)^* = (q, z^{-1})$. Since $Hqz^{-1} = Hp$, we have $\overline{qz^{-1}} = p$. The pair $(p, z)^*$ is admissible, since $qz^{-1} \in A$ would give $qz^{-1} = p$ and $pz = q \in A$. Moreover $(p, z)^{**} = (p, z)$, and

$$\gamma_{(p,z)^*} = qz^{-1}p^{-1} = \gamma_{(p,z)}^{-1}$$

Of the two pairs (p, z) and $(p, z)^*$, exactly one has its letter in X.

Step 5: the middle letters survive. Let $d_1, \ldots, d_m$ be admissible pairs, with $m \geq 1$ and $d_{i+1} \neq d_i^*$ for $1 \leq i < m$. Then $\gamma_{d_1} \cdots \gamma_{d_m} \neq 1$. Write $d_i = (p_i, z_i)$ and $q_i = \overline{p_i z_i}$. For $i < m$ let c_i be the longest common prefix of the reduced words q_i and p_{i+1}, and write $q_i = c_i s_i$ and $p_{i+1} = c_i t_i$. Then $q_i^{-1} p_{i+1} = s_i^{-1} t_i$, and the word $\rho_i = s_i^{-1} t_i$ is reduced, because when s_i and t_i are both non-empty their first letters differ. The word

$$p_1\, z_1\, \rho_1\, z_2\, \rho_2 \cdots \rho_{m-1}\, z_m\, q_m^{-1}$$

equals $\gamma_{d_1} \cdots \gamma_{d_m}$ in F, and each of its pieces is reduced. By Step 4, p_1 does not cancel against z_1, nor z_m against q_m^{-1}. For $i < m$ there are three cases.

1. s_i and t_i are both empty. Then ρ_i is empty and $p_{i+1} = q_i$. If $z_{i+1} = z_i^{-1}$, then $d_{i+1} = (q_i, z_i^{-1}) = d_i^*$, which is excluded. So z_i and z_{i+1} do not cancel.

2. s_i is non-empty. Then ρ_i begins with the first letter of q_i^{-1}, and z_i does not cancel against it, because the word $p_i z_i q_i^{-1}$ is reduced (Step 4). If t_i is non-empty, then ρ_i ends with the last letter of p_{i+1}, which does not cancel against z_{i+1}, because the word $p_{i+1} z_{i+1} q_{i+1}^{-1}$ is reduced. If t_i is empty, then $\rho_i = s_i^{-1}$ ends with y^{-1}, where y is the first letter of s_i, and $p_{i+1} y$ is a prefix of q_i, so it lies in A by Step 2. A cancellation of y^{-1} against z_{i+1} would mean $z_{i+1} = y$, so $p_{i+1} z_{i+1} \in A$, against the admissibility of d_{i+1}.

3. s_i is empty and t_i is non-empty. Then $\rho_i = t_i$ ends with the last letter of p_{i+1}, which does not cancel against z_{i+1}, as in (2). It begins with the letter y that follows q_i in p_{i+1}, so $q_i y$ is a prefix of p_{i+1} and lies in A by Step 2. If $y = z_i^{-1}$, then $q_i z_i^{-1} \in A$, against the admissibility of d_i^*. So z_i and y do not cancel.

Hence the word is reduced. It contains the letters $z_1, \ldots, z_m$, so it is not empty, and $\gamma_{d_1} \cdots \gamma_{d_m} \neq 1$.

Step 6: H is free. Let $F(I)$ be the free group on the set I, and let $\psi : F(I) \to H$ be the homomorphism with $\psi(\iota) = \gamma_\iota$ for $\iota \in I$, given by theorem 2.3.27. Its image is the subgroup generated by Y, which is H by Step 3. A nontrivial element of $F(I)$ is a non-empty reduced word $\iota_1^{\epsilon_1} \cdots \iota_m^{\epsilon_m}$ with $\iota_i \in I$ and $\epsilon_i = \pm 1$, and by proposition 2.3.26 and Step 4, ψ sends it to $\gamma_{d_1} \cdots \gamma_{d_m}$, where $d_i = \iota_i$ if $\epsilon_i = 1$ and $d_i = \iota_i^*$ if $\epsilon_i = -1$. Suppose $d_{i+1} = d_i^*$ for some i. If $\epsilon_i = 1$, then $d_{i+1} = \iota_i^*$ has its letter in X^{-1}, so $\epsilon_{i+1} = -1$ and $\iota_{i+1}^* = \iota_i^*$, that is, $\iota_{i+1} = \iota_i$. If $\epsilon_i = -1$, then $d_{i+1} = \iota_i^{**} = \iota_i$ has its letter in X, so $\epsilon_{i+1} = 1$ and $\iota_{i+1} = \iota_i$. Either way the letters $\iota_i^{\epsilon_i}$ and $\iota_{i+1}^{\epsilon_{i+1}}$ are formal inverses, which a reduced word does not contain. So Step 5 applies, ψ sends every nontrivial element to a nontrivial element, and ψ is injective. Hence ψ is an isomorphism from $F(I)$ onto H, and H is free on $Y = \psi(I)$: for a group K and a function $f : Y \to K$, the homomorphism $F(I) \to K$ extending $\iota \mapsto f(\gamma_\iota)$, composed with ψ^{-1}, extends f, and it is the only such homomorphism because Y generates H.

B.2 Using Tree's

A perhaps more intuitive proof of this theorem comes from groups acting on trees. A group is free if and only if it acts freely on a non-empty tree, and a subgroup of a group acting freely on a tree acts freely on the same tree, so it is free. The characterization of free groups by free actions on trees uses graph theory that this appendix does not develop, and the argument is carried out in [72, Subgroups of free groups are free].

C

Basic Topology and Topological Groups

This appendix is not a substitute for a proper introduction to topology. It is a review, or a test of knowledge, of the topology used elsewhere in this book: the Zariski topology of chapter 31, the completions of chapter 25, and the Krull topology on the Galois group of an infinite extension in theorem 50.8.8. To that end, it is a speed-run of definitions and basic concepts. A full treatment is *Topology* [39], and Munkres' *Topology* [75] is a standard text.

C.1 Definition and Properties

Definition C.1.1: Topology

Let X be a set and $\mathcal{T}_X \subseteq P(X)$ be a subset of the powerset of X such that

1. $\emptyset$ and X are in $\mathcal{T}_X$
2. For any arbitrary collection of elements in $\mathcal{T}_X$, their union is in $\mathcal{T}_X$
3. for any finite collection of elements in $\mathcal{T}_X$, their intersection is in $\mathcal{T}_X$

Then $(X, \mathcal{T}_X)$ is call a *topological space* and $\mathcal{T}_X$ is called a *topology on* X. Elements of $\mathcal{T}_X$ are called *open sets*.

Usually we omit the $\mathcal{T}_X$ and simply call X the topology, thus we say that $Y \subseteq X$ is open if and only if $Y \in \mathcal{T}_X$. If $x \in X$, then a *neighbhorhood* of X will be an *open set* $U \in \mathcal{T}$ such that $x \in U$. In some book, a neighbhorhood is simply some set containing x and need not be open; sometimes to

emphasize that the neighbhorhood is open, it is called an *open neighbhorhood*. The *neighbhorhood system* of an element $x \in X$ is the collection of all open neighbhorhoods containing x. Topologies can also be defined in terms of closed sets:

Proposition C.1.2

Let X be a set and $\mathcal{T}_X^C \subseteq P(X)$ be subset of the powerset such that

1. $\emptyset$ and X are in $\mathcal{T}_X^C$
2. For any finite collection of elements in $\mathcal{T}_X^C$, their union is in $\mathcal{T}_X^C$
3. for any arbitrary collection of elements in $\mathcal{T}_X^C$, their intersection is in $\mathcal{T}_X^C$

Then the collection of complements $\mathcal{T}_X = \left\{X \setminus C \;\middle|\; C \in \mathcal{T}_X^C\right\}$ is a topology on X in the sense of definition C.1.1, and $\mathcal{T}_X^C = \{X \setminus U \mid U \in \mathcal{T}_X\}$. Conversely, if $\mathcal{T}_X$ is a topology on X, then $\{X \setminus U \mid U \in \mathcal{T}_X\}$ satisfies the three conditions above. In particular, in any topological space an arbitrary intersection of closed sets is closed and a finite union of closed sets is closed.

***Proof*:**
Throughout, A^c abbreviates $X \setminus A$, and the two De Morgan identities

$$\Big(\bigcap_{i\in I} A_i\Big)^c = \bigcup_{i\in I} A_i^c \qquad \Big(\bigcup_{i\in I} A_i\Big)^c = \bigcap_{i\in I} A_i^c$$

are used in both directions. Each holds because $x \notin \bigcap_i A_i$ says exactly that $x \notin A_i$ for some i, and $x \notin \bigcup_i A_i$ says exactly that $x \notin A_i$ for every i.

Assume the three conditions. Condition (1) gives $\emptyset = X^c \in \mathcal{T}_X$ and $X = \emptyset^c \in \mathcal{T}_X$, which is the first axiom of definition C.1.1. For an arbitrary family $\{C_i^c\}_{i\in I}$ of members of $\mathcal{T}_X$ the first De Morgan identity gives $\bigcup_i C_i^c = (\bigcap_i C_i)^c$, and $\bigcap_i C_i \in \mathcal{T}_X^C$ by condition (3), so the union lies in $\mathcal{T}_X$. For a finite family $C_1^c, \ldots, C_n^c$ the second identity gives $\bigcap_{k=1}^n C_k^c = (\bigcup_{k=1}^n C_k)^c$, and $\bigcup_{k=1}^n C_k \in \mathcal{T}_X^C$ by condition (2), so the intersection lies in $\mathcal{T}_X$. Hence $\mathcal{T}_X$ is a topology. Since $C = (C^c)^c$ for every $C \subseteq X$, the assignment $C \mapsto C^c$ is an involution of $P(X)$, so $\mathcal{T}_X^C = \{U^c \mid U \in \mathcal{T}_X\}$.

For the converse, let $\mathcal{T}_X$ be a topology and put $\mathcal{T}_X^C = \{U^c \mid U \in \mathcal{T}_X\}$, the closed sets. The same two identities, read from right to left, turn the three axioms of definition C.1.1 into conditions (1), (3) and (2) for $\mathcal{T}_X^C$ in that order. The last sentence of the statement is conditions (3) and (2).

Many times, we define a topology through the use of a topological basis (not to be confused with a vector-space basis)

Definition C.1.3: Topological Basis

Let X be a set. Then a subset of the powerset $\mathcal{B} \subseteq P(X)$ is called a *topological basis* (or just *basis* if unambiguous) where:

1. for every $x \in X$, there is some $U \in \mathcal{B}$ such that $x \in U$
2. For every $U, V \in \mathcal{B}$ and every $x \in U \cap V$, there exists a $B \in \mathcal{B}$ such that $x \in B \subseteq U \cap V$

If only the first condition is met, then $\mathcal{B}$ is called a *topological subbasis* (or *subbasis* for short). The topology $\mathcal{T}_\mathcal{B}$ on X is the topology where $U \in \mathcal{T}_\mathcal{B}$ if and only if U is the union of some subfamily of $\mathcal{B}$. If $\mathcal{B}$ is a subbasis, then $\mathcal{T}_\mathcal{B}$ consists of the unions of finite intersections of members of $\mathcal{B}$.

Two topologies that can be naturally defined on any set X are the *trivial topology* of $\mathcal{T}(X) = \{\emptyset, X\}$ and the *discrete topology* of $\mathcal{T}(X) = P(X)$. The Euclidean topology is a common topology defined on $\mathbb{R}^n$ for $n \geq 1$. Another common topology is defined on real or complex vector-spaces using a function called a *norm* (very similar to the euclidean norm used in when defining euclidean domains): a norm is a function $\|\cdot\| : V \to \mathbb{R}$ where

1. $\|x + y\| \leq \|x\| + \|y\|$
2. $\|c \cdot x\| = |c| \cdot \|x\|$
3. $\|x\| = 0$ if and only if $x = 0$

Then then the collection of all $B_r(x) = \{y \in X \mid \|x - y\| < r\}$ forms a topological basis for a topology. Another common way of defining a topological space is by using a metric: if (X, d) is a metric space, then the collection of all $B_r(x) = \{y \in X \mid d(x, y) < r\}$ forms a basis for X.

We relate two topologies by taking *continuous functions* between them:

Definition C.1.4: Continuous Function

Let X, Y be topological spaces and $f : X \to Y$ be a function. Then f is called a continuous function is the pre-iamge of every open set of Y is in X:

$$f^{-1}(U) \in \mathcal{T}(X)$$

Common examples of continuous functions are the polynomials functions from $\mathbb{R}^n$ to $\mathbb{R}^m$ given the euclidean topology in both cases. If a function is also bijective, then we call such a function a bijective continuous function. Unlike homomorphisms (be it groups, rings, etc.) a bijective continuous function does *not* imply the inverse function is continuous, or equivalently, that the image of open sets are open (an example follows definition C.1.5), and so we give a special name to a bicontinuous bijective function:

Definition C.1.5: Homeomorphim

Let $(X, \mathcal{T}_X)$ and $(Y, \mathcal{T}_Y)$ be two topological spaces. Then a function $f : X \to Y$ is called a *homeomorphism* if f is bijective and

$$f^{-1}(\mathcal{T}_Y) = \mathcal{T}_X$$

examples of homeomorphisms are the identity function, and $f(x) = x^3$ on $\mathbb{R}$ in the euclidean topology. A function that is bijective and continuous but is not a homeomorphism is the identity function from X to X where the domain has the discrete topology and the codomain has the trivial topology. Note that for any topological space X, the identity function is continuous, the composition of continuous functions is continuous, and associativty of continuous functions follows from the associativity of functions. Hence, the collection of topological spaces and continuous maps from a category

Definition C.1.6: Category Of Top

The collection of all topologies on any set and the collection of continuous maps between topologies forms a category, labelled as **Top**, with objects being topologies and morphisms begin continuous maps. Homeomorphisms are the isomorphisms of **Top**.

If the codomain of a continuous function is $\mathbb{R}$ or $\mathbb{C}$, continuous functions can be added and multiplied:

Proposition C.1.7: Arithmetics of Continuous Functions

Let X be a topological space, let A be $\mathbb{R}$ or $\mathbb{C}$ with the Euclidean topology, and let $f : X \to A$ and $g : X \to A$ be continuous functions. Then $f + g$, fg and cf for $c \in A$ are continuous functions.

***Proof*:**
Write $|\cdot|$ for the absolute value on A, so that the Euclidean topology has the balls $B_r(a) = \{b \in A \mid |b - a| < r\}$ as a basis. A set $U \subseteq A$ is open exactly when every $u \in U$ has some $B_\epsilon(u) \subseteq U$. A union of balls has this property, since for $u \in B_r(a)$ the triangle inequality gives $B_{r-|u-a|}(u) \subseteq B_r(a)$, and conversely a set with this property is the union of the balls it contains.

Let h be one of $f + g$, fg and cf, let $U \subseteq A$ be open, and let $x_0 \in h^{-1}(U)$. Choose $\epsilon > 0$ with $B_\epsilon(h(x_0)) \subseteq U$, and put $a_0 = f(x_0)$ and $b_0 = g(x_0)$. It suffices to find an open set V containing x_0 with $h(V) \subseteq B_\epsilon(h(x_0))$, since then $h^{-1}(U)$ is a union of open sets.

Sum. Take $V = f^{-1}\big(B_{\epsilon/2}(a_0)\big) \cap g^{-1}\big(B_{\epsilon/2}(b_0)\big)$, which is open because f and g are continuous. For $x \in V$,

$$|f(x) + g(x) - a_0 - b_0| \le |f(x) - a_0| + |g(x) - b_0| < \epsilon$$

Product. Put $\delta = \min\big(1, \epsilon/(2|b_0| + 2), \epsilon/(2|a_0| + 2)\big)$ and $V = f^{-1}\big(B_\delta(a_0)\big) \cap g^{-1}\big(B_\delta(b_0)\big)$. For $x \in V$ write $a = f(x)$ and $b = g(x)$. Then $|b| < |b_0| + \delta \le |b_0| + 1$, so

$$|ab - a_0b_0| \le |a - a_0||b| + |a_0||b - b_0| < \delta(|b_0| + 1) + |a_0|\delta \le \epsilon$$

Scalar multiple. If $c = 0$, then cf is constant, and every preimage under it is $\emptyset$ or X. If $c \neq 0$, take $V = f^{-1}\big(B_{\epsilon/|c|}(a_0)\big)$, so that $|cf(x) - ca_0| = |c||f(x) - a_0| < \epsilon$ for $x \in V$.

Given an arbitrary set $U \subseteq X$, we may consider the set of all closed subsets containing U. Since the arbitrary intersection of closed sets is closed (proposition C.1.2), there is a notion of smallest closed subsets *containing* U. Similarly, we may consider all open subsets *contained* in U, and take their union, giving the dual

Definition C.1.8: Closure And Interior

Let $U \subseteq X$ be an arbitrary set. Then

1. The *closure* of U, denoted $\overline{U}$ is the intersection of all closed sets containing U
2. The *interior* of U, denoted $\text{int}(U)$, is the union of all open sets contained in U.

Given a topological space, injective and surjective maps give rise to natural spaces, and the product of sets has a natural topology:

Definition C.1.9: Subspace, Quotient Space, and Product Space

Let X be a topological space. Then

1. the subset $Y \subseteq X$ is a *subsapce* of X if it is endowed with the topology given by the sets $\{U \cap Y \mid U \subseteq X \text{ open}\}$
2. a set of equivalence space $Y = X/\sim$ is a *quotient topology* if it is endowed with the topology where $U \subseteq Y$ is open if and only if $\pi^{-1}(U) \subseteq X$ is open (where $\pi : X \to Y$ is the natural projection)
3. Given a collection of topological spaces $\{X_i\}_{i\in I}$ for an indexing set I, the product topology is the topology endowed on products of the sets $Y = \prod_{i\in I} X_i$ where $\pi_i^{-1}(U)$ forms a sub-basis for Y.

Proposition C.1.10: Universal Properties Of Subspaces, Quotients And Products

Let Z be a topological space.

1. If $Y \subseteq X$ carries the subspace topology and $\iota : Y \to X$ is the inclusion, then a function $f : Z \to Y$ is continuous if and only if $\iota \circ f$ is continuous.
2. If $X/\sim$ carries the quotient topology and $\pi : X \to X/\sim$ is the projection, then a function $g : X/\sim \to Z$ is continuous if and only if $g \circ \pi$ is continuous.
3. If $\prod_{i\in I} X_i$ carries the product topology and π_i are the projections, then a function $f : Z \to \prod_{i\in I} X_i$ is continuous if and only if every $\pi_i \circ f$ is continuous.

***Proof*:**
A composite of continuous maps is continuous, since $(k \circ h)^{-1}(W) = h^{-1}(k^{-1}(W))$. The maps ι, π and π_i are continuous: $\iota^{-1}(U) = U \cap Y$ is open in Y, $\pi^{-1}(W)$ is open for W open in $X/\sim$ by the definition of the quotient topology, and $\pi_i^{-1}(U)$ is one of the subbasic open sets of the product. This gives the forward implication in each part.

1. Suppose $\iota \circ f$ is continuous. An open subset of Y has the form $U \cap Y$ with U open in X, and $f^{-1}(U \cap Y) = (\iota \circ f)^{-1}(U)$ is open in Z.
2. Suppose $g \circ \pi$ is continuous, and let $W \subseteq Z$ be open. Then $\pi^{-1}\big(g^{-1}(W)\big) = (g \circ \pi)^{-1}(W)$ is open in X, which by the definition of the quotient topology says that $g^{-1}(W)$ is open in $X/\sim$.
3. Suppose every $\pi_i \circ f$ is continuous. Then $f^{-1}\big(\pi_i^{-1}(U)\big) = (\pi_i \circ f)^{-1}(U)$ is open for every subbasic open set $\pi_i^{-1}(U)$. By definition C.1.3, every open set of the product is a union of finite intersections of subbasic open sets, and f^{-1} preserves unions and intersections, so the preimage of every open set is open.

Part (2) is dual to part (1): it tests continuity of maps out of a quotient by composing with the projection, where part (1) tests continuity of maps into a subspace by composing with the inclusion.

Recall that a topological space has varying notion of separation defined on it. The most prominent of which is the Hausdorff axiom (also known as T_2):

Definition C.1.11: Hausdorff space (T_2)

Let X be a topological space, and let $x, y \in X$ be arbitrary different points. Then X is called *Hausdorff* if there always exists open sets U, V such that $x \in U$, $y \in V$, and $U \cap V = \emptyset$.

There are two weaker conditions that do show up in this book:

1. Fréchet (T_1) means that for each $x, y \in X$, there exists open neigbhorhoods U, V such that $x \in U$, $y \in V$, but $y \notin U$ and $x \notin V$. Note that U and V need not be disjoint. Key feature of T_1 is that all singletons are closed.
2. Even weaker is Kolmogorov (T_0) (Zariski topologies are T_0 but not T_1)

Proposition C.1.12: Hausdorff And Diagonals

Let X be a topological space. Then X is Hausdorff if and only if the diagonal $\Delta = \{(x, x) \mid x \in X\} \subseteq X \times X$ is closed in the product topology.

***Proof*:**

First record the shape of the basic open sets of $X \times X$. By definition C.1.9 the sets $\pi_1^{-1}(U) = U \times X$ and $\pi_2^{-1}(V) = X \times V$, for U and V open in X, form a subbasis, so by definition C.1.3 the finite intersections of such sets form a basis. A finite intersection of them is $U \times V$ with U the intersection of the first-coordinate factors and V the intersection of the second-coordinate factors, both open by definition C.1.1. So a subset of $X \times X$ is open exactly when it is a union of sets $U \times V$ with U, V open in X.

Suppose X is Hausdorff and let $(x, y) \in (X \times X) \setminus \Delta$, so that $x \neq y$. By definition C.1.11 there are open sets $U \ni x$ and $V \ni y$ with $U \cap V = \emptyset$. The basic open set $U \times V$ contains (x, y) and misses Δ, because a point $(z, z) \in U \times V$ would put z in $U \cap V$. Every point of $(X \times X) \setminus \Delta$ therefore has a basic open neighborhood inside that set, so $(X \times X) \setminus \Delta$ is a union of basic open sets and is open. Hence Δ is closed.

Conversely, suppose Δ is closed and let $x \neq y$ in X. Then (x, y) lies in the open set $(X \times X) \setminus \Delta$,

so by the first paragraph there are open $U, V \subseteq X$ with $(x, y) \in U \times V \subseteq (X \times X) \setminus \Delta$. Thus $x \in U$ and $y \in V$, and $U \cap V = \emptyset$, because a point $z \in U \cap V$ would put (z, z) into $U \times V$ and into Δ at once. These are the open sets required by definition C.1.11, so X is Hausdorff.

A final tool that is very common in topology is that of the *sequences*[1]

Definition C.1.13: Sequence

Let X be any set. Then a *sequence*, is a function $f : \mathbb{N} \to X$. Usually, the element $f(n)$ is labeled as x_n for some dummy variable x, and the function f is represented as $(x_n)_{n=1}^{\infty}$ or simply (x_n) for short.

Sequences become interesting once they are in a topological space, and there is a notion of them "approaching" a point. In a metric space, we can define this notion using epsilon-balls. However, there is a more general notion of convergence for topological spaces that are non-metrizable

Definition C.1.14: Convergent Sequence

Let X be a topological space, (x_n) a sequence in X, and $x \in X$ an element of X. Then (x_n) is said to *converge to* x if for every neigbhorhoods U of x, there exists a natural number $S(U) \in \mathbb{N}$ such that

$$x_n \in U \qquad \forall n \geq S(U)$$

Proposition C.1.15: Convergent Sequence In Hausdroff Spaces

Let X be a *Hausdorff* topological space and (x_n) a convergent sequence in X. Then (x_n) converges to *at most* one point. The resulting point is called the *limit point*.

***Proof*:**
Suppose (x_n) converges to x and to y with $x \neq y$. By definition C.1.11 there are open sets $U \ni x$ and $V \ni y$ with $U \cap V = \emptyset$. Applying definition C.1.14 to the neighborhood U of x produces $S(U) \in \mathbb{N}$ with $x_n \in U$ for all $n \geq S(U)$, and applying it to the neighborhood V of y produces $S(V) \in \mathbb{N}$ with $x_n \in V$ for all $n \geq S(V)$. Take $m = \max(S(U), S(V))$. Then x_m lies in U and in V, so $U \cap V \neq \emptyset$, contradicting the choice of U and V. Hence no two distinct points can both be limits of (x_n).

The hypothesis is not removable. If X carries the trivial topology $\{\emptyset, X\}$ of the discussion after definition C.1.3 and $|X| > 1$, the only neighborhood of any point is X itself, so every sequence converges to every point of X.

For most cases that are considered in algebra and analysis, every point $x \in X$ has a "countable neighborhood basis", which essentially translates to every open set is "locally" a countable union of open sets. This property is called *first-countable*. It is not important for this book, but it is important to be able to state the following result:

[1] More generally, ultra-filters or nets may be more appropriate for the topological setting, however they are not necessary for this review of topology

Proposition C.1.16: Closed Sets In Hausdroff Spaces w.r.t. Sequences

Let $U \subseteq X$ be any subset of a first-countable Hausdorff topological space X, and let $\lim U$ denote the collection of all limit points of all convergent sequences $(x_n) \subseteq U$. Then

$$\overline{U} = \lim U$$

***Proof*:**

The inclusion $\lim U \subseteq \overline{U}$ uses neither hypothesis. Let $x \in \lim U$, witnessed by a sequence $(x_n) \subseteq U$ converging to x, and suppose $x \notin \overline{U}$. By definition C.1.8 the set $\overline{U}$ is an intersection of closed sets, hence closed by proposition C.1.2, so $X \setminus \overline{U}$ is an open set containing x and disjoint from U. By definition C.1.14 there is $S \in \mathbb{N}$ with $x_n \in X \setminus \overline{U}$ for all $n \geq S$, contradicting $x_S \in U$. Hence $x \in \overline{U}$.

For $\overline{U} \subseteq \lim U$, let $x \in \overline{U}$ and let $\{B_n\}_{n\in\mathbb{N}}$ be a countable neighborhood basis at x, which exists because X is first-countable. Put $V_n = B_1 \cap \cdots \cap B_n$, an open set containing x by definition C.1.1, and note $V_1 \supseteq V_2 \supseteq \cdots$ and that every open $W \ni x$ contains some B_n and hence some V_n. Each V_n meets U: otherwise $X \setminus V_n$ would be a closed set containing U, forcing $\overline{U} \subseteq X \setminus V_n$ and contradicting $x \in \overline{U} \cap V_n$. Using axiom A.1.2 on the family $\{V_n \cap U\}_{n\in\mathbb{N}}$ of non-empty sets, choose $x_n \in V_n \cap U$ for every n. Given an open $W \ni x$, pick n_0 with $V_{n_0} \subseteq W$. For $n \geq n_0$ the containments $x_n \in V_n \subseteq V_{n_0} \subseteq W$ hold, so (x_n) converges to x in the sense of definition C.1.14. As $(x_n) \subseteq U$, this gives $x \in \lim U$.

Neither inclusion used the Hausdorff hypothesis. It is carried in the statement only so that proposition C.1.15 applies and each of the sequences above has a single limit point, which is what makes the phrase "the limit point" legitimate.

Most spaces covered in a topological class, and all topological spaces covered in this book, have this property and hence closedness can be characterized with sequences. If $\overline{U} = X$ (i.e. the closure gives the entire space), then we give such a set a name

Definition C.1.17: Dense Set

Let X be a topological space. Then if $U \subseteq X$ is a subset of X such that $\overline{U} = X$, then U is called a *dense set*.

These are very important in real and functional anslysis, and they show up in the discussion of completion in chapter 25.

If X is a metric space, we can define the notion of a cauchy sequence:

Definition C.1.18: Cauchy Sequence

Let X be a metric space with metric d. Then (x_n) is a *cauchy sequence* if for every $\epsilon > 0$, there exists an $N \in \mathbb{N}$ such that for all $n, m > N$,

$$d(x_n, x_m) < \epsilon$$

Given any metric space, we can "complete" it by adding all of the cauchy sequence that do not converge in the following way: for any two cauchy sequences, they are called *equivalent* if $d(x_n, y_n) \to 0$. Then

the collection of equivalence classes of cauchy sequences is called the *completion of the metric space*. It carries the metric $\lim_n d(x_n, y_n)$, contains X as the classes of constant sequences, and is complete in the sense of the following definition ([24, Existence of the Completion]):

Definition C.1.19: Complete Metric Space

Let X be a metric space. Then X is compelte if all cauchy sequences are convergent sequences

Example C.1.20: Complete Spaces
$\mathbb{R}$ is a complete space, while $\mathbb{Q}$ is not

The notion of completeness given in chapter 25 is in fact a generalization of the above notion, as appendix C.5 below shows.

For comparison to other definitions of dimension presented, the following can be considered one of the "most broad" definitions:

Definition C.1.21: Topological Dimension

Let X be a topological space. The *order* of an open cover $\{U_i\}$ of X is the smallest number n for which each point $x \in X$ belongs to at most n open sets in the open cover. A *refinement* of an open cover $\{U_i\}$ is an open cover $\{V_j\}$ such that each $V_j \subseteq U_i$ for some i. The *Topological dimension* or *Lebesgue Covering Dimension* is the minimum number n such that every finite open cover has a refinement of order $n + 1$.

C.2 Construction Topologies

The subspace, product, and quotient topology are all special examples of the following two constructions:

Definition C.2.1: Weak [initial] Topology

Let X be a set and let $F = \{f_\alpha : X \to Y_\alpha\}_{\alpha \in A}$ be a collection of maps from X to topological spaces Y_α. Then the coarsest topology on X which makes each f_α continuous is called the *weak topology* generated by F.

Note that it is not interesting to ask what is the finnest topology on X that makes all the maps continuous: it is the discrete topology on X.

Proposition C.2.2: Existence Of The Weak Topology

In the setting of definition C.2.1, let $\mathcal{T}_F$ be the collection of all unions of finite intersections of sets $f_\alpha^{-1}(U)$ with $\alpha \in A$ and $U \subseteq Y_\alpha$ open, the empty intersection being X. Then $\mathcal{T}_F$ is a topology on X for which every f_α is continuous, and $\mathcal{T}_F \subseteq \mathcal{T}'$ for every topology $\mathcal{T}'$ on X for which every f_α is continuous. So $\mathcal{T}_F$ is the weak topology, and the finite intersections of the sets $f_\alpha^{-1}(U)$ form a basis for it.

***Proof*:**
The empty union gives $\emptyset \in \mathcal{T}_F$, and the empty intersection gives $X \in \mathcal{T}_F$. A union of unions of finite intersections is again one. For two members $\bigcup_j B_j$ and $\bigcup_k C_k$ of $\mathcal{T}_F$, with every B_j and C_k a finite intersection,

$$\left(\bigcup_j B_j\right) \cap \left(\bigcup_k C_k\right) = \bigcup_{j,k} B_j \cap C_k$$

and each $B_j \cap C_k$ is again a finite intersection, so by induction $\mathcal{T}_F$ is closed under finite intersections. Hence $\mathcal{T}_F$ is a topology by definition C.1.1. It contains every $f_\alpha^{-1}(U)$, which is the continuity of every f_α. If $\mathcal{T}'$ makes every f_α continuous, then $\mathcal{T}'$ contains every $f_\alpha^{-1}(U)$, and being closed under finite intersections and arbitrary unions it contains $\mathcal{T}_F$. So $\mathcal{T}_F$ is a coarsest such topology, and it is the only one, since another coarsest topology would both contain $\mathcal{T}_F$ and be contained in it. Finally, the finite intersections of the sets $f_\alpha^{-1}(U)$ satisfy both conditions of definition C.1.3, since they cover X and are closed under finite intersections, and $\mathcal{T}_F$ consists of their unions.

Example C.2.3: Weak Topology

1. Let $\{X_\alpha\}_{\alpha \in A}$ be some collection of topologies and $X = \prod_{\alpha \in A} X_\alpha$. Let $\Pi = \{\pi_\alpha : X \to X_\alpha\}$ be the collection of functions. Then the weak topology on X generated by Π is *precisely* the product topology of definition C.1.9: by definition C.1.3 and proposition C.2.2, both consist of the unions of finite intersections of the sets $\pi_\alpha^{-1}(U)$.
2. Let X be any topological space and $A \subseteq X$ any subset. Let $\iota : A \to X$ be the inclusion map. Then the weak topology on A generated by ι is the *subspace* topology.

One of the great advantages of of defining weak topologies is that we can make the collection of f_α and spaces X_α anything we want. This flexibility will the definition's of many interesting topologies on funcitonal spaces (ex. collection of smooth functions on compact spaces, collection of bounded continuous functions, or simply collection of bounded functions, and so forth). All such spaces are of key importance in funtional analysis. Weak topologies are also a special case of a much more general construction, which we'll explore at the end of this chapter.

Finally, there is also the dual of weak topologies where we take maps that map *into* X.

Definition C.2.4: Final Topologies

Let Y be a set, $\{X_\alpha\}_{\alpha \in A}$ be a collection of topological spaces, and $F = \{f_\alpha : X_\alpha \to Y\}$ be a collection of maps into Y. Then the finest topology on Y that makes each f_α continuous is called the *final topology*. In particular, $U \subseteq Y$ is open if and only if $f_\alpha^{-1}(U)$ is open in X_α for each $\alpha \in A$

The sets U described in definition C.2.4 do form the finest such topology. Preimages commute with unions and intersections, $f_\alpha^{-1}\left(\bigcup_i U_i\right) = \bigcup_i f_\alpha^{-1}(U_i)$ and $f_\alpha^{-1}(U \cap V) = f_\alpha^{-1}(U) \cap f_\alpha^{-1}(V)$, and $f_\alpha^{-1}(\emptyset) = \emptyset$ and $f_\alpha^{-1}(Y) = X_\alpha$, so these sets form a topology by definition C.1.1. Every f_α is continuous for it by construction, and in any topology on Y for which every f_α is continuous each open set is one of these sets, so that topology is contained in this one. While the weak (or initial) topology seeks for a domain with the coarsest topology, final topologies seek a codomain with the finnest topology. This is because the coarsest topology on the co-domain will always create continuous

maps. Unlike the initial topology, the final topology is not given the name "strong" to contrast the name "weak" for initial topologies. There is in fact a topology known as the strong topolgoy on a space X: If $\|\cdot\|$ is a norm on a real or complex vector space X[2], the strong topology on X is the topology generated by all the balls $B_r(x)$ for all $x \in X$ and $r > 0$. The contrast between strong and weak topologies will make more sense when studying functional analysis, where useful topologies on vector spaces are often defined by families of seminorms and not by a single norm [51, Section 5.4].

Example C.2.5: Final Topologies

Let X be a topological space, $\sim$ an equivalence relation on X, and $\pi : X \to X/\sim$ the projection map. Then the final topology on $X/\sim$ generated by π is the *quotient topology* of definition C.1.9, since both declare U open exactly when $\pi^{-1}(U)$ is open.

Both the initial and final topologies can be generalized even further. If you have read Part XII, the initial and final topologies are the topologies that limits and colimits in **Top** carry on the corresponding limits and colimits of sets. These two also go by the name of *projective limit* and *injective limit*.

C.3 Compactness and Connectedness

Definition C.3.1: Compact Space

Let X be a topological space. If $\{U_i\}_{i\in I}$ is a collection of open sets such that $\bigcup_{i\in I} U_I = X$, then $\{U_i\}_{i\in I}$ is called an *open cover*. An *open subcover*, or *subcover* for short, is a subst of an open cover. If any open cover of X adminits a finite subcover, then X is *compact*.

Proposition C.3.2: Closed Subset Of Compact Spaces

Let $U \subseteq X$ be a closed subset of a compact space X. Then U is compact as a subspace.

***Proof*:**

Let $\{V_i\}_{i\in I}$ be an open cover of U in the subspace topology. By definition C.1.9 each V_i has the form $V_i = W_i \cap U$ for some W_i open in X. The set $X \setminus U$ is open, since U is closed, and

$$X = U \cup (X \setminus U) \subseteq \left(\bigcup_{i\in I} W_i\right) \cup (X \setminus U)$$

because every point of U lies in some $V_i \subseteq W_i$. So $\{W_i\}_{i\in I} \cup \{X \setminus U\}$ is an open cover of X. By definition C.3.1 it has a finite subcover, and enlarging that subcover by $X \setminus U$ if needed, there are indices $i_1, \ldots, i_k \in I$ with $X = W_{i_1} \cup \cdots \cup W_{i_k} \cup (X \setminus U)$. Intersecting with U and using $(X \setminus U) \cap U = \emptyset$ gives

$$U = (W_{i_1} \cap U) \cup \cdots \cup (W_{i_k} \cap U) = V_{i_1} \cup \cdots \cup V_{i_k}$$

so $\{V_i\}_{i\in I}$ admits a finite subcover. As the cover was arbitrary, U is compact.

[2] See [31, Norm and Induced Norm].

Definition C.3.3: Connected Space

Let X be a topological space. Then if there exists no non-trivial proper clopen subsets, X is connected. Equivalently, X is connected if there does not exist two disjoint non-empty open sets $U_1, U_2 \subseteq X$ such that $X = U_1 \cup U_2$.

C.4 Topological Groups

In this book, topological groups show up in the completion of rings (chapter 25) and in the representations of locally compact abelian groups (section 53.4.1). The topological considerations in both of those cases were purposefully scarce to not have any topological requirements for learning those materials. However, having a topological perspective brings out a deeper perspective, and so they are further explored in this section.

Definition C.4.1: Topological Group

Let G be a topological space. Then if there exists a binary operation $\cdot : G \times G \to G$ satisfying the axioms of a group that is also *continuous* (where $G \times G$ has the product topology), and a $(_)^{-1} : G \to G$ mapping $g \mapsto g^{-1}$ that is *continuous*, then G is a *topological group*

Though we have defined topological groups, the same definition can be done for any other algebraic object we've worked with, notably *topological rings*, *topological R-modules*, and *topological R-algebras*. A topological group is the same thing as a *group object* in the category **Top** (example 67.4.4).

Example C.4.2: Topological Group

1. For any group G, if G is equipped with the discrete topology it is a topological group, and all homomorphisms are continuous between any other topological group. In this way, the theory of topological groups can be thought as subsuming group theory. Any group with the indiscrete topology (also known as trivial topology) is also a topological group.
2. If $H \leqslant G$ is also a topological space, then H is a topological group with the subspace topology.
3. The real numbers $\mathbb{R}$ under addition and $\mathbb{R}^\times$ under multiplication are topological groups. Addition and multiplication are continuous by proposition C.1.7, applied to the coordinate projections, which are continuous for the product topology, and proposition C.1.10 restricts the multiplication to the subspace $\mathbb{R}^\times$. Negation $t \mapsto (-1)t$ is a scalar multiple of the identity. Inversion $t \mapsto 1/t$ is continuous on $\mathbb{R}^\times$: for $t_0 \neq 0$ and $\epsilon > 0$, every t with $|t - t_0| < \min(|t_0|/2, \epsilon t_0^2/2)$ satisfies $|t| > |t_0|/2$ and $|1/t - 1/t_0| = |t - t_0|/(|t||t_0|) < \epsilon$. More generally, $\mathbb{R}^n$ is a topological group, or any *topological vector-space* (a vector-space where the action is continuous as well) is a topological group
4. The circle $S^1 = U(1) = \{x \in \mathbb{C} \mid |x| = 1\}$, a subgroup of $\mathbb{C}^\times$ with the subspace topology, and the n-torus $(S^1)^n$ are topological groups.
5. The general linear group over the reals $\mathrm{GL}_n(\mathbb{R})$ is a topological group. Similarly, the special linear group,$\mathrm{SL}_n(\mathbb{R}) = \{A \in \mathrm{GL}_n \mid \det(A) = 1\}$, is a topological group.

6. Take $O(n) \subseteq \mathrm{GL}(n)$, where $O(n) = \{A \in \mathrm{GL}_n(\mathbb{R}) \mid AA^t = I\}$. This is a topological group known as the *orthogonal group*, since it consists of all orthonormal basis of $\mathbb{R}^n$. Similarly, we can define $U(n) = \left\{A \in \mathrm{GL}_n(\mathbb{C}) \;\middle|\; A\overline{A}^t = I\right\}$ is a topological group known as the *unitary group*. Similarly to $\mathrm{SL}_n(\mathbb{R})$, we have:

$$\mathrm{SO}(n) = \mathrm{SL}_n(\mathbb{R}) \cap O(n) \qquad \mathrm{SU}(n) = \mathrm{SL}_n(\mathbb{C}) \cap U(n)$$

   Note that all these groups are *compact*.

7. (If you know some Differential Geometry) Any Lie group is naturally a topological group. An example of a topological group that is not a Lie group is $\mathbb{Q}$ with the subspace topology induced by $\mathbb{R}$.

8. If you have covered the completion chapter of *Commutative Algebra* [20], then the p-adic integers, $\mathbb{Z}_p$ has the induced inverse-limit topology (in this case, the p-adic topology). This group is compact, homeomorphic to the Cantor set, and totally disconnected without being discrete (hence cannot be a Lie Group, since a Lie group is locally connected and a totally disconnected one is therefore discrete)

9. Similarly to $\mathbb{Z}_p$, giving $\mathbb{Q}$ a different p-adic metric, we can take a different completion to form $\mathbb{Q}_p$, which is not a Lie group either, for the same reason.

Proposition C.4.3: Topological Criterion

Let G be a group and a topological space. Then G is a topological group if and only if the map $q : G \times G \to G$, $(x, y) \mapsto xy^{-1}$, is continuous

***Proof*:**
Two remarks are used in both directions. As in the proof of proposition C.1.12, the sets $U \times V$ with U, V open in G form a basis for $G \times G$, so a map into $G \times G$ is continuous as soon as the preimage of every such $U \times V$ is open, preimages commuting with the unions that build the remaining open sets. Also, a composite $g \circ f$ of continuous maps is continuous, since $(g \circ f)^{-1}(W) = f^{-1}(g^{-1}(W))$ for every W.

Suppose G is a topological group, and write $m(x, y) = xy$ and $\iota(x) = x^{-1}$ for the two maps that definition C.4.1 requires to be continuous. Let $\sigma : G \times G \to G \times G$ be $\sigma(x, y) = (x, y^{-1})$. For U, V open,

$$\sigma^{-1}(U \times V) = \left\{(x, y) \;\middle|\; x \in U,\ y^{-1} \in V\right\} = U \times \iota^{-1}(V)$$

which is open because ι is continuous. So σ is continuous, and $q = m \circ \sigma$ is continuous.

Conversely, suppose q is continuous. Let $j : G \to G \times G$ be $j(x) = (e, x)$, where e is the identity. For U, V open, $j^{-1}(U \times V)$ equals V when $e \in U$ and equals $\emptyset$ otherwise, and both are open, so j is continuous. Since $q(j(x)) = ex^{-1} = x^{-1}$, inversion $\iota = q \circ j$ is continuous. Now $\sigma(x, y) = (x, \iota(y))$ is continuous by the computation of the previous paragraph, which used only the continuity of ι, and

$$q(\sigma(x, y)) = q(x, y^{-1}) = x(y^{-1})^{-1} = xy$$

so $m = q \circ \sigma$ is continuous. Both maps required by definition C.4.1 are continuous, and G is a topological group.

Definition C.4.4: Topological Homomorphism/Isomorphism

Let $f : G \to H$ be a function between topological groups. Then if f is a continuous homomorphism (resp. a homeomorphic isomorphism) then f is called a *topological homomorphism* (resp. *topological isomorphism*)

Example C.4.5: Topological Isomorphism

Naturally, the identity map is a topological isomorphism. If the topology is discrete, every homomorphism/isomorphism is a topological homomorphism/isomorphism.

It is possible that a homomorphism/continuous map is not a continuous map/homomorphism. As an example of a continuous, even homeomorphic map, that is not a homomorphism is the following: let $g \in G$ with $g \neq 1$ and $\varphi_g : G \to G$ be the map sending $x \mapsto gx$. It is not a homomorphism, since $\varphi_g(1) = g$. It is a homeomorphism: it is the composite of the map $x \mapsto (g, x)$, which is continuous because the preimage of a basic open set $U \times V$ of $G \times G$ is V when $g \in U$ and $\emptyset$ otherwise, with the continuous multiplication, and its inverse $\varphi_{g^{-1}}$ is continuous for the same reason. This example is particularly interesting since it shows that every $g \in G$ induces a homeomorphism! A space Y is called a *homogeneous space* if for any two points $y, y' \in Y$ some homeomorphism of Y sends y to y', and G is one, since $\varphi_{yx^{-1}}$ sends x to y. As a consequence of this, if U is a neighborhood of 1, then gU is a neighborhood of g, meaning that the topology of G is determined by the neighborhoods of 1!

Let $H \leqslant G$, and give the set G/H of left cosets the quotient topology of definition C.1.9 for the projection $\pi : G \to G/H$, $\pi(x) = xH$.

Proposition C.4.6: Quotients Of Topological Groups

Let G be a topological group, let $H \leqslant G$, and let $\pi : G \to G/H$ be the projection, with G/H carrying the quotient topology.

1. The projection π is open: $\pi(U)$ is open for every open $U \subseteq G$.
2. For each $g \in G$, the map $\bar{\varphi}_g : G/H \to G/H$, $xH \mapsto gxH$, is a homeomorphism, and $\bar{\varphi}_{yx^{-1}}$ sends xH to yH. In particular, G/H is a homogeneous space.
3. If $H \trianglelefteq G$, then the quotient group G/H, with the quotient topology, is a topological group.

***Proof*:**

By example C.4.5, every left translation is a homeomorphism of G, and the same argument, with $x \mapsto (x, g)$ in place of $x \mapsto (g, x)$, shows that every right translation $\rho_g(x) = xg$ is one.

1. Let $U \subseteq G$ be open. An element x lies in $\pi^{-1}(\pi(U))$ exactly when $xH = uH$ for some $u \in U$, that is, when $x \in UH$. So $\pi^{-1}(\pi(U)) = UH = \bigcup_{h \in H} \rho_h(U)$ is open, and $\pi(U)$ is open by the definition of the quotient topology.
2. The map $\bar{\varphi}_g$ is well defined, since $xH = x'H$ gives $gxH = gx'H$, and $\bar{\varphi}_g \circ \pi = \pi \circ \varphi_g$. For $W \subseteq G/H$ open, $\pi^{-1}\big(\bar{\varphi}_g^{-1}(W)\big) = \varphi_g^{-1}\big(\pi^{-1}(W)\big)$ is open, so $\bar{\varphi}_g^{-1}(W)$ is open and $\bar{\varphi}_g$ is continuous. Its inverse $\bar{\varphi}_{g^{-1}}$ is continuous for the same reason, so $\bar{\varphi}_g$ is a homeomorphism,

and $\bar{\varphi}_{yx^{-1}}(xH) = yH$.

3. The map $\bar{q}(xH, yH) = xy^{-1}H$ is well defined. If $x'H = xH$ and $y'H = yH$, write $x' = xh_1$ and $y' = yh_2$ with $h_1, h_2 \in H$. Then $x'y'^{-1} = xy^{-1}\big(yh_1h_2^{-1}y^{-1}\big)$, and $yh_1h_2^{-1}y^{-1} \in H$ because H is normal, so $x'y'^{-1}H = xy^{-1}H$. By proposition C.4.3, it suffices to show that $\bar{q}$ is continuous on $G/H \times G/H$. Let $W \subseteq G/H$ be open and let $\bar{q}(xH, yH) \in W$. The map $\pi \circ q$, where $q(x, y) = xy^{-1}$, is continuous by proposition C.4.3, so $(\pi \circ q)^{-1}(W)$ is an open subset of $G \times G$ containing (x, y), and it contains a basic open set $U \times V$ with $x \in U$ and $y \in V$. By part (1), $\pi(U)$ and $\pi(V)$ are open, so $\pi(U) \times \pi(V)$ is open in the product topology, and it contains (xH, yH). For $u \in U$ and $v \in V$, $\bar{q}(uH, vH) = \pi(q(u, v)) \in W$. So $\bar{q}^{-1}(W)$ contains an open neighborhood of each of its points, and it is open.

The first isomorphism theorem does not carry over to topological groups as it stands: for a continuous homomorphism f, the groups $G/\ker(f)$ and $f(G)$ need not be isomorphic as topological groups.

Example C.4.7: A Continuous Bijective Homomorphism That Is Not An Isomorphism
Let G be $\mathbb{R}$ with the discrete topology and K be $\mathbb{R}$ with the Euclidean topology, both topological groups under addition by example C.4.2. The identity map $f : G \to K$ is a continuous bijective homomorphism, since every subset of G is open. Its kernel is trivial, and $G/\ker(f)$ carries the discrete topology, since its projection from G is a bijection and every subset of G is open. So $G/\ker(f)$ is not isomorphic to $f(G) = K$ as a topological group: a homeomorphism would carry the open one-point set $\{0\}$ to a one-point open subset of K, while every non-empty open subset of K contains a ball $B_r(a)$ with $r > 0$, which is infinite.

Some authors make being Hausdorff (or at least T_1) part of the definition of the group. This limitation is not imposed in this definition, since in algebraic geometry, there will be non-Hausdorff spaces (ex. the a-adic topology on certain topological rings are non-Hausdorff). For Topological groups, there is a way to always find a quotient topology that is Hausdorff:

Proposition C.4.8

Let G be a topological group, $e \in G$ the identity, and $H = \bigcap_{\substack{U \subseteq G \text{ open} \\ e \in U}} U$. Then:

1. H is a normal subgroup
2. H is the closure of $\{e\}$, i.e. $\overline{\{e\}} = H$
3. G/H is Hausdorff
4. G is Hausdorff if and only if $H = \{e\}$

***Proof*:**
Write $\mathcal{U}$ for the collection of open subsets of G containing e, so that $H = \bigcap_{U \in \mathcal{U}} U$. Two preliminary facts get used throughout.

Translations are homeomorphisms. Fix $a \in G$ and let $\lambda_a(x) = ax$. The map $x \mapsto (a, x)$ is continuous, since the preimage of a basic open set $U \times V$ of $G \times G$ is V when $a \in U$ and is $\emptyset$ otherwise. Composing with the multiplication of definition C.4.1 shows λ_a is continuous, and $\lambda_{a^{-1}}$ is a two-sided inverse for it that is continuous for the same reason, so λ_a is a homeomorphism.

The same argument applies to right translation $\rho_a(x) = xa$.

Small sets around e. Given $U \in \mathcal{U}$, the map $q(x, y) = xy^{-1}$ of proposition C.4.3 is continuous and satisfies $q(e, e) = e \in U$, so $q^{-1}(U)$ is an open set containing (e, e) and therefore contains a basic open $W_1 \times W_2$ with $e \in W_1$ and $e \in W_2$. Setting $W = W_1 \cap W_2 \in \mathcal{U}$ gives $WW^{-1} \subseteq U$.

(1) Let $a, b \in H$ and let $U \in \mathcal{U}$. Choose $W \in \mathcal{U}$ with $WW^{-1} \subseteq U$. Then $a, b \in H \subseteq W$, so $ab^{-1} \in WW^{-1} \subseteq U$. Since $U \in \mathcal{U}$ was arbitrary, $ab^{-1} \in H$, and $e \in H$ because e lies in every member of $\mathcal{U}$. So H is a subgroup. For normality, fix $g \in G$ and let $c_g = \lambda_g \circ \rho_{g^{-1}}$, a homeomorphism of G with $c_g(e) = e$. Then $U \mapsto c_g(U)$ is a bijection of $\mathcal{U}$ onto itself, and a bijection of G carries intersections to intersections, so

$$gHg^{-1} = c_g\Big(\bigcap_{U \in \mathcal{U}} U\Big) = \bigcap_{U \in \mathcal{U}} c_g(U) = \bigcap_{V \in \mathcal{U}} V = H$$

(2) By definition C.1.8 together with proposition C.1.2, a point a lies in $\overline{\{e\}}$ if and only if every open set containing a contains e. For if some open $V \ni a$ omits e, then $G \setminus V$ is a closed set containing e, so $\overline{\{e\}} \subseteq G \setminus V$ and $a \notin \overline{\{e\}}$, and if $a \notin \overline{\{e\}}$, then $V = G \setminus \overline{\{e\}}$ is an open set containing a and omitting e. Now take $a \in H$ and V open with $a \in V$. The set $a^{-1}V = \lambda_{a^{-1}}(V)$ is open and contains e, so $H \subseteq a^{-1}V$. Part (1) gives $a^{-1} \in H$, so $a^{-1} = a^{-1}v$ for some $v \in V$, forcing $v = e$ and $e \in V$. Hence $H \subseteq \overline{\{e\}}$. Conversely take $a \in \overline{\{e\}}$ and $U \in \mathcal{U}$. The set $aU^{-1} = \{au^{-1} \mid u \in U\}$ is the image of the open set U^{-1} under λ_a, hence open, and it contains $ae^{-1} = a$. So $e \in aU^{-1}$, which says $e = au^{-1}$ for some $u \in U$, that is $a = u \in U$. Hence $a \in H$.

(3) First, $HU = U$ for *every* open $U \subseteq G$. Given $u \in U$, the set $Uu^{-1} = \rho_{u^{-1}}(U)$ is open and contains e, so $H \subseteq Uu^{-1}$ and $Hu \subseteq U$, while $U \subseteq HU$ because $e \in H$. Let $\pi : G \to G/H$ be the projection. For U open, $\pi^{-1}(\pi(U)) = UH = HU = U$ using normality, so $\pi(U)$ is open in the quotient topology of definition C.1.9. Now let $aH \neq bH$, so that $a^{-1}b \notin H$ and there is $U \in \mathcal{U}$ with $a^{-1}b \notin U$. Choose $W \in \mathcal{U}$ with $WW^{-1} \subseteq U$. The sets $\pi(aW)$ and $\pi(bW)$ are open and contain aH and bH, since $e \in W$. They are disjoint. For if $aw_1H = bw_2H$ with $w_1, w_2 \in W$, then $w_2^{-1}b^{-1}aw_1 \in H$, so $b^{-1}a \in w_2Hw_1^{-1} = w_2w_1^{-1}H$ by normality, and inverting gives $a^{-1}b \in Hw_1w_2^{-1} \subseteq HU = U$, which contradicts the choice of U. By definition C.1.11, G/H is Hausdorff.

(4) Suppose G is Hausdorff and let $a \in H$ with $a \neq e$. By definition C.1.11 there are disjoint open sets $U \ni e$ and $V \ni a$. Then $U \in \mathcal{U}$, so $a \in H \subseteq U$ and $a \in U \cap V = \emptyset$, which is impossible. Hence $H = \{e\}$. Conversely suppose $H = \{e\}$ and let $a \neq b$ in G. Then $a^{-1}b \neq e$, so $a^{-1}b \notin H$ and there is $U \in \mathcal{U}$ with $a^{-1}b \notin U$. Choose $W \in \mathcal{U}$ with $WW^{-1} \subseteq U$. The sets aW and bW are open by the translation fact and contain a and b. If $aw_1 = bw_2$ with $w_1, w_2 \in W$, then $a^{-1}b = w_1w_2^{-1} \in WW^{-1} \subseteq U$, against the choice of U. So $aW \cap bW = \emptyset$ and G is Hausdorff.

Topological groups are explored in a great many areas, and a few of them are listed here without detail. Perhaps the most studied topological groups are the *locally compact* ones, in which every point has an open neighborhood contained in a compact set. These are very useful in analysis. Every locally compact Hausdorff group carries a *Haar measure*, a nonzero Radon measure invariant under left translation and unique up to a positive scalar [51, Theorems 11.8 and 11.9]. The representation theory of locally compact groups leads to the *Fourier transform*: the irreducible unitary representations of $\mathbb{R}$ are the characters $t \mapsto e^{2\pi i \xi t}$ with $\xi \in \mathbb{R}$, and the Fourier transform decomposes the translation action of $\mathbb{R}$ on the Hilbert space $L^2(\mathbb{R})$ over these characters (section 53.4.1). Finally, topological groups show up in *Hilbert's fifth problem*. A continuous homomorphism between Lie groups is automatically

smooth [97, Continuous Homomorphisms Are Smooth], so a topological group carries at most one smooth structure making it a Lie group. Hilbert's fifth problem asks whether every topological group that is a topological manifold, that is, locally homeomorphic to $\mathbb{R}^n$, admits such a structure. The answer, due to Andrew Gleason, Deane Montgomery and Leo Zippin, is yes, and the structure can even be taken *real analytic*.

C.5 Completion in Topology

The last subject of topological groups we will explore here is the *completion* of topological groups, since it generalizes some of the results of *Commutative Algebra* [20] (completion). This definition of Cauchy generalizes that of the definition of a Cauchy sequence in a metric space by realizing that we only need to have a notion of "continuous subtraction" to define a Cauchy sequence. Throughout this section the groups are commutative and written additively.

Definition C.5.1: Cauchy Sequence In Topological Group

Let G be a commutative topological group and $(x_n) \subseteq G$ be a sequence. Then (x_n) is a *Cauchy sequence* if for every neighborhood U around 0, there exists a natural number $s(U) \in \mathbb{N}$ such that

$$x_n - x_m \in U \qquad \forall n, m > s(U)$$

Two Cauchy sequences (x_n) and (y_n) are *equivalent* if $(x_n - y_n)$ converges to 0, that is, if for every neighborhood U around 0 there is an $s(U) \in \mathbb{N}$ with $x_n - y_n \in U$ for all $n > s(U)$.

Just like for metric spaces, the collection of equivalence classes of Cauchy sequences is the completion of the group G, which we denote as $\hat{G}$. For any $g \in G$, the constant sequence (g) is a Cauchy sequence, and we identify G in $\hat{G}$ by the map $\iota : G \to \hat{G}$ via $g \mapsto [(g)]$. Note that ι is *not* in general injective.

Proposition C.5.2: The Completion Of A Topological Group

Let G be a commutative topological group. Then:

1. equivalence of Cauchy sequences is an equivalence relation, and $[(x_n)]+[(y_n)] = [(x_n+y_n)]$ is a well-defined operation making $\hat{G}$ an abelian group
2. ι is a homomorphism with kernel
$$\ker \iota = \bigcap_{\substack{0 \in U \\ U \text{ open}}} U$$
so ι is injective if and only if G is Hausdorff
3. a continuous homomorphism $f\colon G \to H$ of commutative topological groups induces a homomorphism $\hat{f}\colon \hat{G} \to \hat{H}$, $[(x_n)] \mapsto [(f(x_n))]$, and $\widehat{g \circ f} = \hat{g} \circ \hat{f}$ for a second continuous homomorphism $g\colon H \to K$

***Proof*:**
For every neighborhood U of 0 there is an open set W containing 0 with $W - W \subseteq U$: the map $q(x, y) = x - y$ is continuous (proposition C.4.3) and $q(0, 0) = 0$, so the open set $q^{-1}(U)$ contains a basic open set $W_1 \times W_2$ around $(0, 0)$, and $W = W_1 \cap W_2$ works. In particular, if $z \in W$, then $-z = 0 - z \in W - W \subseteq U$.

1. Reflexivity holds because $x_n - x_n = 0$ lies in every neighborhood of 0. If $x_n - y_n \in W$ for all large n, then $y_n - x_n \in U$ for all large n, which gives symmetry. For transitivity, if $(x_n) \sim (y_n)$ and $(y_n) \sim (z_n)$, then $x_n - y_n$ and, by symmetry, $z_n - y_n$ lie in W for all large n, so $x_n - z_n = (x_n - y_n) - (z_n - y_n) \in W - W \subseteq U$. If (x_n) and (y_n) are Cauchy, then

$$(x_n + y_n) - (x_m + y_m) = (x_n - x_m) - (y_m - y_n) \in W - W \subseteq U$$

for all large n, m, so $(x_n + y_n)$ is Cauchy. If $(x'_n) \sim (x_n)$ and $(y'_n) \sim (y_n)$, then $(x'_n + y'_n) - (x_n + y_n) = (x'_n - x_n) - (y_n - y'_n)$ lies in $W - W \subseteq U$ for all large n, so the sum of classes is well defined. The sequence $(-x_n)$ is Cauchy, since $(-x_n) - (-x_m) = -(x_n - x_m)$ and $x_n - x_m \in W$ for all large n, m, so $-(x_n - x_m) \in W - W \subseteq U$ by the first paragraph, and the group axioms hold termwise, with identity $[(0)]$ and inverse $[(-x_n)]$.

2. The map ι is a homomorphism by the definition of the sum. A constant sequence (g) is equivalent to (0) exactly when g lies in every neighborhood of 0, that is, in every open set containing 0, which gives the kernel. By proposition C.4.8(4), this intersection is $\{0\}$ exactly when G is Hausdorff.

3. Let V be a neighborhood of 0 in H. Then $f^{-1}(V)$ is a neighborhood of 0 in G, since f is continuous and $f(0) = 0$. If (x_n) is Cauchy, then $f(x_n) - f(x_m) = f(x_n - x_m) \in V$ for all large n, m, so $(f(x_n))$ is Cauchy, and in the same way f carries equivalent sequences to equivalent sequences. So $\hat{f}$ is well defined, it is a homomorphism because f is, and $\widehat{g \circ f}([(x_n)]) = [(g(f(x_n)))] = \hat{g}(\hat{f}([(x_n)]))$, completing the proof.

This construction is quite general: we can allow for $G = \mathbb{Q}$ with the euclidean topology, then $\hat{G} = \mathbb{R}$. We can also allow for $G = \mathbb{Q}$, and define a different metric (known as the p-metric), which will give us $\hat{G} = \mathbb{Q}_p$. We will focus on a particular case that useful for commutative algebra and show how it relates to completion.

Define a topology on a commutative group G by taking a descending sequence of subgroups[3]:

$$G = G_0 \supseteq G_1 \supseteq \cdots \supseteq G_n \supseteq \cdots$$

This is called a *filtration* of the group G. Declare $U \subseteq G$ open when for every $x \in U$ there is an n with $x + G_n \subseteq U$. These sets form a topology, called the *subgroup topology*: a union of such sets is again one, and if $x + G_n \subseteq U$ and $x + G_m \subseteq V$, then $x + G_{\max(n,m)} \subseteq U \cap V$ because the G_n decrease. Each coset $x + G_n$ is open, since $y + G_n = x + G_n$ for $y \in x + G_n$, so the cosets $x + G_n$ form a neighborhood basis at x, and $U \subseteq G$ is a neighborhood of 0 if and only if U contains some G_n. With this topology G is a topological group: if V is open and $x - y \in V$, choose n with $(x - y) + G_n \subseteq V$, and then the open set $(x + G_n) \times (y + G_n)$ is carried into $(x - y) + G_n \subseteq V$ by subtraction, so subtraction is continuous and proposition C.4.3 applies. An example of such a topology would be:

$$\mathbb{Z} \supseteq p\mathbb{Z} \supseteq p^2\mathbb{Z} \supseteq \cdots \supseteq p^n\mathbb{Z} \supseteq \cdots$$

[3] If G were not commutative, we would take a descending sequence of normal subgroups

The subgroup topology is interesting in that every subgroup G_n is open and closed (that is, clopen). First, for any $g \in G_n$, $g + G_n \subseteq G_n$, and so G_n is open. Thus, for any $h \notin G_n$, $h + G_n$ is open (since translation is a homeomorphism), and so:

$$H = \bigcup_{h \notin G_n} h + G_n$$

is open and disjoint from G_n. In fact, $H^c = G_n$, showing that G_n is *closed*.

Now, since G with the subgroup topology is a topological group, we can define $\hat{G}$ in the exact same way. Since the open sets are derived from a descending chain of subgroups G, Cauchy sequences induce a special type of sequence called a *coherent sequence*. Let (x_k) be a Cauchy sequence in G with the subgroup topology generated by (G_n). As G_n is a neighborhood of 0, $x_k - x_l \in G_n$ for all large k, l, so in G/G_n, the image of (x_k) must be eventually constant, say equal to ξ_n. When considering G_{n+1}, we get the eventual value ξ_{n+1}, and for k large, $x_k + G_{n+1} = \xi_{n+1}$ and $x_k + G_n = \xi_n$. So the natural projection

$$p_{n+1} : G/G_{n+1} \to G/G_n$$

maps ξ_{n+1} to ξ_n. The collection of these ξ_n's is called a *coherent sequence*. We chose the maps to be projection maps, however we may imagine a similar such sequence with any such functions, as long as they map to the right elements. Thus, being a little more general, a coherence sequence is a collection (ζ_n) such that for a collection of functions f_n, we have:

$$f_{n+1}(\zeta_{n+1}) = \zeta_n \qquad \forall n \in \mathbb{N}$$

The coherent sequences for the projections p_{n+1} form a subgroup of $\prod_n G/G_n$ under componentwise addition, because each p_{n+1} is a homomorphism.

Proposition C.5.3: Cauchy Sequences And Coherent Sequences

Let G be a commutative group with a filtration (G_n) and the subgroup topology. Sending the class of a Cauchy sequence to the coherent sequence (ξ_n) constructed above is a well-defined isomorphism from $\hat{G}$ onto the group of coherent sequences. In particular, equivalent Cauchy sequences define the same coherent sequence, and every coherent sequence is defined by a Cauchy sequence.

***Proof*:**
For $k \leq l$, the composite of the projections $G/G_l \to G/G_k$ sends $g + G_l$ to $g + G_k$, so, by induction on $l - k$, a coherent sequence ξ with $\xi_l = g + G_l$ has $\xi_k = g + G_k$ for every $k \leq l$. Write Φ for the map in the statement.

Well defined and additive. If $(x_k) \sim (y_k)$, then for each n the difference $x_k - y_k$ lies in the neighborhood G_n of 0 for all large k, so $x_k + G_n = y_k + G_n$ for all large k, and the two eventual values in G/G_n agree. If the images of (x_k) and (y_k) in G/G_n are eventually ξ_n and η_n, then that of $(x_k + y_k)$ is eventually $\xi_n + \eta_n$, so Φ is a homomorphism.

Injective. If $\Phi([(x_k)]) = 0$, then for each n, $x_k \in G_n$ for all large k. Every neighborhood of 0 contains some G_n, so (x_k) converges to 0, that is, $(x_k) \sim (0)$.

Surjective. Let ξ be a coherent sequence and choose $g_n \in G$ with $\xi_n = g_n + G_n$. For $k, l \geq n$, the first paragraph gives $g_k + G_n = \xi_n = g_l + G_n$, so $g_k - g_l \in G_n$. As every neighborhood of 0 contains some G_n, (g_k) is a Cauchy sequence, and its image in G/G_n is ξ_n for every $k \geq n$. Hence $\Phi([(g_k)]) = \xi$, completing the proof.

For this reason, the collection of all coherent sequences is also the completion of G, and is also denoted $\hat{G}$.

This now brings us to the same definition as given in chapter 25 in the case of Abelian groups: an *inverse system* is a collection of groups $\{A_n\}$ and homomorphisms f_n such that

$$f_{n+1} : A_{n+1} \to A_n$$

Then the group of all coherent sequences is called the *limit*, and is denoted $\varprojlim A_n$, where the homomorphism f_n are usually implicitly understood. With this notation, proposition C.5.3 says that:

$$\hat{G} \cong \varprojlim G/G_n$$

The most common subgroup topology and inverse system is when $G = R$ is a commutative ring and $G_n = I^n$ for an ideal I, with $I^0 = R$. In this case, the subgroup topology of R is called the *I-adic topology*, or simply the *I-topology*. Recall that we have defined a norm on a vector-space to define a topology. We can similarly define a norm generating the I-adic topology. Fix a real number $C > 1$ and define

$$\|x\| = C^{-n} \qquad \text{if} \qquad x \in I^n,\ x \notin I^{n+1}$$

If $x \in I^n$ for all $n \in \mathbb{N}$, then we will say that $\|x\| = 0$. Then through this norm, we can define a distance

$$d(x, y) = \|x - y\|$$

which is a metric when $\bigcap_n I^n = 0$. If $x - y \in I^n$, then $d(x, y) \leq C^{-n}$, and if $x - y \notin I^n$, then $x - y \in I^m \setminus I^{m+1}$ for some $m < n$ and $d(x, y) = C^{-m} > C^{-n}$. So $d(x, y) \leq C^{-n}$ exactly when $x - y \in I^n$, the open balls of d are the cosets $x + I^n$, and d defines the I-adic topology. In particular, a sequence is Cauchy for d exactly when it is Cauchy for the I-adic topology, and $d(x_k, y_k) \to 0$ exactly when $x_k - y_k \to 0$. Hence, when $\bigcap_n I^n = 0$, the completion of the metric space (R, d) described before definition C.1.19 is the completion $\hat{R}$ above, which is $\varprojlim R/I^n$ by proposition C.5.3. This new metric we have defined is also more powerful than the usual euclidean metric, namely:

$$\|x + y\| \leq \max(\|x\|, \|y\|) \qquad d(x, y) \leq \max(d(x, z), d(z, y))$$

since I^n is closed under addition. This metric condition is *much* stronger and is called an *ultra-metric*.

Proposition C.5.4: Balls In An Ultrametric

Let d be a metric on a set X with $d(x,y) \leq \max(d(x,z), d(z,y))$ for all $x, y, z \in X$, and write $B_r(x) = \{y \in X \mid d(x,y) < r\}$. Then:

1. Given a collection of any three points $x, y, z \in X$ one of the following three equalities must hold:

$$d(x,y) = d(y,z) \qquad d(x,z) = d(y,z) \qquad d(x,y) = d(z,x)$$

   Hence, every triple *must* form an isosceles triangle.

2. If $B_r(x)$ is an open ball then every point inside the ball is its center: if $d(x,y) < r$, then

$$B_r(x) = B_r(y)$$

3. Two balls that intersect are nested: if $B_r(x) \cap B_s(y) \neq \emptyset$ and $r \leq s$, then

$$B_r(x) \subseteq B_s(y)$$

4. If $r > 0$, then $B_r(x)$ is clopen.

***Proof*:**

1. Suppose the second equality fails, and by exchanging the names x and y if necessary, let $d(x,z) < d(y,z)$. Then $d(x,y) \leq \max(d(x,z), d(z,y)) = d(y,z)$, and $d(y,z) \leq \max(d(y,x), d(x,z))$, where the maximum must be $d(y,x)$ because $d(x,z) < d(y,z)$. So $d(x,y) = d(y,z)$. In the exchanged case this equality reads $d(x,y) = d(z,x)$.

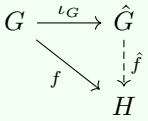
2. If $z \in B_r(x)$, then $d(y,z) \leq \max(d(y,x), d(x,z)) < r$, so $B_r(x) \subseteq B_r(y)$. Since $d(y,x) < r$ as well, exchanging x and y gives the reverse inclusion.

3. Let $z \in B_r(x) \cap B_s(y)$. By (2), $B_r(x) = B_r(z)$ and $B_s(y) = B_s(z)$, and $B_r(z) \subseteq B_s(z)$ because $r \leq s$.

4. The ball $B_r(x)$ is open, and its complement is open: if $y \notin B_r(x)$, then $B_r(y)$ does not meet $B_r(x)$, since otherwise $B_r(y) = B_r(x)$ by (3) applied in both directions, and $y \in B_r(y)$ would lie in $B_r(x)$, completing the proof.

What is notable is that completion is the beginning of real analysis (and hence also PDEs), and given the strong algebraic structure introduced we also have variants such completions coming up in complex analysis. In [77], we shall use different completion of $\mathbb{Z}$ with p-adic metrics to construct fields in which we are "keeping track' of a single prime that is splitting or ramifying.

A commutative group G together with a filtration $G = G_0 \supseteq G_1 \supseteq \cdots$ by subgroups is called a *filtered group*. Its *completion* is the group of coherent sequences



$$\hat{G} = \varprojlim G/G_n = \{(\xi_n)_{n\geq 0} \mid \xi_n \in G/G_n,\ p_{n+1}(\xi_{n+1}) = \xi_n \text{ for all } n\}$$

with componentwise addition, where $p_{n+1} \colon G/G_{n+1} \to G/G_n$ is the natural projection. By proposition C.5.3 it is the completion of G for the subgroup topology. The map $\iota_G \colon G \to \hat{G}$, $g \mapsto (g+G_n)_n$, is

a homomorphism, and $\hat{G}$ is itself a filtered group with $\hat{G}_n = \left\{ \xi \in \hat{G} \;\middle|\; \xi_n = 0 \right\}$, a decreasing sequence because $\xi_{n+1} = 0$ forces $\xi_n = p_{n+1}(\xi_{n+1}) = 0$. A filtered group H is called *complete and Hausdorff* if ι_H is an isomorphism. The kernel of ι_H is $\bigcap_m H_m$, so ι_H is injective exactly when $\bigcap_m H_m = 0$. A homomorphism $f\colon G \to H$ of filtered groups is continuous for the subgroup topologies exactly when for every m there is an n with $f(G_n) \subseteq H_m$. If f is continuous, the open subgroup H_m has an open preimage containing 0, which therefore contains some G_n. Conversely, under the condition, if $V \subseteq H$ is open and $f(x) \in V$, then V contains some coset $f(x) + H_m$, and $f(x + G_n) \subseteq f(x) + H_m \subseteq V$ for an n with $f(G_n) \subseteq H_m$, so $f^{-1}(V)$ is open.

Theorem C.5.5: Universal Property Of Completion

Let G and H be filtered groups with H complete and Hausdorff, and let $f\colon G \to H$ be a continuous homomorphism, that is, for every m there is an n with $f(G_n) \subseteq H_m$. Then there is a unique continuous homomorphism $\hat{f}\colon \hat{G} \to H$ with $\hat{f} \circ \iota_G = f$:

***Proof*:**
For $k \le l$ the composite $G/G_l \to G/G_k$ of the projections $p_l, \dots, p_{k+1}$ sends $g + G_l$ to $g + G_k$. So, by induction on $l - k$, a coherent sequence ξ with $\xi_l = g + G_l$ has $\xi_k = g + G_k$ for every $k \le l$.

Existence. For each m choose $n(m)$ with $f(G_{n(m)}) \subseteq H_m$. Replacing each $n(m)$ by the largest of $n(0), \dots, n(m)$, which is allowed because the G_n decrease, we may assume $n(0) \le n(1) \le \cdots$. The homomorphism

$$f_m\colon G/G_{n(m)} \to H/H_m \qquad g + G_{n(m)} \mapsto f(g) + H_m$$

is well defined, since $f(G_{n(m)}) \subseteq H_m$. For $\xi \in \hat{G}$ put $\eta_m = f_m(\xi_{n(m)})$. The sequence $\eta = (\eta_m)_m$ is coherent: writing $\xi_{n(m+1)} = g + G_{n(m+1)}$, the first paragraph gives $\xi_{n(m)} = g + G_{n(m)}$, so $\eta_{m+1} = f(g) + H_{m+1}$ projects to $f(g) + H_m = \eta_m$. Hence $\eta \in \hat{H}$, and we put $\hat{f}(\xi) = \iota_H^{-1}(\eta)$. Each component of $\xi \mapsto \eta$ is a composite of homomorphisms, so $\hat{f}$ is a homomorphism. For $g \in G$, the sequence $\xi = \iota_G(g)$ has $\xi_{n(m)} = g + G_{n(m)}$, so $\eta_m = f(g) + H_m$ for every m, that is, $\eta = \iota_H(f(g))$, and $\hat{f}(\iota_G(g)) = f(g)$. Finally, if $\xi \in \hat{G}_{n(m)}$, then $\eta_m = f_m(0) = 0$, so $h = \hat{f}(\xi)$ satisfies $h + H_m = (\iota_H(h))_m = \eta_m = 0$, that is, $\hat{f}(\hat{G}_{n(m)}) \subseteq H_m$, and $\hat{f}$ is continuous.

Uniqueness. Let $F_1, F_2\colon \hat{G} \to H$ be continuous homomorphisms with $F_1 \circ \iota_G = F_2 \circ \iota_G = f$, and let $D = F_1 - F_2$. Then $D \circ \iota_G = 0$, and for every m there is an n with $D(\hat{G}_n) \subseteq H_m$, obtained by taking the larger of the indices for F_1 and for F_2. Let $\xi \in \hat{G}$ and $m \ge 0$, choose such an n, and write $\xi_n = g + G_n$ with $g \in G$. Then $\xi - \iota_G(g)$ has nth component 0, so it lies in $\hat{G}_n$, and

$$D(\xi) = D(\xi - \iota_G(g)) + D(\iota_G(g)) = D(\xi - \iota_G(g)) \in H_m$$

As m was arbitrary, $D(\xi) \in \bigcap_m H_m = \ker \iota_H = 0$, so $F_1(\xi) = F_2(\xi)$, completing the proof.

D

Lattice Theory

D.1 Lattice Theory

We first generalize the notion of gcd and lcm for partial orders:

Definition D.1.1: GCD and LCM for Partially ordered sets

Let $(S, \leq)$ be a partially ordered set. Then

1. a *lowerbound* of a subset $T \subseteq S$ is an element $l \in S$ such that $l \leq t$ for all $t \in T$. A *greatest lower bound* (gcd) is a lowerbound g such that for any other lower-bound l, $l \leq g$. In lattice theory, the greatest lower bound is also called the *meet* or *infimum*
2. an *upperbound* of a subset $T \subseteq S$ is an element $u \in S$ such that $t \leq u$ for all $t \in T$. A *least upper bound* (lcm) is a upper-bound ℓ such that for any other upper-bounds u, $\ell \leq u$. In lattice theory, the least upper bound is also called the *join* or *supremum*

A meet or join, if it exists, is unique: two greatest lower bounds g and g' of T satisfy $g \leq g'$ and $g' \leq g$, so $g = g'$ by antisymmetry, and the same argument applies to least upper bounds. If the meet/join of a subset exists for a subset $T \subseteq S$, then it is denoted:

$$\bigwedge_{t \in T} t \qquad \text{and} \qquad \bigvee_{t \in T} t$$

Definition D.1.2: Lattice

Let $(S, \leq)$ be a partially ordered set. Then

1. If for any two $a, b \in S$, $a \wedge b$ exists, then S is called a *lower semi-lattice*
2. If for any two $a, b \in S$, $a \vee b$ exists, then S is called a *upper semi-lattice*
3. If S is both a lower and upper semi-lattice, S is called a *lattice*.

Proposition D.1.3: Properties Of Lattice Binary Operation

Let L be a lattice. Then $\vee$ and $\wedge$ as binary operations are

idempotent, commutative, associative, and order preserving.

Furthermore, by using induction, every finite non-empty subset has a meet and join

***Proof*:**

A subset of L has at most one greatest lower bound. For if g and g' are both, then $g \leq g'$ and $g' \leq g$ as each is a lower bound, so $g = g'$ by the antisymmetry of definition A.1.4. The same argument bounds least upper bounds, so the notations $a \wedge b$ and $a \vee b$ of definition D.1.2 name single elements.

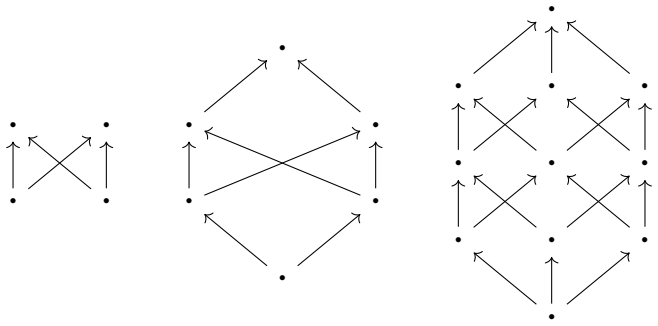
It is enough to argue for $\wedge$. Reversing the order relation of L exchanges lower bounds with upper bounds and greatest with least, so it turns every statement about $\wedge$ into the corresponding statement about $\vee$, and L with the reversed order is again a lattice.

Idempotent. The element a is a lower bound of $\{a\}$ by the reflexivity of definition A.1.4, and any lower bound l of $\{a\}$ satisfies $l \leq a$. So a is the greatest lower bound of $\{a\} = \{a, a\}$, that is $a \wedge a = a$.

Commutative. The sets $\{a, b\}$ and $\{b, a\}$ are equal, so they have the same lower bounds and the same greatest lower bound.

Associative. The element $(a \wedge b) \wedge c$ is a lower bound of $\{a, b, c\}$, since it is below $a \wedge b$, hence below a and b, and it is below c. If l is any lower bound of $\{a, b, c\}$, then $l \leq a$ and $l \leq b$ give $l \leq a \wedge b$, and $l \leq c$ then gives $l \leq (a \wedge b) \wedge c$. So $(a \wedge b) \wedge c$ is the greatest lower bound of $\{a, b, c\}$. The same computation identifies $a \wedge (b \wedge c)$ as the greatest lower bound of $\{a, b, c\}$, and the two agree by uniqueness.

Order preserving. Suppose $a \leq a'$. Then $a \wedge b \leq a \leq a'$ by transitivity and $a \wedge b \leq b$, so $a \wedge b$ is a lower bound of $\{a', b\}$ and therefore $a \wedge b \leq a' \wedge b$.



Finite subsets. Let $T = \{a_1, \ldots, a_n\}$ with $n \geq 1$. For $n = 1$ the meet is a_1. For $n > 1$, the argument given for associativity shows by induction that $(a_1 \wedge \cdots \wedge a_{n-1}) \wedge a_n$ is a lower bound of T and dominates every lower bound of T, so it is the meet of T.

Example D.1.4: Lattices

1. $\mathbb{N}, \mathbb{Z}, \mathbb{Q}, \mathbb{R}$ and ordered fields (section 21.1) with their order all form lattices, with $a \wedge b = \min(a, b)$ and $a \vee b = \max(a, b)$, since in a total order the smaller of a and b lies above every

lower bound of $\{a, b\}$, and dually.

2. Let S be a set with powerset $P(S)$. Then with $\cup$ and $\cap$, $P(S)$ is a lattice
3. Let S be the collection of all (subgroups/ideals/submodules) of (group/ring/module). Then S forms a lattice with $A \cap B \in S$ and $\langle A \cup B \rangle \in S$. In the ideal/submodule case, $\langle A \cup B \rangle = A + B$.
4. Any partially ordered set can be represented by a graph where an edge represents where $x \leq y$ if $x \to y$. Then the following are examples of non-lattices:

5. Let X be a topological space. Then the open sets of X, ordered by inclusion, form a lattice with $U \vee V = U \cup V$ and $U \wedge V = U \cap V$, both open by definition C.1.1.

Unlike most algebraic structures encountered with two binary operations, lattices are *not* distributive in general. In the lattice of subgroups of $\mathbb{Z}/2 \times \mathbb{Z}/2$, let A, B and C be the subgroups generated by $(1, 0)$, $(0, 1)$ and $(1, 1)$. Then $B \vee C$ contains $(0, 1) + (1, 1) = (1, 0)$, so it is the whole group, and

$$A \wedge (B \vee C) = A \qquad (A \wedge B) \vee (A \wedge C) = \{0\}$$

since distinct subgroups of order 2 meet in $\{0\}$. Lattices have the following alternative:

Proposition D.1.5: Absorption Law

Let L be a lattice and $x, y \in L$. Then:

$$x \wedge (x \vee y) = x \qquad x \vee (x \wedge y) = x$$

***Proof*:**
By definition D.1.1 the element $x \vee y$ is an upper bound of $\{x, y\}$, so $x \leq x \vee y$. Together with $x \leq x$ this makes x a lower bound of $\{x, x \vee y\}$. Any lower bound l of $\{x, x \vee y\}$ satisfies $l \leq x$ by definition. So x is the greatest lower bound of $\{x, x \vee y\}$, which by the uniqueness established in proposition D.1.3 gives $x \wedge (x \vee y) = x$.

For the second identity, $x \wedge y$ is a lower bound of $\{x, y\}$, so $x \wedge y \leq x$, and with $x \leq x$ this makes x an upper bound of $\{x, x \wedge y\}$. Any upper bound u of that set satisfies $x \leq u$. So x is the least upper bound of $\{x, x \wedge y\}$, that is $x \vee (x \wedge y) = x$.

Using the above result, we can formulate lattices purely algebraically:

Proposition D.1.6: Algebraic Definition Of A Lattice

Let L be a set with binary operations $\vee$ and $\wedge$ that are associative and commutative and satisfy the absorption laws of proposition D.1.5. Then the relation

$$x \leq y \qquad \text{if and only if} \qquad x \wedge y = x$$

is a partial order on L under which L is a lattice, and $x \wedge y$ and $x \vee y$ are the meet and the join of $\{x, y\}$ for that order

***Proof*:**
Two identities come first.

Both operations are idempotent. The second absorption law with y replaced by a gives $a \vee (a \wedge a) = a$. Feeding that into the first absorption law with $x = a$ and $y = a \wedge a$ gives

$$a = a \wedge \big(a \vee (a \wedge a)\big) = a \wedge a$$

and then $a \vee a = a \vee (a \wedge a) = a$ by the first law again.

The two descriptions of the order agree. If $x \wedge y = x$, then

$$x \vee y = (x \wedge y) \vee y = y \vee (y \wedge x) = y$$

using commutativity and the second absorption law. If $x \vee y = y$, then $x \wedge y = x \wedge (x \vee y) = x$ by the first absorption law. So $x \leq y$ holds exactly when $x \vee y = y$.

Now check the three conditions of definition A.1.4. Reflexivity is $x \wedge x = x$, which is idempotency. For antisymmetry, $x \leq y$ and $y \leq x$ give $x = x \wedge y = y \wedge x = y$. For transitivity, $x \leq y$ and $y \leq z$ give

$$x \wedge z = (x \wedge y) \wedge z = x \wedge (y \wedge z) = x \wedge y = x$$

so $x \leq z$.

Next, $x \wedge y$ is the greatest lower bound of $\{x, y\}$. It is a lower bound, since $(x \wedge y) \wedge x = (x \wedge x) \wedge y = x \wedge y$ gives $x \wedge y \leq x$, and the same computation with the roles of x and y exchanged gives $x \wedge y \leq y$. If $l \leq x$ and $l \leq y$, then

$$l \wedge (x \wedge y) = (l \wedge x) \wedge y = l \wedge y = l$$

so $l \leq x \wedge y$.

Finally, $x \vee y$ is the least upper bound of $\{x, y\}$. The first absorption law gives $x \wedge (x \vee y) = x$, so $x \leq x \vee y$, and commutativity gives $y \wedge (y \vee x) = y$, so $y \leq x \vee y$. If $x \leq u$ and $y \leq u$, then $x \vee u = u$ and $y \vee u = u$ by the description of the order proved above, whence

$$(x \vee y) \vee u = x \vee (y \vee u) = x \vee u = u$$

so $x \vee y \leq u$. Every pair therefore has a meet and a join, and L is a lattice by definition D.1.2.

Naturally, a lattice homomorphism is an order-homomorphism (a map φ with $\varphi(x) \leq \varphi(y)$ whenever $x \leq y$) such that $\varphi(x \vee y) = \varphi(x) \vee \varphi(y)$ and $\varphi(x \wedge y) = \varphi(x) \wedge \varphi(y)$. Note that not all order-

homomorphisms are lattice homomorphisms. The map φ from $P(\{1,2\})$ to the two-element chain $0<1$ sending $\{1,2\}$ to 1 and the other three subsets to 0 preserves order, but

$$\varphi(\{1\}\vee\{2\})=\varphi(\{1,2\})=1 \qquad \varphi(\{1\})\vee\varphi(\{2\})=0\vee 0=0$$

However an order-isomorphism, a bijection φ with $x\le y$ if and only if $\varphi(x)\le\varphi(y)$, is a lattice-isomorphism. The element $\varphi(x\vee y)$ is an upper bound of $\{\varphi(x),\varphi(y)\}$, since $x,y\le x\vee y$. Any upper bound has the form $\varphi(v)$, as φ is onto, and then $x\le v$ and $y\le v$, so $x\vee y\le v$ and $\varphi(x\vee y)\le\varphi(v)$. Hence $\varphi(x\vee y)=\varphi(x)\vee\varphi(y)$, and dually $\varphi(x\wedge y)=\varphi(x)\wedge\varphi(y)$. The inverse of φ is again an order-isomorphism, so it preserves both operations as well.

Lattices as they are can be considered as two commutative *semigroups* with a compatible structure (see section 7); the absorption being the unique feature of lattices. If furthermore the lattice is bounded, then it shall have a monoid structure.

Definition D.1.7: Bounded Lattice

Let L be a lattice. Then L is said to be *bounded* if there exists an minimal element (denoted 0 or $\bot$) and a maximal element (denoted 1 or $\top$) such that for all $x\in L$:

$$\bot\le x\le\top \qquad \text{equiv.} \qquad 0\le x\le 1$$

As an algebraic structures, we can think of a bounded lattice as a set $(L,\vee,\wedge,0,1)$ such that $(L,\vee,\wedge)$ is a lattice, 0 is the identity element for the join operation $\vee$, and 1 is the identity element for the meet operation $\wedge$:

$$a\vee 0=a \qquad a\wedge 1=a$$

If we require the stronger condition that every subset $S\subseteq L$ of a lattice has a supremum and infimum, we get the following stronger notion:

Definition D.1.8: Complete Lattice

Let L be a lattice. Then if every subset $S\subseteq L$ has a gcd and lcm, then L is said to be a *complete lattice*

This makes L a bounded lattice, for $L\subseteq L$ must have a gcd and lcm. Every finite set can be made into a complete lattice, however $\mathbb{N},\mathbb{Q},\mathbb{R}$ are incomplete. Every non-empty closed and bounded subset C of $\mathbb{R}$, such as $[0,1]$, is complete: a non-empty $T\subseteq C$ has a supremum and an infimum in $\mathbb{R}$, which lie in C because each is a limit of a sequence in T and C is closed, and the empty subset has supremum $\min C$ and infimum $\max C$, which exist by the case $T=C$. More notably, $P(X)$ for any set X, as well as the collection of (subgroups/ideals/submodules) of (groups/rings/modules) forms a complete lattice.

Given any lattice, it can be embedded in a complete lattice. Rather interestingly, this shall link to Galois connections and the closure map:

Definition D.1.9: Closure Map

Let $(S,\le)$ be a partially ordered set. Then a *closure map* is an order-homomorphism $\Gamma:S\to S$ that is idempotent, $(\Gamma\circ\Gamma)=\Gamma$, and expanding, $(\Gamma(x)\ge x$ for all $x\in S)$. An element $x\in S$ is *closed relative to* Γ if $\Gamma(x)=x$.

The closure map is so named since the closure map $A \mapsto \overline{A}$ is the quintessential closure map.

Lemma D.1.10: Closed Element Infimum and Supremum

Let L be a complete lattice, let Γ be a closure map on L, and let $C \subseteq L$ be the set of elements closed relative to Γ. Then C is closed under the infimums of L, and C is itself a complete lattice in which the infimum of $T \subseteq C$ is the infimum $\bigwedge T$ taken in L and the supremum of T is $\Gamma\big(\bigvee T\big)$.
The set C need *not* be closed under the supremums of L.

***Proof*:**
Let $T \subseteq C$ and put $m = \bigwedge T$, the infimum taken in L, which exists by definition D.1.8. For each $t \in T$ the relation $m \leq t$ and the order preservation of Γ give $\Gamma(m) \leq \Gamma(t) = t$, so $\Gamma(m)$ is a lower bound of T and therefore $\Gamma(m) \leq m$. Since Γ is expanding, $m \leq \Gamma(m)$, so $\Gamma(m) = m$ by antisymmetry and $m \in C$. This is the first assertion, and it says at the same time that $\bigwedge T$ is the infimum of T inside C.

Now put $s = \bigvee T$, again taken in L, and let $\hat{s} = \Gamma(s)$. Idempotency gives $\Gamma(\hat{s}) = \hat{s}$, so $\hat{s} \in C$. For $t \in T$ the relations $t \leq s \leq \Gamma(s) = \hat{s}$ show $\hat{s}$ is an upper bound of T. If $u \in C$ is any upper bound of T in C, then $s \leq u$ and $\hat{s} = \Gamma(s) \leq \Gamma(u) = u$. So $\hat{s}$ is the supremum of T inside C. Every subset of C therefore has an infimum and a supremum in C, and C is a complete lattice by definition D.1.8.

For the last assertion, take $X = \mathbb{R}$ with the Euclidean topology, $L = P(X)$ ordered by inclusion, and $\Gamma(A) = \overline{A}$ the topological closure of definition C.1.8. This Γ is a closure map. It preserves inclusions, since every closed set containing B contains A when $A \subseteq B$. It is expanding, since A is contained in each of the sets being intersected. It is idempotent, since $\overline{A}$ is already closed. Its closed elements are the closed subsets of $\mathbb{R}$. The supremum in L of the family $\big\{[1/n, 1]\big\}_{n \geq 1}$ is the union $(0, 1]$, which is not closed, while the supremum of that family inside C is $\Gamma\big((0, 1]\big) = [0, 1]$.

Next, we define the Galois connection more generally:

Definition D.1.11: Antitone Galois Connection

Let X, Y be two partially ordered sets. Then a *galois connection* between X, Y is a pair of order-reversing homomorphism, say $\alpha : X \to Y$ and $\beta : Y \to X$ such that for all $x \in X$ and $y \in Y$:

$$(\beta \circ \alpha)(x) \geq x \qquad (\alpha \circ \beta)(y) \geq y$$

Naturally, the Galois correspondence is a Galois connection, and the generalization to closed groups shows the correspondence in the infinite case.

Lemma D.1.12: Galois Connection And Lattices

Let X, Y be partially ordered sets and (α, β) a Galois connection. Then

1. α, β, induce order-reversing mutually inverse bijections between $\mathrm{im}(\alpha)$ and $\mathrm{im}(\beta)$
2. $\alpha \circ \beta$ and $\beta \circ \alpha$ are closure maps
3. If X, Y are complete lattices, $\mathrm{im}(\alpha)$ and $\mathrm{im}(\beta)$ are complete lattices

***Proof*:**
Everything rests on the two identities

$$\alpha \circ \beta \circ \alpha = \alpha \qquad \beta \circ \alpha \circ \beta = \beta$$

For the first, definition D.1.11 gives $(\beta \circ \alpha)(x) \geq x$, and applying the order-reversing α turns this into $\alpha\big(\beta(\alpha(x))\big) \leq \alpha(x)$. The same definition applied to the element $y = \alpha(x)$ of Y gives $\alpha\big(\beta(\alpha(x))\big) \geq \alpha(x)$. Antisymmetry gives equality. The second identity is the same argument with the roles of α and β exchanged.

(1) For $v = \alpha(x) \in \mathrm{im}(\alpha)$ the first identity gives $\alpha\big(\beta(v)\big) = \alpha\big(\beta(\alpha(x))\big) = \alpha(x) = v$, and for $u = \beta(y) \in \mathrm{im}(\beta)$ the second gives $\beta\big(\alpha(u)\big) = u$. In particular β carries $\mathrm{im}(\alpha)$ into $\mathrm{im}(\beta)$ and α carries $\mathrm{im}(\beta)$ into $\mathrm{im}(\alpha)$, and the two restrictions are mutually inverse. Each is order-reversing, being a restriction of an order-reversing map.

(2) Write $\Gamma_X = \beta \circ \alpha$. A composite of two order-reversing maps preserves order, so Γ_X is an order-homomorphism, and $\Gamma_X(x) \geq x$ is part of definition D.1.11. The first identity gives

$$\Gamma_X \circ \Gamma_X = \beta \circ (\alpha \circ \beta \circ \alpha) = \beta \circ \alpha = \Gamma_X$$

so Γ_X is idempotent and is a closure map in the sense of definition D.1.9. The same holds for $\Gamma_Y = \alpha \circ \beta$ on Y.

(3) The elements of X closed relative to Γ_X are exactly the elements of $\mathrm{im}(\beta)$. For if $\Gamma_X(x) = x$ then $x = \beta(\alpha(x)) \in \mathrm{im}(\beta)$, and if $x \in \mathrm{im}(\beta)$ then $\Gamma_X(x) = x$ by part (1). So when X is a complete lattice, lemma D.1.10 applies to Γ_X and makes $\mathrm{im}(\beta)$ a complete lattice, with infimums inherited from X and with the supremum of $T \subseteq \mathrm{im}(\beta)$ equal to $\Gamma_X\big(\bigvee T\big)$. The same argument with Γ_Y makes $\mathrm{im}(\alpha)$ a complete lattice when Y is one. The supremums are the ones described above and are in general not those of the ambient lattice, as the last part of lemma D.1.10 shows.

Theorem D.1.13: Lattice Embedding Theorem

Let $(L, \leq)$ be a partially ordered set. Then L can be embedded in a complete lattice $\hat{L}$ in such a way that every infimum and every supremum that exists in L is preserved.

***Proof*:**
For $A \subseteq L$ write

$$A^u = \{z \in L \mid a \leq z \text{ for all } a \in A\} \qquad A^\ell = \{w \in L \mid w \leq a \text{ for all } a \in A\}$$

for the sets of upper and lower bounds of A. Both operations reverse inclusion, since a bound

for a larger set is a bound for a smaller one, and both satisfy $A \subseteq A^{u\ell}$ and $A \subseteq A^{\ell u}$, since every element of A sits below every upper bound of A and above every lower bound. So the pair $(A \mapsto A^u,\ B \mapsto B^\ell)$ is a Galois connection on $(P(L), \subseteq)$ in the sense of definition D.1.11.

The poset $(P(L), \subseteq)$ is a complete lattice, the infimum of a family of subsets being its intersection and the supremum its union. By lemma D.1.12 the map $\Gamma(A) = A^{u\ell}$ is a closure map on $P(L)$, and by lemma D.1.10 the set

$$\hat{L} = \left\{ A \subseteq L \;\middle|\; A^{u\ell} = A \right\}$$

of its closed elements is a complete lattice, in which the infimum of a family is its intersection and the supremum of a family is Γ applied to its union.

Define $\varphi : L \to \hat{L}$ by $\varphi(x) = D(x) = \{y \in L \mid y \leq x\}$. This lands in $\hat{L}$: the upper bounds of $D(x)$ are the elements above every $y \leq x$, and since $x \in D(x)$ these are exactly the elements above x, so $D(x)^u = \{z \mid x \leq z\}$, and the same computation run downwards gives $D(x)^{u\ell} = D(x)$. The map φ is an order embedding. For if $x \leq y$ then transitivity gives $D(x) \subseteq D(y)$, and if $D(x) \subseteq D(y)$ then $x \in D(x) \subseteq D(y)$ gives $x \leq y$. In particular φ is injective, since $D(x) = D(y)$ forces $x \leq y$ and $y \leq x$.

Let $T \subseteq L$ be non-empty. Then

$$\bigcap_{t \in T} \varphi(t) = \{y \in L \mid y \leq t \text{ for all } t \in T\} = T^\ell$$

Suppose T has an infimum m in L. Then $m \in T^\ell$ and every element of T^ℓ lies below m, so $T^\ell = D(m) = \varphi(m)$. The left side is the infimum of $\varphi(T)$ in $\hat{L}$, so φ carries the infimum of T to the infimum of $\varphi(T)$.

For supremums, the upper bounds of $\bigcup_{t \in T} \varphi(t) = \bigcup_{t \in T} D(t)$ are the elements above every $y \leq t$ for every t, and since $t \in D(t)$ these are exactly the elements above every t, so $\left(\bigcup_{t \in T} \varphi(t)\right)^u = T^u$. Suppose T has a supremum s in L. Then $T^u = \{z \mid s \leq z\}$, and applying $(-)^\ell$ gives $T^{u\ell} = D(s)$, because an element below every $z \geq s$ is below s and conversely. Hence the supremum of $\varphi(T)$ in $\hat{L}$, which is $\Gamma\left(\bigcup_{t \in T} \varphi(t)\right) = T^{u\ell}$, equals $\varphi(s)$.

The empty subset takes one more line. An infimum of $\emptyset$ in L is a greatest element $\top$, and $\varphi(\top) = D(\top) = L$, which is the greatest element of $\hat{L}$ and so the infimum of the empty family there. A supremum of $\emptyset$ in L is a least element $\bot$, and $\varphi(\bot) = \{\bot\} = L^\ell = \emptyset^{u\ell}$, which is the least element of $\hat{L}$.

Examples of Lattices

Lattices are rather general objects. As it turns out, when working the set of sub-objects of an R-module with $(+, \cap)$, we get some more interesting behavior:

Definition D.1.14: Modular Lattice

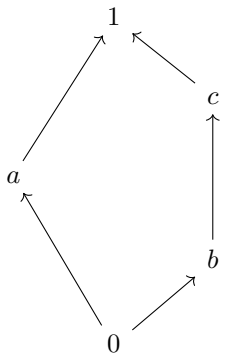
Let L be a lattice. Then L is called *modular* if whenever $x \leq z$,

$$x \vee (y \wedge z) = (x \vee y) \wedge z$$

Note that for any lattice, if $x \leq z$ then x and $y \wedge z$ are lower bounds of $\{x \vee y, z\}$ and hence:

$$x \vee (y \wedge z) \leq (x \vee y) \wedge z$$

Thus, a lattice is modular if and only if $x \leq z$ implies $x \vee (y \wedge z) \geq (x \vee y) \wedge z$. Note that the opposite of a modular lattice is modular, hence the theory is self-dual. As mentioned, the name modular lattice comes straight form the lattice of submodules:



Example D.1.15: Modular Lattices

Letting $(\vee, \wedge) = (+, \cap)$, and taking the lattice of submodules of an R-module. Then if $A \subseteq C$, then taking $x \in (A + B) \cap C$ we have $x = a + b \in C$ for some appropriate $a \in A \subseteq C$. Then $b = x - a \in C$, and $x = a + b \in A + (B \cap C)$

Detecting when a lattice fails to be modular is similar to how to detect a complete bipartite graph:

Proposition D.1.16: Detecting Modular Lattice

Let L be a lattice. Then L is modular if and only if it does not contain a sub-lattice isomorphic to N_5:

***Proof*:**

In the pictured lattice N_5 the order is $0 < b < c < 1$ and $0 < a < 1$, with a incomparable to b and to c, so $a \wedge c = 0$ and $a \vee b = 1$. Taking $x = b$, $y = a$ and $z = c$, the hypothesis $x \leq z$ of definition D.1.14 holds, while

$$b \vee (a \wedge c) = b \vee 0 = b \qquad (b \vee a) \wedge c = 1 \wedge c = c$$

differ. So N_5 is not modular. The modular law is an identity in $\vee$ and $\wedge$, so it passes to sub-lattices, and a lattice with a sub-lattice isomorphic to N_5 cannot be modular.

For the converse, suppose L is not modular. Then there are $x \leq z$ and y in L with $x \vee (y \wedge z) \neq (x \vee y) \wedge z$, and by the inequality recorded after definition D.1.14 the failure is

$$b := x \vee (y \wedge z) \quad < \quad c := (x \vee y) \wedge z$$

Put $a = y$, $0 = y \wedge z$ and $1 = x \vee y$. Four computations, each using proposition D.1.3 to rearrange meets and joins, pin down the configuration.

First, $a \wedge c = y \wedge (x \vee y) \wedge z = y \wedge z = 0$, since $y \leq x \vee y$. Second, $b \leq c$ gives $a \wedge b \leq a \wedge c = 0$, while $0 = y \wedge z \leq x \vee (y \wedge z) = b$ and $0 \leq y = a$, so $a \wedge b = 0$. Third, $a \vee b = y \vee x \vee (y \wedge z) = x \vee y = 1$,

since $y \wedge z \leq y$. Fourth, $a \vee c \geq a \vee b = 1$ and $a \vee c \leq 1$ because $a = y \leq 1$ and $c \leq x \vee y = 1$, so $a \vee c = 1$.

Now the five elements are distinct. If $b = 0$, then $x \vee (y \wedge z) = y \wedge z$, so $x \leq y \wedge z \leq y$ and $1 = x \vee y = y = a$, whence $c = (x \vee y) \wedge z = y \wedge z = 0 = b$, against $b < c$. If $c = 1$, then $0 = a \wedge c = a \wedge 1 = y$, so $y = y \wedge z$ and $y \leq z$, whence $b = x \vee (y \wedge z) = x \vee y = 1$ and $b \geq c$, again against $b < c$. So $0 \leq b < c \leq 1$ with $b \neq 0$ and $c \neq 1$, and the chain $0 < b < c < 1$ is strict. As for a, the relation $b \leq a$ would give $a \wedge b = b \neq 0$ and $a \leq b$ would give $a \vee b = b \neq 1$, so a is incomparable to b, and the identical argument with c in place of b makes a incomparable to c. Finally $a \neq 0$ because $a \vee b = 1 \neq b$, and $a \neq 1$ because $a \wedge c = 0 \neq c$.

The set $\{0, a, b, c, 1\}$ is closed under $\vee$ and $\wedge$, since the four computations above handle the pairs involving a, the pair $\{b, c\}$ gives $b \wedge c = b$ and $b \vee c = c$, and 0 and 1 are the least and greatest of the five. It is therefore a sub-lattice, and the order described above is that of N_5.

Modular lattices help generalize results such as part (2) of theorem 3.7.9 (that any two composition series of a finite group have the same length).

Proposition D.1.17: Modular Lattices And Finite Maximal Chains

Let L be a modular lattice. Then any two finite maximal chains have the same length

***Proof*:**
Say that v *covers* u when $u < v$ and no $w \in L$ satisfies $u < w < v$. A chain of L is maximal when no element of L can be added to it and leave a chain, in the sense of definition A.1.4. The *length* of a finite chain with $k + 1$ elements is k.

A finite maximal chain runs from a least to a greatest element by covers. Let $C : u_0 < u_1 < \cdots < u_k$ be a finite maximal chain. If some w satisfied $u_i < w < u_{i+1}$, then $C \cup \{w\}$ would be a chain properly containing C, so each u_{i+1} covers u_i. If some $w \in L$ satisfied $w < u_0$, the same objection applies, so u_0 is minimal in L, and then for any $y \in L$ the element $u_0 \wedge y$ satisfies $u_0 \wedge y \leq u_0$, so minimality forces $u_0 \wedge y = u_0$ and $u_0 \leq y$. Hence u_0 is the least element $\bot$ of L, and dually u_k is the greatest element $\top$.

Main claim. If a modular lattice M has a maximal chain of length k, then every chain of M has at most $k + 1$ elements. Argue by induction on k. For $k = 0$ the chain is a single element that is both least and greatest, so M has one element and every chain has one element. Let $k \geq 1$ and let $\bot = x_0 \lessdot x_1 \lessdot \cdots \lessdot x_k = \top$ be a maximal chain, where $\lessdot$ marks a cover. The interval $M' = \{v \in M \mid x_1 \leq v\}$ is closed under $\vee$ and $\wedge$, hence a lattice, and it inherits the identity of definition D.1.14, so it is modular. Its least element is x_1 and its greatest is $\top$, and $x_1 \lessdot x_2 \lessdot \cdots \lessdot x_k$ is a maximal chain of M' of length $k - 1$. By induction every chain of M' has at most k elements.

Let $u_0 < u_1 < \cdots < u_r$ be a chain of M and consider $u_0 \vee x_1 \leq u_1 \vee x_1 \leq \cdots \leq u_r \vee x_1$, a chain of M' by proposition D.1.3. Suppose $u_i \vee x_1 = u_{i+1} \vee x_1$ for some i. Since $u_i \leq u_{i+1}$, definition D.1.14 applies with $x = u_i$, $y = x_1$ and $z = u_{i+1}$ and gives

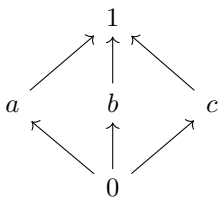
$$u_i \vee (x_1 \wedge u_{i+1}) = (u_i \vee x_1) \wedge u_{i+1} = (u_{i+1} \vee x_1) \wedge u_{i+1} = u_{i+1}$$

the last step because $u_{i+1} \leq u_{i+1} \vee x_1$. If $x_1 \wedge u_{i+1} \leq u_i$ held, the left side would be u_i and $u_i = u_{i+1}$, which is false, so $x_1 \wedge u_{i+1} \neq \bot$. As $\bot \lessdot x_1$ and $\bot \leq x_1 \wedge u_{i+1} \leq x_1$, this forces $x_1 \wedge u_{i+1} = x_1$, that is $x_1 \leq u_{i+1}$. Let i_0 be the least index at which such a coincidence occurs.

For $j > i_0$ the relation $x_1 \leq u_{i_0+1} \leq u_j$ gives $u_j \vee x_1 = u_j$, and these are strictly increasing, so no further coincidence occurs. Hence the chain $\{u_i \vee x_1\}$ has at least r distinct members, and the induction bound gives $r \leq k$. So $u_0 < \cdots < u_r$ has at most $k+1$ elements, proving the main claim.

Now let C and D be finite maximal chains of L, of lengths m and n. Applying the main claim to the maximal chain C and the chain D gives $n+1 \leq m+1$, and applying it the other way round gives $m+1 \leq n+1$. Hence $m = n$.

A little more restrictive than modular lattices are *distributive* lattices:



Definition D.1.18: Distributive Lattice

Let $(L, \vee, \wedge)$ be a lattice. Then L is a *distributive lattice* if one of the two equivalent conditions hold for all $x, y, z \in L$:

1. $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$
2. $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$

Proposition D.1.19: Detecting Distributive Lattices

Let L be a lattice. Then L is a distributive lattice if and only if L does not have a sublattice isomorphic to N_5 or M_5, where M_5 is the lattice:

***Proof*:**
Both forms of the distributive law get used, so start with their equivalence. Assume form (2) of definition D.1.18. Then

$$(x\vee y)\wedge(x\vee z) = \big((x\vee y)\wedge x\big)\vee\big((x\vee y)\wedge z\big) = x\vee\big((z\wedge x)\vee(z\wedge y)\big) = \big(x\vee(x\wedge z)\big)\vee(y\wedge z) = x\vee(y\wedge z)$$

The first equality is form (2) applied with $x \vee y$ in the leading slot. The second applies proposition D.1.5 to the left summand and form (2) to the right. The third is proposition D.1.3 and the fourth is proposition D.1.5 again. Reversing the order of L turns this derivation into the derivation of form (2) from form (1).

Suppose L is distributive. Both forms are identities in $\vee$ and $\wedge$, so every sublattice of L is distributive. Neither N_5 nor M_5 is distributive. For N_5, form (1) applied with $x \leq z$ gives $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z) = (x \vee y) \wedge z$, so a distributive lattice is modular and proposition D.1.16 rules N_5 out. In M_5 the elements a, b, c give $a \wedge (b \vee c) = a \wedge 1 = a$ against $(a \wedge b) \vee (a \wedge c) = 0 \vee 0 = 0$. So L has no sublattice isomorphic to either.

For the converse, suppose L is not distributive. If L is not modular, then proposition D.1.16 produces a sublattice isomorphic to N_5 and there is nothing more to do. So assume L is modular

and fix x, y, z with $x \wedge (y \vee z) \neq (x \wedge y) \vee (x \wedge z)$. Both $x \wedge y$ and $x \wedge z$ lie below x and below $y \vee z$, so

$$(x \wedge y) \vee (x \wedge z) \quad < \quad x \wedge (y \vee z)$$

Set

$$d = (x \wedge y) \vee (y \wedge z) \vee (z \wedge x) \qquad e = (x \vee y) \wedge (y \vee z) \wedge (z \vee x)$$

Each of the three meets in d lies below each of the three joins in e, for instance $x \wedge y \leq x \leq x \vee y$ and $x \wedge y \leq y \leq y \vee z$ and $x \wedge y \leq x \leq z \vee x$, so $d \leq e$. Put

$$a = d \vee (x \wedge e) \qquad b = d \vee (y \wedge e) \qquad c = d \vee (z \wedge e)$$

all of which lie in the interval between d and e.

Since $d \leq e$, definition D.1.14 gives $a = d \vee (x \wedge e) = (d \vee x) \wedge e$, and $d \vee x = x \vee (y \wedge z)$ because the summands $x \wedge y$ and $z \wedge x$ of d lie below x. Writing $X = x \vee (y \wedge z)$, and Y, Z for the corresponding elements built from y and from z, this says $a = X \wedge e$, $b = Y \wedge e$ and $c = Z \wedge e$.

The three joins. Since $X \leq x \vee y$ and $X \leq z \vee x$, the meet $X \wedge e$ collapses to $X \wedge (y \vee z)$, and definition D.1.14 applied to $y \wedge z \leq y \vee z$ gives

$$a = X \wedge (y \vee z) = \big((y \wedge z) \vee x\big) \wedge (y \vee z) = (y \wedge z) \vee \big(x \wedge (y \vee z)\big)$$

Now $z \wedge x \leq x$ and $z \wedge x \leq z \leq y \vee z$, so $z \wedge x \leq x \wedge (y \vee z)$, and $y \wedge z \leq y$, so

$$a \vee Y = (y \wedge z) \vee \big(x \wedge (y \vee z)\big) \vee y \vee (z \wedge x) = y \vee \big(x \wedge (y \vee z)\big) = (y \vee x) \wedge (y \vee z)$$

the last step being definition D.1.14 applied to $y \leq y \vee z$. Since $a \leq e$, a further application of definition D.1.14 gives $a \vee b = a \vee (Y \wedge e) = (a \vee Y) \wedge e$, and e lies below both $x \vee y$ and $y \vee z$, so

$$a \vee b = (y \vee x) \wedge (y \vee z) \wedge e = e$$

The construction of d, e, a, b, c is symmetric in x, y, z, so the same computation gives $b \vee c = c \vee a = e$.

The three meets. Reversing the order of L leaves L modular, as recorded after definition D.1.14, exchanges d with e, and fixes a, b and c, since $a = d \vee (x \wedge e) = (d \vee x) \wedge e$ exhibits a in both of the two dual forms. So the previous paragraph, carried out in the reversed order, gives $a \wedge b = b \wedge c = c \wedge a = d$.

The five elements are distinct. Suppose $a = d$. Then $e = a \vee b = d \vee b = b$ and likewise $e = c$, so $d = b \wedge c = e$. The same argument applies to b and to c, and if $a = e$ then $d = a \wedge b = e \wedge b = b$, which returns to the previous case. So it is enough to rule out $d = e$. If $d = e$, then $a = X \wedge e = d$, and meeting the two descriptions of a with x gives, on the one hand,

$$\big((y \wedge z) \vee (x \wedge (y \vee z))\big) \wedge x = \big(x \wedge (y \vee z)\big) \vee (x \wedge y \wedge z) = x \wedge (y \vee z)$$

by definition D.1.14 applied to $x \wedge (y \vee z) \leq x$, and on the other hand, writing $s = (x \wedge y) \vee (z \wedge x) \leq x$,

$$d \wedge x = \big(s \vee (y \wedge z)\big) \wedge x = s \vee (x \wedge y \wedge z) = s$$

by definition D.1.14 applied to $s \leq x$. These two say $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$, contradicting the choice of x, y, z. Hence $d \neq e$, and d, a, b, c, e are five distinct elements with a, b, c pairwise incomparable, since $a \leq b$ would give $a \wedge b = a \neq d$.

The set $\{d, a, b, c, e\}$ is closed under $\vee$ and $\wedge$, by the six computations above together with $d \leq a, b, c \leq e$, so it is a sublattice isomorphic to M_5.

The power-set $P(X)$ is the canonical distributive lattice with $(\cup, \cap)$. In fact a lattice is distributive if and only if it is isomorphic to a sublattice of $P(X)$ for some appropriate X. To see this, we require the following build-up

Definition D.1.20: Lattice Irreducible Elements

Let L be a lattice. Then an element $i \in L$ is called *sup-irreducible* (or just *irreducible*) if i is not a minimal element and:

$$x \vee y = i \quad \Rightarrow \quad x = i \text{ or } y = i$$

The collection of irreducible elements is denoted $\mathrm{Irr}(L)$.

In $P(X)$, singletons are irreducible.

Proposition D.1.21: Lattice And Irreducible

Let L be a lattice satisfying the descending chain condition. Then every element $x \in L$ is the join of a finite subset of $\{i \in \mathrm{Irr}(L) \mid i \leq x\}$, where the join of the empty set is read as the least element of L. Consequently $x = \bigvee \{i \in \mathrm{Irr}(L) \mid i \leq x\}$

***Proof*:**
First, L has a least element. The descending chain condition says every non-empty subset of L has a minimal element, so L itself has one, say $\bot$, and for any $y \in L$ the element $\bot \wedge y$ satisfies $\bot \wedge y \leq \bot$, so minimality forces $\bot \wedge y = \bot$ and $\bot \leq y$. The same computation shows $\bot$ is the only minimal element of L, so by definition D.1.20 an element failing to be irreducible is either $\bot$ or admits $u \vee v = i$ with $u \neq i$ and $v \neq i$.

Let S be the set of elements of L that are *not* a join of a finite set of irreducible elements. Suppose $S \neq \emptyset$ and let x be a minimal element of S, which exists by the descending chain condition. Then $x \neq \bot$, since $\bot$ is the join of the empty set, and $x \notin \mathrm{Irr}(L)$, since otherwise x is the join of $\{x\}$. By the previous paragraph there are $u, v \in L$ with $u \vee v = x$, $u \neq x$ and $v \neq x$. Both lie below x, so $u < x$ and $v < x$, and minimality of x in S puts $u, v \notin S$. Writing u and v as finite joins of irreducible elements and joining the two finite sets writes x as one as well, contradicting $x \in S$. Hence $S = \emptyset$.

Let $F \subseteq \mathrm{Irr}(L)$ be finite with $x = \bigvee F$. Every $i \in F$ satisfies $i \leq x$, so F is contained in $T = \{i \in \mathrm{Irr}(L) \mid i \leq x\}$. Now x is an upper bound of T by the definition of T, and any upper bound u of T is an upper bound of F, hence satisfies $x = \bigvee F \leq u$. So x is the least upper bound of T, that is $x = \bigvee T$.

Definition D.1.22: Order Ideal

Let S be a partially ordered set. Then a [left] order ideal $I \subseteq S$ is a subset such that if $y \in I$ and:

$$x \leq y \in I \quad \Rightarrow \quad x \in I$$

Order ideals naturally create a distributive lattice given any partially ordered set:

Proposition D.1.23: Order Ideals And Partially Ordered Sets

Let S be a partially ordered set. Then the order ideals, ordered by inclusion, produce a distributive lattice, denoted $\text{Ideals}(S)$

***Proof*:**
Let I and J be order ideals of S. If $x \leq y$ with $y \in I \cup J$, then y lies in one of the two, and that one contains x by definition D.1.22, so $x \in I \cup J$. If $x \leq y$ with $y \in I \cap J$, then $x \in I$ and $x \in J$ by the same definition, so $x \in I \cap J$. Hence $\text{Ideals}(S)$ is closed under finite unions and intersections.

Ordered by inclusion, $I \cup J$ is an upper bound of $\{I, J\}$, and any order ideal containing both contains their union, so $I \vee J = I \cup J$. Dually $I \cap J$ is a lower bound of $\{I, J\}$ contained in every order ideal contained in both, so $I \wedge J = I \cap J$. Every pair has a meet and a join, so $\text{Ideals}(S)$ is a lattice by definition D.1.2.

Distributivity is the corresponding identity for sets. For order ideals I, J, K and any $x \in S$, the statement $x \in I \cap (J \cup K)$ says that $x \in I$ and that x lies in J or in K, which says exactly that $x \in (I \cap J) \cup (I \cap K)$. So form (2) of definition D.1.18 holds.

Theorem D.1.24: Finite Distributive Lattices And Ideals

Let L be a finite lattice, and give $\text{Irr}(L)$ the order it inherits from L. Then L is a distributive lattice if and only if

$$L \cong \text{Ideals}(\text{Irr}(L))$$

***Proof*:**
If $L \cong \text{Ideals}(\text{Irr}(L))$, then L is distributive, since proposition D.1.23 makes the right side distributive and a lattice isomorphism carries the identity of definition D.1.18 across.

Assume L is distributive. A finite lattice satisfies the descending chain condition, so proposition D.1.21 applies. Define

$$\varphi : L \to \text{Ideals}(\text{Irr}(L)) \qquad \varphi(x) = T(x) = \{i \in \text{Irr}(L) \mid i \leq x\}$$

Each $T(x)$ is an order ideal of $\text{Irr}(L)$, since $j \leq i \leq x$ with j irreducible gives $j \in T(x)$.

Meets. An irreducible i satisfies $i \leq x \wedge y$ exactly when $i \leq x$ and $i \leq y$, so $\varphi(x \wedge y) = T(x) \cap T(y) = \varphi(x) \wedge \varphi(y)$.

Joins. The inclusion $T(x) \cup T(y) \subseteq T(x \vee y)$ is clear. For the reverse, let $i \in \text{Irr}(L)$ with $i \leq x \vee y$. Form (2) of definition D.1.18 gives

$$i = i \wedge (x \vee y) = (i \wedge x) \vee (i \wedge y)$$

so by definition D.1.20 either $i = i \wedge x$ or $i = i \wedge y$, that is $i \leq x$ or $i \leq y$. Hence $\varphi(x \vee y) = T(x) \cup T(y) = \varphi(x) \vee \varphi(y)$.

Injectivity. If $T(x) = T(y)$, then proposition D.1.21 gives $x = \bigvee T(x) = \bigvee T(y) = y$.

Surjectivity. Let J be an order ideal of $\text{Irr}(L)$ and put $x = \bigvee J$, a join of a finite set and hence available by proposition D.1.3, with the empty join read as the least element of L. Every $j \in J$

satisfies $j \leq x$, so $J \subseteq T(x)$. Conversely let $i \in T(x)$. If $J = \emptyset$, then x is the least element of L and $i \leq x$ makes i minimal, which definition D.1.20 forbids, so $J \neq \emptyset$, say $J = \{j_1, \ldots, j_r\}$ with $r \geq 1$. Iterating form (2) of definition D.1.18 gives

$$i = i \wedge (j_1 \vee \cdots \vee j_r) = (i \wedge j_1) \vee \cdots \vee (i \wedge j_r)$$

and iterating definition D.1.20 gives $i = i \wedge j_k$ for some k, that is $i \leq j_k$. Since J is an order ideal, $i \in J$. Hence $T(x) = J$ and φ is onto.

A bijection preserving both operations is a lattice isomorphism, so $L \cong \text{Ideals}(\text{Irr}(L))$.

For a distributive lattice that is not finite, prime ideals take the place of irreducible elements in the embedding into a power-set.

Definition D.1.25: Ideals Of A Lattice

Let L be a lattice. An *ideal* of L is a non-empty order ideal $I \subseteq L$ (definition D.1.22) such that $x \vee y \in I$ whenever $x, y \in I$. An ideal P is *prime* if $P \neq L$ and $x \wedge y \in P$ implies $x \in P$ or $y \in P$.

Lemma D.1.26: Prime Ideal Theorem

Let L be a distributive lattice, let I be an ideal of L, and let $a \in L \setminus I$. Then there is a prime ideal P of L with $I \subseteq P$ and $a \notin P$.

***Proof*:**
Let $\mathcal{I}$ be the set of ideals J of L with $I \subseteq J$ and $a \notin J$, ordered by inclusion. It contains I. Let $\mathcal{C}$ be a chain in $\mathcal{I}$. If $\mathcal{C}$ is empty, then I is an upper bound for it. Otherwise put $J_0 = \bigcup \mathcal{C}$, a non-empty order ideal. If $x, y \in J_0$, then x and y lie in members of $\mathcal{C}$ of which one contains the other, so $x \vee y$ lies in the larger one. So J_0 is an ideal, it contains I and omits a, and it is an upper bound for $\mathcal{C}$ in $\mathcal{I}$. By theorem A.2.3, $\mathcal{I}$ has a maximal element P.

Since $a \notin P$, $P \neq L$. Suppose $x \wedge y \in P$ with $x \notin P$ and $y \notin P$. The set

$$P_x = \{z \in L \mid z \leq p \vee x \text{ for some } p \in P\}$$

is an ideal: it contains x, it is an order ideal by transitivity, and $z_1 \leq r_1 \vee x$ and $z_2 \leq r_2 \vee x$ with $r_1, r_2 \in P$ give $z_1 \vee z_2 \leq (r_1 \vee r_2) \vee x$ with $r_1 \vee r_2 \in P$. It contains P, since $r \leq r \vee x$ for $r \in P$, and it contains $x \notin P$, so the maximality of P forces $P_x \notin \mathcal{I}$, that is, $a \in P_x$, and $a \leq p_1 \vee x$ for some $p_1 \in P$. The set $P_y = \{z \in L \mid z \leq p \vee y \text{ for some } p \in P\}$ is an ideal as well: it contains y, it is an order ideal by transitivity, and $z_1 \leq r_1 \vee y$ and $z_2 \leq r_2 \vee y$ with $r_1, r_2 \in P$ give $z_1 \vee z_2 \leq (r_1 \vee r_2) \vee y$. It contains P, since $r \leq r \vee y$ for $r \in P$, and it contains $y \notin P$, so the maximality of P forces $a \in P_y$, and $a \leq p_2 \vee y$ for some $p_2 \in P$. Put $p = p_1 \vee p_2 \in P$. The two forms of definition D.1.18 are equivalent, as the proof of proposition D.1.19 shows at its start, and form (1) gives

$$a \leq (p \vee x) \wedge (p \vee y) = p \vee (x \wedge y)$$

The right side lies in P, since p and $x \wedge y$ do, so $a \in P$, a contradiction. Hence P is prime.

Theorem D.1.27: Distributive Lattices And Power-Sets

A lattice L is distributive if and only if it is isomorphic to a sublattice of $(P(X), \cup, \cap)$ for some set X, that is, to a non-empty family of subsets of X closed under $\cup$ and $\cap$, ordered by inclusion. If L is distributive and X is the set of prime ideals of L, then $V(x) = \{P \in X \mid x \notin P\}$ defines a lattice isomorphism V from L onto such a family.

***Proof*:**
A non-empty family $\mathcal{F} \subseteq P(X)$ closed under $\cup$ and $\cap$ is a lattice with $\vee = \cup$ and $\wedge = \cap$, and it is distributive, since the set identity $A \cap (B \cup C) = (A \cap B) \cup (A \cap C)$ is form (2) of definition D.1.18. A lattice isomorphic to $\mathcal{F}$ is distributive, since an isomorphism carries the identity across.

Conversely, let L be distributive, let X be the set of prime ideals of L, and let $P \in X$ and $x, y \in L$. The element $x \wedge y$ lies in P exactly when x or y does: if $x \in P$, then $x \wedge y \leq x$ puts $x \wedge y$ in P, likewise for y, and the converse is primality. The element $x \vee y$ lies in P exactly when x and y both do: P is closed under joins, and $x, y \leq x \vee y$. Taking complements in X,

$$V(x \wedge y) = V(x) \cap V(y) \qquad V(x \vee y) = V(x) \cup V(y)$$

So $V(L)$ is closed under $\cup$ and $\cap$, and V preserves both operations. It is injective. If $x \neq y$, then by antisymmetry $x \not\leq y$ or $y \not\leq x$, say $x \not\leq y$. The set $\{z \in L \mid z \leq y\}$ is an ideal not containing x, so lemma D.1.26 gives a prime ideal P containing y and not x, and then $P \in V(x) \setminus V(y)$. Hence V is a bijection from L onto $V(L)$ preserving both operations, that is, a lattice isomorphism.

A final important lattice naturally arises in mathematical logic, known as a *boolean lattice*. In a Boolean lattice, the meet, join, and "complement" correspond to conjunction, disjunction, and negation in mathematical logic:

Definition D.1.28: Boolean Lattice

Let L be a bounded lattice (hence containing a 0 and 1). Then a *complement* of an element $a \in L$ is an element a' such that $a \wedge a' = 0$ and $a \vee a' = 1$. Then L is a *Boolean lattice* if it is distributive and every element has a complement.

Distributivity is what makes the complement unique: if b and c both complement a then $b = b \wedge 1 = b \wedge (a \vee c) = (b \wedge a) \vee (b \wedge c) = b \wedge c$, and symmetrically $c = c \wedge b$, so $b = c$. Without it uniqueness fails, as M_5 shows, where each of the three incomparable elements complements the other two. Complementation is not a lattice homomorphism: it is an order-reversing involution, satisfying De Morgan's laws $(x \wedge y)' = x' \vee y'$ and $(x \vee y)' = x' \wedge y'$.

Example D.1.29: Boolean Lattice

For an easy example of a Boolean lattice take the power-set $P(X)$ with compliment $Y' = X \setminus Y$. For a more interesting example, let R be a Boolean ring (i.e. a ring such that for $x \in R$, $x^2 = x$). Then define a partial order on R via:

$$x \leq y \qquad \text{if and only if} \qquad xy = x$$

Then we get a boolean lattice via

$$x \wedge y = xy \qquad x \vee y = x + y + xy \qquad x' = 1 - x$$

Interestingly, the all Boolean lattices can be converted into Boolean rings, for a Boolean lattice $(L, \vee, \wedge, (-)', 0, 1)$ define:

$$x + y = (x' \wedge y) \vee (x \wedge y') \qquad xy = x \wedge y$$

denote this ring $R(L)$. Then

$$\mathrm{L}(\mathrm{R}(L)) = L \qquad \mathrm{R}(\mathrm{L}(R)) = R$$

Since power-sets are naturally boolean lattices, they offer themselves to the following classification theorem:

Theorem D.1.30: Finite Boolean Lattice Classification

Let L be a finite lattice. Then L is a boolean lattice if and only if there exists a set X such that

$$L \cong P(X)$$

***Proof*:**
First, $P(X)$ is a Boolean lattice. It is a lattice under $\cup$ and $\cap$ (example D.1.4), distributive by the set identity $A \cap (B \cup C) = (A \cap B) \cup (A \cap C)$, which is form (2) of definition D.1.18, bounded by $\emptyset \subseteq A \subseteq X$, and $X \setminus A$ complements A. A lattice isomorphism preserves the order, since $x \leq y$ exactly when $x \wedge y = x$, so it carries least and greatest elements to least and greatest elements, complements to complements, and the distributive identity across. Hence a lattice isomorphic to $P(X)$ is Boolean.

Conversely, let L be a finite Boolean lattice. It is distributive, so theorem D.1.24 gives $L \cong \mathrm{Ideals}(\mathrm{Irr}(L))$. No two distinct irreducible elements are comparable. Suppose $j < i$ with $i, j \in \mathrm{Irr}(L)$, and let j' be a complement of j. Form (2) of definition D.1.18 and $i \wedge j = j$ give

$$i = i \wedge 1 = i \wedge (j \vee j') = (i \wedge j) \vee (i \wedge j') = j \vee (i \wedge j')$$

so by definition D.1.20 either $j = i$, which $j < i$ excludes, or $i \wedge j' = i$, that is, $i \leq j'$. In the second case $j \leq i \leq j'$, so $j = j \wedge j' = 0$. But 0 is the least element of L, hence minimal, and an irreducible element is not minimal, a contradiction. So in $\mathrm{Irr}(L)$, with its inherited order, $x \leq y$ holds only when $x = y$, every subset of $\mathrm{Irr}(L)$ is an order ideal in the sense of definition D.1.22, and $\mathrm{Ideals}(\mathrm{Irr}(L))$ is all of $P(\mathrm{Irr}(L))$ with the operations $\cup$ and $\cap$. Hence $L \cong P(\mathrm{Irr}(L))$.

To generalize to general boolean lattices, we require the following lemmas:

Lemma D.1.31: Stone Space Basis

Let L be a Boolean lattice, and let X be the set of prime ideals of L in the sense of definition D.1.25. Then the sets

$$V(a) = \{P \in X \mid a \notin P\} \qquad a \in L$$

form a basis for a topology on X. Furthermore, $V(0) = \emptyset$, $V(1) = X$, $V(a \wedge b) = V(a) \cap V(b)$, and $V(a') = X \setminus V(a)$

***Proof*:**
Every prime ideal P contains 0, since it is non-empty and $0 \leq p$ for any $p \in P$, so $0 \in P$ because P is an order ideal. Hence $V(0) = \emptyset$. No prime ideal contains 1, since every $a \in L$ satisfies $a \leq 1$, so $1 \in P$ would give $P = L$, against properness. Hence $V(1) = X$.

Next, $V(a \wedge b) = V(a) \cap V(b)$. If $a \in P$, then $a \wedge b \leq a$ puts $a \wedge b$ in P, and likewise if $b \in P$, so $a \wedge b \notin P$ forces $a \notin P$ and $b \notin P$. Conversely, if $a \wedge b \in P$, then primality gives $a \in P$ or $b \in P$.

These two facts give the conditions of definition C.1.3. Every $P \in X$ lies in $V(1) = X$, which is the first condition. For the second, let $P \in V(a) \cap V(b)$. The member $V(a \wedge b)$ of the family contains P and is contained in $V(a) \cap V(b)$, since the two sets are equal. So the family $\{V(a) \mid a \in L\}$ is a basis for a topology on X.

Finally, $V(a) \cap V(a') = V(a \wedge a') = V(0) = \emptyset$ by definition D.1.28. And $V(a) \cup V(a') = X$, because if a prime ideal P contained both a and a', then $1 = a \vee a' \in P$, since prime ideals are closed under joins, contradicting $V(1) = X$. A set disjoint from $V(a)$ whose union with $V(a)$ is X is $X \setminus V(a)$, so $V(a') = X \setminus V(a)$.

Theorem D.1.32: Boolean Lattice Classification

Let L be a lattice. Then L is a Boolean lattice if and only if there exists a set X such that L is isomorphic to a *field of sets* on X, that is, to a family $\mathcal{F} \subseteq P(X)$, ordered by inclusion, that contains $\emptyset$ and X and is closed under $\cup$, $\cap$ and $A \mapsto X \setminus A$.

***Proof*:**
A field of sets $\mathcal{F}$ on X is a sublattice of $P(X)$, so it is distributive by theorem D.1.27. It is bounded by $\emptyset$ and X, and $X \setminus A \in \mathcal{F}$ complements $A \in \mathcal{F}$, so $\mathcal{F}$ is a Boolean lattice. As in the proof of theorem D.1.30, a lattice isomorphic to a Boolean lattice is Boolean.

Conversely, let L be a Boolean lattice and X the set of its prime ideals. It is distributive, so by theorem D.1.27 the map V is a lattice isomorphism from L onto the sublattice $V(L)$ of $P(X)$. By lemma D.1.31, $V(0) = \emptyset$, $V(1) = X$ and $V(a') = X \setminus V(a)$, so $V(L)$ contains $\emptyset$ and X and is closed under complements. Hence $V(L)$ is a field of sets on X.

As mentioned, the above topology has a special name:

Definition D.1.33: Stone Space

Let L be a Boolean lattice and X the collection of prime ideals of L. Then with the above basis, X is called the *stone space*.

Proposition D.1.34: Stone Space Properties

Let X be the stone space of a Boolean lattice L. Then X is compact and Hausdorff, and it is totally disconnected: no subset of X with more than one point is connected in the subspace topology.

***Proof*:**
Write $V(a) = \{P \in X \mid a \notin P\}$ as in lemma D.1.31. For distinct $P, Q \in X$ there is an $a \in L$ with $Q \in V(a)$ and $P \in V(a')$. Indeed $P \not\subseteq Q$ or $Q \not\subseteq P$, and after exchanging the names P and Q if necessary there is an $a \in P \setminus Q$. Then $Q \in V(a)$ and $P \notin V(a)$, that is, $P \in X \setminus V(a) = V(a')$ by lemma D.1.31.

Hausdorff. The open sets $V(a) \ni Q$ and $V(a') \ni P$ are disjoint, since $V(a') = X \setminus V(a)$.

Totally disconnected. Let $S \subseteq X$ contain distinct points P and Q, and take a as above. The sets $S \cap V(a)$ and $S \cap V(a')$ are open in S, disjoint, non-empty, as they contain Q and P, and their union is S. So S is not connected (definition C.3.3).

Compact. Let $\mathcal{O}$ be an open cover of X. Each member of $\mathcal{O}$ is a union of basic open sets $V(a)$, so the set T of those $a \in L$ for which $V(a)$ lies inside some member of $\mathcal{O}$ satisfies $\bigcup_{a \in T} V(a) = X$. It suffices to find $a_1, \ldots, a_n \in T$ with $V(a_1) \cup \cdots \cup V(a_n) = X$, since a member of $\mathcal{O}$ containing each $V(a_k)$ then gives a finite subcover. Suppose there are none, and let I be the set of $z \in L$ with $z \leq a_1 \vee \cdots \vee a_n$ for some $n \geq 0$ and $a_1, \ldots, a_n \in T$, the empty join being 0. Then I is an ideal in the sense of definition D.1.25: it contains 0, it is an order ideal, and two such bounds join to a bound of the same kind. If $1 \in I$, then $1 = a_1 \vee \cdots \vee a_n$ for some $a_k \in T$, and lemma D.1.31 and theorem D.1.27 give $X = V(1) = V(a_1) \cup \cdots \cup V(a_n)$, against the assumption. So $1 \notin I$, and lemma D.1.26, which applies since L is distributive, gives a prime ideal $P \supseteq I$. Every $a \in T$ lies in I, hence in P, so P lies in no $V(a)$ with $a \in T$, contradicting $\bigcup_{a \in T} V(a) = X$.

For any topological space Y, the clopen subsets of Y form a field of sets on Y: $\emptyset$ and Y are clopen, the complement of a clopen set is clopen, and a union or intersection of two clopen sets is open by definition C.1.1 and closed by proposition C.1.2. So they form a Boolean lattice $\mathrm{L}(Y)$ by theorem D.1.32. A compact Hausdorff totally disconnected space is called a *Stone space*, and proposition D.1.34 says that the stone space of a Boolean lattice is one.

E

Model Theory

Model theory studies a mathematical structure through the first-order sentences it satisfies. A *first-order language* fixes symbols for operations, relations and constants, and its formulas are built from these symbols, equality, the logical connectives and the quantifiers $\forall x$ and $\exists x$, whose variables range over the elements of a structure and never over its subsets. The language of ordered fields has the symbols $+$, $\cdot$, $-$, 0, 1 and $\leq$, and $\mathbb{R}$ is a structure for it. A substructure A of a structure B is *elementary* if every formula with parameters from A holds in A exactly when it holds in B.

E.1 Löwenheim-Skolem Theorem

Theorem E.1.1: Downward Löwenheim-Skolem Theorem

Let $\mathcal{L}$ be a countable first-order language and B a structure for $\mathcal{L}$. Then B has a countable elementary substructure.

The proof closes a countable subset of B under witnesses for the existential statements that hold in B. It needs the formal definitions of formulas and of satisfaction, which this appendix does not develop, and is given in [71, Downward Löwenheim-Skolem Theorem].

The theorem shows that the first-order algebra of $\mathbb{R}$ does not determine $\mathbb{R}$. Apply it to $\mathbb{R}$ in the language of ordered fields. The result is a countable subset $K \subseteq \mathbb{R}$, closed under the operations and ordered by the restriction of $\leq$, in which exactly the same first-order sentences hold as in $\mathbb{R}$. In particular K is an ordered field, since the ordered field axioms are such sentences, and $K \ncong \mathbb{R}$, since $\mathbb{R}$ is uncountable. So no collection of first-order statements about $+$, $\cdot$ and $\leq$ characterizes $\mathbb{R}$ up to isomorphism. The completeness of $\mathbb{R}$, that every non-empty subset bounded above has a supremum, quantifies over subsets, so it is not a first-order sentence of this language.

Part XIV

Glossary, Index, Bibliography

Glossary of Algebraic Structures

In this chapter, we list many of the algebraic structures discussed throughout the book. These are categorized by subject and are roughly grouped by the order in which they appear with priority given to grouping properties together and examples together. To find where these objects appear in the textbook, see the appendix (which is sorted in alphabetical order).

Fundamental Structures

- Set; Relation, Equivalence Relation, Partial Order, Total Order
- Function (Injective, Surjective, Bijective); Cardinality
- Number Systems ($\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Q}$, $\mathbb{R}$, $\mathbb{C}$); Modular Arithmetic ($\mathbb{Z}/n\mathbb{Z}$)
- Graph, Lattice; Matrix

Groups

Basic Group Types and Properties

- Group; Abelian Group; Subgroup; Normal Subgroup; Characteristic Subgroup
- Quotient Group; Homomorphism, Isomorphism, Endomorphism, Automorphism (including Inner Automorphism, Outer Automorphism)
- Kernel, Image; Center, Centralizer, Normalizer
- Order of a Group, Order of an Element; Generators and Relations, Presentations of Groups

Examples of Groups

- Cyclic Group (C_n, $\mathbb{Z}/n\mathbb{Z}$); Symmetric Group (S_n); Alternating Group (A_n)
- Dihedral Group (D_n); Quaternion Group (Q_8)

- Matrix Groups (e.g., $GL_n(F)$, $SL_n(F)$, $O_n(F)$, $SO_n(F)$)
- Free Group; Free Abelian Group

Group Actions

- Group Action; Orbit, Stabilizer; Class Equation; Cayley Graph

Constructions and Decompositions

- Direct Product of Groups; Semi-Direct Product of Groups; Internal Direct Product
- Extensions of Groups; Fundamental Theorem of Finitely Generated Abelian Groups

Specialized Group Types

- Simple Group; Solvable Group; Nilpotent Group; Polycyclic Group; Perfect Group

Generalizations of Groups

- Monoid; Groupoid

Rings

Rngs $\supset$ Rings (Unital) $\supset$ Commutative Rings $\supset$ Integral Domains
$\supset$ Factorization Domains $\supset$ Unique Factorization Domains (UFDs)
$\supset$ Principal Ideal Domains (PIDs) $\supset$ Euclidean Domains
$\supset$ Fields $\supset$ Algebraically Closed Fields

Basic Types

- Division Rings (Skew Fields); Noetherian Rings; Artinian Rings
- Dedekind Domains; Valuation Rings, Discrete Valuation Rings (DVRs)

Examples of Rings

- Polynomial Rings ($R[x]$, $R[x_1, \ldots, x_n]$); Formal Power Series ($R[[x]]$)
- Matrix Rings ($M_n(R)$); Group Rings ($R[G]$)
- Ring of Fractions / Localization ($D^{-1}R$, R_S, R_f, R_P); Completion of a Ring ($\hat{R}_I$)

Ring Concepts

- Ring Homomorphisms, Isomorphisms
- Ideals (including Principal Ideal; Prime Ideal; Maximal Ideal; Radical Ideal, Nilradical; Comaximal Ideals; Homogeneous Ideals; Fractional Ideals)
- Quotient Rings; Units, Zero Divisors, Nilpotent Elements
- Characteristic of a Ring; Integral Extensions, Integrally Closed Domains (Normal Domains)

Modules

Basic Module Types and Properties

- R-Module (Left, Right, Bimodule); Submodule; Quotient Module
- Module Homomorphism (Linear Transformation), Isomorphism
- Simple Module (Irreducible Module); Semisimple Module; Indecomposable Module
- Free Module, Rank of a Free Module; Projective Module; Injective Module; Flat Module
- Finitely Generated Module; Noetherian Module, Artinian Module
- Cyclic Module; Torsion Elements, Torsion Module, Torsion-Free Module; Annihilator of a Module

Constructions

- Direct Sum / Direct Product of Modules; Tensor Product of Modules ($M \otimes_R N$)
- Exact Sequences (Short, Long, Split)

Special Modules

- Vector Spaces (over a field k) (including Subspace, Quotient Space; Basis, Dimension; Dual Space (V^*), Dual Basis, Double Dual (V^{**}); Linear Functionals, Bilinear/-Multilinear Forms; Inner Product Spaces, Normed Spaces)
- R-Algebras (as R-modules)

Fields

- Field Extension (K/F) (including Degree of an Extension ($[K : F]$); Finite Extension; Algebraic Element, Transcendental Element; Algebraic Extension, Transcendental Extension; Simple Extension ($F(\alpha)$), Primitive Element; Normal Extension; Separable Extension, Separable Degree ($[K : F]_s$); Galois Extension)
- Minimal Polynomial ($m_{\alpha,F}(x)$); Splitting Field; Algebraic Closure ($\bar{F}$)
- Galois Group ($\mathrm{Gal}(K/F)$, $\mathrm{Aut}_F(K)$) (including Fixed Field; Galois Correspondence)
- Roots of Unity, Cyclotomic Polynomials ($\Phi_n(x)$), Cyclotomic Fields ($\mathbb{Q}(\zeta_n)$)
- Finite Fields / Galois Fields ($\mathbb{F}_q$, $\mathbb{F}_{p^n}$); Ordered Fields, Real Fields
- Absolute Values on Fields, p-adic Valuation; Trace ($\mathrm{Tr}_{K/F}(\alpha)$), Norm ($N_{K/F}(\alpha)$), Discriminant

Algebras

- Associative Algebra (R-Algebra, k-Algebra); Commutative Algebra; Division Algebra
- Lie Algebra; Path Algebra (of a Quiver)
- Tensor Algebra ($T(M)$); Symmetric Algebra ($S(M)$); Exterior Algebra ($\Lambda(M)$)
- Graded Algebra; Central Simple Algebra (CSA); Brauer Group ($\mathrm{Br}(k)$)

Structures from Commutative Algebra & Algebraic Geometry

- Noetherian Ring, Artinian Ring; Dedekind Domain; Valuation Ring, Discrete Valuation Ring (DVR)
- Localization (R_P, R_f, $S^{-1}R$); Completion ($\hat{R}_I$)
- Integral Extension, Integrally Closed Domain (Normal Domain)
- Algebraic Set (Affine, Projective); Variety (Affine, Projective, Quasi-Projective)
- Coordinate Ring ($k[V]$, $k^P[V]$); Zariski Topology
- Regular Function/Map, Rational Function/Map; Dimension (Krull, Transcendental)
- Hilbert Function, Hilbert Polynomial; Stalk ($\mathcal{O}_{X,p}$)
- Spectrum of a Ring ($\mathrm{Spec}(R)$), Affine Scheme

Number Theoretic Structures

- Algebraic Number Field, Ring of Integers ($\mathcal{O}_K$); Algebraic Number, Algebraic Integer
- Discriminant (of a field, of a basis, Δ_K)
- Norm (of an element $N_{K/F}(\alpha)$, of an ideal $N(\mathfrak{a})$); Trace (of an element $\mathrm{Tr}_{K/F}(\alpha)$)
- Ideal Class Group ($\mathrm{Cl}(K)$), Class Number (h_K)
- Roots of Unity, Cyclotomic Polynomials ($\Phi_n(x)$), Cyclotomic Fields ($\mathbb{Q}(\zeta_n)$)
- Fractional Ideals; Ramification Index (e), Inertia Degree (f) (including Decomposition Group (D_P), Inertia Group (I_P); Frobenius Element/Automorphism (Frob_P))

Representation Theory Structures

- Representation (Linear, Matrix) (including Irreducible Representation, Simple Module; Semisimple Representation, Semisimple Module; Indecomposable Representation; Trivial Representation; Regular Representation; Permutation Representation; Induced Representation)
- G-Module ($k[G]$-module); Character, Character Table; Class Function
- Semisimple Ring (Artin-Wedderburn Theorem); Quiver, Quiver Representation (including Path Algebra)

Homological Algebra Structures

- Chain Complex, Cochain Complex (including Cycles, Boundaries (Cocycles, Coboundaries))
- Homology ($H_n(C_\bullet)$), Cohomology ($H^n(C^\bullet)$)
- Exact Sequence (Long Exact Sequence in

(Co)homology) (including Snake Lemma)

- Resolution (Projective, Injective, Free, Flat)
- Derived Functor (L_iF, R^iF) (including Ext Functors ($\mathrm{Ext}^i_R(M,N)$); Tor Functors ($\mathrm{Tor}_i^R(M,N)$))
- Homotopy (Chain Homotopy, Homotopy Equivalence); Mapping Cone
- Derived Category ($D(A)$), Homotopy Category ($K(A)$), Triangulated Category; Spectral Sequence

Category Theory Concepts

- Category (Small, Locally Small); Object
- Morphism (Homomorphism, Isomorphism, Monomorphism, Epimorphism, Endomorphism, Automorphism)
- Functor (Covariant, Contravariant) (including Additive Functor, Exact Functor; Faithful Functor, Full Functor, Essentially Surjective Functor)
- Natural Transformation, Natural Isomorphism; Equivalence of Categories
- Duality, Opposite Category (C^{op}); Commutative Diagram

Universal Properties

- Universal Property (general concept); Initial Object, Final Object (Zero Object)
- Product, Coproduct (Direct Product, Direct Sum, Free Product)
- Kernel, Cokernel (in Abelian Categories); Equalizer, Coequalizer
- Limit, Colimit (Inverse/Projective Limit, Direct/Injective Limit)
- Free Objects (Free Group, Free Module, Free R-algebra, Polynomial Ring as free commutative R-algebra)
- Adjoint Functors (e.g., Free-Forgetful Adjoints, Hom-Tensor Adjoint)

What Next?

Congratulations on reaching the end of the book[1]! Having parsed through the material of the book, the reader must be on the edge of their seat wondering what comes next! From my current understanding, the ultimate goal is to understand better the properties of numbers or the properties of geometric objects that arise out of polynomials (or more generally out of commutative or non-commutative rings). This results in classification results, tools to better understand these results, new ways of solving equations, and so forth. The number of branching points is vast; this book shall address what is currently some common general starting points, given the reader is in the 21st century.

The reader should be aware that at this stage, it is important to gain some experience in many other fields of mathematics such as algebraic topology [76], differential geometry [79], Lie Groups [97], real analysis [85](particularly Fourier analysis), PDEs [32] (for at least the idea of elliptic operators and harmonic PDEs), and complex analysis [78]. All these fields interconnect to various extents in the study of number theory, representation theory, and algebraic geometry.

It must be pointed out that the topics covered here are *not* a comprehensive list of areas of research, simply large ones. Other areas that are not covered in detail here that have active research include, but are not limited to, the model theory of algebraically and differentially closed fields, probabilistic linear optimization, mathematics of AI (which can be thought of as a continuation of linear algebra and functional analysis), higher order category theory, P vs. NP as an Invariance Theory problem, and so forth.

Algebraic Geometry

A lot of focus is within the domain of *algebraic geometry*. The reader has the background material to start reading the next EYTNKA textbook *EYNTKA Algebraic Geometry* ([13]), or read classical texts such as *Hartshorne's Algebraic geometry* ([58]) or *Vakil's The Rising Sea* ([99]). The starting point of modern algebraic geometry is the *affine scheme* (developed in *Algebraic Geometry* [13]) which generalizes varieties by defining the geometric counter-part to number rings, rings with nilpotents or

[1] or welcome curious reader to how the book ends!

zero-divisors, rings that are not finitely generated, and overall any commutative ring. These shall be the "model spaces" that are glued together to create *schemes*, where "glued together" is geometrically understood as forming equivalence classes between the points that are being glued and is algebraically understood as adding compatibility relations between functions (essentially, think of the example of projective space where $f \in \mathrm{Hom}(U_1, R), g \in \mathrm{Hom}(U_2, R)$ such that $f(z) = g(1/z)$ on $U_1 \cap U_2$). A lot of the build-up in modern algebraic geometry is translating the concepts of differential geometry over $\mathbb{R}$ or $\mathbb{C}$ (ex. smoothness, dimensions, irreducibility, compactness, Hausdorffness, Poincaré duality, monodromy, Riemann-Roch) into the non-analytic setting of schemes. This translation abstracts many of the notions that will require a good deal of build-up, but the reward is a unified language to deal with number theory and varieties which have many of the geometric intuitions one would expect, as well as novel geometric intuitions unique to schemes with not analytic counter-part. A lot of similarities shall be shared between differential geometry and scheme theory, but important differences shall also emerge (ex. points containing other points, existence of distinct points that are arbitrarily closed to each other, functions that are not determined by their value at every point).

Schemes are the starting point for the study of many different modern fields, but they can be studied in and of themselves. For example to find classification of different types of schemes; this research often involves the use of *moduli spaces* and the theory of *stacks*.

Another very important problem in Algebraic Geometry is the *Hodge Conjecture*, which roughly says that homological information about a smooth *projective* complex variety X can be given by nice subvarieties of X. In particular, without defining any of our terms, it asks which *rational* cohomology classes in $H^{2k}(X, \mathbb{Q}) \cap H^{k,k}(X)$ are combinations of the classes of closed subvarieties Z of X. Both restrictions carry weight: without rationality the statement fails at once, and the analogous statement for compact Kähler manifolds is false as well, by a counterexample of Voisin. The projective case is where the conjecture lives, and there the analytic and algebraic pictures agree by GAGA [57]. Solving the conjecture or finding a counter-example would be rewarded the reader $1 million by the Clay Institute. The reader interested in the Hodge Conjecture wanting to continue the EYTNKA series can read *K-theory* for an introduction to vector/fiber-bundles and their algebraic generalizations [81], *Algebraic Topology* for the cohomology background [76], *Algebraic Geometry* for the algebraic background [13], *Differential Topology* for the Kähler manifold background [79], and [28] for putting this all together.

Elliptic Curves

The advantage of scheme theory is in full effect when studying curves (Noetherian integral separated 1-dimensional schemes of finite type over k). The study of curves splits according to the genus g, the invariant that Riemann-Roch ties to the dimensions of spaces of functions with prescribed poles (see [78] or [13]). Curves of genus 1 carrying a marked rational point are called *elliptic curves*, and Riemann-Roch embeds each one as a non-singular plane cubic, so studying them is studying non-singular degree 3 equations. When in char $\neq 2, 3$ we can algebraically say that the study of elliptic curves is the study of equation $y^2 = x^3 + ax + b$. Finding all rational solutions to such polynomials is still an open problem; the *Birch and Swinnerton-Dyer Conjecture* would, if proven, explain how many solutions there exists, and the person(s) who succeeds to prove it would win $1 million from the Clay Institute of Mathematics[2]. Due to scheme theory there are natural ways of understanding "bad reductions" (think of ramified primes), of defining a covering space using galois theory (like in homotopy theory), and keeping track of when curves intersect non-transversally (with

[2]It is one of the Millennium problems set at the beginning of the 21st century

multiplicity higher than 1).

The reader interested can start on the EYTNKA textbook *Elliptic Curves* ([25]) or look at *Silvermen's Arithmetic of Elliptic Curves* ([93]).

Number Theory and Arithmetic Geometry

Scheme theory over number fields or number rings is called *Arithmetic Geometry*. A huge amount of progress in modern theory was made by using tools in arithmetic geometry, for example the proof of Fermat's Last Theorem (that for no natural number $n \geq 3$ does $x^n + y^n = z^n$ have a solution in nonzero integers) was proved through the lens of Arithmetic Geometry and analytic number theory. Much of modern number theory builds directly on the algebraic foundations presented in this book.

A major area of research is the *Langlands program* which aims to generalize Artin's reciprocity (see *Class Field Theory*, [77]) which can be thought of the 1-dimensional case of Langland's reciprocity. The 2-dimensional case strongly involved elliptic curves and the related modular forms and automorphic forms. An introduction to the required background covering these topics includes [25], [13], and [92].

With the advent of complex analysis, many problems in number theory can be studied using certain meromorphic functions. Of central interest is the *Riemann-Zeta function*

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} = \prod_{p \text{ prime}} \frac{1}{1 - p^{-s}}$$

which can be analytically extended to $\mathbb{C} \setminus \{1\}$ and captures an incredible amount of information about the distribution of primes (and by the proven *Weil Conjectures* any smooth projective variety over a finite field has an associated zeta function capturing its arithmetic properties). The *Riemann Hypothesis*, one of the Millennium problems, states that all the [non-trivial][3] roots of $\zeta(s)$ lie on the line $L = \{z \in \mathbb{C} \mid \text{Re}(z) = 1/2\}$. By some application of Fourier analysis, this would drastically improve our understand of how many primes $p \leq n$ there exists for any $n \in \mathbb{N}$, and would resolve many open problems. Proving that all [nontrivial] zeros are on L or that there is at least one [nontrivial] zero that is not on L would give the person(s) who proved it $1 million by the Clay Institute.

Geometric Group Theory

part I mainly focused on finite groups. Infinite groups are much harder to grasp, however there are many infinite groups that naturally show up in geometric settings and have a metric that can be imposed on them. Studying these groups falls under *Geometric group theory* which views infinite groups themselves as geometric objects. By equipping a group with a metric, one can study its large-scale geometry to deduce its algebraic properties. This approach has led to the resolution of major conjectures in topology, Agol's proof of the virtual Haken conjecture among them. (Thurston's Geometrization Conjecture does imply the *Poincaré Conjecture*, another Millennium problem, but Perelman proved it by Ricci flow rather than by group-theoretic means.)

[3] There are roots that are given by the Gamma function which are considered to be related to the prime at infinity, and is not important for the usual, finite, prime

Derived Algebraic Geometry and Higher Algebra

Schemes are incredibly powerful, but are not adept with "singular" spaces or when taking "non-regular" quotients; categorically they do not behave well under limits and colimits. *Derived geometry* is a redevelopment of commutative algebra inspired by abstract topology. It replaces rings with derived objects that retain homological information, allowing for a more robust theory of intersections and moduli spaces that works in greater generality. This field often draws on *higher category theory* to create a unified language for geometry.

Motivic and Chromatic Homotopy Theory

Algebraic topology uses algebraic invariants, such as homology groups, to classify and distinguish topological spaces. The algebraic tools themselves have become the focus of intense study. *Chromatic homotopy theory* seeks to organize how shapes can be mapped into one another (homotopy) by filtering it through algebraic data coming from the theory of formal groups. *Motivic homotopy theory* builds a direct bridge, or "motive," between algebraic geometry and topology. The ultimate goal is a structural understanding of shape itself, with the calculation of the *stable homotopy groups of spheres* remaining one of the field's major goals.

Anabelian Geometry

Anabelian geometry is asking if we can recover an arithmetic variety X given information about the (étale) fundamental group of X. While Motivic Homotopy Theory seeks to build a dictionary of algebraic invariants to describe a space, anabelian geometry focuses on the first étale homotopy group, $\pi_1^{\text{ét}}$, and posits that for a special class of "hyperbolic" varieties, $\pi_1^{\text{ét}}$ contains all the necessary information to recover the variety.

The central algebraic invariant in this field is the *étale fundamental group*, denoted $\pi_1^{\text{ét}}(X)$. Its connection to the homotopy $\pi^{\mathbf{Top}}$ group comes from how the universal cover $E \to X$ and the intermediate covers have a galois correspondence to the subgroups of $\pi^{\mathbf{Top}}$. An example of a simple étale fundamental group is those for a field k, where $\pi_1^{\text{ét}}(\operatorname{Spec} k) = \operatorname{Gal}_k(k_s)$ where k_s is the maximal separable extension of k. More generally, for a variety X defined over a number field like $\mathbb{Q}$, its étale fundamental group is a profinite group that captures not only the topological shape of X (as seen over the complex numbers) but also the entirety of its arithmetic structure.

The "anabelian" hypothesis is the conjecture that this reconstruction is only possible when the group is sufficiently complex and far from being abelian.

- **Abelian Case (Fails):** For an object like an elliptic curve, whose fundamental group is abelian, this principle fails. Many different elliptic curves can have the same fundamental group, so the group does not uniquely determine the geometry.
- **Anabelian Case (Conjectured to Succeed):** For a "hyperbolic" variety, such as a curve of genus two or more, the étale fundamental group is a non-abelian group. The anabelian hypothesis posits that there is enough information to uniquely determine the original variety.

This makes anabelian geometry a subfield of arithmetic geometry in its goals, but leaning more towards the philosophy of geometric group theory: it seeks to understand geometry by studying the algebraic properties of an associated group. An unsolved problem (as of writing this book) is

the *Section Conjecture* which attempts to use the structure of $\pi_1^{\text{ét}}(X)$ to describe the set of rational points on X, offering a new (non-abelian) approach to solving Diophantine equations.

Thanks for reading!
